Furthermore, the study by Elseidi (2024), which utilized a combined ARIMA-Prophet framework to predict high-frequency temperature data, reported results similar to this study. Elseidi's study achieved an MAE of 1.78 and an RMSE of 2.12, which are slightly higher than Prophet's results in this study. This indicates that Prophet is highly suitable for short-term predictions, such as temperature and plant growth in hydroponics (Elseidi, 2024).

Another study by Pindiga (2022), which predicted stock indices using ARIMA and Prophet, reported that Prophet performed better with an MAE of 2.65 and an RMSE of 3.15, compared to ARIMA, which had an MAE of 3.24 and an RMSE of 3.67. These findings still show that the Prophet model in this study provides more accurate predictions compared to stock index predictions by Pindiga (Pindiga, 2022).

Overall, the evaluation results demonstrate that Prophet excels in environments requiring predictions of variables with consistent change patterns, such as plant growth in hydroponic systems, compared to its application to more volatile data such as stock prices and temperature data. The benchmarking results reinforce the study's findings that Prophet is a more suitable model for predictions in hydroponic farming systems

F. Deployment

The deployment phase of this study entailed turning the Prophet model into a fully functional web-based application for simulating hydroponic lettuce growing. This approach was carried out on the Streamlit platform, which was chosen for its ease of use and versatility when developing interactive online apps [46]. The major purpose of this deployment was to give users, primarily hydroponic farmers and academics, with a simple tool for simulating lettuce growth in real time using environmental data. The following Fig. 11 shows the homepage of the HydroSim application resulting from the model deployment using the Streamlit platform.

The Prophet model, which has demonstrated the best performance in predicting lettuce growth during the rainy season, has been integrated into Streamlit, allowing users to input important hydroponic variable data such as temperature, humidity, light intensity, water quality indicators, and the number of lettuce leaves. After receiving the data, the program runs the Prophet model in the background to forecast, simulate growth patterns, and provide estimates in a simple and user-friendly interface. Key performance parameters, such as the number of leaves and harvest time, are provided, offering actionable information to users. In addition, interactive elements are included, allowing users to modify factors and quickly observe how these changes affect the expected outcomes, making this application not only informative but also instructive for understanding the dynamics of hydroponic agriculture.

Fig. 11. Homepage HydroSim.

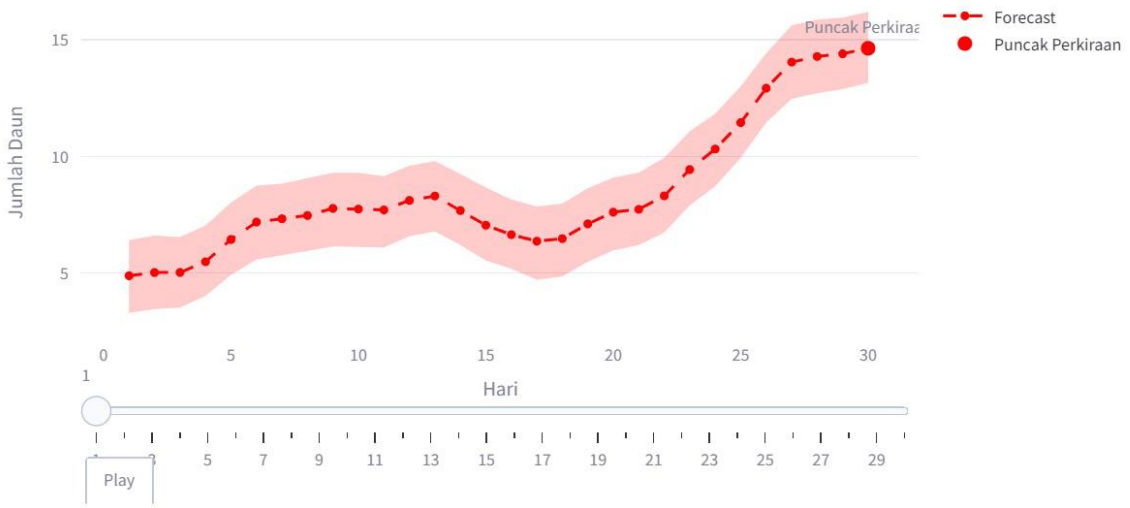

Fig. 12. Simulation forecasting results based on days.

Referring to Fig. 12, the forecast results produced by the model are displayed after the user submits their data. Users can choose how many days ahead they would like to simulate the growth. Additionally, they can press the play button to see an animated, interactive graph of the growth simulation over time. Users also have the flexibility to select a specific day for simulation by dragging the marker to their preferred point on the timeline, offering an interactive and customizable way to visualize the predicted growth.

Fig. 13. Forecasting table and lettuce illustration.

Apart from the animated growth chart, a dynamic illustration of a lettuce plant is included, changing according to the day being predicted on the graph above. This allows users to visually see how the plant may develop over time. Additionally, a forecasting table is presented, which provides detailed daily predictions. The table includes columns like "ds," which displays the forecast date, and "yhat," which shows the primary predicted value for leaf count. The "yhat_lower" column gives the lower limit of the prediction range, representing the minimum likely estimate, while the "yhat_upper" column indicates the upper limit, showing the maximum expected leaf count for each prediction. Fig. 13 shows forecasting table and lettuce illustration.

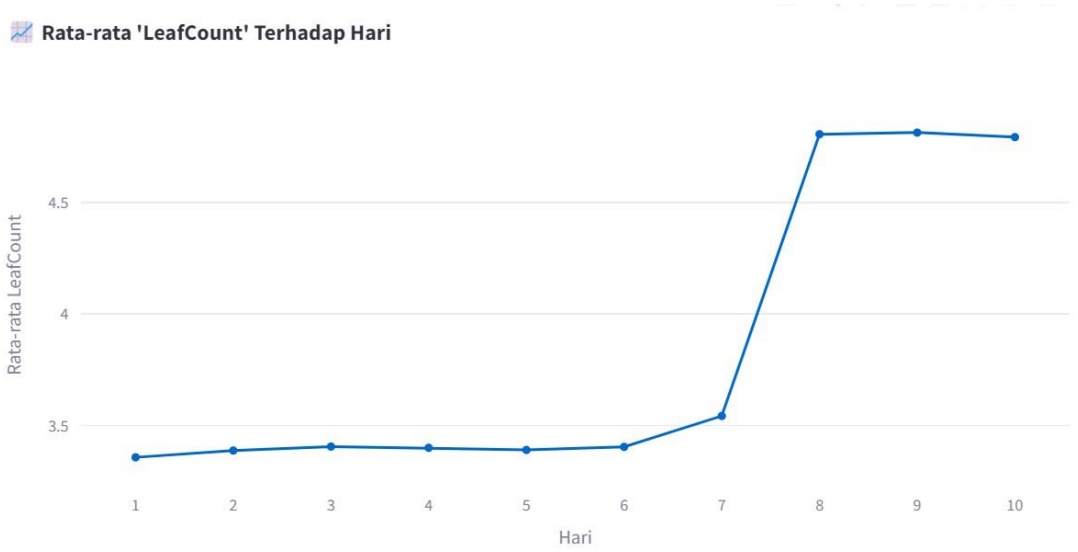

Fig. 14. Average value growth variable.

Fig. 14 explains the average value feature of each leaf count variable, allowing users to select which variable they want to see the average value of. The HydroSim application also includes a variety of features designed to assist both users and farmers in interpreting the data for practical use. One key feature is the ability to visualize average growth variable charts, particularly the Leaf Count. This chart allows users to observe how different growth variables behave over time, offering a detailed perspective on the factors influencing lettuce development. By providing a graphical representation of this data, the feature helps users better understand the dynamics of plant growth, such as how environmental conditions or nutrient levels impact leaf production. These insights can be crucial for making informed adjustments to hydroponic systems, ensuring that optimal growing conditions are maintained.

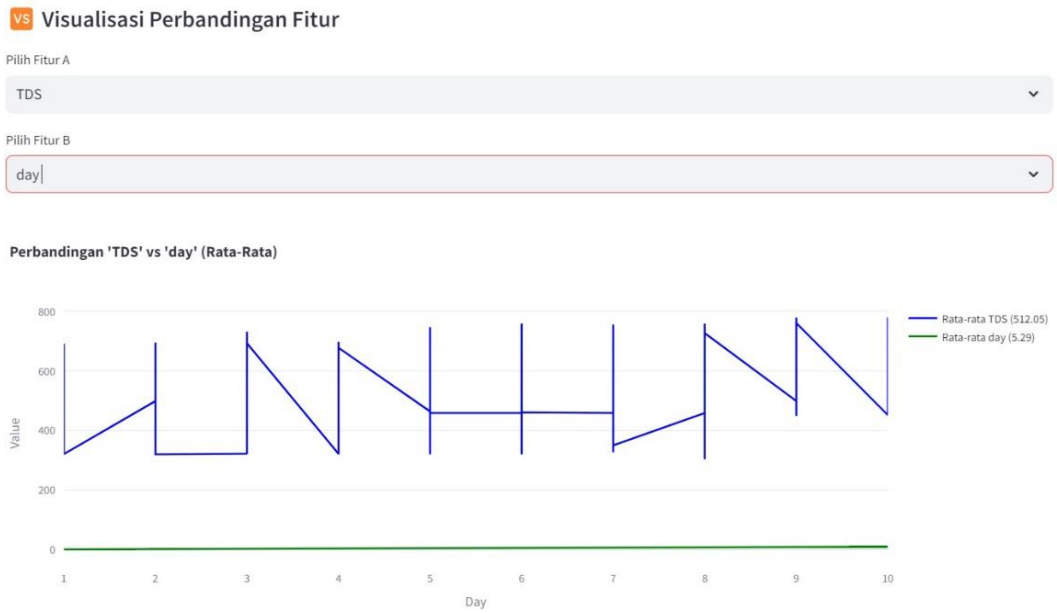

Fig. 15. Comparison between variable.

The variable comparison feature can be seen in Fig. 15, where users can compare two selected variables to observe the graphical pattern comparison of both variables. Another valuable feature integrated into HydroSim is the variable comparison tool, designed to provide users with insights into how different environmental and growth variables correlate with one another. As demonstrated in Fig. 15, users can choose which variables they would like to compare, such as water temperature, nutrient levels, and light intensity, and the application will generate a detailed comparative graph. This helps users better understand how environmental factors and growth metrics interact, making it easier to identify patterns or anomalies. The comparison tool empowers users to make more informed decisions about optimizing their hydroponic systems based on the relationships between key variables, ultimately improving plant growth outcomes.

Fig. 16. Conclusion information.

Fig. 16 shows the summary information display from the HydroSim application, which provides information on the percentage increase in the number of leaves simulated according to the selected number of days and information on the number of leaves that increased after simulation. This implementation represents a substantial improvement in precision agricultural technology by providing a real-time, data-driven solution for improving lettuce growth and resource management while remaining cost-effective and user-friendly. The use of Streamlit in model deployment provides a lightweight and scalable solution that is easily accessible via web browsers, without requiring substantial technical knowledge, making it suitable for widespread adoption by a variety of user groups from small-scale farmers, major research institute, to commercial hydroponic farmers.

IV. Conclusion

This research concluded with the successful implementation of real-time automatic hydroponic growth simulation for lettuce using ARIMA and Prophet models, specifically designed for the rainy season in Indonesia. Through meticulous data collection using calibrated instruments, this study captures crucial environmental variables, providing an accurate foundation for model development. The Prophet model has proven to be superior, achieving a Mean Absolute Error (MAE) of 1.475 and a Root Mean Square Error (RMSE) of 1.808, highlighting its effectiveness in managing time series data to simulate plant growth. The integration of models into a web-based platform provides practical and user-friendly tools for predicting lettuce growth, enhancing the decision-making process for researchers and farmers by offering data-driven insights into environmental management. The contribution of this study lies in its focus on tropical climates and the use of real-time data for automation in hydroponic systems.

Future research will prioritize expanding the model by incorporating data from other seasons, particularly the dry season, to address environmental challenges and enhance its robustness across diverse climatic conditions. Furthermore, datasets from other hydroponic crops, such as spinach, bok choy, water spinach, and tomatoes, will be integrated to extend the model's applicability. This direction aligns with prior studies, such as Smith et al. (2022) [47], who emphasized multi-crop modeling for resource optimization, and Lee et al. (2023) [48], who demonstrated improved system adaptability in diverse hydroponic conditions. Hybrid modeling approaches will also be explored, combining techniques like ARIMA, Prophet, and advanced machine learning algorithms such as LSTM and Random Forest. Zhang et al. (2021) [49] highlighted the effectiveness of hybrid methods in improving simulation accuracy for complex environments, making this a promising avenue for further enhancement. These efforts aim to develop a more versatile, scalable, and high-performing hydroponic automation system to support sustainable agricultural practices. By addressing these aspects, future studies can enhance the precision, scalability, and reliability of automated hydroponic growth simulations.

Improved Real-Time Smoke Detection Model Based on RT-DETR

Yuanpan ZHENG*, Zeyuan HUANG, Binbin CHEN, Chao WANG, Yu ZHANG
School of Computer Science and Technology, Zhengzhou University of Light Industry, Zhengzhou 450000, Henan, China

***Abstract*—Fire remains a major threat to society and economic activities. Given the real-time demands of smoke detection, most research in deep learning has focused on Convolutional Neural Networks. The Real-Time Detection Transformer (RT-DETR) introduces a promising alternative for this task. This paper extends RT-DETR to address challenges such as morphological variations and interference in smoke detection by proposing the Realtime Smoke Detection Transformer (RS-DETR). RS-DETR uses smoke images with concentration data as input and employs a deformable attention module to manage morphological changes, enabling robust feature extraction. Additionally, a Cross-Scale Smoke Feature Fusion Module (CS-SFFM) is integrated to enhance detection accuracy for small and thin smoke targets through multi-scale feature resampling and fusion. To improve convergence speed and stability, Efficient Intersection over Union (EIoU) replaces Generalized Intersection over Union (GIoU) in feature scoring. The improved model achieves an average precision of 93.9% on a custom dataset, representing a 5.7% improvement over the original model, and demonstrates excellent performance across various detection scenarios.**

***Keywords*—RT-DETR; smoke detection; deformable convolution; multi-scale feature fusion; EIoU; image enhancement; dark channel**

I. INTRODUCTION

Fire is a highly destructive disaster that poses significant risks to human society and economic activities. In 2022, fires caused approximately 17,040 casualties globally, including 3,790 deaths—the highest number since 2013 [1]. Early fire warning systems are crucial for minimizing damage.

Traditional fire detection methods primarily rely on physical sensors to identify early-stage smoke. However, these approaches are less effective outdoors, require frequent maintenance, and offer limited coverage [2]. Such limitations often lead to false alarms and missed detections, underscoring the inadequacy of traditional methods for modern fire prevention.

Early image-based smoke detection used manual feature classifiers like SVM and Random Forests, but these had limited robustness due to hardware and design constraints. With advances in hardware, deep learning methods have become the standard, offering better robustness, generalization, and integration with existing surveillance systems [3]. CNN-based models have gained attention for their precision [4], but they often require complex post-processing, increasing optimization difficulty and computational load, which can compromise robustness [5].

The DETR (Detection Transformer) [6] series introduced a new solution by applying the Transformer architecture to computer vision. DETR leverages self-attention to model global contextual information, transforming object detection into a set prediction task, thereby simplifying the process and enabling end-to-end detection. However, the extensive use of attention mechanisms makes DETR models complex and less suitable for real-time tasks [7]. To address this, Zhao et al. [8] proposed the RT-DETR model, capable of real-time detection. RT-DETR introduces an attention-based intra-scale feature interaction module and a cross-scale feature fusion module, enhancing training speed and detection performance. The structure of the RT-DETR model is shown in Fig. 1.

RT-DETR, as the first real-time Transformer-based detection model, offers greater robustness and easier optimization compared to the YOLO series models [9-16], while avoiding the computational overhead of NMS. Recognizing its potential for fire smoke detection, this paper selects RT-DETR-r18 as the baseline and introduces improvements in smoke feature extraction and multi-scale feature fusion. Key contributions include:

1) To better evaluate the model's effectiveness in real fire detection scenarios, this paper addresses the shortcomings of existing datasets and common interference factors in smoke detection. A high-quality smoke target detection dataset was constructed by filtering unannotated images from existing datasets, collecting smoke images from the internet, and manually annotating them.

2) Smoke morphology often changes significantly over time and due to various interference factors. To capture these graphical features, this paper uses the dark channel prior method to process smoke data, setting the model input as a four-dimensional tensor that includes smoke concentration information. Additionally, a large kernel deformable convolutional attention mechanism based on channel priors is designed to extract robust smoke information, effectively handling variations in smoke's spectral characteristics and spatial distribution.

3) Early smoke targets with high detection value are usually small and have blurred edges. To address the baseline model's low accuracy in identifying small targets captured from a distance, this paper optimizes and improves the cross-scale feature fusion module of the model using methods such as feature map scaling strategies, 3D convolution, and 3D pooling. This resolves the issue of losing detailed feature information

during feature fusion, enhancing the model's smoke detection accuracy while reducing the model parameters.

4) The baseline model's feature query loss function, which uses Generalized Intersection over Union (GIoU), suffers from slow convergence. To address this, this paper employs Efficient Intersection over Union (EIoU) as the regression loss in feature scoring. EIoU considers both bounding box coordinates and dimensions, accelerating model convergence, improving stability, and reducing redundant detections.

The structure of this paper is as follows: Section II reviews related work on fire smoke detection; Section III elaborates on the algorithmic optimization proposed for the fire smoke detection task; Section IV presents experiments and analysis of the proposed model, compares it with mainstream detection models, and validates the effectiveness of the proposed approach; Section V summarizes the main contributions of this paper and discusses future research directions.

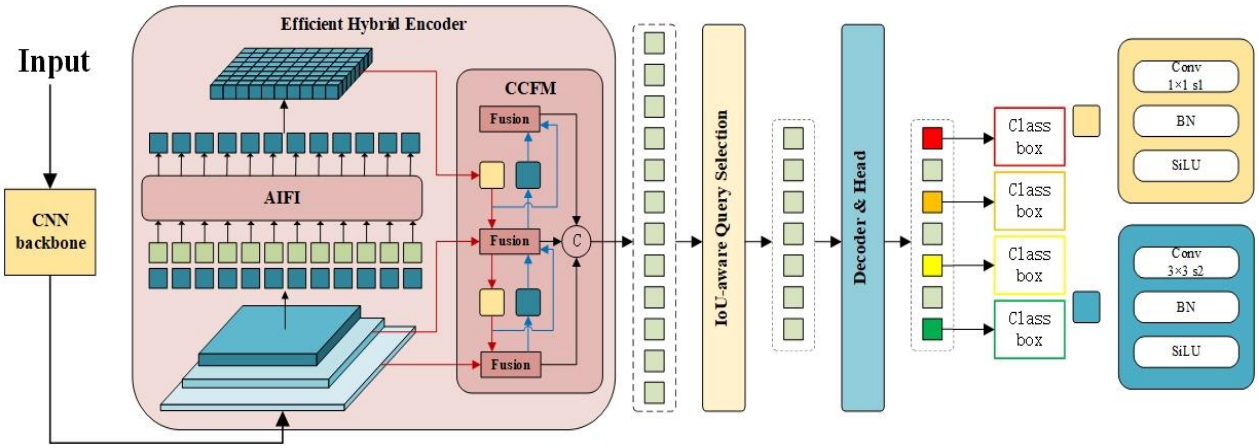

Fig. 1. The general architecture of RT-DETR.

II. Related Work

In recent years, significant progress has been made in fire smoke detection using deep learning. This section introduces related work on fire smoke detection based on different model architectures.

A. CNN-based Fire Smoke Detection

Frizzi et al. [17] utilized CNNs for smoke and flame detection by performing sliding window sampling on the feature map of the last convolutional layer instead of the original image, and recognizing smoke and flames in each block. Lin et al. [18] employed various backbone networks as feature extractors, combining them with Faster R-CNN [19], SSD [20], and R-FCN [21] frameworks for smoke detection. Zhang et al. [22] proposed a multi-scale convergence-coordinated feature pyramid network, which enhanced feature fusion efficiency and optimized NMS processing, thereby improving the accuracy and efficiency of detecting small and medium-sized fire smoke. Wang et al. [23] incorporated a self-attention mechanism into YOLOX [24] to enhance the model's ability to capture long-range dependencies. They also combined a self-collaborative mechanism with PAN [25] to achieve feature sharing and reduce redundant features, resulting in robust fire smoke detection. Zhan et al. [26] addressed the challenge of detecting highly transparent smoke by proposing a feature fusion scheme based on deconvolution and dilated convolution. This approach fused shallow visual information with deep semantic information along the channel dimension, enabling high-precision detection of distant aerial smoke. Sathishkumar et al. [27] introduced a transfer learning method based on lifelong learning to overcome the decline in model performance caused by insufficient training data, achieving efficient and accurate fire detection.

B. Transformer-based Fire Smoke Detection

To address these issues, Li et al. [28] leveraged the NMS-free algorithm concept from DETR and applied multi-scale deformable attention in the encoder of Deformable-DETR [29], along with lightweight optimizations. They also introduced a normalization-based attention mechanism, which accelerated network convergence and reduced deployment requirements. However, the model still suffers from repeated detections and insufficient detection accuracy. Similarly, Huang et al. [30] used Deformable-DETR as the baseline, integrating a multi-scale context contrast local feature module and a dense pyramid pooling module into the feature extraction module. This approach improved the detection accuracy for small and blurry smoke. However, the model's structure remains relatively complex, posing challenges for real-time detection tasks. Although these Transformer-based approaches eliminate the need for post-processing, the extensive stacking of attention mechanisms results in slow convergence and high deployment requirements, which still do not fully meet the practical demands of fire smoke detection.

III. Improvement Scheme

Feature extraction and feature fusion are two equally important components in object detection models. Feature extraction is responsible for deriving meaningful features from images, while feature fusion ensures the effective integration of these features, enabling the model to accurately detect objects in various complex scenarios. Given the susceptibility of smoke features to external interference and the uncertainty in scale, this chapter focuses on improving the baseline model in two key areas: robust smoke feature extraction and multi-scale feature fusion. The improved model is illustrated in Fig. 2.

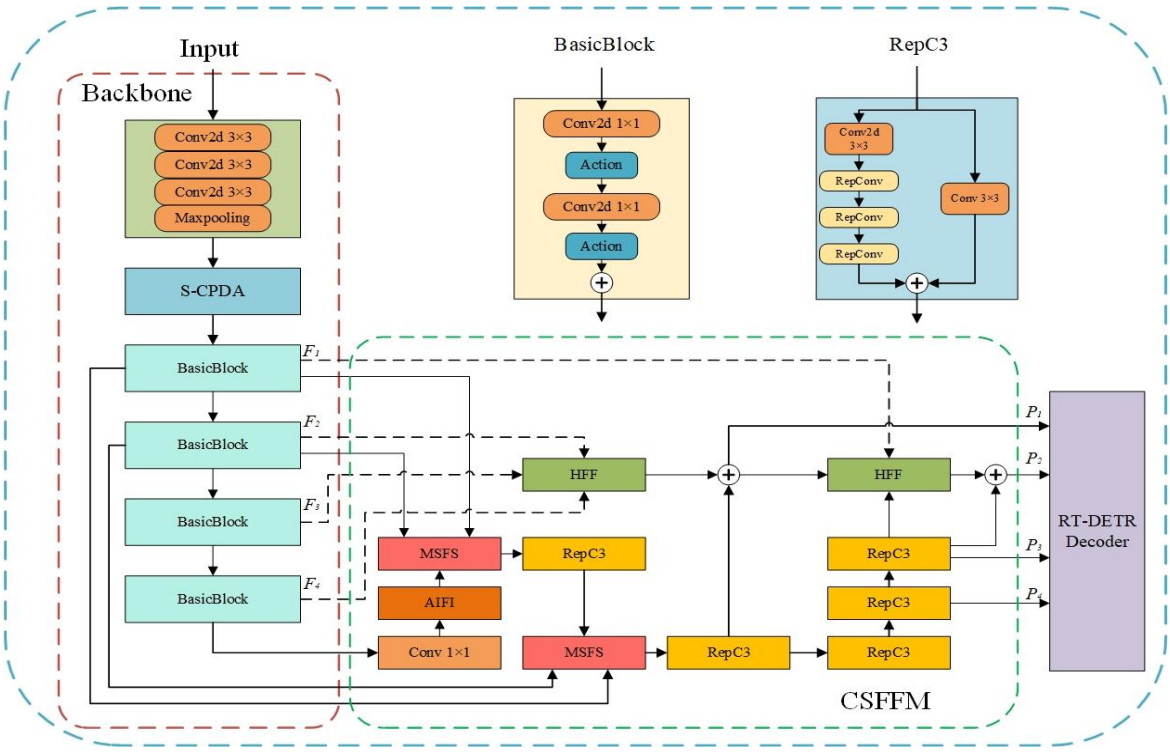

Fig. 2. Improved realtime smoke detection transformer, RS-DETR.

A. Robust Smoke Feature Extraction

Smoke is subject to significant variations in scale, shape, and spectral information due to environmental factors such as wind direction, wind speed, temperature, and humidity, as well as the thermodynamic and fluid dynamic properties of the smoke itself. These variations significantly impact the effectiveness of smoke detection tasks. Consequently, smoke detection models developed in the past often exhibited insufficient generalization capabilities, making it difficult to apply them across different scenarios.

This study addresses smoke's graphical characteristics by focusing on both spectral features and spatial distribution variations. A four-dimensional vector, generated by combining the smoke's transmittance grayscale image and its RGB image, is used as the network input. Additionally, a specially designed attention mechanism is employed for robust smoke feature extraction to meet the demands of a highly generalizable network.

1) Smoke feature extraction aggregating concentration information: Smoke concentration is a crucial indicator of smoke intensity, exhibiting significant variation depending on the emission strength of the smoke. This variation greatly impacts the performance of neural network models in smoke detection tasks. Calculating the transmittance of smoke regions is a common and accurate method for estimating smoke concentration. To enhance the network's detection accuracy across different smoke concentrations and improve the algorithm's generalization capability in various scenarios, the network input is configured as a four-dimensional tensor generated by combining the smoke transmittance grayscale image, obtained through the dark channel prior method [31], with the smoke RGB image. The synthesized model input is illustrated in Fig. 3. The process of calculating the smoke transmittance image using the dark channel prior method can be described as follows:

$$A = I(y) \tag{1}$$

$$t(x) = 1 - \omega \min_{y \in \Omega(x)} \left(\min_{c \in \{r,g,b\}} \frac{I^c(y)}{A^c} \right) \tag{2}$$

$$J_{dark}(x) = \min_{y \in \Omega(x)} \left(\min_{c \in \{r,g,b\}} I^c(y) \right) \tag{3}$$

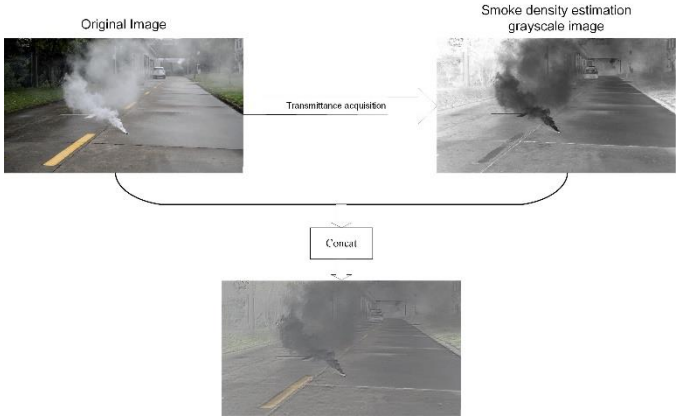

Fig. 3. Concentration Feature Aggregation (CFA).

where, I represents the input image, and c denotes the color channel. Eq. (1) defines the dark channel, where $\Omega(x)$ is a window centered at x. Eq. (2) provides the atmospheric light estimation, where A is the estimated atmospheric light value, and $I(y)$ is the pixel value at the position with the highest intensity in the original image. Eq. (3) estimates the transmission rate, where $I^c(y)$ represents the intensity value of the c-th color channel at position y in the input image I, and A^C represents the value of atmospheric light in the c-th color channel.

2) Smoke feature extraction attention: The attention mechanism consists of two components: a channel attention module and a spatial attention module. These modules are integrated into the backbone network to enhance the extraction of smoke features. The structure of the attention mechanism is shown in Fig. 4. The overall process can be described as Eq. (4):

$$Output = CA(F) + SA(CA(F)) \tag{4}$$

where CA represents the channel attention, and SA represents the spatial attention.

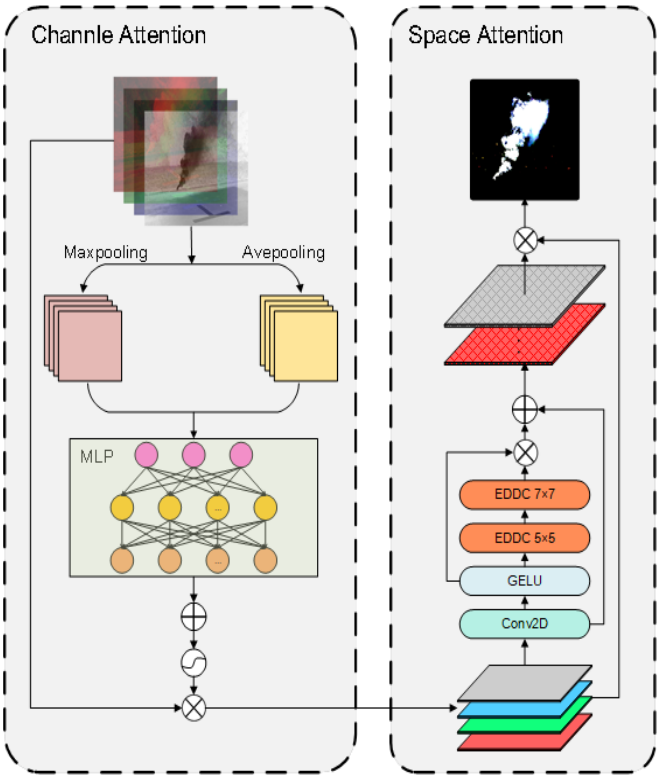

Fig. 4. Smoke channel-prior large-kernel deformable attention (S-CLDA).

a) Channel attention: The smoke channel information is extracted using the channel attention module. The Convolutional Block Attention Module (CBAM) [32] is employed, which aggregates the spatial information of the image through both average pooling and max pooling. This aggregation method produces a series of spatial indicators that capture the core attributes of smoke. These indicators are then processed by a simplified shared multi-layer perceptron (MLP), and the channel attention map is obtained by summing the MLP outputs. The MLP includes a hidden layer, designed to maintain the model's expressive capability while minimizing the number of parameters. The size of the hidden layer is specifically set to:

$$H = \frac{inchannels}{r} \times 1 \times 1 \tag{5}$$

where, H represents the size of the hidden layer, and r denotes the reduction ratio. This design carefully balances the model's lightweight nature with its ability to learn complex inter-channel relationships. By performing element-wise summation of the average pooling and max pooling results processed by the MLP, a detailed and expressive smoke channel attention map is generated.

The channel attention component can be expressed as:

$$F_{channel} = \sigma(MLP(F_{AVG}) + MLP(F_{MAX})) \tag{6}$$

$$F' = F \otimes F_{channel} \tag{7}$$

where, σ represents the sigmoid function, F denotes the input feature map, F' represents the output feature map, and AVG and MAX represent the average pooling and max pooling operations, respectively.

This strategy not only enhances the model's focus on critical channels within the smoke color features but also optimizes the use of computational resources by adjusting the hidden layer dimensions. This approach enables efficient aggregation of diverse channel information related to smoke, thereby improving the accuracy, robustness, and generalization capability of the smoke detection model.

b) Spatial attention: In the spatial attention module, the complex geometric variations exhibited by smoke due to its diffusive nature present a challenge. Using traditional convolutional kernels with fixed geometric structures across different smoke locations lacks adaptability to the dynamic morphology and scale changes of smoke. This limitation impedes the precise capture of spatial distributions and their variations. Additionally, valuable features in the thin edge regions of smoke may be suppressed during convolution operations due to their weaker signal strength, which can adversely affect the network's ability to learn the overall morphological characteristics of smoke.

To address these issues, we introduce deformable convolution [33] technology within the spatial attention module. This approach utilizes an additional convolutional layer to adjust the sampling region, resulting in adaptive convolutional kernels that improve the representation of smoke. To prevent the suppression of weak features, parallel convolution operations are employed, as shown in Fig. 5. A large kernel strategy [34] is implemented using depthwise convolution, dilated convolution, and 1×1 convolution to achieve a larger receptive field, allowing for the extraction of complete smoke region features. The enhanced deformable convolution can be expressed as Eq. (8):

$$y_{ed}(p_0) = \sum_{k=1}^{K^2} w_k \cdot (x(p_0 + p_k) + x(p_0 + p_k + \Delta p_k)) \quad (8)$$

p_0 represents the output position, w_k denotes the weight at the k-th position in the convolutional kernel, p_k is the standard positional offset of the kernel, and Δp_k is the learnable offset.

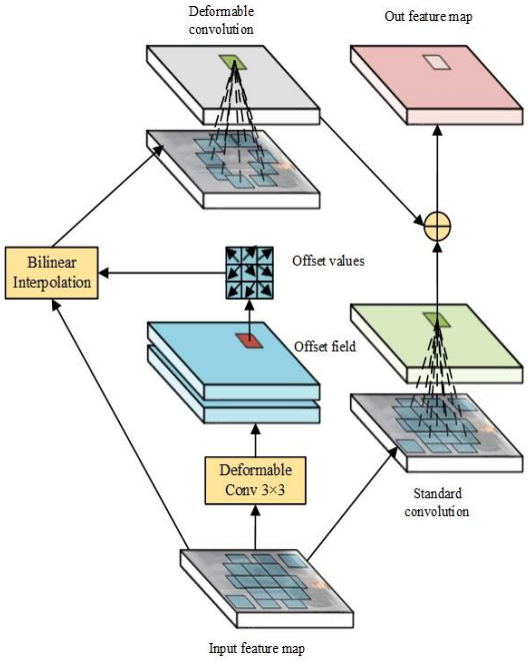

Fig. 5. Enhanced Deformable Depthwise Convolution (EDDC).

The equation for determining the kernel size of a $K \times K$ convolutional kernel in depthwise convolution and depthwise dilated convolution is:

$$DW = (2d-1) \times (2d-1) \quad (9)$$

$$DW_D = \left\lceil \frac{K}{d} \right\rceil \times \left\lceil \frac{K}{d} \right\rceil \quad (10)$$

where, K represents the kernel size, and d denotes the dilation rate.

The spatial attention component can be expressed as:

$$X' = GELU(X) \quad (11)$$

$$A = Conv_{1\times1}(EDDC(EDDC(X'))) \quad (12)$$

$$Output = Conv_{1\times1}(A \otimes X') + X \quad (13)$$

where, A represents the feature map processed by the EDDC module.

By introducing deformable convolution, the kernel offsets are calculated using bilinear interpolation, and a large kernel convolution strategy is implemented through depth-wise convolution and related techniques. This approach expands the receptive field while controlling the increase in the number of parameters, enabling the model to adapt to the complex spatial distribution of smoke. The channel attention and spatial attention modules focus on the spectral features and spatial distribution features of smoke, respectively, allowing for targeted extraction of robust smoke features.

A. Cross-Scale Smoke Feature Fusion Module

Transformer-based detectors utilize self-attention mechanisms for object localization, allowing them to cover the entire image. However, these models often focus more on larger target regions, resulting in suboptimal performance when detecting small objects. A common solution to this issue is multi-scale feature fusion using feature summation or concatenation. However, simple addition or concatenation methods lack selectivity across scales and lead to relatively independent channels after fusion. Implementing dynamic scale attention or more complex fusion strategies could address these limitations, but they would significantly increase computational complexity, thereby affecting the model's detection efficiency.

Ming Kang et al. [35] proposed the use of Gaussian blur to simulate images at different observation scales, effectively preserving both image details and structural features, and facilitating the fusion of deep and shallow features. This approach mitigates the information loss that often occurs with traditional concatenation and stacking methods.

Building on this idea, this paper redesigns the cross-scale smoke feature fusion module by employing a nearest-neighbor interpolation scheme to supplement the detail information of feature maps at different scales. This approach enables multi-level feature fusion with minimal information loss. Given that early smoke often appears as small targets, a small object detection branch is added to enhance detection accuracy. The structure of the cross-scale smoke feature fusion module is illustrated in Fig. 6.

In this module, RepC3 is the native component from RT-DETR, enhancing feature extraction and representation by stacking residual convolutional blocks. This design improves the model's expressive capability.

The Multi-Scale Feature Scaling Module (MSFS) applies adaptive pooling and nearest-neighbor interpolation to both large- and small-scale feature maps, adjusting their sizes to match the medium-scale feature map before channel concatenation. This approach magnifies small target features while preserving edge clarity and background information, enabling the network to capture more precise detail features. This module can be described as:

$$\begin{aligned} l' = &\ adaptive\ max\ pool2d(l, size) \\ &+ adaptive\ avg\ pool2d(l, size) \end{aligned} \quad (14)$$

$$s' = interpolate(s, size, mode = nearest) \quad (15)$$

$$Out_{lms} = concat(l', m, s', dim = 1) \quad (16)$$

where, l, m, and s represent the large, medium, and small-scale feature maps, respectively, $size$ refers to the size of the medium-scale feature map, and lms denotes the output after the concatenation of the feature maps.

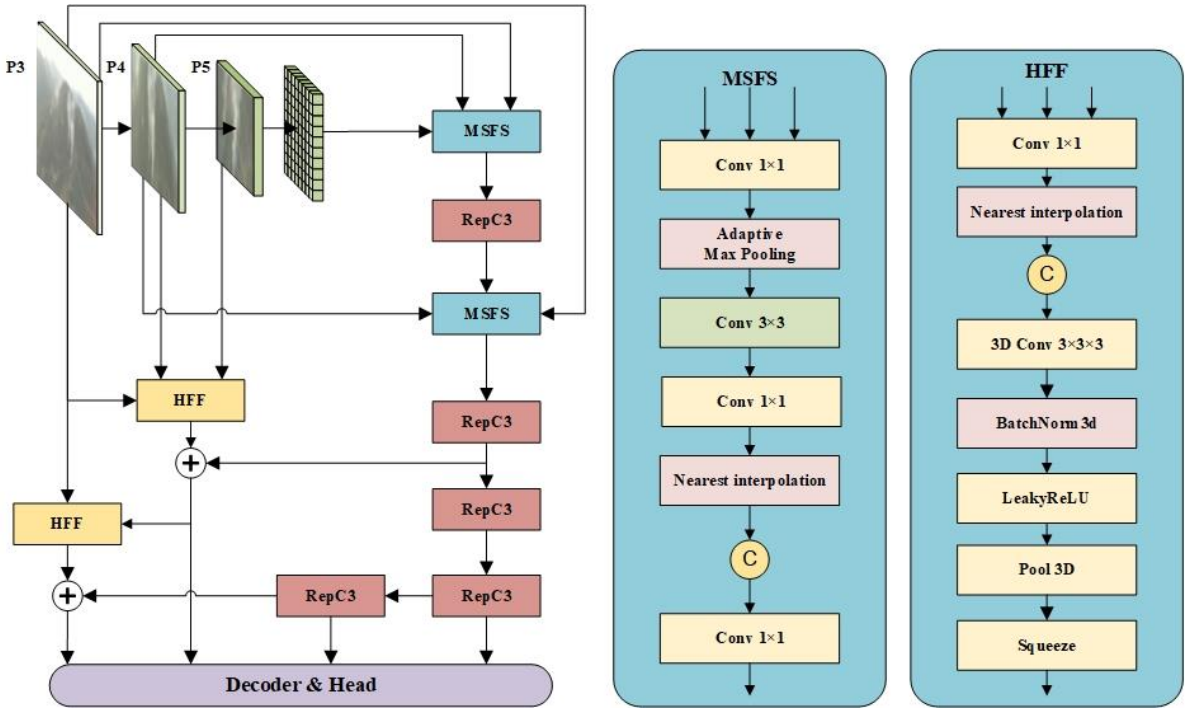

Fig. 6. Cross-Scale Smoke Feature Fusion Module (CS-SFFM).

The Hierarchical Feature Fusion Module (HFF) upscales the smaller-scale feature maps P_s and P_m to match the resolution of the larger-scale feature map P_l. Then, the three adjusted feature maps are fused using 3D convolution, followed by max pooling to process the output. This approach retains high-level semantic information while incorporating low-level detail, providing the network with more expressive features. The HFF can be described as:

$$P_s' = interpolate\ (P_m\ ,\ size\ of\ P_l) \tag{17}$$

$$combine = cat\left(unsqueeze(\ P_l'\ ,\ P_m'\ ,\ P_s')\right) \tag{18}$$

$$conv3d = Conv3d\left(combine\right) \tag{19}$$

$$act = LeakyReLU\left(bn\left(conv3d\right)\right) \tag{20}$$

$$x = squeeze\left(MaxPool3d\left(act\right)\right) \tag{21}$$

where P represents the feature map, l, m, and s represent different feature map levels, and P' denotes the feature map after upsampling.

Compared to the CCFM module used in RT-DETR, the CS-SFFM module achieves cross-scale multi-level feature fusion through scaling and feature stacking, making more effective use of information from different scales. Furthermore, it constructs a micro-scale feature branch specifically for small object detection, utilizing the large, medium, and small-scale features. This design enhances the ability to detect early-stage, smaller-scale smoke, thereby improving detection accuracy.

Fig. 7. Dataset annotation status.

B. Loss Function Optimization

In the label matching phase during training, RT-DETR utilizes a combination of Hungarian matching and IoU soft labels to align localization and classification, which allows the decoder to obtain higher-quality initial object queries. RT-DETR employs GIoU [36], which provides a more comprehensive evaluation by focusing on the minimum enclosing box of the predicted and ground truth boxes, addressing the issue when these boxes do not overlap. However, when the predicted box is entirely within the ground truth box,

GIoU degrades to IoU, leading to slower regression speed. Additionally, due to the often irregular shape of smoke and its blurred boundaries, GIoU's focus on the pixel-level overlapping area makes it difficult to perform an effective evaluation.

EIoU [37] minimizes the height difference between the predicted and ground truth boxes while focusing on the minimum enclosing box, enabling more accurate box evaluation for detection targets with blurred boundaries and irregular shapes. EIoU can be divided into three components: IoU loss L_{IoU}、distance loss L_{dis}、and aspect ratio loss L_{asp}, The expressions are as Eq. (22):

$$\begin{aligned} L_{EIoU} &= L_{IoU} + L_{dis} + L_{asp} \\ &= 1 - IoU + \frac{1}{2}\left(\frac{d_{center}^2}{d_{diag}^2} + \frac{\alpha \square AR_{diff}^2}{AR_{sum}^2}\right) \end{aligned} \tag{22}$$

where, d_{center} is the Euclidean distance between the center points of the predicted box and the ground truth box. d_{diag} is the length of the diagonal of the enclosing box. AR_{diff} is the difference in aspect ratios between the predicted box and the ground truth box. AR_{sum} is the sum of the aspect ratios of the predicted box and the ground truth box. α is a coefficient used to adjust the weight of the aspect ratio loss.

Compared to GIoU, EIoU accounts for uncertainty by introducing a probability distribution to model the position of the bounding box. This approach more accurately reflects the relative position and size between bounding boxes, and through expectation calculations, it prevents the loss from being reduced to zero even when the predicted box is very close to the ground truth box, thus avoiding overfitting caused by perfect scores during training. Additionally, EIoU introduces a scaling factor that can dynamically adjust based on the target size. This ensures that even if the overlap between the predicted box and the ground truth box is small for small targets, the score will not be overly penalized, thereby improving the model's accuracy and robustness in detecting small objects. For these reasons, we chose EIoU to replace GIoU in the label matching phase.

IV. Experiment and Algorithm Performance Evaluation

To validate the effectiveness of the model improvements, we conducted ablation experiments on the enhanced model using a self-constructed dataset. Additionally, we tested the performance of several representative real-time object detection models, the original RT-DETR-r18 model, and the improved model on the same dataset to assess their ability to detect fire smoke in the shortest possible time. The performance of the improved model was thoroughly evaluated.

A. Dataset

Currently, the number of publicly available real-world outdoor fire smoke datasets is limited. To develop a detection model with optimal performance, it is crucial to consider the most challenging detection scenarios. These include interference factors such as backlighting, long distances, strong winds, color variations, dense targets, and complex backgrounds. We collected 7,834 smoke images from unannotated public datasets and the internet, further filtering them based on these interference factors. After ensuring that all types of interference were represented and removing low-quality images, we selected 1,868 images, each containing at least one smoke target. These images were manually annotated using the Labelimg tool to create a custom YOLO-format smoke dataset. Fig. 7 shows dataset annotation status. The dataset was then randomly divided into training and test sets in an 8:2 ratio. All image sizes were adjusted to 640×640 to enhance detection speed.

Data preprocessing involved color space conversion and random mosaic processing to further augment the dataset and improve the model's robustness across different detection scenarios.

B. Implementation Details

1) Hardware and software environment: The hardware environment for the experiments in this paper is shown in Table I.

TABLE I. Experimental Environment

CPU	AMD EPYC 7773X @ 3.50GHz
GPU	GeForce RTX 4090
RAM	80G
Operating System	Ubuntu 20.04
Programming Language	Python 3.8
Deep Learning Framework	Pytorch 2.0.0
GPU Acceleration Library	Cuda 11.8

2) Training hyperparameter settings: The hyperparameters used in the experiments are listed in Table II.

TABLE II. Training Hyperparameter Settings

HYPERPARAMETER	Value
Optimizer	AdamW
Epochs	150
Batch size	16
Learning rate decay	cosine
Learning rate	0.0001
Weight decay	0.0001

3) Evaluation metrics: When evaluating the smoke detection performance of the model, we used five metrics: Recall, Average Precision (AP), model parameters (Params), Giga Floating Point Operations Per Second (GFLOPS), and Frames Per Second (FPS).

Recall is a crucial metric for assessing the detection capability of the model. It represents the proportion of correctly detected smoke instances out of all actual smoke samples. The calculation formula is as follows:

$$Recall = \frac{TP}{TP + FN} \tag{23}$$

where, TP refers to the number of smoke instances correctly detected by the model, while FN refers to the number of smoke

instances that the model failed to detect. A high recall indicates that the model can more comprehensively detect smoke.

AP represents the model's average detection accuracy across different confidence thresholds. The calculation formula is as follows:

$$Precision = \frac{TP}{TP + FP} \tag{24}$$

$$AP = \int_0^1 P(R)\,dR \tag{25}$$

where, AP represents the Average Precision, $P(R)$ denotes the precision value at a given recall R, N is the total number of classes.

Model parameters refer to the total number of trainable parameters in the model, which is an indicator of the model's complexity and storage requirements. A larger number of parameters typically implies a higher model complexity, potentially requiring more computational resources and storage space. The calculation formula is as follows:

$$Params = \sum_{l=1}^{L} Params_l \tag{26}$$

where, L is the total number of layers in the model, and $Params_l$ represents the number of parameters in the l -th layer.

Model computational cost refers to the total number of computational operations required during inference or training. It is an important metric for assessing the complexity and operational efficiency of a model. A higher computational cost typically indicates that the model requires more computational resources and time to complete inference or training.

$$Total\ GFLOPs = \sum_{i=1}^{L} GFLOPs_i \tag{27}$$

where L represents the total number of layers in the model, and $GFLOP_{Si}$ denotes the computational cost of the i -th layer.

FPS indicates the number of image frames a model can process per second during operation, serving as a key metric for evaluating the model's real-time performance. A higher FPS value signifies faster processing speed, making the model more suitable for real-time detection scenarios, such as video surveillance systems. The calculation of FPS typically considers the model's inference time and processing capability.

$$FPS = \frac{N}{T} \tag{28}$$

where N represents the number of processed image frames, and T is the total time taken to process these N frames.

Considering the concept of transfer learning, the experiments utilized pre-trained weights obtained from training on the VOC 2007 dataset. These pre-trained weights were used as initialization for training on the dataset in this study.

C. Ablation Experiments

1) Network input ablation experiment: To validate the effectiveness of the input aggregation strategy for concentration features and evaluate the efficacy of using CFA as network input, we conducted ablation experiments on both RT-DETR and YOLOV8m, focusing on their impact on model detection accuracy. The experimental results are shown in Table III. Using CFA as model input improves the detection accuracy for smoke. In RT-DETR, using CFA as input resulted in AP50 and AP95 scores of 0.882 and 0.585, respectively, representing an improvement of 1.2% and 0.9% compared to using RGB input, which achieved scores of 0.870 and 0.574. In YOLOV8m, using CFA as input yielded AP50 and AP95 scores of 0.856 and 0.602, respectively, reflecting increases of 1.1% and 2.1% over RGB input. These results indicate that replacing RGB images with CFA images as network input can effectively enhance the model's performance in smoke detection tasks.

TABLE III. ABLATION STUDY ON INPUT TYPES

Model	Input Type	AP_{50}	AP_{95}
RT-DETR	RGB	0.870	0.574
	CFA	0.882	0.585
YOLOV8m	RGB	0.845	0.581
	CFA	0.856	0.602

2) Effectiveness of improvements: To evaluate the benefits of each improvement in the enhanced network model for smoke detection tasks, we conducted six ablation experiments focusing on the three main improvements. To ensure that the experiments accurately reflect the impact of the network structure improvements and eliminate additional interference, all experiments used CFA images as the network input and were trained for 150 epochs on the custom dataset. Table IV presents the experimental results of the models under different configurations. First, we tested the baseline model, and then we sequentially added different improvement schemes. The specific experiments are as follows:

TABLE IV. ABLATION STUDY ON IMPROVED MODULES

Experiment Number	Improvement Scenarios			Evaluation Indicators					
	EIoU	S-CLDA	CSFFM	$Recall(\%)$	$AP_{50}(\%)$	$AP_{95}(\%)$	$Params(M)$	$GFLOPs$	$FPS(Hz)$
1	×	×	×	0.860	0.882	0.585	20.18	57.3	**65**
2	√	×	×	0.873	0.887	0.592	20.18	57.3	65
3	√	√	×	0.884	0.920	0.616	20.48	67.3	48
4	√	×	√	0.878	0.915	0.627	**15.07**	59.7	52
5	×	√	√	0.889	0.933	0.641	15.47	68.3	46
6	√	√	√	**0.895**	**0.939**	**0.648**	15.47	68.3	45

a) In Experiment 1, the baseline model was used without any improvement schemes. The results were: recall of 0.867, AP50 of 0.882, AP95 of 0.585, with a parameter count of 20.18 million and a computational requirement of 57.3 GFLOPS.

b) In Experiment 2, EIoU was incorporated, increasing recall to 0.873, AP50 to 0.887, and AP95 to 0.592, while the parameter count and computational load remained nearly unchanged.

c) In Experiment 3, building on the addition of EIoU, the S-CLDA was further introduced. The inclusion of attention mechanisms significantly improved the model's responsiveness and accuracy in detecting smoke targets, with recall rising to 0.902, AP50 reaching 0.920, and AP95 increasing to 0.616. The parameter count slightly increased to 20.48 million, and due to the integration of deformable convolutions and depth-wise separable convolutions, the computational cost modestly rose to 67.3 GFLOPS.

d) In Experiment 4, the CCFM was replaced with CS-SFFM, in addition to EIoU. This new strategy provided more refined cross-scale feature fusion with minimal information loss, significantly enhancing the model's ability to accurately localize targets. Recall increased to 0.897, AP50 reached 0.915, and AP95 rose to 0.627. Since CS-SFFM uses 3D convolutions and 3D pooling for feature fusion instead of multiple stacked convolutional layers, the computational cost slightly increased to 59.7 GFLOPS, while the parameter count significantly decreased to 15.07 million.

e) In Experiment 5, both S-CLDA and CS-SFFM were applied, while EIoU was omitted from the loss function. Despite the absence of EIoU optimization, the introduction of the remaining improvement modules still considerably enhanced the model's smoke detection performance. Recall rose to 0.911, AP50 reached 0.933, and AP95 increased to 0.641.

f) In Experiment 6, all improvement schemes were implemented simultaneously. This configuration yielded the best model performance, with recall increasing to 0.923, AP50 reaching 0.939, and AP95 rising to 0.648. The parameter count and computational cost were maintained at 15.47 million and 68.3 GFLOPS, respectively.

The experimental results demonstrate that replacing GIoU with EIoU enhances model accuracy without increasing additional parameters or computational load. The application of S-CLDA and CS-SFFM positively impacts both recall rate and detection accuracy in smoke detection tasks.

These improvements enhance detection performance while effectively controlling the growth in computational cost and significantly reducing the number of model parameters. In summary, the proposed improvements effectively enhance the model's performance in executing smoke detection tasks.

D. Performance Comparison Experiments

To validate the effectiveness of the proposed algorithm, four mainstream real-time object detection algorithms—YOLOv5m, YOLOv6m, YOLOv7, and YOLOv8m—were selected for comparison, along with the baseline model RT-DETR-r18.

1) Comparison of evaluation metrics: In the fire smoke detection task, we compared the training curves of the mainstream YOLO series algorithms with the baseline algorithm and our proposed model. The corresponding curves were plotted to provide a more intuitive observation of their training progress and differences, as shown in Fig. 8.

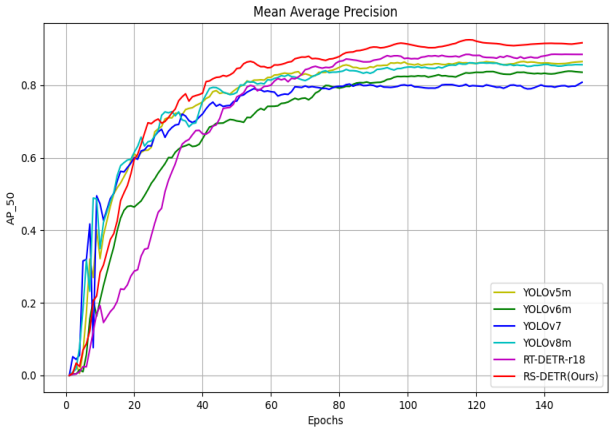

Fig. 8. Different algorithms' AP50 variations during training.

All models achieved convergence within 150 epochs. Our model demonstrated excellent performance in terms of accuracy and maintained high stability throughout the entire training process. Although the baseline model's accuracy was only slightly lower than that of our model, it exhibited significant fluctuations during training and had a slower convergence rate, falling behind the other algorithms. Overall, the improved model outperformed the baseline model in both detection accuracy and training stability.

The test results of each model on the self-built dataset are shown in Table V. Our algorithm achieved the best accuracy with 15.47 million parameters, an AP50 of 0.939, and an AP95 of 0.648. This success can be attributed to the more targeted and accurate smoke feature extraction enabled by the S-CLDA attention mechanism, as well as the refined multi-level feature fusion facilitated by CS-SFFM, which preserves more low-level features through adaptive pooling and interpolation.

TABLE V. COMPARATIVE EXPERIMENTS ON SELF-BUILT DATASET

Compare Models	Evaluation Indicators				
	Recall	AP_{50}	AP_{95}	*Param*	*GFLOPs*
YOLOv5m	0.839	0.863	0.564	21.2	64.6
YOLOv6m	0.802	0.834	0.544	24.85	161.7
YOLOv7	0.782	0.805	0.537	36.9	104.7
YOLOv8m	0.825	0.856	0.602	25.85	79.3
RT-DETR-r18	0.860	0.882	0.585	20.18	57.3
RS-DETR(ours)	**0.895**	**0.939**	**0.638**	**15.47**	68.3

2) Multi-scale smoke detection comparison experiments: Fire smoke undergoes significant scale variations at different stages, with early-stage smoke, which is often of high detection value, typically being smaller in size. To assess the model's

detection performance across different stages of smoke, we designed a multi-scale smoke detection experiment. To visually represent the model's effectiveness in detecting smoke targets of varying scales, we applied the K-means [38] algorithm to cluster the test set and then divided the test set based on the clustering results. The clustering outcomes are shown in Fig. 9, where the centroids of the large, medium, and small target clusters correspond to [0.107, 0.131], [0.246, 0.325], and [0.333, 0.587], respectively.

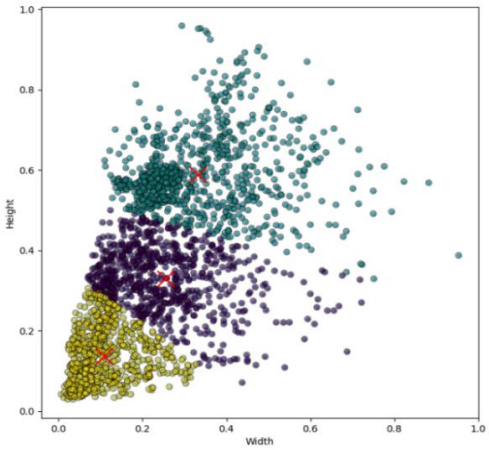

Fig. 9. Analysis of smoke scale distribution.

As shown in Table VI, after filtering and dividing the dataset, the test set of 374 images includes 145 images with small smoke targets, 152 images with medium smoke targets, and 77 images with large smoke targets.

TABLE VI. TEST SET TARGET SEGMENTATION RESULTS

Target Scale	Small Objects	Medium Objects	Large Objects
Target Quantity	145	152	77

Fig. 10 presents the statistical results of each algorithm's performance in detecting smoke targets of different scales. The results indicate that in the multi-scale smoke detection comparison, RS-DETR outperformed other mainstream real-time detection algorithms across all smoke scales. Compared to the YOLO series detection models, the improved model demonstrated particularly outstanding performance in detecting small-scale smoke. This improvement can be attributed to the CS-SFFM module in RS-DETR, which employs bilinear interpolation for scaling, effectively mitigating the loss of fine-grained feature details. Consequently, the model demonstrates enhanced sensitivity in capturing the distinctive characteristics of small-scale smoke targets, thereby reducing the likelihood of misclassification as background.

3) Comparison of detection results under interference factors: To validate the model's detection performance under various interference factors, we selected smoke images with strong wind, backlighting, long distances, color differences, and dense targets for comparison. The detection results are shown in Fig. 11. The results indicate that YOLOv5m performed poorly in detecting smoke targets with color differences and exhibited repeated detections when faced with distant, backlit targets. YOLOv6m and YOLOv7 both experienced missed or false detections in scenarios involving background interference, dense small targets, and backlighting. YOLOv8m also showed missed detections when detecting smoke targets with color differences. The baseline model encountered missed detections and false detections when dealing with dense small targets and backlit targets, likely due to the NMS-free strategy's inability to accurately determine whether to retain detection boxes for adjacent targets. The improved algorithm presented in this paper was able to correctly detect smoke targets in all these challenging scenarios, demonstrating higher detection accuracy and robustness, thereby meeting the practical application requirements for fire smoke detection.

4) Heatmap comparison: Heatmaps are a visualization technique used to display the intensity distribution of objects detected by a model within an input image. They typically indicate the location and confidence of the detected targets, with brighter areas representing higher confidence levels. We compared the heatmaps generated by the baseline model and the improved model, as shown in Fig. 12. The heatmap on the left corresponds to the baseline model, RT-DETR-r18, showing that the model primarily focuses on the central region of the smoke, with lower attention to the edges. In contrast, the second heatmap corresponds to our improved model, where the highlighted areas cover both the main body and the diffuse portions of the smoke, nearly encompassing the entire smoke region. Additionally, the heatmap of our model demonstrates higher attention to the overall structure of the smoke and effectively responds to thin smoke, indicating greater confidence in detecting smoke targets. These observations confirm that the improved model outperforms RT-DETR-r18 in smoke detection tasks.

V. CONCLUSION

This paper introduces an enhanced fire smoke detection algorithm based on RT-DETR, focusing on improving accuracy, real-time performance, and robustness against various interference factors. Key improvements include using the dark channel prior method for smoke concentration input, integrating the S-CLDA attention mechanism for robust feature extraction, and optimizing multi-scale feature fusion through the CSFFM module with 3D convolution and interpolation. The EIoU loss function further enhances detection accuracy for small targets and reduces redundant detections. Experiments on a self-made smoke detection dataset show that the improved model outperforms mainstream YOLO models and the RT-DETR-r18 baseline in AP50 and AP95 metrics while maintaining high detection speed. Specifically, the model achieved a 5.9% increase in AP50 and a 5.7% increase in AP95 with a 23.3% reduction in parameters, balancing accuracy and efficiency. This study confirms the potential of RT-DETR in fire smoke detection and demonstrates the effectiveness of the proposed improvements. Future work will focus on further optimizing the model, exploring advanced feature extraction and fusion strategies, and validating the model's robustness across diverse datasets and real-world scenarios to provide more reliable and efficient fire detection technology.

***Abstract*—Financial bubbles have long been a focus of researchers, particularly due to the severe negative impacts following the bursting of financial bubbles. Therefore, the ability to effectively predict financial bubbles is of paramount importance. The aim of this study is to measure and predict the stock market price bubble in China from January 2015 to December 2023. To achieve this, we utilized the GSADF test, currently the most effective, to identify and measure the situation of the stock market price bubble in China. Subsequently, we selected inflation rate, consumer confidence index, stock yield, and price-earnings ratio as explanatory/predictive variables. Finally, four machine learning methods were employed to forecast the stock market price bubble in China. The results indicate that a price bubble occurred in the Chinese stock market during the first half of 2015, before the outbreak of the COVID-19 pandemic in China in January 2020. Furthermore, the comparison reveals that among the machine learning methods, logistic regression is the most suitable and effective for China, while other methods such as deep learning and decision trees also hold certain value.**

***Keywords*—Stock price bubbles; machine learning; Chinese stock market**

I. INTRODUCTION

Asset price bubbles refer to asset prices that exceed their fundamental values, and their occurrence has consistently had significant impacts on the economies of nations and the lives of their citizens [1]. Whether considering global instances, such as the Japanese real estate and stock market bubbles during 1986 to 1991, the late 1990s dot-com bubble in the United States, or from the perspective of China, such as the 2009s Chinese stock market bubble that occurred following the U.S. subprime mortgage crisis, it is evident that financial bubbles exert considerable influence on economies, particularly with regard to adverse effects. When a financial bubble bursts, they can precipitate the collapse of financial institutions and push nations to the brink of bankruptcy. Moreover, they not only impact the development of a single country but sometimes also trigger global financial crises or induce worldwide economic downturns [2]. Generally, following the occurrence of these crises, governments are compelled to allocate substantial resources and implement a variety of measures to attempt to stabilize and salvage the national economy.

Furthermore, for investors and the public, the negative consequences of financial bubbles make it difficult for confidence to be restored in the market. Most of the public lacks experience and risk management abilities, and they are most heavily affected by the bursting of financial bubbles. When they go bankrupt, it causes societal upheaval [3]. Therefore, studying and forecasting financial bubbles are of paramount importance for governments and regulatory authorities. Such endeavors enable governments to implement appropriate economic policies at the right juncture to mitigate the adverse effects of financial bubbles. Moreover, in the current context of economic globalization, where nations and various types of markets are interconnected, the detrimental impacts of financial bubbles can have broader repercussions. China that is the world's second-largest economy possesses unique characteristics and complexities in its stock market. The emergence of a stock market bubble in China not only affects its domestic economy but also has ramifications for the global economy. Consequently, accurate prediction of stock market bubbles in China holds positive implications for both the Chinese and global economies. Such predictions can offer valuable guidance for investors, provide early warnings for financial institutions, and prompt regulatory authorities to take necessary actions to deal with the existence of bubbles.

The Chinese stock market was established in 1990 with the founding of the Shanghai Stock Exchange. From the establishment of the Chinese stock market in 1990 to 1996, there were four price bubbles in the early stage of the Chinese stock market, and each price fluctuation was extremely violent. In 1999, China promulgated the Securities Law, which created a favorable environment for the further development of the Chinese stock market, attracting more investors to participate in the stock market. However, it also led to the re-emergence of stock market price bubbles. Subsequently, in 2001, China's accession to the World Trade Organization (WTO) resulted in a surge of foreign capital inflows, providing significant impetus for the rapid growth of the Chinese economy. This also led to the rapid development of the Chinese stock market, with an expansion in market size and increased trading activity, attracting more investors. Concurrently, the Chinese government implemented a series of reform and opening-up policies, including financial market reform and state-owned enterprise reform, promoting further development and healthy growth of the Chinese stock market. During this period, the Chinese stock market reached a historical high of 2245 points, representing a cumulative increase of 66.7%. Subsequently, it experienced a slow bear market, with the stock index falling to a low of 998 points. From 2007 to 2008, amidst favorable global economic development and China's hosting of the 2008

Olympic Games, the stock index reached a new high of 6124 points in 2007, soaring more than fivefold. However, with the outbreak of the global financial tsunami triggered by the U.S. subprime mortgage crisis, the stock market plummeted to 1664 points in October 2008. This time, the stock market bubble burst rapidly.In the early 2010s, driven by economic growth and increased participation of domestic and foreign investors, the Chinese stock market experienced rapid expansion. However, this period also witnessed market turbulence, especially the stock market crash in 2015, prompting government intervention to stabilize the market. Subsequently, the Chinese stock market underwent further reforms aimed at improving market efficiency and sustainability. Measures such as the introduction of the Science and Technology Innovation Board (STAR Market) and the implementation of IPO registration system aimed to promote innovation and enhance the quality of listed companies. As of the end of 2023, the market capitalization of the Chinese stock market was approximately 85.54 trillion Yuan, while China's GDP in 2023 reached 126.06 trillion Yuan, accounting for approximately 67.86% of China's GDP [4]. There are a total of 5,346 listed companies in the Chinese domestic stock market, with the industries of manufacturing, information transmission, software and information technology services, and wholesale and retail trade ranking among the top three in terms of the number of listed companies [4]. Since its establishment in 1990, the Chinese stock market has experienced rapid development over the past 30 years. However, along with this rapid growth, the Chinese stock market has also encountered a series of issues, particularly manifested in the frequent occurrence of stock market bubbles. The Chinese market is typically sensitive to various rumors, leading to price manipulation of many stocks by rumor mongers. The main reasons for these issues lie in the lack of transparency in the market information and fluctuations in investor sentiment. Therefore, the government and regulatory authorities should remain vigilant at all times to detect financial bubbles promptly and formulate corresponding policies to protect stock market investors, especially retail investors, and stabilize the economic market.

Research on stock price bubbles typically addresses several key questions and objectives, which can be categorized into three main areas. First, it evaluates the factors that contribute to the formation of stock price bubbles. Second, it identifies the early stages of stock price bubbles using the GSADF method. Finally, it develops and validates effective machine learning models and techniques for early detection of stock price bubbles, aimed at improving the accuracy of bubble identification. By addressing these research questions and objectives, this study seeks to provide a comprehensive understanding of stock price bubbles, with a particular focus on the Chinese market, and to offer practical recommendations for enhancing market stability and investor decision-making.

II. Theoretical Literature Review

A. Theoretical Literature Review about Measuring Stock Market Bubble

In research conducted throughout history, there has been a wealth of studies devoted to measuring financial market bubbles. These studies encompass various types of markets, such as stock markets, real estate markets, cryptocurrency markets, and others. Given that this paper focuses on the domain of stock markets and specifically examines price bubbles within this context, it provides a concise overview of measuring bubbles in the stock market domain, with particular emphasis placed on studies employing statistical models applied to time-series data.

Dickey (1979) proposed the Augmented Dickey-Fuller (ADF) test in 1979 to examine whether time series data exhibit unit roots, indicating non-stationarity [5]. In the realm of finance, the ADF test is also utilized to investigate the presence of asset price bubbles. This method, grounded in unit root testing, entails regression analysis of time series data to assess the presence of unit roots within the sequence. The existence of a unit root suggests non-stationarity and the potential existence of a price bubble; conversely, the absence of a unit root indicates stationarity and a lower likelihood of a price bubble. The significance of the test results is typically determined by setting thresholds, thereby ascertaining the presence or absence of a price bubble. Wang (2020) employed the ADF test to evaluate the existence of bubbles in the Chinese stock market [6].

Cheung (1995) introduced the Supremum Augmented Dickey-Fuller (SADF) test as an enhancement to the Augmented Dickey-Fuller (ADF) test [7]. Similar to the ADF test, the SADF test is employed to examine whether time series data possess unit roots, thereby determining the presence of non-stationarity. However, the SADF test introduces the concept of "supremum," allowing for testing across multiple lag lengths and identifying the optimal lag length. By doing so, the SADF test can more accurately ascertain the non-stationarity of time series data and provide more precise unit root test results. Consequently, the SADF test is considered a more reliable method than the ADF test in some cases, particularly when dealing with long or unstable time series data. Homm and Breitung (2012) utilized this test to detect stock market bubbles and, through a process of simulation and comparison of evaluation criteria, determined the SADF test to be the most optimal among the methods employed [8]. While effective in identifying single bubble events, the SADF test may encounter challenges in practical applications where multiple bubbles occur in sufficiently large samples. Although successful in identifying notable historical bubbles, the SADF test failed to detect the bubble associated with the 2007 – 2008 debt crisis.

Phillips et al. (2011) proposed the Generalized Supremum Augmented Dickey-Fuller (GSADF) test as an advancement and refinement of the Supremum Augmented Dickey-Fuller (SADF) test [9]. Similar to the SADF test, the GSADF test is utilized to examine whether time series data exhibit unit roots, thereby determining non-stationarity. However, the GSADF test introduces the Maximized Average Power (MAP) statistic, which allows for the testing of unit root presence and location at each stage, rendering it more flexible in determining the existence and location of unit roots. By considering the possibilities across multiple lag lengths, the MAP statistic enhances the flexibility of the test, leading to a more accurate determination of non-stationarity in time series data. This

enables the GSADF test to be applicable to a wider range of hypotheses and more flexible in determining the existence and location of unit roots. Through the utilization of the GSADF test, researchers can more accurately identify non-stationarity in time series data. Phillips et al. (2015b) employed both the SADF and GSADF tests to empirically apply them to Standard & Poor's 500 stock market data spanning from January 1871 to December 2010[10]. The new GSADF method successfully identified historical events of prosperity and collapse during this period, such as the Panic of 1873 (October 1879 to April 1880) and the Dot-com bubble (July 1997 to August 2001).

Based on the comprehensive review of methods for measuring the stock market domain, we have found that the Generalized Supremum Augmented Dickey-Fuller (GSADF) measurement is currently the most effective among the detection methods. Therefore, in our study of measuring price bubbles in the Chinese stock market, we will utilize the GSADF method.

B. Theoretical Literature Review about Machine Learning in Financial Field

In recent years, machine learning methods have garnered increasing attention from scholars, whether in forecasting financial crises [11], predicting financial bubbles [12][13], or anticipating stock price trends [14] [15]. They all have provided researchers with a novel set of tools and solutions for investigation.

Ouyang and Lai (2021) utilized machine learning algorithms to assess systemic risk warnings in China [11],. Their study revealed that the Attention-Long Short-Term Memory (Attention-LSTM) neural network model within the machine learning algorithms demonstrated higher accuracy compared to other models. This suggests that in the context of China, the Attention-LSTM neural network model holds significant value for systemic risk assessment and early warning.

Başoğlu Kabran and Ünlü (2021) employed machine learning techniques to forecast financial bubbles [12]. They utilized the Support Vector Machine (SVM) algorithm within the domain of machine learning for predicting financial bubbles and compared this approach against alternative methods, concluding that the Support Vector Machine exhibited superior effectiveness in forecasting financial bubbles. The study focused on predicting bubbles within the Standard & Poor's 500 Index.

Tran et al. (2023) employed machine learning methods to predict financial bubbles in the Vietnamese stock market from 2001 to 2021 [13]. They utilized six different algorithms within machine learning to forecast these financial bubbles and compared these algorithm results. Their findings concluded that the Random Forest and Artificial Neural Network algorithms outperformed traditional statistical methods in predicting financial bubbles in the Vietnamese stock market.

Gu et al. (2020) applied machine learning methods to empirical asset pricing [14]. They found that decision trees and neural networks exhibited the best predictive performance among machine learning algorithms. The outstanding predictive capability of these two algorithms primarily stems from their ability to capture complex nonlinear interactions among predictive variables, a task often challenging for other algorithms. Using these two machine learning algorithms yielded performance twice as high as traditional statistical methods. Furthermore, this study identified return reversal and momentum, stock liquidity, stock volatility, and valuation ratios as the most influential factors in asset pricing among the predictive variables.

Zhou et al. (2023) utilized a Deep Neural Network (DNN) model within the domain of machine learning to forecast stock premiums [15] .The research spanned from December 1950 to December 2016, employing monthly data. Stock premiums were computed as the difference between the logarithmic returns of the Standard & Poor's 500 Index (including dividends) and those of risk-free assets. The investigation compared the DNN model from machine learning against the Ordinary Least Squares (OLS) model and Historical Average (HA) model from traditional statistical analysis, ultimately revealing the superior predictive efficacy of the DNN model. Researchers enhanced the predictive capability of the DNN model by incorporating 14 predictive variables. They attributed the DNN model's superior predictive performance primarily to its ability to automatically extract high-dimensional features from data and identify various predictive patterns within the dataset.

Based on the literature discussed above, it is evident that machine learning algorithms exhibit superior performance in classification and time series regression problems. However, it is important to note that the predicted results may vary significantly among different models depending on the dataset utilized, and there is no universally applicable method to ensure consistently superior performance.

Drawing upon the synthesized literature, it becomes apparent that the utilization of machine learning for predicting financial bubbles in the stock market is a relatively novel approach, with limited research attention received thus far. So far, only Başoğlu Kabran and Ünlü (2021) employed machine learning methods to predict bubbles in the S&P 500 index, as well as Tran et al. (2023) in forecasting bubbles in the Vietnamese stock market from 2001 to 2021, as mentioned earlier in the text. Research in the financial domain primarily focuses on predicting financial crises and stock price trends [12] [13]. There is a dearth of corresponding studies in China regarding the prediction of stock market price bubbles, particularly concerning the utilization of machine learning algorithms. To the best of our knowledge, there have been no studies utilizing machine learning methods to forecast stock market price bubbles in China. Therefore, the purpose of this study is to measure and predict the price bubble in the Chinese stock market, and compare the performance of the machine learning algorithms used to select the most suitable model for the price bubble in the Chinese stock market.

III. RESEARCH DESIGN

The primary objective of our study is to measure the stock market price bubbles in China from January 2015 to December 2023, with January 2020 serving as the demarcation point [16], dividing the time period into pre-China COVID-19 and post-China COVID-19 phases, and using carefully selected four

explanatory variables — namely, the inflation rate in macroeconomic factors, the consumer confidence index in sentiment factors, and stock yield and price-to-earnings ratio in market factors to predict the occurrence of stock market price bubbles in China. In this research, we employ the Generalized Supremum Augmented Dickey-Fuller (GSADF) test to identify and measure the presence of stock market price bubbles in China and select four machine learning algorithms for prediction. Ultimately, by comparing the performance results of the four machine learning algorithms, we find the best model for predicting stock market price bubbles in China. This study theoretically contributes empirical evidence to the application of machine learning in forecasting financial bubbles and practically offers early warnings to investors and decision-makers, enabling them to make appropriate financial decisions.

IV. Data and Methodology

A. Data

We utilized the stock market index data of China (Shanghai Composite Index) from January 2015 to December 2023 and employed the Generalized Supremum Augmented Dickey–Fuller (GSADF) method to identify price bubbles in the Chinese stock market during this period. The Chinese stock market index or the Shanghai Composite Index refers to the capitalization-weighted index of all companies listed on the Shanghai Stock Exchange. The monthly dataset of the Chinese stock market comprises 108 data points, while the weekly dataset comprises 470 data points. Among these, it was observed that price bubbles occurred in the Chinese market for 6 months and 25 weeks respectively. The measurement method for price bubbles in the Chinese stock market is the Generalized Supremum Augmented Dickey–Fuller method, which is elaborately described in Section II.A.

In employing machine learning methods, for the convenience of training and testing, we opted for four machine learning algorithm models. We divided the data into two datasets: one for training and the other for testing. Specifically, the training dataset comprises weekly data from January 2015 to December 2023, while the testing dataset comprises monthly data from the same period. The training dataset comprises stock market bubble conditions derived from weekly data publicly disclosed on the official website of the Shanghai Stock Exchange. In contrast, the testing dataset consists of stock market bubble conditions derived from monthly weighted average data disclosed on the same website. Due to the disparate sources of weekly and monthly data, the datasets for training and testing during the same time periods are not identical. However, both datasets all cover the period from January 2015 to December 2023. For instance, the training dataset for January 2015 consists of four weekly data points from that month, whereas the testing dataset consists of the monthly data for January 2015.

The daily and intraday data are unsuitable for this research due to the insufficient labeling of bubbles in the Chinese stock market. Using daily data results in significant classification issues with the labels. To mitigate this problem, the study shifts to analyzing weekly and monthly observations [17]. The selection of evaluation metrics must align with the nature of the classification problem. For such tasks, pertinent metrics include AUC, F-measure, accuracy, precision, and sensitivity [18].

This essentially ensures that the condition of stock price bubbles in the training dataset is four times that in the testing dataset. The purpose of this arrangement is to ensure that both the training and testing datasets contain sufficient data for model development and application in machine learning.

In employing machine learning methods, we incorporated four explanatory variables into the algorithmic model. These four explanatory variables consist of the inflation rate from macroeconomic factors, the consumer confidence index from sentiment factors, and the stock yield and price-earnings ratio from market factors. Within the time frame selected from January 2015 to December 2023, they were also segregated into a testing dataset comprising solely monthly data and a training testing dataset comprising solely weekly data.

The measurement of price bubbles in the Chinese stock market (Shanghai Composite Index) was obtained through the Generalized Supremum Augmented Dickey–Fuller (GSADF) program in the EViews software. For data analysis, we utilized corresponding algorithms in machine learning tools — specifically, logistic regression, deep learning, decision tree, and support vector machine—via the RapidMiner software.

B. Methodology

This study is divided into two parts. The first part involves the detection of price bubbles in the Chinese stock market, while the second part involves the use of four machine learning algorithms to predict the occurrence of price bubbles in the Chinese stock market.

In the first part, we utilized monthly and weekly stock market price data from China spanning from 2015 to 2023 to identify financial bubble occurrences. During this timeframe, with January 2020 marking the dividing line, we segmented the data into pre-COVID-19 pandemic and post-COVID-19 pandemic periods. In January 2020, the Chinese government officially declared the emergence of the COVID-19 pandemic in China and implemented nationwide controls [16]. The purpose of this section of the study using detection methods is to identify the occurrence of price bubbles in the Chinese stock market on a monthly and weekly basis during this period. The monthly and weekly data of the Chinese stock indices (Shanghai Composite Index) were obtained through web scraping from the official website of the Shanghai Stock Exchange.

In the second part, we utilized four machine learning algorithms to forecast price bubbles in the Chinese stock market and employed four explanatory variables to predict the occurrence of price bubbles in the Chinese stock market. The dependent variable is the occurrence of monthly/weekly price bubbles in the Chinese stock market, with the outcomes being the results obtained from the first part of the study. When price bubbles occurred in the Chinese stock market, we assigned a value of 1 to the corresponding month/week, and when price bubbles did not occur, we assigned a value of 0 to the

corresponding month/week. The explanatory variables we employed include the inflation rate from macroeconomic factors, the consumer confidence index from sentiment factors, and the stock yield and price-earnings ratio from market factors. The monthly data for these explanatory variables were sourced from the official website of the National Bureau of Statistics of China and the Wind financial database website. Overall, we selected inflation rate, consumer confidence index, stock yield, and price-earnings ratio, these four significant economic indicators, to forecast price bubbles in the Chinese stock market using their data. Since most of these data are monthly, we utilized the EViews tool to convert monthly data into weekly data.

1) The Generalized Supremum Augmented Dickey–Fuller (GSADF) method for measuring price bubbles in the Chinese stock market: In the first part, the method utilized for measuring price bubbles in the Chinese stock market involved employing the currently most effective time series measurement technique, specifically tailored for detecting asset price bubbles—the Generalized Supremum Augmented Dickey–Fuller (GSADF) test [19]. This method was initially proposed by Philialps et al. (2015b) in 2015 and evolved from the augmented Dickey–Fuller (ADF) test and supremum augmented Dickey–Fuller (SADF) test. It utilizes recursive regression techniques to investigate the presence of unit roots when faced with an alternative right-tail explosion hypothesis, enabling the identification of multiple bubble periods within a time series dataset. Rejection of the null hypothesis during the test indicates the existence of asset price bubbles. In the Generalized Supremum Augmented Dickey–Fuller (GSADF) test, critical values for the test statistics are typically obtained through 2000 Monte Carlo simulations [20], aiding in determining the onset and conclusion of asset price bubbles.

The aim of Generalized Supremum Augmented Dickey–Fuller (GSADF) test was to analyze statistical properties on the upper end of the Augmented Dickey–Fuller (ADF) test concerning a time series. By comparing the maximum values generated from the test statistics with predetermined threshold values obtained from the distribution, analysts can make conclusions about the volatility of the observed values.

Phillips et al. (2015b) proposed a more generalized version of the Supremum Augmented Dickey–Fuller (SADF) test, known as the Generalized Supremum Augmented Dickey–Fuller (GSADF) test [10]. Unlike the original SADF test, which involves fixing the starting point of the sample and progressively recursing through minimum sub-samples to the entire sample, the GSADF test allows for both the starting and ending points of the sample to be flexible. It involves recursively regressing the equation for SADF by simultaneously shifting the starting and ending points of the sample forward. Subsequently, the upper bound of the Augmented Dickey–Fuller (ADF) test is obtained based on this, followed by taking the upper bound of a series of SADF statistics.

The fundamental steps of the Generalized Supremum Augmented Dickey–Fuller (GSADF) test are as follows: first, determine the minimum sample window size k_0. Then, allow the starting point of the sub-sample k_1 and the ending point of the sub-sample k_2 to vary between $[0, k_2 - k_0]$ and $[k_0, T]$, respectively. For each sub-sample in this series, conduct an Augmented Dickey–Fuller (ADF) test to obtain a series of ADF statistics. The formula for constructing the GSADF statistic is shown below in Eq. (1).

$$GSADF(k_0) = \sup_{k_1 \in [0, k_2 - k_0]} \sup_{k_2 \in [k_0, T]} \left\{ ADF_{k1}^{k2} \right\} \quad (1)$$

The Generalized Supremum Augmented Dickey–Fuller (GSADF) test is based on regressing the same equation over a series of sub-samples of the time series data. Its null hypothesis and alternative hypothesis are identical. Therefore, the obtained statistic is compared with the critical value on the right side based on a certain significance level. If the statistic exceeds the critical value, the null hypothesis is rejected, and the alternative hypothesis is accepted: a bubble exists.

For estimating the timing of bubble onset and collapse, given the complex evolution of asset prices, Phillips et al. (2015b) represent the three stages of asset price dynamics with the following Eq. (2) [10]:

$$p_t = p_{t-1} I\{t < \tau_e\} + \rho_n p_{t-1} I\{\tau_e \ll t \ll \tau_f\} + \left(\sum_{k=\tau_f}^{t} \varepsilon_t + P_{\tau_f}^*\right) I\{t > \tau_f\} + \varepsilon_k I\{t \geq\} \varepsilon_k \sim iid(0, \sigma^2) \quad (2)$$

Among them Pn>1, $P_{\tau_f}^* = p_{\tau_e} + p^*$, p_{τ_e} represent asset prices before the formation of a bubble, $P^* = \sum_{t=1}^{\tau_f - \tau_e} \varepsilon_t$ indicates the deviation of prices from pre-bubble levels after the bubble forms, τ_f indicates the moment of bubble burst. when $t < \tau_e$, the asset price sequence p_t follows a unit root process, indicating the absence of bubbles in prices. when $\tau_e << t << \tau_f$, Pn > 1, the asset price series exhibits an explosive process. When $t > \tau_f$, the asset price series reverts to a unit root process. The BSADF statistic is calculated based on recursive selection of samples for upper-bound unit root testing. The Eq. (3) for BSADF is provided below.

$$BSADF_{k_2}(k_0) = \sup\left\{BADF_{k_1}^{k_2}\right\} \; k_1 \in [0, k_2 - k_0], k_2 \in [k_0, T] \quad (3)$$

When the statistic first exceeds its corresponding right-tailed unit root test critical value, it indicates the onset of a bubble. Subsequently, when the statistic first falls below its corresponding right-tailed unit root test critical value, it indicates the collapse of the bubble. However, it is important to note that as the recursive testing selects an increasing sample size, the sample critical values also exhibit an increasing trend. Therefore, it necessitates significant computational effort to calculate finite sample critical values for each sub-sample based on Monte Carlo simulation.

2) Machine learning approaches to forecasting price bubbles in the Chinese stock market

a) Logistic regression: Logistic regression is a statistical method used to model binary classification problems, typically employed to predict the probability of an event occurrence. In this study, we will utilize logistic regression to forecast the presence of price bubbles in the Chinese stock market. Four explanatory variables will be inputted into the model, which ultimately generates the probability of price bubble occurrences in the Chinese stock market. This probability is derived using the Eq. (4) presented below.

$$P(y=1|x)=\frac{1}{1+e^{-(\beta_0-\beta_1x_1+\beta_2x_2+\cdots+\beta_nx_n)}} \quad (4)$$

Logistic regression is generally considered a fundamental method in machine learning. This algorithm is relatively easy to understand and implement, making it accessible to a broad spectrum of users. Consequently, due to its excellent interpretability, logistic regression is frequently employed in practical applications within financial institutions.

b) Deep learning: Deep learning is typically regarded as an advanced algorithm within the realm of machine learning. It is a machine learning method based on artificial neural networks, which utilize multi-layered neural network architectures for feature learning and representation learning, thereby achieving the learning and prediction of complex data patterns. The core idea of deep learning involves gradually extracting abstract features from input data through multiple layers of non-linear transformations, enabling the solution of higher-level tasks such as image recognition, speech recognition, and natural language processing.

The advantages of deep learning algorithms lie in their powerful adaptability, capable of learning complex non-linear relationships and applicable to various types of data. They automatically learn feature representations from input data without the need for manual feature engineering. Deep learning also exhibits strong generalization capabilities, enabling learned patterns from the training set to be generalized to unseen data, thereby enhancing the reliability and stability of models in practical applications.

c) Decision tree: The decision tree algorithm is also considered a fundamental machine learning algorithm. It learns and extracts a series of decision rules based on a given dataset through a tree-like structure. This algorithm utilizes metrics such as Gini coefficient or entropy to determine the optimal allocation of each split, ensuring the maximization of purity for each split. In decision trees, decision rules are presented in a tree structure, starting from the root node and traversing through a series of internal nodes to reach the leaf nodes, where each leaf node represents a category or output result.

The advantages of the decision tree algorithm lie in its simplicity, ease of implementation, and interpretability. It also offers flexibility in data handling, hence finding wide application in many fields. However, the performance of the decision tree algorithm may be limited when dealing with complex data and high-dimensional feature spaces.

d) Support vector machine: The Support Vector Machine (SVM) algorithm is an advanced method in machine learning. It belongs to the category of supervised learning algorithms, primarily used for classification and regression analysis. The core idea of SVM is to find a hyperplane that maximizes the margin between classes, thus optimizing classification performance. Alternatively, its fundamental principle is to identify an optimal hyperplane in the feature space that maximally separates samples of different classes while maintaining the maximum margin between classes. The classification in Support Vector Machines is conducted using Eq. (5).

$$f(x)=sign(w\cdot x+b) \quad (5)$$

Where x represents the feature vector of a given new input sample, w is the normal vector to the hyperplane, b is the bias term, and sign( ) denotes the sign function. When w∗x+b is greater than 0, the result is 1, and when it is less than 0, the result is -1. Ultimately, this function result informs us about the class membership of sample x.

The advantages of Support Vector Machines (SVMs) include effective handling of small sample sizes, high-dimensional, and non-linear datasets. For high-dimensional and non-linear data, SVMs can utilize kernel functions to map low-dimensional non-linear separable problems into high-dimensional spaces for linear classification.

Popular machine learning algorithms such as logistic regression, deep learning, decision trees, and support vector machines have shown considerable promise in detecting and predicting stock price bubbles due to their ability to analyze extensive datasets, identify patterns, and adapt to new information. For instance, logistic regression can estimate the probability of a bubble by analyzing historical data. Deep learning methods are particularly effective for anomaly detection, as they learn the typical patterns in data and identify deviations that could signal bubble formation. Decision trees and random forests excel in handling non-linear relationships and interactions between features, making them proficient at recognizing conditions indicative of bubbles. Support vector machines can classify similar data points and detect outliers, which may also suggest bubble formations [21]. Together, these algorithms offer valuable insights into market dynamics and potential bubble developments.

V. Empirical Results and Discussion

A. The Results of Measuring Price Bubbles in the Chinese Stock Market using the Generalized Supremum Augmented Dickey-Fuller (GSADF) Method

In this study, we employed the Generalized Supremum Augmented Dickey-Fuller (GSADF) method to measure the presence of price bubbles in the Chinese stock market from January 2015 to December 2023. The monthly average data and the weekly average data publicly released by the Shanghai Stock Exchange served as the source of the Chinese stock market index (Shanghai Composite Index) for this research. When executing the GSADF procedure using the Eviews software, the study adhered to the program's setting specifying a minimum window of 14 observations. The measurement process commenced from January 2015.

TABLE I. STATISTICAL DATA ON THE OCCURRENCE OF PRICE BUBBLES IN THE CHINESE STOCK MARKET

Serial number	*Bubble occurrence time*	*SSECI price*	*Peak*
1	2015/01/05-2015/01/09	3258.63	0.826567
2	2015/01/12-2015/01/16	3258.21	0.8910738
3	2015/01/19-2015/01/23	3189.73	0.9233272
4	2015/01/26-2015/01/30	3347.26	0.9555806
5	2015/02/02-2015/02/06	3148.14	0.987834
6	2015/02/09-2015/02/13	3063.51	1.2599515
7	2015/02/16-2015/02/17	3206.14	1.532069
8	2015/02/23-2015/02/27	3256.48	1.8041865
9	2015/03/02-2015/03/06	3332.72	2.076304
10	2015/03/09-2015/03/13	3224.31	2.50627625
11	2015/03/16-2015/03/20	3391.16	2.9362485
12	2015/03/23-2015/03/27	3640.10	3.36622075
13	2015/03/30-2015/04/03	3710.61	3.796193
14	2015/04/06--2015/04/10	3899.42	3.6476376
15	2015/04/13--2015/04/17	4072.72	3.4990822
16	2015/04/20--2015/04/24	4301.35	3.3505268
17	2015/04/27-2015/04/30	4441.93	3.2019714
18	2015/05/04-2015/05/08	4441.34	3.053416
19	2015/05/11-2015/05/15	4231.27	2.545104
20	2015/05/18-2015/05/22	4277.90	2.036792
21	2015/05/25-2015/05/29	4660.08	1.52848
22	2015/06/01-2015/06/05	4633.10	1.020168
23	2015/06/08-2015/06/12	5045.69	0.68747
24	2015/06/15-2015/06/19	5174.42	0.354772
25	2015/06/22-2015/06/26	4471.61	0.022074

Table I presents the results of identifying price bubbles in the Chinese stock market. This table provides the time occurrence of price bubbles in the Chinese stock market, the overall market prices of the Chinese stock market (Shanghai Composite Index prices) for each period, and the peak values calculated for each bubble period. In Fig. 1, we visually illustrate the time periods during which price bubbles occurred in the Chinese stock market from January 2015 to December 2023. The blue line in the Fig. 1 represents the GSADF statistic sequence, while the orange line denotes the asymptotic critical values obtained from 2000 Monte Carlo simulations using the EViews software tool. By comparing the GSADF statistic sequence (blue line) with the 95% critical value sequence (orange line), the timing of overall market price bubbles in the Chinese stock market (represented by the Shanghai Composite Index prices) is identified. During this period, there were six months with price bubbles on a monthly basis and 25 weeks experiencing financial bubbles on a weekly basis. Notably, we observe a prolonged financial bubble in the first half of 2015. Following the identification of price bubbles in the Chinese stock market from January 2015 to December 2023, we designate months/weeks with identified occurrences of stock market price bubbles as 1, while months/weeks without price bubbles are marked as 0. This preparation aims to facilitate the subsequent creation of datasets for the four machine learning prediction stages.

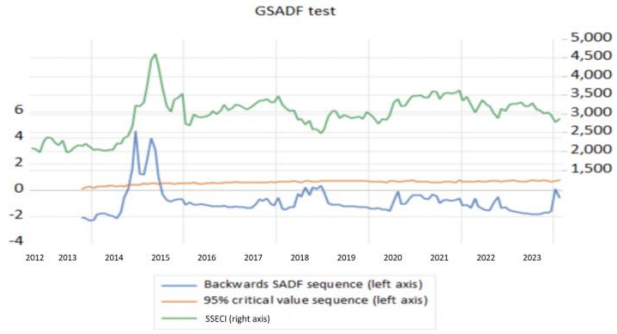

Fig. 1. Chinese Stock market price bubbles from January 2015 to December 2023.

B. The Result of Predicting the Price Bubble in the Chinese Stock Market Using Four Machine Learning Algorithms

In this study, we will employ four machine learning algorithms to predict the occurrence of price bubbles in the Chinese stock market. These four machine learning algorithms are logistic regression, deep learning, decision tree, and support vector machine.

For machine learning models, we optimize the models using the hyperparameter of Area Under the Curve (AUC). In machine learning, particularly in evaluating binary classification models, AUC typically refers to the area under the Receiver Operating Characteristic (ROC) curve. AUC quantifies the entire two-dimensional area underneath the ROC curve, providing a single measure to assess the classifier's performance across various thresholds, with values ranging between 0 and 1. A higher AUC value indicates better model performance, while an AUC value closer to 0.5 suggests performance closer to random guessing. Throughout this process, various hyperparameter values are experimented with to enhance the model. Post-training, AUC is computed using the test dataset. The hyperparameter combination resulting in the highest AUC is designated as optimal. This approach ensures the selection of hyperparameters based on the model's classification performance, with AUC serving as the key metric.

The following Table II presents the performance of the four machine learning algorithm models utilized in our study.

TABLE II. THE PERFORMANCE RESULTS OF THE FOUR MACHINE LEARNING ALGORITHM MODELS

Algorithm	*AUC*	*F Measure*	*Accuracy*	*Precision*	*Sensitivity*
Logistic Regression	1	86.7%	98.5%	90.0%	90.0%
Deep Learning	1	79.3%	96.3%	70.0%	100.0%
Decision Tree	0.992	80.0%	97.8%	90.0%	80.0%
Support Vector Machine	0.558	Not Available	94.8%	Not Available	0.0%

From Table II, we observe that the performance of the logistic regression model surpasses that of other algorithms in terms of AUC, F-measure, accuracy, and precision. The logistic regression model achieves an AUC of 1, an F-measure of 86.7%, accuracy of 98.5%, and precision of 90.0%, all of which are the highest among all algorithms. This indicates its capability to accurately classify the presence of bubbles in the Chinese stock market. However, in terms of sensitivity, the logistic regression model exhibits a lower value compared to the deep learning model, at 90.0%, suggesting a relatively weaker ability of the logistic regression model to correctly identify positive instances. This outcome suggests that while the logistic regression model demonstrates excellent performance in predicting instances of stock market bubbles in China, it may lack flexibility in handling certain types of data and feature representations, leading to relatively lower performance in identifying positive instances.

Furthermore, the deep learning model exhibits perfect performance in terms of AUC and sensitivity, with values of 1 (100.0%), indicating that the model can perfectly distinguish between positive and negative instances at all possible thresholds, without any misclassifications. It can perfectly identify all positive instances without missing any. However, the results for F-measure (79.3%), accuracy (96.3%), and precision (70.0%) suggest that the deep learning model, in predicting the occurrence of bubbles in the Chinese stock market, strikes a compromise between precision and recall, resulting in a certain number of misclassifications overall, with a higher rate of false positives when predicting positive instances. In contrast, the decision tree algorithm performs moderately across all aspects and can serve as a baseline for evaluating the performance of these four machine learning models. Meanwhile, the support vector machine model either performs the worst in all aspects or yields results that are not available, indicating its unsuitability for predicting the occurrence of bubbles in the Chinese stock market.

Solely based on the AUC scores of model performance, we observe that within the machine learning algorithms utilized, both the logistic regression model and the deep learning model achieved perfect scores of 1. This score signifies their ability to maintain a low false positive rate while achieving a high true positive rate. Essentially, this value indicates their proficiency in distinguishing periods of stock market bubbles from those without. However, upon considering the other four performance metrics, overall, the logistic regression model outperforms. Solely based on AUC scores, the other two models — the decision tree model and the support vector machine model — exhibit relatively lower scores. While the decision tree model's score (0.992) demonstrates some competitiveness, the score of the support vector machine model (0.558) indicates relatively poor performance in classification tasks, akin to random guessing. Although the latter two models — the decision tree model and the support vector machine model — may offer some insights, their performance in analyzing the occurrence of stock market bubbles in China lags behind that of logistic regression and deep learning.

Based on the above results, we compared the outcomes of four machine learning methods. These four machine learning algorithms are commonly employed approaches for addressing classification problems in finance. Logistic regression and decision tree are considered fundamental machine learning methods, while deep learning and support vector machine are classified as advanced machine learning methods. The findings indicate that the fundamental machine learning methods (logistic regression and decision tree) outperform the advanced machine learning methods (deep learning and support vector machine) in terms of F-measure, accuracy, and precision. Overall, this suggests that in the specific domain of predicting stock market price bubbles in China, simple fundamental machine learning methods may be more suitable, and there may be no need to blindly pursue complex advanced algorithms, as doing so may yield counterproductive outcomes.

Our research findings differ from Başoğlu Kabran and Ünlü (2021), who utilized machine learning methods to predict the S&P 500 index and concluded that SVM was the best approach [12]. There are two reasons for these discrepancies. First, differences exist in the explanatory variables selected for the input models. Second, variations in the sizes of the datasets utilized by both studies contribute to these disparities. However, it is noteworthy that our study is the first to employ a comparative approach involving multiple machine learning methods to forecast market bubbles in China, the second-largest economy globally. Moving forward, we plan to conduct broader empirical research within the Chinese market context.

Our research results differ from those of Tran et al. (2023), who applied machine learning methods to predict the Vietnamese stock market from 2001 to 2021, concluding that random forest and artificial neural network algorithms outperformed traditional statistical methods in forecasting financial bubbles in the Vietnamese stock market [13]. There are three main reasons for these discrepancies. Firstly, differences exist in the explanatory variables selected as inputs to the models. Secondly, disparities in the time periods of the datasets used in both studies contribute to the variations observed. Lastly, discrepancies arise from the distinct machine learning methods employed in each study. In contrast, our study represents the first comprehensive application of multiple machine learning methods to predict stock market bubbles in China, the world's second-largest economy. Looking ahead, we plan to conduct broader empirical research in diverse market contexts and with a wider array of machine learning methodologies.

C. Robustness Test

In order to ensure the accuracy and reliability of the machine learning models obtained, we conducted robustness tests on them. For this purpose, we divided the data into two equal parts, the first part covering the period from January 2015 to December 2018, and the second part covering the period from January 2020 to December 2023. The main reason for this division is that in January 2020, the Chinese government officially announced the emergence of the COVID-19 pandemic in China and implemented nationwide controls [16]. We utilized the two best-performing machine learning models, namely the logistic regression model and the Deep Learning model, to predict the occurrence of stock market price bubbles during these two data set periods.

Subsequently, we trained and tested the models within their respective data sets. Afterwards, we evaluated the performance of the obtained models using relevant metrics, including accuracy, AUC, and sensitivity. Finally, we analyzed the results of the robustness tests conducted for each time period to compare the performance of the models in different time periods.

From Table III, we can observe that the accuracy of both models remains stable across the two time periods, with the logistic regression model averaging 94.05% and the deep learning model averaging 97.75%. Regarding the AUC, both logistic regression and deep learning models maintain stability across the two time periods, with average values of 0.978 and 1, respectively. However, we note a sensitivity decline in the logistic regression model towards the dataset, particularly during the period from January 2020 to December 2023. In contrast, the deep learning model demonstrates more consistent performance in sensitivity. Overall, both the logistic regression and deep learning models exhibit robustness.

TABLE III. THE ROBUSTNESS TEST RESULT

	Logistic regression			***Deep learning***		
	January 2015 - December 2018	***January 2020 - December 2023***	***Average***	***January 2015 - December 2018***	***January 2020 - December 2023***	***Average***
Accuracy	93.3%	94.8%	94.05%	100.0%	95.5%	97.75%
AUC	1	0.956	0.978	1	1	1
Sensitivity	100.0%	90%	95%	100.0%	100.0%	100.0%

The stability testing method employed in this study ensures the reliability of the predictive models for detecting stock market price bubbles in China, allowing for a clear understanding of variations in model performance over time. This facilitates making practical decisions in real-world financial applications.

Logistic regression is ideally suited for binary outcomes, making it an excellent option for identifying the presence or absence of a bubble. Given the small size of the dataset, deep learning models tend to underperform relative to logistic regression. However, it's important to note that larger datasets come with their own set of challenges.

D. Summary of discussion

Stock price bubbles prediction applying advanced machine learning techniques is potentially extends existing financial theories. It offers empirical evidence that can either support or challenge traditional models of bubble formation and economic cycles. The adaptability and continuous learning capability of machine learning models underscore the dynamic nature of financial bubbles and economic cycles.

The explanatory variables we employed include the inflation rate from macroeconomic factors (IR), the consumer confidence index from sentiment factors (CCI), the stock yield (SY), and price-earnings ratio from market factors (RET).

Table IV displays the relative importance of different attributes (variables) in predicting an outcome, likely in a logistic regression model. The inflation rate from macroeconomic factors (IR) has the highest weight, indicating it is the most important predictor in the model. Its relative importance value of 0.539 suggests it contributes significantly more to the prediction compared to the other attributes. The consumer confidence index from sentiment factors (CCI) attribute is the second most important predictor. Its weight of 0.154 indicates that while it is less influential than IR, it still plays a substantial role in the model. The stock yield (SY) attribute has a weight of 0.116, making it the third most important predictor. Its contribution is notable but less significant compared to IR and CCI. The price-earnings ratio from market factors (RET) attribute has the smallest weight of 0.018, indicating it has the least influence on the prediction. Its relative importance is minimal compared to the other attributes. The model relies heavily on the IR attribute for its predictions, which means understanding and accurately measuring this variable is critical. While CCI and SY are important, their contributions are secondary. Adjustments or improvements in measuring these variables could still enhance model performance.

TABLE IV. THE RELATIVE VARIABLE IMPORTANCE VALUES IN THE CHINESE STOCK MARKET (SHANGHAI COMPOSITE INDEX)

Variable	***Weights (Importance Value)***
inflation rate(IR)	0.539
consumer confidence index(CCI)	0.154
stock yield (SY)	0.116
price-earnings ratio (RET)	0.018

VI. CONCLUSIONS

In this study, we employed the widely acknowledged Generalized Supremum Augmented Dickey-Fuller (GSADF) method to identify the presence of price bubbles in the stock market and utilized data spanning from January 2015 to December 2023 to forecast the occurrence of price bubbles in the Chinese stock market. The findings reveal that a price bubble occurred in the Chinese stock market during the first half of 2015, before COVID-19, while no financial bubbles were observed at other times. Among the predictive models, the logistic regression model demonstrated the best performance with an F-measure score of 86.7%, followed by the deep learning model and the decision tree model, which exhibited slightly inferior yet respectable performance, with F-measure scores of 79.3% and 80.0%, respectively. From a practical standpoint, these results furnish valuable machine learning models for real-time detection and prediction of stock market price bubbles, thereby enabling governmental decision-makers, regulatory authorities, and market oversight agencies to formulate and implement corresponding economic policies aimed at mitigating the adverse effects stemming from financial bubbles. From a theoretical perspective, the utilization of diverse machine learning algorithms in predicting

financial bubbles in this study holds significant reference and generalization implications for the application of machine learning techniques in financial market research. Moreover, the macroeconomic factor (inflation rate), investor sentiment factor (consumer confidence index), and market factors (stock yield and price-earnings ratio) into the machine learning prediction models enables us to delve further into the complex mechanisms underlying the emergence of financial market bubbles and advance the predictive understanding of such phenomena.

This study has made significant contributions both theoretically and practically, particularly in utilizing machine learning, a novel tool, to forecast price bubbles in the stock market of China that is the world's second-largest economy, providing empirical evidence.The research findings highlight the suitability of the foundational algorithm in machine learning, the logistic regression model, for predicting price bubbles in the Chinese stock market. Nevertheless, other machine learning algorithms such as deep learning and decision tree algorithms also exhibit potential in the domain of financial bubble prediction.This study highlights to policymakers and regulators the significance of promptly enacting policies to reduce both the probability and ramifications of financial bubbles.For central banks and regulatory bodies, utilizing advanced machine learning tools to measure financial bubbles facilitates the formulation of appropriate monetary policies to regulate capital behavior in the economy, thereby reducing speculative activities in financial asset trading and stabilizing the entire financial system.For investors, based on the insights gleaned from this study, they can more effectively allocate their investment portfolios by leveraging machine learning algorithms ability to predict financial price bubbles, deciding opportune moments for long and short positions. Moreover, during market bubble occurrences, i.e., when market prices are excessively high, investors can seize suitable opportunities to sell assets and generate corresponding profits.

In subsequent research, other scholars can utilize the machine learning methods employed in this study to forecast bubble situations in varying locales markets, such as Hong Kong, Singapore, the United States, and others. These machine learning methods can likewise be harnessed to anticipate bubbles across diverse market categories, including but not limited to the real estate market, cryptocurrency market, etc. Furthermore, analysis can be conducted on the interplay of financial bubbles between dissimilar markets, such as the stock market and real estate market, both of which hold significant economic sway. Understanding these dynamics can enable regulatory authorities to implement effective financial policies, thereby preventing the formation of financial bubbles or controlling their occurrence, ultimately fostering a healthy and robust market investment environment. This study utilized a limited number of machine learning models, which may have resulted in certain limitations in the obtained results. In the future, employing a wider variety of machine learning models can further advance research in the prediction of stock market bubbles. In addition, speculative bubbles across different markets exhibit both common characteristics and distinct features and impacts. Investigating the relationships between speculative bubbles in various markets and understanding the mechanisms of bubble transmission to develop more effective regulatory strategies presents a significant challenge for future research. Furthermore, addressing the issue of insufficient datasets is a critical concern that needs to be prioritized.

ACKNOWLEDGMENT

***Abstract*—In the modern world, frequent travel has become a necessity, with vehicles being the primary mode of transportation. Ensuring human safety while traveling is paramount. To address this, it is essential to adopt a combination of numerous static and dynamic parameters to achieve optimal route design in today's complex transportation systems. This study introduces a methodology titled 'Multi-Factor Risk Assessment and Route Optimization for Safe Human Travel', which consists of three stages: Route Optimization, Risk Factor Analysis, and Data Collection. To assess the safety of various routes, a combination of dynamic and static factors is considered. These include traffic, weather, and road conditions, as well as vehicle-related factors such as type, age, and the surrounding road environment. By analyzing simulated data, the technique identifies potential risks and optimizes travel paths accordingly. For segmented routes, risk factors are calculated using both static and dynamic parameters, ensuring a comprehensive safety assessment. Prioritizing user safety, the system dynamically adjusts routes to offer the most cost-effective and safest travel options. This study lays a robust foundation for intelligent transportation systems, aimed at ensuring safer travel for users across a range of scenarios.**

Keywords*—Multi-factor risk assessment; route optimization; human travel safety; static and dynamic parameters; risk factor analysis

I. Introduction

Travel safety is a key issue in transportation, particularly as the number of vehicles and the complexity of urban environments increase. The focus in traditional route planning is on reducing travel time or distance, but it frequently ignores important safety considerations, leaving travelers exposed to dangers like accidents, injuries, and crime [1]. These shortcomings highlight the necessity for more holistic methods that place safety on par with efficiency when optimizing routes [2].

This paper addresses these challenges by presenting a novel approach that integrates multiple safety parameters for risk assessment in route optimization. As urbanization and population growth continue, the need for safe, reliable transportation systems is increasingly critical. Recent advancements in risk assessment and route optimization, particularly in dynamic road conditions, are essential for improving the safety of drivers and pedestrians alike [3].

The motivation for this study arises from the pressing need to address the limitations of traditional navigation systems, which often neglect crucial safety factors. The proposed approach leverages a combination of static and dynamic parameters to offer a more comprehensive and adaptive framework for route optimization. By incorporating factors such as traffic density, weather conditions, road environments, and vehicle attributes, the system ensures a holistic evaluation of travel risks. This methodology aims to enhance traveler safety by reducing the likelihood of accidents, fostering user confidence, and supporting the development of intelligent transportation systems.

The primary contribution of this study is the development of a multi-factor risk assessment and route optimization model that dynamically evaluates routes based on safety and efficiency. By tailoring recommendations to different demographics, transportation modes, and real-time conditions, this approach ensures inclusivity and adaptability in route planning. Furthermore, the integration of real-time data enhances the system's ability to adjust dynamically to changing conditions, paving the way for safer and more intelligent transportation networks.

This approach moves beyond conventional navigation by incorporating real-time data and multi-factor analysis to prioritize safety and reduce hazards. Traditional systems that focus primarily on travel time and distance have often overlooked important factors influencing safety and fail to account for the ever-changing road environments and the varying needs of travelers. Multi-Factor risk assessment models now address a broad range of considerations, including time of travel, traffic density, vehicle types, demographics, road conditions, lighting, and traffic patterns [4]. This complete approach optimizes routes not only for efficiency but also for the specific safety needs of different individuals and communities, improving overall travel safety.

Multi-Factor models recognize that higher traffic density, particularly during peak hours, can enhance safety by providing more visibility and reducing risks such as theft or harassment [5]. By incorporating time-sensitive routing that considers traffic density, users can opt for routes that may take longer but offer greater safety.

Optimal routes vary significantly for pedestrians, cyclists, motorcyclists, and those using private or rented vehicles. By tailoring recommendations based on the mode of transport, the system ensures that each user's safety is prioritized.

Demographics and traveler population also play a crucial role in multi- Factor risk assessment. Routes are adapted to reflect the age, gender, and travel patterns of users, fostering safer travel for all.

The use of real-time data enables systems to adjust routes based on current weather, road maintenance, and the availability of lighting, offering a dynamic and comprehensive approach to safer travel. By incorporating these elements into the routing process, multi-Factor models provide a comprehensive approach to safe navigation, addressing the full spectrum of risks that travelers may encounter.

This paper outlines the development and application of multi-factor risk assessment and route optimization models. These models represent a significant advancement in ensuring safer travel for all, paving the way for a future where transportation systems are as safe as they are efficient. The paper is structured as follows: Section II presents the literature review, Section III covers the methodology, Section IV provides the implementation, Section V presents the results and discussion, and Section VI provides the conclusion.

II. Literature Review

Safe human route optimization has emerged as a critical area of research due to the growing need for enhancing road safety, crime activities and minimizing accident risks. A wide range of models and methodologies have been developed, incorporating factors such as road conditions, weather, traffic, and human demographics to provide tailored, safer route options. This literature review explores various strategies and models proposed for optimizing safe travel routes, focusing on both static and dynamic risk factors to ensure safer navigation.

Lingamaneni Indraja et al. [6] examined the correlation between accidents, road conditions, and weather, developing a predictive model using machine learning algorithms like Support Vector Machines and Logistic Regression to identify safe, less accident-prone routes. Yash S. Asawa et al. [7] introduced a User-Specific Safe Route Recommendation System that visually represents safe routes on maps using historical crime data. It operates in two tiers: a Decision Network to capture user-specific features and Geospatial Data Analysis to generate personalized safe routes.

Aruna Pavate et al. [8] developed a system using K-means clustering to categorize routes into security levels, helping women avoid high-crime areas. Isha Puthige et al. [9] devised a danger index based on multiple crime factors at specific locations, using clustering algorithms to identify safe paths. Aliasgar Eranpurwala et al. [10] created the "GoWomaniya" app to help women find safe routes in real-time during moments of distress, leveraging mobile technology.

Deepa Bura et al. [11] developed a model using Google Maps to assess the safety of routes, considering risk factors like security and path quality. Roxan Salehab et al. [12] applied supervised machine learning to predict road sign status in Sweden, contributing to transportation safety by maintaining accurate navigation aids. Deepak Kumar Sharma et al. [13] utilized Random Forest algorithms to predict crash risks based on historical accident data, including weather and road conditions.

Juncai Jiang et al. [14] proposed a framework for assessing urban road collapse risks, using SMOTE and Convolutional Neural Networks to predict road integrity. Mukherjee, D et al. [15] combined historical crash data with proactive pedestrian-vehicular risk assessments to identify and rank high-risk intersections in Kolkata, enhancing pedestrian safety.

Lakshmi et al. [16] conducted a systematic review of Safe Route Guidance Systems, focusing on traffic forecasting, congestion avoidance, and traffic signaling. Llopis-Castelló et al. [17] compared the Highway Safety Manual with geometric design consistency to estimate crash occurrences on road segments in North Carolina.

Al-Bdairi et al. [18] investigated injury severity in weather-related crashes, identifying factors like time of day, driver fatigue, and lack of streetlights that increase accident risks. Qiannan Wang et al. [19] explored how population density impacts autonomous vehicle navigation risks, emphasizing the need for risk-aware path planning. Changhong Zhou et al. [20] developed a road disaster risk assessment model using neural networks and a fuzzy comprehensive evaluation, incorporating environmental and geological factors to predict road disasters.

Nishat Tasnim et al. [21] studied how road geometry, traffic volume, and other features influence accident occurrence. Shan Jiang et al. [22] introduced the Safe Route Mapping (SRM) model, combining crash estimates and conflict risks from driver data to predict route safety. Paul Litzinger et al. [23] proposed an algorithm that incorporates real-time weather forecasts into route planning to enhance safety and efficiency.

Nikhitha Pulmamidi et al. [24] proposed a model for identifying safe routes based on user experience, considering factors like road conditions, weather, and accident frequency. Krishnaraj Pawooskar et al. [25] developed a safety score based on features like hospitals, streetlights, and police stations along routes. Helai Huang et al. [26] emphasized the importance of dynamic traffic conditions and stationary road factors in conflict-based travel route safety assessments. The Road Safety Technical Report [27] highlighted the need for tailored safety solutions based on specific road and traffic conditions.

The reviewed studies demonstrate the importance of integrating diverse factors such as road geometry, weather conditions, and user demographics in optimizing safe routes. Collectively, these efforts contribute to a more complete understanding of route safety optimization, paving the way for smarter, more responsive systems that enhance safety, awareness, and efficiency for all road users.

However, most of these studies focus on single factors or use simplistic models that do not account for the complex interactions between different parameters. This study aims to develop a multi-factor risk assessment model that evaluates the safety of travel routes by considering both static and dynamic factors. The model will use the driven data to classify routes based on their risk levels and identify the safest route between a given source and destination.

III. Methodology

The proposed methodology for "Multi-Factor Risk Assessment and Route Optimization for Safe Human Travel" is

designed to address the complexities of modern transportation systems by integrating multiple static and dynamic factors. This approach prioritizes safety, aiming to create a transportation landscape that not only optimizes route efficiency but also enhances the well-being and safety of all users.

The system is divided into three major phases: Data Collection, Risk Factor Analysis, and Route Optimization as shown in Fig. 1. These phases work together find best route based on static and real-time data (dynamic data).

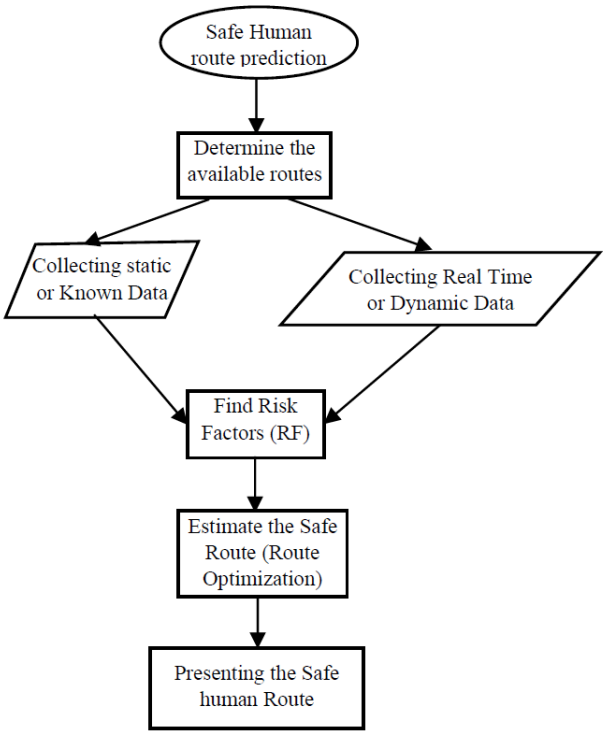

Fig. 1. Phases of route optimization.

A. Data Collection

In the context of Multi-Factor Risk Assessment and Route Optimization for Safe and Efficient Human Travel, the methodology involves a detailed analysis and integration of both static and dynamic parameters as shown in Table I. These parameters are essential for evaluating the safety of various routes and optimizing them to ensure secure travel.

The system accounts for 10 static parameters to ensure route safety. First, the type of vehicle or transport mode is crucial, as different vehicles have distinct requirements for road width, speed limits, and flexibility. Gender-specific concerns are also considered, particularly to avoid areas prone to harassment or crime, especially at certain times of the day. Age is a key factor, influencing mobility and vulnerability; routes safer and more accessible for children, the elderly, and people with mobility challenges are prioritized. For solo travelers, the system suggests safer or more populated routes by factoring in the number of travelers.

TABLE I. LIST OF STATIC AND DYNAMIC PARAMETERS USED

Name of the Parameter	Symbolic Representation
Static Parameters	
Vehicle Type / Transport mode	v
Gender	g
Age	a
Number of Persons travelling	n
Lighting facility	L
Road types	R_t
Public spaces existence	P_s
Road Environment	R_e
Road Complexity	R_x
Availability of CCTV	C
Dynamic Parameters	
Traffic condition	T_c
Weather condition	W_c
Road Conditions	R_c
Time	t

Lighting facilities are critical for night-time safety, so the system prioritizes well-lit routes in the evening and at night. Road type is also considered, as different types offer varying safety levels. Public spaces, such as parks, malls, and police stations, are seen as beneficial, so routes near these areas are preferred. The surrounding environment is evaluated to avoid potentially hazardous zones like forest areas. Road complexity is another factor, with simpler routes being recommended over those with more curves.

Dynamic parameters are also integrated for real-time optimization. Traffic conditions are monitored in real-time to meet the safe condition when mode population density, reducing accident risks and improving travel efficiency. Weather conditions, such as rain, snow, and fog, are tracked, and the system adjusts to avoid dangerous routes during adverse weather. Road conditions, including potholes, construction, and surface quality, are factored in to steer travelers away from hazardous areas. Time of day is another key factor, as poorly lit or high-accident areas are avoided during late hours.

The methodology for multi-factor risk assessment and route optimization begins with data collection. For the data simulation, the available routes between source and destination need to be identified. After the routes are identified, the route may be divided into partitions. A partition refers to a section of the route with a different road type. For example, the entire route section may consist of rural village roads, state highways, or national high ways. Before set the values to static and dynamic parameters, each route is divided into 100-m segments.

The static and dynamic parameter values for each segment are simulated using a randomizer function in Python. To generate random values with the randomizer function, we initialize the static parameter value, such as road type. Based on the road type, the randomizer uses a uniform distribution to set the values for public space existence, road environment, and road complexity for the chosen percentage (minimum and maximum). The dynamic parameters are generated using a normal distribution with the chosen percentage (minimum and maximum) based on the road type and public space existence.

The algorithm for the randomizer function is provided in Algorithm 1:

Algorithm 1: Randomizer Function (generate values)

```
Segment the selected route;
Initialize the road type of each segment;
For all road segments () do
    For parameters (Ps, Re, Rx, C, Tc, Wc, Rc) do
        if parameter_type is "static" then
            Generate a value using a uniform distribution within
            the range [min_value, max_value]
        else if parameter_type is "dynamic" then
            Generate a value using a normal distribution within
            the range [min_value, max_value]
        End
        Return generated value for the parameter
    End
End
```

B. Parameter Value Fixation

We identified 14 key parameters that significantly impact travel safety. Each parameter is symbolically represented and assigned a value between 0 and 1, indicating its influence on the overall risk factor. The value fixations on parameters are given as follows:

1) Vehicle type / transport mode (v): Different types of vehicles have varying levels of stability, speed, and safety features, which influence their risk factor. For example, two-wheelers are generally considered more vulnerable than cars or vans, hence assigned a higher risk value (0.7 for two-wheelers, 0.5 for cars, and 0.3 for vans).

2) Gender (g): Research indicates that gender can impact travel behavior and risk perception. Male travelers are feeling safer and ready to face risk than Female travelers. Hence the value is fixed as 0.9 for female and 0.6 for males. The average gender risk factor is calculated based on the average risk factor of all persons travelling.

3) Age (a): Age influences factors such as reflexes, experience, and risk-facing tendencies. Younger travelers (aged 0-15 years) have a higher risk value (0.9) due to inexperience. Travelers aged 15-30 years are assigned a risk value of 0.5. Those aged 30-45 years are considered the safest, with a lower risk value of 0.2. Travelers aged 46-60 years have a risk value of 0.3, while those over 60 years are considered to have moderate risk, with a value of 0.5. The average age risk factor is calculated based on the number of persons traveling.

4) Number of persons traveling (n): The risk value for traveling decreases as the group size increases, with a risk value of 0.8 for solo travelers, 0.5 for two persons, 0.3 for groups of 3-5, and the lowest risk value of 0.1 for groups larger than five.

5) Lighting facility (L): Adequate lighting reduces the risk of accidents, robberies and other criminal activities. Segments with no artificial lighting are assigned the highest risk value (1), while light-facilitated segments have a value of 0. During the day, the value is set to 0 since there is no need of artificial light. At night, the value is also set to 0 if adequate lighting exists; otherwise, it is set to 1. This parameter is also depending on the public space existence and road types.

6) Road types (Rt): The risk values for different road types decrease with increasing road capacity, with rural roads having a risk value of 0.8, state highways (SH) at 0.6, two-way national highways (NH) at 0.5, four-way NH at 0.4, six-way NH at 0.3, and eight-way NH at 0.2.

7) Public spaces existence (Ps): The presence of public spaces such as parks, shopping areas, villages, and towns impacts the risk value. A value of 1 assigned if no public spaces exist, indicating higher risk, and a value of 0 if public spaces are present, indicating lower risk.

8) Road environment (Re): The risk values for different road environments vary, segments with villages having a risk value of 0.45, towns at 0.4, and metro areas being the safest at 0.2. More hazardous environments include forests segments with a risk value of 0.7, hilly region segments at 0.9, and plain region segments at 0.5.

9) Road complexity (Rx): The risk values for road complexity decrease as the curve angle increases. Segments with curves between 10°-30° have the highest risk value of 0.9, while curves between 30°-50° have a risk of 0.8, and curves from 50°-70° have a risk of 0.7. For more moderate curves, values range from 0.5 for 70°-100°, 0.4 for 100°-140°, 0.3 for 140°-160°, and the lowest risk of 0.1 is assigned to curves between 160°-180° (straight roads).

10)Availability of CCTV (C): The availability of CCTV significantly enhances safety, with segments equipped with cameras having a risk value of 0, indicating lower risk, while segments without CCTV have a higher risk value of 1, reflecting increased safety concerns.

11)Traffic condition (Tc): The traffic conditions make significate effect on the risk factors. Red, indicating a higher presence of people, is the safest with a risk value of 0.3. Orange represents a moderate risk with a value of 0.6, while blue, signifying fewer co-travelers, is the most hazardous with a risk value of 0.8.

12)Weather condition (Wc): Weather conditions significantly affect route safety, with accidents more likely in adverse conditions. Rainy weather has the highest risk value at 0.8, followed by foggy conditions at 0.7. Cloudy weather presents a moderate risk with a value of 0.5, while sunny weather offers the safest conditions with the lowest risk value of 0.3.

13)Road conditions (Rc): Poor road conditions, characterized by ridges and troughs, increase the risk of accidents (value 0.8), whereas plain roads are safer (value 0.2). These values are fixed for each segment on the route.

14)Time (t): Risk values vary throughout the day, with early morning presenting the highest risk at 0.9 due to factors like reduced visibility and increased fatigue. Morning conditions have a risk value of 0.5, while the risk decreases to 0.4 in the afternoon. Evening and midnight have similar risk values of 0.3 and 0.7 respectively, reflecting different factors such as changing light conditions and reduced alertness.

C. Finding Risk Factors

Finding the risk factors for safe human routing involves analysing a combination of static and dynamic parameters to identify potential hazards and vulnerabilities in a given route. The risk factors are identified for the available routes from the source to the destination. The detailed calculation is provided in the implantation section 4.A.

D. Route Optimization

Finally, the safe route is identified using the risk factors calculated for all routes. The safe route measurement and explanation is provided in Section IV(B) This approach ensures that the routing system enhances safety for all users under a variety of conditions.

IV. Implementation

The safety of a travel route is influenced by various factors, which can be broadly categorized into static and dynamic parameters. Static parameters are those that do not change frequently and include factors such as the type of vehicle, the travelers age, and the road environment. Dynamic parameters, on the other hand, are subject to change over time and include traffic conditions, weather, and road conditions.

A. Risk Factor Calculation

For every source and destination pair, multiple routes can typically be identified, each offering a different path between the two points. These routes are referred to as R_j, where $1 \leq j \leq m$, with m representing the total number of possible routes.

To ensure safety and optimize the selection process, it is essential to calculate the risk factor associated with each possible route. As said in Section III(A), each route R_j is divided into smaller, manageable segments of 100 meters, denoted as S_i. Segmenting the route in this way allows for a detailed and accurate analysis of the risk factors associated with each segment of the journey.

The risk factor for each segment, S_i, is determined by analyzing a combination of static and dynamic parameters. The Static Risk Factor (S_{RFi}) for ith segment is calculated as the average value of ten specific static parameters.

$$S_{RF_i} = \frac{v+g+a+n+L+R_t+P_s+R_e+R_x+C}{10} \quad (1)$$

The Dynamic Risk Factor (D_{RFi}) for each segment S_i is calculated by considering four key parameters that reflect the changing conditions such as traffic, weather, road condition and time of travel of the route.

$$D_{RF_i} = \frac{T_c+W_C+R_c+t}{4} \quad (2)$$

Hence, the Risk Factor (RF_i) of the i^{th} segment is determined by averaging both the Static Risk Factor (S_{RFi}) and the Dynamic Risk Factor (D_{RFi}).

$$RF_i = \frac{S_{RF_i}+D_{RF_i}}{2} \quad (3)$$

This approach ensures that the RF_i reflects a complete assessment of the segment's safety, taking into account both the constant, essential risks associated with static parameters and the fluctuating risks introduced by dynamic conditions. By calculating the RF_i for each segment, the overall safety of the route can be accurately evaluated by summing all segments' risk factors as follows:

$$R_j = \frac{\sum_{i=1}^{N} RF_i}{N} \quad (4)$$

The risk factor for the j^{th} route from the source to the destination is denoted as R_j. This factor represents the level of risk associated with that specific route, considering static and dynamic factors. By quantifying R_j, the overall safety of each route can be assessed, which is crucial for optimizing travel and minimizing potential risks during journey.

B. Route Optimization

The safest route (SR) is determined by evaluating the risk factors associated with all identified routes. By analyzing the calculated risk factors, the route with the lowest risk is identified as the safest. This process involves comparing each route's risk factor to ascertain which one presents the least potential for danger, thereby ensuring the most secure travel option.

$$SR = min(R_j) \quad \text{where } 1<j<m \quad (5)$$

The implementation of this approach is designed to identify the safest route by thoroughly evaluating all relevant parameters from the available routes. By integrating both static and dynamic factors, such as vehicle type, road conditions, lighting, real-time traffic, and weather, the system ensures that each route recommendation prioritizes safety. This methodology not only identifies the safest possible routes but also encourages travelers to follow to these recommendations, thereby enhancing overall travel security and reducing potential risks.

V. Results and Discussion

In this section, we present analysis of the multi-factor risk assessment and route optimization methodology applied to various identified routes between source and destination. This section explores the effectiveness of the proposed system in identifying and recommending the safest routes by evaluating the impact of static and dynamic parameters on travel safety.

To implement our proposed methodology, we selected Maragathapuram (near Villupuram), Tamil Nadu, as the source and Parvathipuram, Vadalur, Tamil Nadu, as the destination. Parvathipuram is situated in the Vadalur town area. We considered five distinct routes from Maragathapuram to Parvathipuram, all with similar distances but varying slightly in their specifics. These routes traverse diverse topographies, including rural villages, towns, state highways (SH), and national highways (NH), encompassing both two-way and four-way roads. Additionally, the routes include sections passing through rural town near the destination. The routes were partitioned based on road types, and details are provided in Table II.

TABLE II. POSSIBLE ROUTES AND PARTITIONS FROM SOURCE TO DESTINATION

Sl. No.	Route Number	Partition Type (Road Type)	Partition Size (km)	Number of segments
1	1	Rural Village	3.7	37
2	1	NH38-4 ways	5.3	53
3	1	SH68	17	170
4	1	NH36- 2 ways/ 4-ways	23.5	235
5	1	NH532- 4ways	1	100
6	1	Rural Twon	0.8	80
7	2	Rural Village	4.6	46
8	2	Bye Pass Road - 4 ways	9.7	87
9	2	NH36- 2 ways / 4 ways	38.3	383
10	2	NH532- 4ways	1	100
11	2	Rural Twon	0.8	80
12	3	Rural Village	4.3	43
13	3	NH38-4 ways	3.5	35
14	3	NH38-Town	4.2	42
15	3	NH332-2 ways	5	50
16	3	NH36- 2 ways / 4 ways	41.3	413

27	5	SH602	27.9	279
28	5	NH36- 2 ways/ 4-ways	11.4	114
29	5	NH532- 4ways	1	100
30	5	Rural Twon	0.8	80

For the route analysis from Maragathapuram to Parvathipuram, Route 1 includes rural village road, NH38, SH68, NH36, NH532, and a rural town segment. Route 2 features rural village road, a four-lane bypass, NH36, NH532, and a rural town. Route 3 starts with rural village road, NH38, NH38-Town, NH332, NH36, NH532, and ends in a rural town. Route 4 consists of rural village road, NH38, SH9, NH36, NH532, and a rural town segment. Route 5 includes rural village road, NH38, SH602, NH36, NH532, and concludes with a rural town. All five routes start from the same rural village road with little variation due to connect with next partition and end with NH532 and rural town segments of same distance.

C. Risk Factor Analysis

Based on the partition details provided in the Table II and values fixed for parameters in the section 3.B, we have simulated values for all the parameters of all partitions by seriously considering the partitions types. The chosen mode of transport is a car, with four passengers (three men and one woman), and the average age-related risk factor for the group is 0.4. The data was simulated using default values for three parameters: lighting facility was assigned 0 risk due to daytime travel, weather condition was set to sunny, and the travel time was set to afternoon. The remaining parameter values were fixed based on partitions and dependent parameters.

The risk factor is calculated for each 100-meter segments using the Eq. (3) with help of Eq. (1) and Eq. (2). The overall risk factor for the route is calculated using the Eq. (4).

The Fig. 2 shows the risk factors of all segments of Route-1. For Route-1, risk factors across partitions range from a minimum of 0.29375 to 0.34625 and a maximum of 0.40125 to 0.59125. Average risk factors vary between 0.35975 and 0.478885135, with specific averages of 0.478885135, 0.422900943, 0.458838235, 0.432356383, 0.35975, and 0.4253125. This variation reflects inconsistencies in risk levels along the route, particularly in village environments.

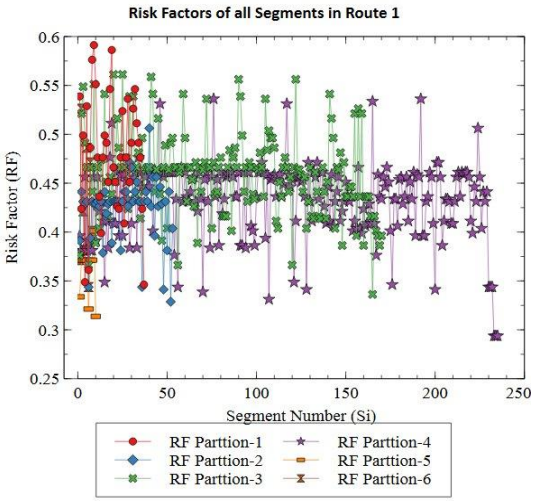

Fig. 2. Risk factors of all segments in route-1.

Fig. 3 presents the risk factors along Route-2. The minimum risk factors for Route-2 range from 0.29375 to 0.34625, while the maximum values vary between 0.40125 and 0.59125. The average risk factors across the five segments are 0.4748, 0.4553, 0.4391, 0.3598, and 0.4253, respectively.

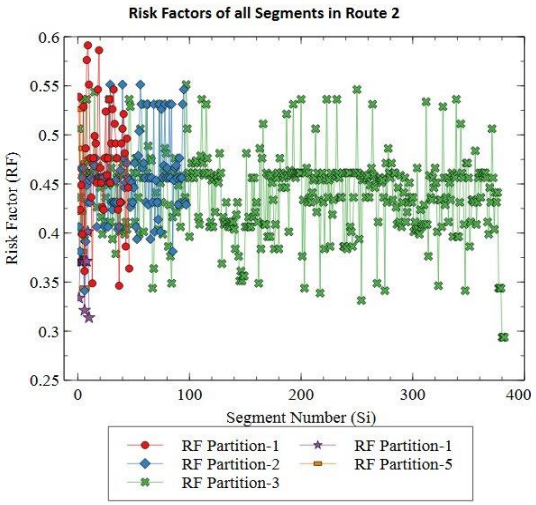

Fig. 3. Risk factors of all segments in route-2.

Route-3 consists of seven partitions and risk factors are calculated. Fig. 4 illustrates the risk factors across all segments of Route-3. The minimum risk factors range from 0.27875 to 0.36125, while the maximum values range from 0.40125 to 0.59125. The average risk factors for the seven segments are 0.4830, 0.4418, 0.3616, 0.4217, 0.4406, 0.3598, and 0.4253, respectively.

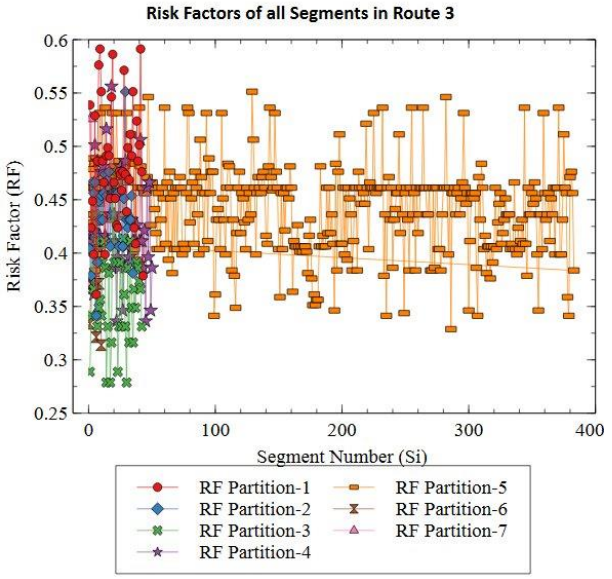

Fig. 4. Risk factors of all segments in route-3.

Route-4 consists of six segments, with the same combinations of road types as discussed in Route-1, but with variations in the distances of state and national highways. It follows a different path compared to Route-1.

Fig. 5 shows the risk factors for all six segments of Route-4, as outlined in Table II. The minimum risk factors range from 0.29375 to 0.34625, while the maximum values range from 0.40125 to 0.59125. The average risk factors for the six segments are 0.4782, 0.4208, 0.4463, 0.4324, 0.3598, and 0.4253, respectively.

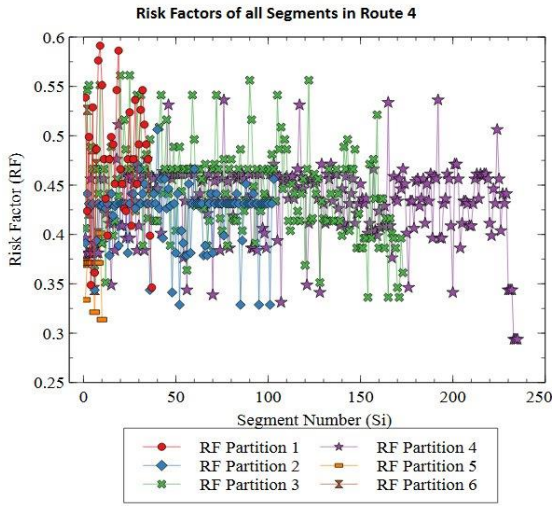

Fig. 5. Risk factors of all segments in route-4.

Similarly, the risk factors for the six segments of Route-5, where the state highway is the major contributing partition, have been calculated. Fig. 6 illustrates the risk factors for all segments of six partitions along Route-5. The minimum risk factors range from 0.29125 to 0.34875, while the maximum values range from 0.33375 to 0.53875. The average risk factors for the six segments are 0.4819, 0.4182, 0.4770, 0.4287, 0.3598, and 0.4253, respectively.

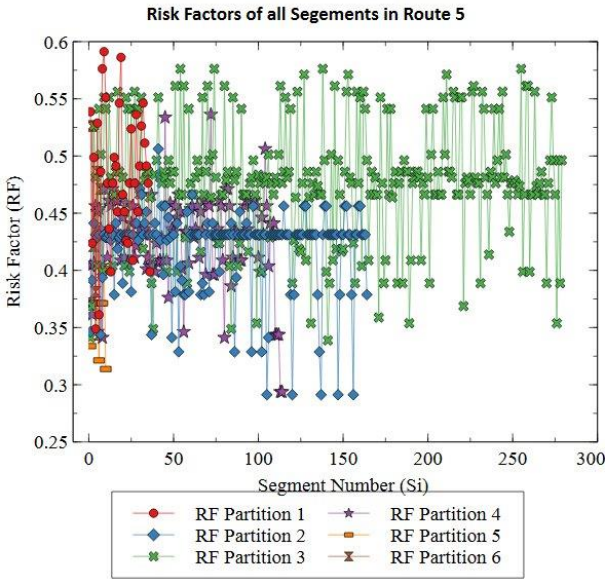

Fig. 6. Risk factors of all segments in route-5.

The risk factors for all partitions across all routes are shown in Fig. 7. The risk factors for the first partition are nearly identical across all routes due to minimal distance variation on the routes. Likewise, the risk factors for the last two partitions are the same, as these partitions remain consistent across all routes.

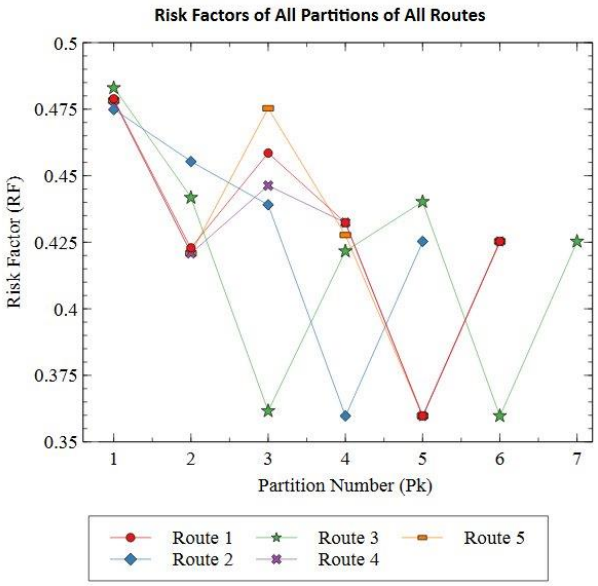

Fig. 7. Risk factors of all partitions in five routes.

The average static, dynamic, and final risk factors for all five routes are shown in Fig. 8. It illustrates that the static risk factor is higher than the dynamic risk factors for all routes except Route 3, which has a larger town area compared to the other routes.

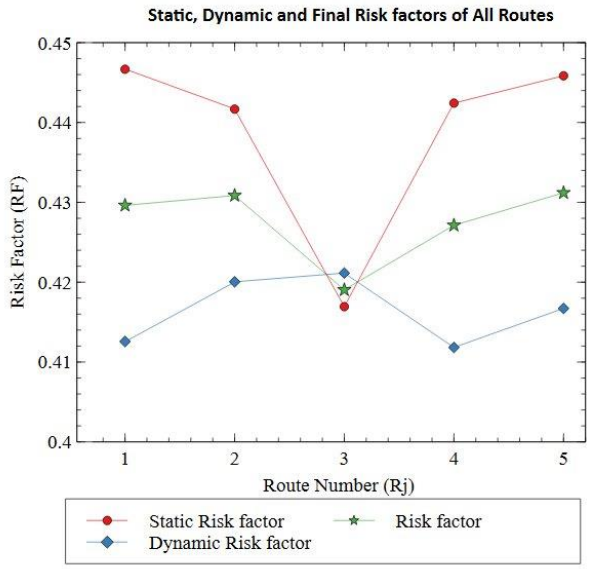

Fig. 8. Static, dynamic and final risk factors of all routes.

D. Safe Route Identification

The safest route is determined using Eq. (5), which calculates the route with the minimum risk factor among the studied routes. In this study, we analyzed five possible routes as given in Table II, each with varying partitions. Fig. 9 presents the risk factor values for all five routes. Route 3 has the lowest risk factor compared to the others.

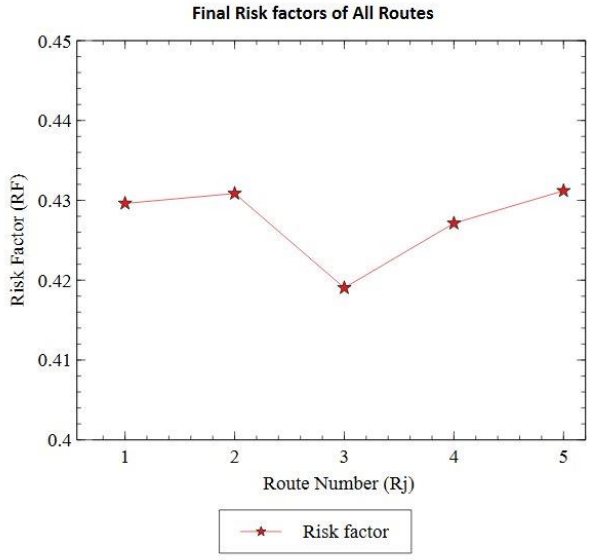

Fig. 9. Risk factors of all routes.

The reduced risk for Route 3 is attributed to several factors. This route passes through more town areas, which typically have better infrastructure and safety measures such as lighting and traffic control. Additionally, Route 3 follows longer stretches of national highways, known for their higher safety standards and better road conditions. Finally, the higher population density along this route also contributes to its lower risk, as densely populated areas have less threatened from the attackers.

The risk factors of five routes are evaluated under varying weather conditions, while maintaining the other parameters constant. Fig. 10 illustrates the impact of different weather conditions on the risk factors across all five routes.

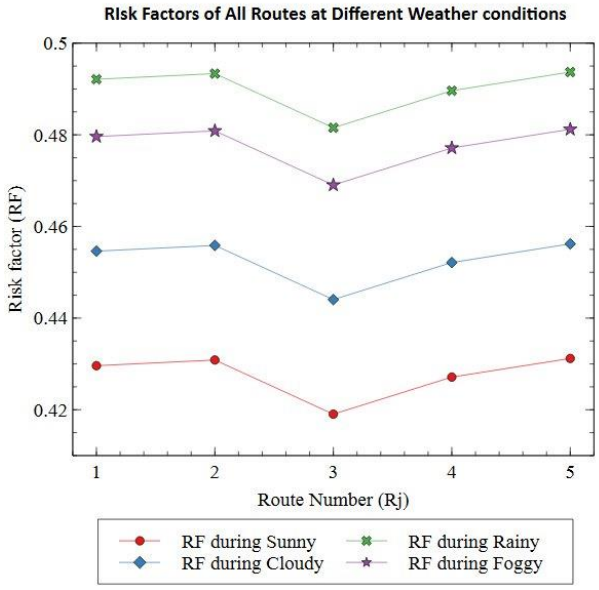

Fig. 10. Risk factors at different weather conditions.

Route 3 consistently offers the lowest risk factor across all weather conditions, as it passes through more densely populated areas.

The time of travel is also taken into account when calculating the risk factors for all five routes. For daytime travel, including morning, afternoon, and evening, the lighting facility value is set to 0, as natural light is sufficient. For night time travel, the lighting facility value is determined based on the presence of public places along the route and the type of route partitions. This adjustment reflects the availability and effectiveness of artificial lighting in reducing risk during night time. Fig. 11 illustrates how travel time influences the overall risk factor calculation across different routes.

The results indicate that Route 3 is the most optimal for daytime travel, yielding the lowest risk factors due to its natural lighting and favorable conditions during daylight hours. Conversely, for nighttime travel, the Route 2 is found to be the safest, offering the lowest risk factors. This is primarily attributed to better lighting infrastructure, the presence of public spaces, and well-defined route partitions that enhance visibility and safety during night hours. These findings highlight the importance of adapting route selection based on the time of travel to minimize risk.

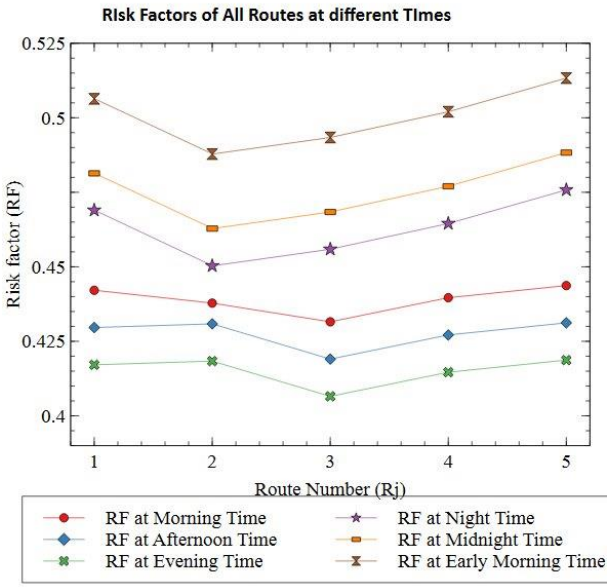

Fig. 11. Risk factors at different travel time.

The results demonstrate the effectiveness of the proposed model in identifying safe travel routes. The inclusion of both static and dynamic parameters ensured a risk assessment, making the model suitable for safe human travelling on the optimal route predicted by the proposed model.

VI. Conclusion

In conclusion, this study presents a multi-factor risk assessment and route optimization methodology aimed at improving travel safety based on the chosen sources and destination places. By incorporating both static and dynamic factors, the system effectively identifies the safest routes based on calculated risk factors. Our analysis reveals that Route 3 is the safest for daytime travel, while Route 2 is optimal for nighttime travel due to better lighting and route partitions. The granular assessment of 100-meter segments along the routes highlights the significant impact of environmental and infrastructural factors on travel safety, including artificial lighting, time of travel, and weather conditions. This adaptable framework, influence widely applicable risk parameters, demonstrates the potential for broader real-world applications in dynamic and changing road networks, ensuring safer route recommendations.

In future work, we aim to enhance the system by integrating real-time data sources, such as live weather updates, traffic congestion reports, and road maintenance data, to provide even more accurate risk assessments. Additionally, we plan to incorporate machine learning techniques to continuously improve the precision of risk predictions based on observed outcomes. By doing so, the system can become more robust and reliable in its route optimization recommendations.

ADNOC Offshore, Abu Dhabi, United Arab Emirates[4]

***Abstract*—The effective operation of water injection pumps is vital for enhancing oil recovery in the oil and gas industry. To ensure optimal pump performance and prevent unplanned downtime, this study focused on implementing predictive maintenance strategies. We began by identifying five critical operational parameters—Seal Pressure 1, Seal Pressure 2, Vibration Data for the Drive End (VIB DE), Vibration Data for the Non-Drive End (VIB NDE), and Ampere. These parameters were monitored and analyzed to evaluate their impact on pump performance and maintenance needs. To achieve this, we applied three machine learning algorithms: Extreme Gradient Boosting (XGBoost), Light Gradient-Boosting Machine (LGBM), and Random Forest. Each algorithm was independently trained and tested on the dataset corresponding to each operational parameter. We assessed their performance using key accuracy metrics, including R squared, Mean Absolute Error (MAE), and Root Mean Square Error (RMSE). Following this, we developed an Ensemble model, combining the predictive outputs of XGBoost, LGBM, and Random Forest. The Ensemble model was then applied to the same parameters to evaluate its ability to address the limitations observed in standalone models. The results demonstrated that the Ensemble model consistently delivered superior performance, achieving lower RMSE and MAE values and higher R squared coefficients across all parameters. This study culminates in the validation of the Ensemble model as a robust and reliable approach for predictive maintenance. By leveraging the strengths of multiple algorithms, the Ensemble model offers significant improvements in accuracy and reliability, contributing to more effective maintenance systems for the oil and gas industry.**

***Keywords*—Ensemble machine learning models; oil and gas industry; predictive maintenance; water injection pumps**

I. Introduction

The oil and gas sector confronts the critical challenge of substantially reducing operational costs while upholding safety standards [1]. Fortuitously, artificial intelligence (AI) has become instrumental in addressing the challenges faced by the oil and gas industry (OGI), capitalizing on technological advancements and the Big Data revolution to facilitate informed decision making and expedite the transition from issue identification to execution [2]. Encompassing a range of operations spanning exploration to distribution, the OGI functions within a multifaceted environment characterized by extensive infrastructure and high-value assets [3]. Efficient maintenance and reliability management are imperative for ensuring optimal production, safety, and cost-effectiveness in this industry [3]. The adoption of predictive maintenance (PdM) emerges as a pivotal methodology, seamlessly integrating data analysis, machine learning (ML) algorithms, and sensor technologies to collect real-time operational and sensor data [4]. This proactive approach plays a crucial role in early failure identification, thereby mitigating the consequences of unforeseen downtime. A thorough examination of the existing literature reveals numerous successful AI implementations across various domains of petroleum engineering [5]. Within the OGI, a particular emphasis on PdM is evident, particularly concerning Water Injection Pumps (WIPs), which play a fundamental role in maintaining reservoir pressure and optimizing oil recovery [3]. By harnessing advanced technologies like ML and deep learning (DL), PdM for WIPs introduces enhanced strategies for predicting failures early and facilitating real-time condition-based proactive maintenance [6]. In contrast, traditional maintenance approaches often lead to unnecessary actions and disruptive costs, while reactive maintenance poses risks to safety and the environment [7]. PdM tackles these challenges by leveraging cutting-edge technologies and data analytics to continuously monitor the real-time health and performance of equipment. The comprehensive data-driven approach employed by PdM models, drawing on real-time data from sensors, control systems, and historical maintenance records, enables the early detection of potential issues [3,8]. This proactive intervention empowers organizations to anticipate and address impending challenges, effectively minimizing downtime, optimizing maintenance strategies, and improving operational efficiency [9]. The integration of PdM models establishes a proactive maintenance paradigm that fortifies reliability, reduces costs, and prolongs the lifecycle of critical assets [3,4]. The early identification and resolution of potential issues provide operators with the capability to circumvent costly breakdowns, mitigate production losses, and ensure uninterrupted operations. PdM also presents the opportunity for more efficient resource planning and allocation, enabling operators to optimize spare parts inventories and streamline maintenance schedules [2,4,5,10].

Digitalization and the Internet of Things (IoT) generate extensive data, driving the significance of Predictive Maintenance (PdM) in optimizing upstream rotating equipment in the Oil, Gas, and Petrochemical (OGP) industry [11, 12].

Efficient operation of Water Injection Pumps (WIPs) enhances oil recovery and operational success [1–3]. PdM minimizes unplanned downtime and improves pump performance, with Deep Learning (DL) playing a pivotal role in recent studies. Janssens et al. [13] used CNNs for health monitoring via infrared thermal images, showcasing potential in anomaly detection, while Sampaio et al. [14] employed ANNs to predict motor failures, albeit with limited performance analysis. Bekar et al. [15] utilized K-means and PCA for motor PdM, facing challenges related to motor type specificity. Falamarzi et al. [16] applied ANN and SVR to tram track gauge prediction, and Susto et al. [17] proposed a PdM system for epitaxy processes, lacking equipment-specific context.

In developing countries, implementing PdM in the OGP sector encounters barriers such as limited skilled personnel, sensor access, infrastructure constraints, financial limitations, and cultural challenges [18-19]. Initiatives for sustainability and diversification, alongside training and infrastructure investments, aim to address these challenges [19-20]. Despite advancements, there is a research gap in applying AI to predict failures in WIPs, critical for health, safety, and environmental outcomes. This study addresses the gap by leveraging ML models like XGBoost and LGBM to predict WIP failures, focusing on asset loss, regulatory compliance, corporate reputation, and production impacts [3–5].

These algorithms, recognized for their high performance, have not been extensively studied in conjunction with ensemble methods such as Random Forest. The Ensemble model demonstrates unparalleled accuracy and increases the accuracy of predictions. This research is driven by the urgency to provide advanced solutions for PdM in the OGI sector, addressing the complexities of diverse operational parameters. This study specifically addresses the maintenance of water injection pumps, focusing on critical factors such as currents, pressure, and vibrations because these factors are crucial for maintenance but are often under-represented in existing research. This study innovatively integrates multiple algorithms within ensemble models to enhance predictive accuracy and address maintenance challenges in water injection pumps. Unlike previous approaches that often lack specificity in algorithm selection for factors such as currents, pressure, and vibrations, a systematic approach is employed to optimize performance in real-world operational environments. This refinement distinguishes the work by effectively applying ensemble techniques to improve Prognostics and Health Management (PHM) systems, particularly in critical applications such as WIPs. The findings of this study are poised to significantly contribute to the field by presenting a holistic and enhanced approach to predictive modeling in industrial settings. In the upcoming sections, this study delves into PdM through ML. Section II explains the methodology, highlighting the significance of the Ensemble model. Section III presents the results and analysis, while discussion is given in Section IV. Limitation and future work is given in Section V and Section VI respectively. Finally, the paper is concluded in Section VII.

II. METHODOLOGY

Predictive maintenance (PdM) in the OGI industry is critical for optimal production, safety, and cost-effectiveness. This study employs an ensemble of ML models—XGBoost, LGBM, and Random Forest—to enhance predictive accuracy. The unique strengths of each algorithm contribute to a robust framework. The ensemble methodology leverages complementary features, addressing individual weaknesses and mitigating biases. This novel approach aims to outperform standalone models, offering more accurate and reliable results. Fig. 1 illustrates the methodology implemented in our study. The flowchart visually outlines the sequential steps involved: data collection from various sources relevant to WIPs performance, including currents, pressure, and vibrations; preprocessing of the collected data to handle missing values, normalize them, and prepare them for analysis; selection of pertinent features influencing WIPs performance; training of machine learning models, comprising individual algorithms and Ensemble models, using the preprocessed data; evaluation of model performance using metrics such as RMSE to determine accuracy; creation of an Ensemble model by combining outputs from multiple models to enhance predictive accuracy; validation of the Ensemble model using test data to ensure reliability; and deployment of the final model for real-time predictive maintenance of water injection pumps, enabling proactive maintenance scheduling. To model and simulate the water injection network system, the relationships between different components and their respective parameters are established using the given formulae and principles of fluid mechanics. This includes deriving equations for the pump model, the water distributing station model, the well model, the tube element model, the node element model, and the system model, as outlined below. The pump model is represented by the quadratic equation:

$$H = AQ^2 + BQ + C \quad (1)$$

where H is the pump outlet pressure, Q is the pump flow rate, and A, B, and C are co-efficient representing the quadratic, linear, and constant terms, respectively. The water distributing station and well model can be expressed as:

$$P = A\,Q + B \quad (2)$$

where P denotes the pressure at the water distributing station or injection well, Q is the flow rate, and A and B are the linear and constant term coefficients, respectively [21]. The tube element model is described by:

$$qi = ki(hk - hj) \quad (3)$$

$$hf = Pi - Pj \quad (4)$$

where qi is the flow rate through pipeline element i, ki is a variable related to the pipe-line element length, inner diameter, and friction coefficient, hk and hj are the gross heads at the two ends of the pipeline element, and hf is the pressure loss across the pipe sec-tion. The pressure loss in the pipe section is calculated using the Darcy formula:

$$hf = Lv^2/2dg \quad (5)$$

where *hf* is the pressure loss, *L* is the pipe section length, d is the diameter, *v* is the fluid flow velocity, and *g* is the gravitational acceleration. Using these relationships, the system of equations is formulated to describe the behavior of the water injection network. Numerical methods are employed to solve

these equations iteratively, allowing for the simulation of network parameters such as pressure and flow rate at all nodes.

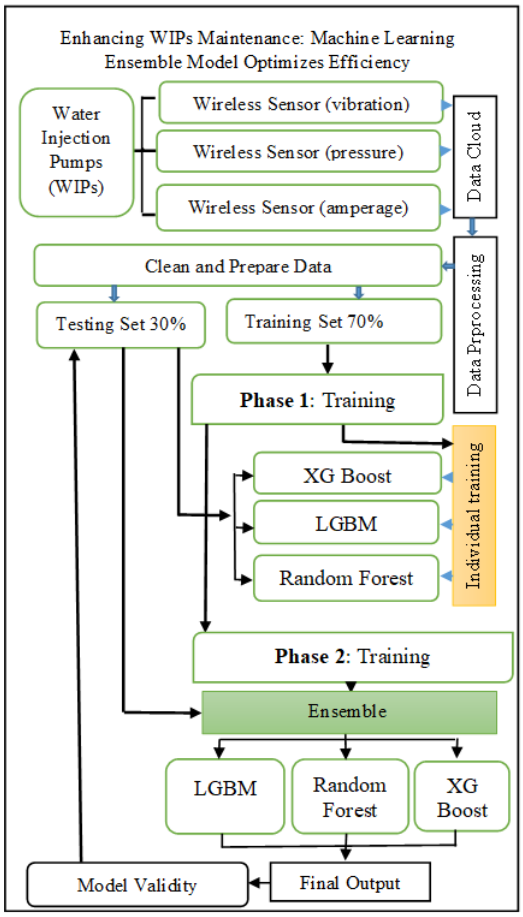

Fig. 1. Methodology flowchart.

A. Ensemble Model Construction

The present study incorporates a diverse ensemble of ML models; namely, X Boost, LGBM, and Random Forest. Each algorithm brings unique strengths, contributing to the overall robustness of the predictive framework. XGBoost's scalability, LGBM's high-performance gradient boosting, and Random Forest's ensemble learning approach individually address distinct aspects of the predictive task. The ensemble methodology aims to leverage the complementary strengths of each algorithm, enhancing predictive accuracy. By fusing the predictive capabilities of XGBoost, LGBM, and Random Forest, the study seeks to capitalize on their collective intelligence, mitigating individual weaknesses. The study asserts that this amalgamation, orchestrated through ensemble techniques, can yield more accurate and reliable results compared to each algorithm operating in isolation. This approach is grounded in the empirical observation that ensemble models often outperform individual algorithms by mitigating biases and reducing overfitting.

B. Data Collection and Preprocessing

The data utilized in this study originates from sensor readings, maintenance records, and operational parameters, collectively offering insights into the pump system's behavior. Sensor data provide real-time insights into operational aspects, including pressure levels, temperatures, and vibrations. Maintenance records offer a historical perspective, detailing interventions over time. Table I presents a succinct overview of the key operational parameters meticulously chosen for the analysis of the Work in Progress WIPs system. Among these parameters are the Ampere, denoting the current employed by the pump; VibDE, representing the vibration in the Drive End bearing; VibNDE denoting the vibration in the Non-Drive End bearing; and 1st Press, and 2nd Press delineating the 1st and 2nd Stage Seal Pressures, respectively.

TABLE I. LIST OF SELECTED RUNNING PARAMETERS FOR WIPS SYSTEM ANALYSIS

Name	Description
1st_Press	1st Stage Seal Press
2nd_Press	2nd Stage Seal Press
VibDE	Vibration in DE bearing
VibNDE	Vibration in NDE bearing
Ampere	The current used by the pump

Evaluating VIB DE and VIB NDE bearings is crucial because they support pump shaft alignment, and their condition directly impacts operational efficiency and reliability [7]. This comprehensive compilation serves as a foundational tool for a nuanced examination, allowing for a detailed assessment of the factors that significantly influence the functionality and performance of the WIPs system.

Preprocessing steps include data cleansing, type conversion, outlier detection, feature selection, correlation analysis, and normalization. Data cleansing addresses inconsistencies and missing values. Type conversion ensures uniformity in calculations. Outlier detection manages outliers that could hinder model training. Feature selection, guided by correlation analysis, reduces model complexity. Normalization and scaling ensure uniform feature scales for effective ML.

C. Data Analysis

An extensive repository of raw data encompassing operational parameters and cumulative operational hours was initially collected. The dataset refinement process involved identifying salient data points that had a high correlation with WIPs. This process aimed to enhance model interpretability and counteract dimensionality augmentation. The selected key operational parameters are Ampere, VibDE, VibNDE, 1st_Press, and 2nd_Press. Feature selection is approached judiciously, ensuring that only the most influential features are considered for each model. The provided code snippet employs the "sweetviz" Python library for exploratory data analysis (EDA), generating comprehensive reports for informed decision making. The analysis involves data cleaning, exclusion of string entries, and construction of a correlation matrix to assess inter-feature relationships. The Correlation Matrix of Feature Influences helps in selecting the pertinent features shown in Fig. 2, contributing to dimensionality re-duction and enhancing model accuracy. This matrix analysis promotes a nuanced understanding of data structure, confounding factors, and noise, ultimately improving the robustness of the research.

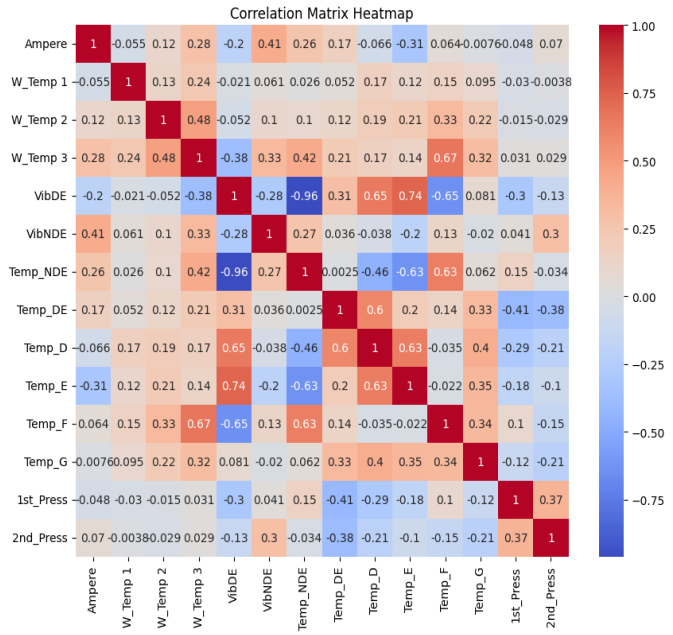

Fig. 2. Correlation matrix of feature influences.

D. Comparative Modeling of Operational Parameters

In this study, an assessment is made of two distinct modeling techniques concerning operational parameters. The Light Gradient Boosting Machine (LGBM), eXtreme Gradient Boosting (XGBoost), and random forest methodologies serve as the primary frameworks for examination [22]. The deliberate selection of multiple modeling techniques enriches the empirical rigor of the research, enabling a comparative analysis of their predictive capabilities and generalization capacities. Rooted in the gradient boosting paradigm, LGBM, XGBoost, and random forest models iteratively enhance accuracy by sequentially fitting weak learners to residuals, capturing intricate data patterns [23]. Chosen for their success in various domains, especially tasks requiring high accuracy and efficiency, these models offer a range of hyperparameter configurations for fine-tuning. By employing two distinct models, the aim is to comprehensively understand their performance variances, strengths, and limitations in capturing the intricate interplay among operational parameters. This deliberate and empirically driven choice enhances the scientific rigor of the research, enriches the depth of analysis, and facilitates a nuanced interpretation of the obtained results.

1) XGboost prediction model: The XGBoost model stands out as a powerful ML algorithm deeply rooted in gradient boosting. Recognized for its versatility and exceptional performance, XGBoost is a valuable asset across various data science and ML domains [24]. Operating as an ensemble of decision trees, XGBoost employs a sequential correction approach to iteratively enhance model performance. This methodology allows it to capture intricate relationships within datasets, while integrated tree pruning controls model complexity for improved computational efficiency [22]. Engineered for optimized speed and efficiency, XGBoost is scalable for large datasets through parallel processing. Its adaptability spans diverse data types, and it excels in both regression and classification tasks [25]. With features such as metric-based feature importance, handling imbalanced datasets, and robust regularization techniques, XGBoost emerges as a versatile and powerful algorithm, known for efficiently tackling complex tasks [26].

2) LightGBM prediction model: The LightGBM model is a high-performance open-source software library designed specifically for gradient boosting. Renowned for its speed, resource efficiency, and scalability, LightGBM finds applications in diverse ML tasks such as classification, regression, and ranking [27]. Unlike some gradient-boosting algorithms, LightGBM employs decision trees as base learners, contributing to its exceptional efficiency. Innovative techniques like Gradient-Based One-Side Sampling (GOSS) and Exclusive Feature Bundling (EFB) further enhance its capabilities for reducing model variance and optimizing feature selection. Notably, LightGBM stands out for its remarkable speed, making it one of the fastest ML libraries capable of efficiently training models on extensive datasets. Its efficiency in memory usage optimization allows it to handle datasets surpassing the memory capacity of alternative libraries [28]. Additionally, LightGBM consistently achieves impressive accuracy, delivering state-of-the-art results across a range of ML tasks, further solidifying its reputation as a powerful and scalable library.

3) Random forest prediction model: Random forest regression, a highly regarded technique in ML, is known for its versatility, robustness, and superior predictive accuracy. This ensemble method combines multiple decision trees, excelling in handling complex nonlinear relationships in diverse prediction tasks [29]. Its acclaim stems from consistently outperforming singular decision trees and other regression models by capturing intricate nonlinear relationships while mitigating overfitting. While recognized for its robustness to outliers and noise, a closer examination is crucial to understand its limits [30]. The algorithm handles high-dimensional data well, but scalability and efficiency are key. Feature importance analysis offers insights, but robustness across datasets is crucial [30]. This analysis aims to provide a nuanced view of random forest regression, emphasizing its strengths and offering alternative scenarios.

III. Results

This section compares XGBoost, LGBM, and Random Forest algorithms in predicting parameters like pressure, vibration, and Ampere values, aiming to assess their real-world effectiveness and reliability.

A. Comparative Analysis of Algorithms

1) XGBoost model for pressure prediction: insights and visual analysis: Tables II and III present a detailed analysis of the XGBoost model's performance metrics for Seal Pressure 1 and Seal Pressure 2, respectively. The XGBoost model for Seal Pressure 1 exhibits commendable metrics, with an RMSE of 5.61, an Mean Absolute Error (MAE) of 2.38, and an R-squared

value of 0.93. These metrics suggest that the model provides accurate predictions, capturing a significant portion of the variance in the data for Seal Pressure 1.

TABLE II. XGBOOST MODEL METRICS FOR SEAL PRESSURE 1

Model	RMSE	MAE	R squared
XGBoost	5.61	2.38	0.93

Table III focuses on Seal Pressure 2, demonstrating the XGBoost model's robust performance with an RMSE of 9.41, an MAE of 4.87, and an R-squared value of 0.91. Despite the slightly higher RMSE and MAE compared to Seal Pressure 1, the model exhibits reasonable accuracy. Interpretation of these metrics should consider specific application needs and tolerance for errors. The R-squared values, nearing 1.0, signify strong correlation, while RMSE and MAE offer insights into prediction errors. Overall, the XGBoost model proves effective in predicting both Seal Pressure 1 and Seal Pressure 2, providing valuable insights for practitioners in pressure prediction scenarios.

TABLE III. XGBOOST MODEL METRICS FOR SEAL PRESSURE 2

Model	RMSE	MAE	R squared
XGBoost	9.41	4.87	0.91

Known for its robustness with complex datasets, the XGBoost algorithm excels in pressure forecasting. This overview explores its application for precise pressure prediction, crucial in diverse sectors. Fig. 3 and Fig. 4 visually compare actual and predicted values, focusing on the initial 25 predictions. Logarithmic scaling enhances clarity, and the limited predictions prevent overcrowding, allowing for a focused evaluation of XGBoost's predictive accuracy.

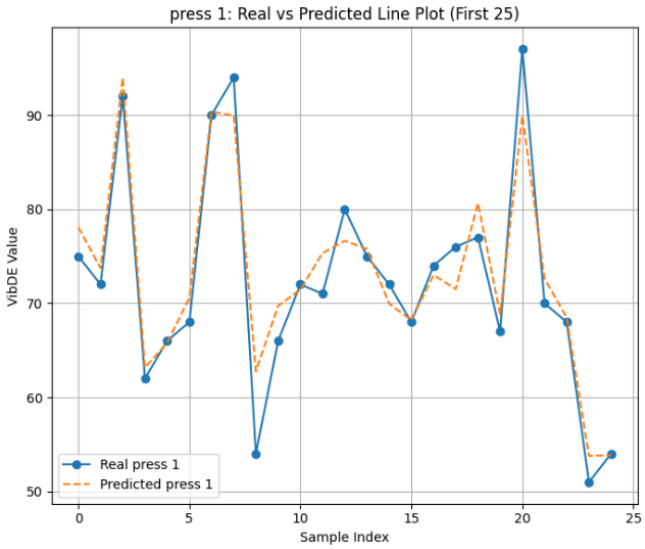

Fig. 3. XGBoost model—line plot analysis of actual vs. predicted pressure 1 (first 25 predictions).

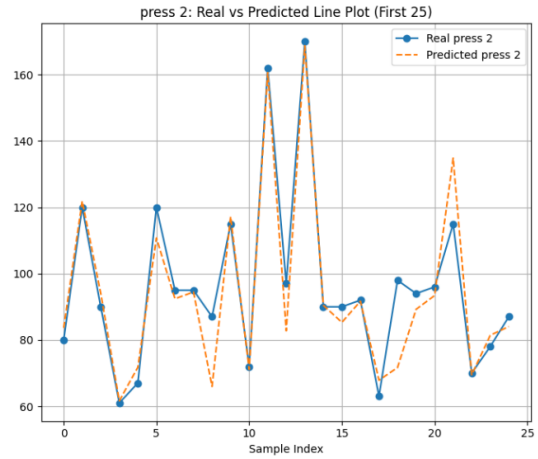

Fig. 4. XGBoost model—focused visualization with limited predictions pressure 2 (first 25 predictions).

2) XGBoost Model for vibration prediction: Insights and visual analysis: Evaluating VIB DE and VIB NDE bearings is crucial for pump system health. In Table IV, focusing on VIB DE, the XGBoost model shows strong performance with an RMSE of 6.32, an MAE of 3.80, and a high R-squared value of 0.99, indicating accurate predictions.

TABLE IV. VIBRATION IN VIB DE—XGBOOST MODEL METRICS

Model	RMSE	MAE	R squared
XGBoost	6.32	3.80	0.99

Table V, evaluating VIB NDE, shows excellence with an RMSE of 3.34, an MAE of 3.80, and an impressive R-squared value of 0.99. These metrics highlight the XGBoost model's proficiency in predicting Non-Drive End-bearing vibration. Comparing Tables IV and V reveals consistent high performance in predicting vibration for both Drive End and Non-Drive End bearings. Strong R-squared values indicate a robust correlation, emphasizing model reliability. Similar MAE values suggest consistent accuracy. Accurate vibration prediction is crucial for identifying potential issues and preventing malfunctions, showcasing the XGBoost model's effectiveness in addressing vibration complexities for overall pump system health and longevity.

TABLE V. VIBRATION IN VIB NDE—XGBOOST MODEL METRICS

Model	RMSE	MAE	R squared
XGBoost	3.34	3.80	0.99

Fig. 5 and Fig. 6 depict the XGBoost model's performance in predicting VIB DE and VIB NDE. Using a line graphs, the visualizations compare the initial 25 predictions with actual values. Applying a logarithmic function enhances scale and normalizes data for a clearer presentation, reducing clutter. The intentional limit of 25 predictions prevents graph overcrowding, ensuring a focused and comprehensive representation.

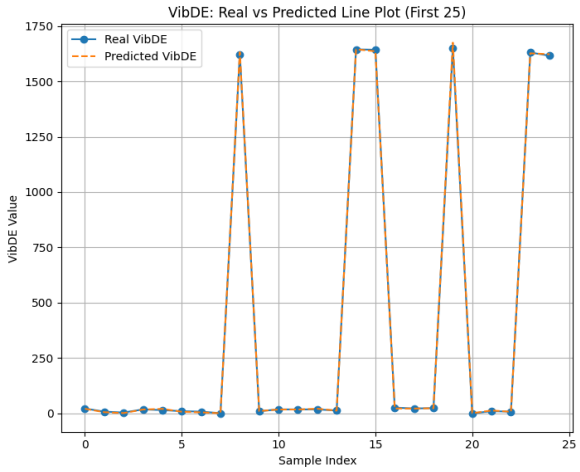

Fig. 5. XGBoost model predictions vs. actual values for VIB DE (line graph).

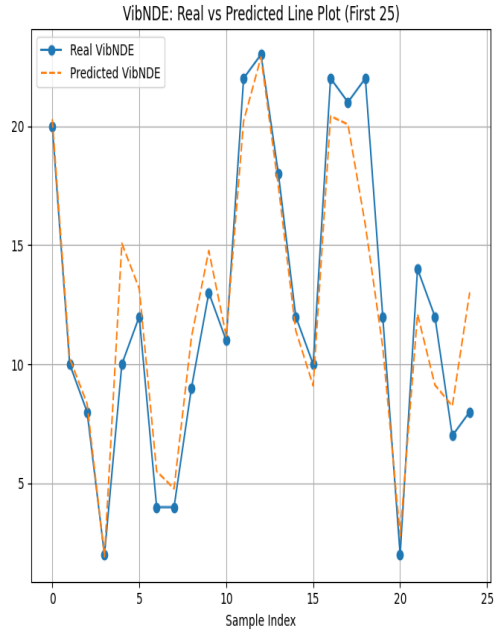

Fig. 6. XGBoost model predictions vs. actual values for VIB NDE (line graph).

3) XGBoost model for AMPERE prediction: insights and visual analysis: Table VI details the predictive performance metrics for the XGBoost model in Ampere measurements forecasting. With an RMSE of 3.28, an MAE of 2.25, and an R-squared value of 0.79, the model shows reasonably accurate predictions for Ampere. While demonstrating proficiency, there is room for improvement, particularly in explaining variance. These metrics serve as benchmarks, guiding potential refinements to enhance precision in future iterations. Insights from Table VI contribute to ongoing efforts to optimize parameters or explore alternative methodologies, crucial for fine-tuning the model and maximizing its effectiveness in real-world applications where accurate Ampere predictions are crucial.

TABLE VI. XGBOOST MODEL METRICS FOR AMPERE PREDICTION

Model	RMSE	MAE	R squared
XGBoost	3.28	2.25	0.79

Fig. 7 visually analyze the XGBoost model's predictive performance, comparing the first 25 predictions with actual values using grouped line plots. The contrast between actual and predicted values highlights the model's accuracy, with line plots depicting continuous performance trends. Applying a logarithmic function enhances clarity and comparability, ensuring better scale and data normalization for a coherent representation. Focusing on the initial 25 predictions prevents visual overcrowding, thereby facilitating a detailed examination of early-phase accuracy.

This approach allows for effective pattern recognition and insights. Overall, these visualizations offer a comprehensive and accessible assessment of the XGBoost model's predictive capabilities, leveraging a combination of graphs and thoughtful data transformations for nuanced understanding and valuable insight.

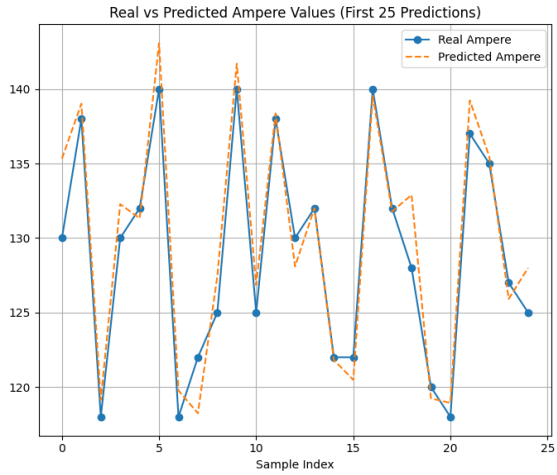

Fig. 7. XGBoost model—line plot analysis of actual vs. predicted values (first 25 predictions).

4) LGBM model for pressure prediction: insights and visual analysis: Examining the outcomes presented in Table VII, it is evident that the LGBM model achieves noteworthy metrics for Seal Pressure 1, with an RMSE of 5.29, an MAE of 2.22, and an R-squared value of 0.94.

TABLE VII. LGBM MODEL METRICS FOR SEAL PRESSURE 1

Model	RMSE	MAE	R squared
LGBM	5.29	2.22	0.94

Moving to Table VIII, the LGBM model's performance for Seal Pressure 2 is notable, featuring an RMSE of 8.98, an MAE of 5.17, and an R-squared value of 0.91. These tabulated results provide a detailed overview of the LGBM model's effectiveness for both Seal Pressure 1 and Seal Pressure 2, facilitating a comprehensive evaluation of its predictive capabilities.

TABLE VIII. LGBM MODEL METRICS FOR SEAL PRESSURE 2

Model	RMSE	MAE	R squared
LGBM	8.98	5.17	0.91

Fig. 8 and Fig. 9 visually showcase the LGBM model's predictive performance in pressure forecasting. Utilizing line plots for a comparative analysis of the initial 25 predictions against actual values, the visualization highlights the LGBM model's effectiveness. Applying a logarithmic function enhances clarity and maintains a normalized scale, ensuring a clearer and less cluttered representation. Focusing on the initial 25 predictions allows for detailed examination of early accuracy, preventing graph overcrowding, and allowing for a interpretable and focused visual representation. These visualizations offer valuable insights into the LGBM model's predictive capabilities, aiding in assessing its performance and reliability in pressure prediction scenarios. The graphical representation facilitates an intuitive understanding of the model's behavior, contributing to a comprehensive evaluation.

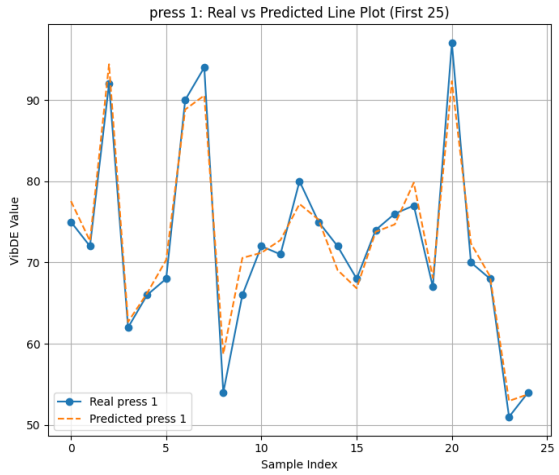

Fig. 8. LGBM Model—Line Plot Analysis of Actual vs. Predicted Pressure (First 25 Predictions).

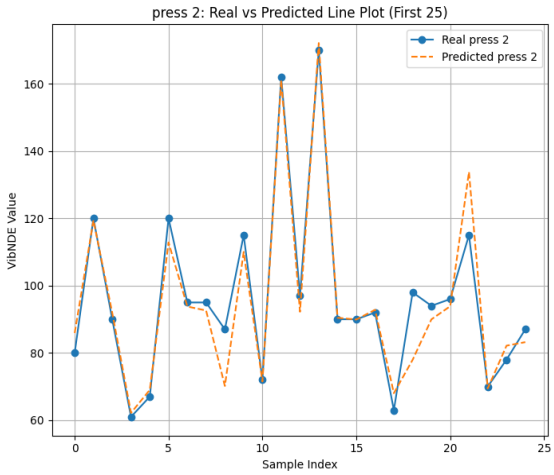

Fig. 9. LGBM Model—Focused Visualization with Limited Predictions (First 25 Predictions).

5) LGBM model for vibration prediction: Insights and visual analysis: The visualizations presented in Fig. 10 depict the performance of the LGBM model in predicting VIB DE and VIB NDE values. The line graphs facilitate a comprehensive comparison of the first 25 predictions with their corresponding actual values. Applying the log function to the values serves the purpose of achieving a better scale and normalization, leading to a clearer and less cluttered visualization. This transformation enhances the interpretability of the data, making it easier to discern patterns and trends in the model's predictions. By limiting the display to the first 25 predictions, the graphs avoid overcrowding, allowing for a focused examination of the model's accuracy in capturing the actual values. This selective approach aids in identifying any discrepancies or areas where the model may exhibit strengths or weaknesses. The discussion of these visualizations should involve a detailed analysis of how well the LGBM model aligns with the actual values, considering factors such as precision, accuracy, and potential areas for improvement. Additionally, any notable patterns or deviations between predicted and actual values should be highlighted and discussed to provide insights into the model's performance and its applicability in predicting VIB DE and VIB NDE.

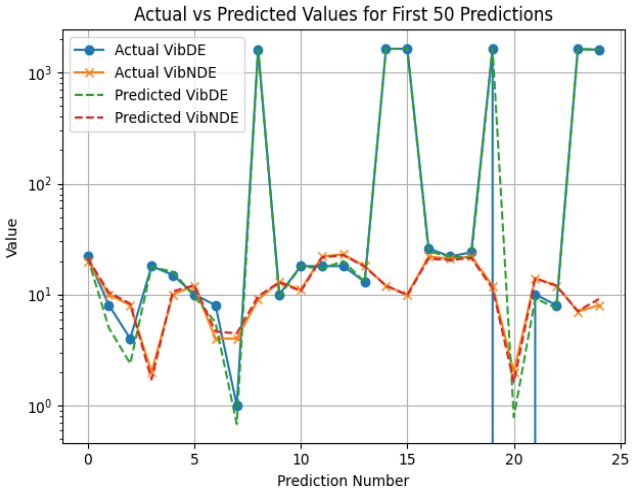

Fig. 10. LGBM Model Predictions vs. Actual Values for VIB NDE.

The LGBM model for VIB DE demonstrates exceptional performance, as indicated by the metrics in Table IX. The Root Mean Squared Error (RMSE) stands impressively low at 45.22, signifying minimal deviation between predicted and actual values. Complementing this, the MAE is commendably low at 6.07, reinforcing the model's accuracy. The high R-squared value of 0.99 emphasizes an excellent fit, showcasing the model's ability to explain the variance in VIB DE.

TABLE IX. PERFORMANCE METRICS FOR VIB DE USING LGBM

Model	RMSE	MAE	R squared
LGBM	45.22	6.07	0.99

Turning to VIB NDE, the LGBM model continues to exhibit strong predictive capabilities, as highlighted in Table X. The RMSE is notably low at 3.46, indicating minimal prediction errors. The MAE, standing at 2.32, further emphasizes the accuracy of the model, with low absolute differences between predicted and actual values. While the R-squared value of 0.84 is slightly lower than in VIB DE, it still signifies a robust model fit and reliable predictions for VIB NDE. The Tables IX and X are collectively underscore the effectiveness of the LGBM model in predicting both VIB DE and VIB NDE.

TABLE X. PERFORMANCE METRICS FOR VIB NDE USING LGBM

Model	RMSE	MAE	R squared
LGBM	3.46	2.32	0.84

6) LGBM model for AmperE prediction: Insights and visual Analysis : Fig. 11 offers a detailed analysis of the LGBM model's Ampere prediction performance using grouped line plots. Comparing the initial 25 predictions with actual values, these visualizations provide insights into the model's accuracy. Line plots offer a continuous overview of the model's performance. Applying a logarithmic function enhances interpretability and comparability, ensuring a clearer and less cluttered visualization. Focusing on the first 25 predictions prevents visual congestion, allowing a detailed examination of early-stage accuracy and facilitating the discernment of performance patterns. The line plots thoughtful data transformations contributes to a nuanced understanding of the LGBM model's predictive performance, facilitating valuable insights from the visualized data.

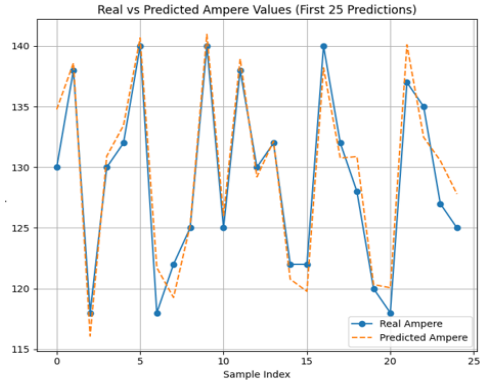

Fig. 11. LGBM Model—Comparison of Actual vs. Predicted Ampere Values (First 25 Predictions).

Table XI succinctly evaluates the LGBM model's performance in predicting Ampere values through the three key metrics—RMSE, MAE, and R-squared. With an RMSE of 3.08 indicating average error magnitude, a low MAE of 2.26 signifying precise predictions, and a high R-squared value of 0.82 showcasing substantial explanatory power, the LGBM model proves effective for Ampere prediction. These metrics affirm the model's reliability and accuracy, positioning it as a valuable tool for forecasting Ampere values across applications. The table provides a concise summary, offering numerical indicators for researchers, practitioners, and decision makers seeking insights into the model's efficacy.

TABLE XI. LGBM MODEL METRICS FOR AMPERE PREDICTION

Model	RMSE	MAE	R squared
LGBM	3.08	2.26	0.82

7) Random forest model for pressure prediction: Insights and visual analysis: Fig. 12 and Fig. 13 visually depict the Random Forest model's predictive performance using line plots, contrasting the initial 25 predictions with actual values. The combination of these visual elements highlights the model's efficacy and provides a comprehensive analysis of its accuracy in predicting the first 25 observations. Applying a logarithmic function enhances clarity and maintains a normalized scale, resulting in a distinct and less cluttered representation. Focusing on the initial 25 predictions offers valuable insights into the model's early predictive behavior, facilitating a detailed examination of accuracy without overcrowding the graphical representation. These visualizations contribute to a nuanced understanding of the Random Forest model's predictive capabilities, offering unique insights through line plots. This visual exploration is crucial for assessing the model's reliability and effectiveness, particularly in scenarios where clarity and precision are paramount.

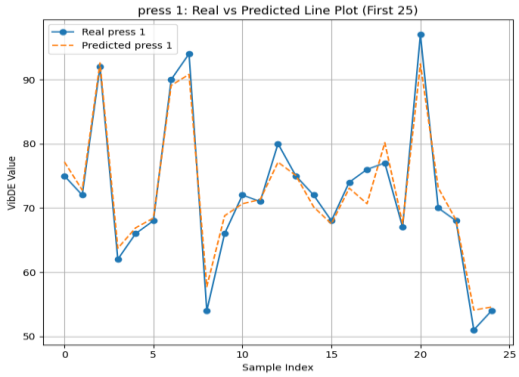

Fig. 12. Random Forest Model—Logarithmic Transformation (First 25 Predictions).

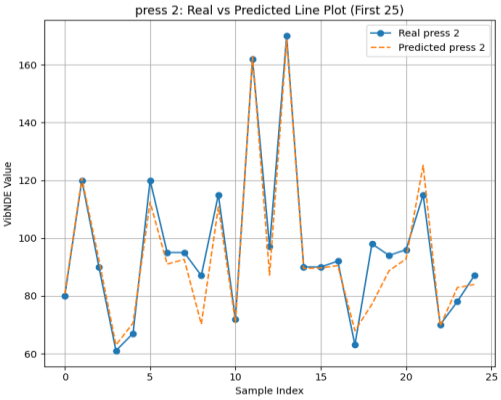

Fig. 13. Random Forest Model—Focused Visualization with Limited Predictions (First 25 Predictions).

In Table XII, the Random Forest model exhibits commendable metrics for Seal Pressure 1, with an RMSE of 4.86, an MAE of 2.01, and an R-squared value of 0.95. These results suggest that the Random Forest model provides accurate predictions, capturing a significant portion of the variance in the data for Seal Pressure 1.

TABLE XII. RANDOM FOREST MODEL METRICS FOR SEAL PRESSURE 1

Model	RMSE	MAE	R squared
Random Forest	4.86	2.01	0.95

Table XIII focuses on Seal Pressure 2, where the Random Forest model demonstrates robust performance with an RMSE of 9.24, an MAE of 4.49, and an R-squared value of 0.91. Despite slightly higher RMSE and MAE values compared to Seal Pressure 1, the model maintains reasonable accuracy. Combined with visualizations, it is evident that the Random Forest model consistently performs well in both seal pressure scenarios. Strong correlation, as indicated by high R-squared values, underscores the model's reliability in predicting seal pressures. The integration of visual and quantitative assessments provides a comprehensive understanding of the Random Forest model's effectiveness.

TABLE XIII. RANDOM FOREST MODEL METRICS FOR SEAL PRESSURE 2

Model	RMSE	MAE	R squared
Random Forest	9.24	4.49	0.91

8) Random forest model for vibration prediction: insights and visual analysis: Fig. 14 and 15 visually analyze the Random Forest model's performance in predicting VIB DE and VIB NDE, employing both bar and line formats to compare the initial 25 predictions with actual values. Applying a log function to the values enhances scaling and normalization, improving visualization clarity. Focusing on the first 25 predictions prevents overcrowding, allowing for a detailed examination of the model's accuracy and nuances in data capture. This approach provides a concise yet meaningful snapshot of the Random Forest model's alignment with actual values, offering valuable insights for further analysis and model refinement.

In Tables XIV and XV, the performance metrics of the Random Forest model in predicting VIB DE and VIB NDE are presented. In Table XIV, the model achieved an RMSE of 9.53, indicating precise predictions with a low average magnitude of errors. The MAE of 3.80 further confirms the model's accuracy, as it represents the average absolute difference between predicted and actual values. The exceptionally high R squared value of 0.99 signifies a remarkable goodness of fit, explaining 99% of the variance in VIB DE.

Turning to Table XV, the Random Forest model showcased a notable RMSE of 3.58 for VIB NDE, indicating accurate predictions with a low average magnitude of errors. The MAE of 2.16 reinforces the model's reliability, showcasing a relatively small average absolute difference from the actual values. The R squared value of 0.83 highlights a strong fit, accounting for 83% of the variance in VIB NDE.

In summary, the Random Forest model demonstrates exceptional predictive accuracy for both VIB DE and VIB NDE. The low RMSE and MAE values, coupled with high R-squared values, underscore the model's effectiveness in capturing and explaining the variance in vibration data. These findings affirm the Random Forest model as a robust tool for vibration prediction in both conditions.

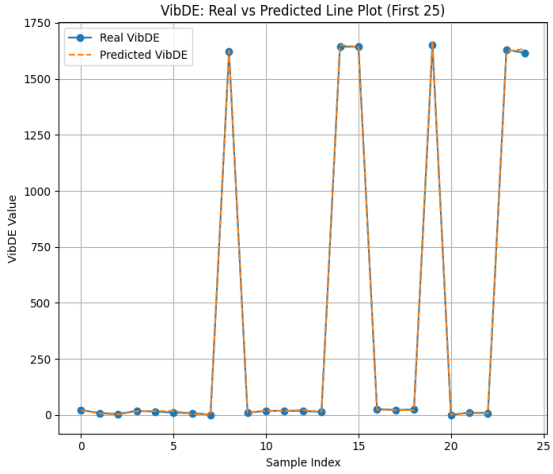

Fig. 14. RandomForest_VIB_DE_Performance_Line.

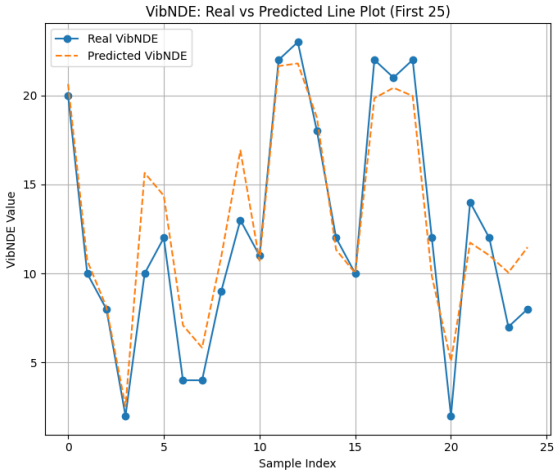

Fig. 15. RandomForest_VIB_NDE_Performance_Line.

TABLE XIV. RANDOM FOREST VIB DE PERFORMANCE

Model	RMSE	MAE	R squared
Random Forest	9.53	3.80	0.99

TABLE XV. RANDOM FOREST VIB NDE PERFORMANCE

Model	RMSE	MAE	R squared
Random Forest	3.58	2.16	0.83

9) Random forest model ampere prediction-insights and visual analysis: The visual representation in Fig. 16 offers a detailed examination of the Random Forest model's efficacy in predicting Ampere values. Utilizing line plots, these visualizations facilitate a comprehensive comparison of the

initial 25 predictions made by the Random Forest model against the actual values. Applying a logarithmic function enhances interpretability and normalization of the data, resulting in a clearer representation of the Random Forest model's predictive accuracy. Focusing on the first 25 predictions prevents visual congestion, allowing a detailed examination of early-stage accuracy and providing valuable insights into the model's predictive behavior for Ampere values.

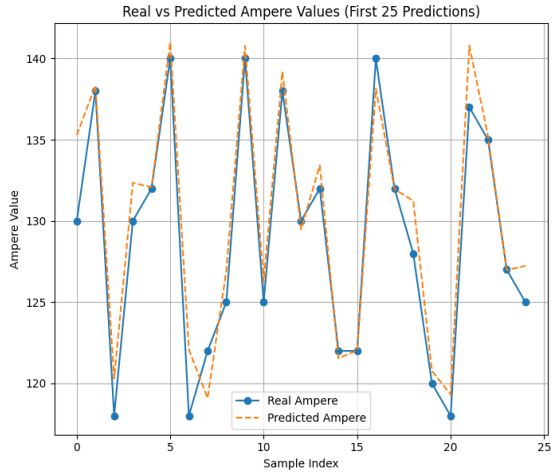

Fig. 16. Random Forest Model - Line Plot Analysis of Actual vs. Predicted Ampere Values (First 25 Predictions).

The performance metrics for Ampere prediction using the Random Forest model, as presented in Table 16, showcase its commendable accuracy. With a low RMSE of 2.96 and a close match between predicted and actual values indicated by an MAE of 2.10, the model demonstrates robust predictive capabilities. The high R-squared value of 0.83 further emphasizes its ability to explain a substantial proportion of the variance in Ampere measurements. In summary, these metrics affirm the Random Forest model's effectiveness in delivering accurate Ampere predictions, underscoring its potential for reliable forecasting in relevant applications.

TABLE XVI. RANDOM FOREST MODEL METRICS FOR AMPERE PREDICTION

Model	RMSE	MAE	R squared
Random Forest	2.96	2.10	0.83

B. Ensemble Approach for Maintenance Prediction

Ensembling XGBoost, LightGBM, and Random Forest models in maintenance prediction, as shown in Fig. 17, combines their predictive outputs to boost accuracy and robustness. This approach capitalizes on the unique strengths of each model—XGBoost's efficiency, LightGBM's speed, and Random Forest's robustness. By fusing these models, the ensemble leverages their collective intelligence, mitigating individual weaknesses. The visual in Fig. 17 illustrates how this collaboration forms a cohesive and reliable maintenance prediction framework, enhancing resilience to uncertainties and improving overall effectiveness in complex scenarios.

To improve predictive outcomes, an ensembling approach combines three models—XGBoost, LGBM, and Random Forest. Ensemble learning—leveraging the strengths of multiple models, mitigating risks of overfitting and underfitting, and enhancing predictive accuracy [17]. It addresses common ML challenges, making models more robust and stable. Ensemble learning excels in capturing complex data relationships, proving effective in scenarios where a single model may struggle. In the voting mechanism, soft voting is preferred for its regression nature. Soft voting, averaging predicted probabilities, offers a nuanced approach over hard voting, which is particularly beneficial when models exhibit varying confidence levels. The advantages of soft voting include enhanced predictive performance and flexibility, making it suitable for imbalanced datasets. In conclusion, strategic ensembling—especially through soft voting—stands as a simple yet effective method for improving ML model performance, particularly in scenarios with varying confidence levels.

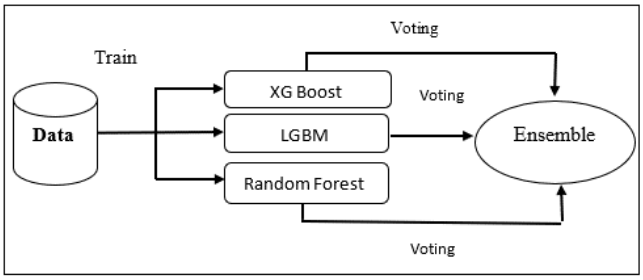

Fig. 17. Ensemble of XGBoost, LightGBM, and Random Forest Models for Maintenance Prediction.

1) Results and analysis of ensemble model prediction for seal pressure: The results from the evaluation of the pump's seal pressure models, presented in Tables XVII and XVIII, demonstrate the performance of XGBoost, LGBM, Random Forest, and the ensemble approach. For Seal Pressure 1 (Table XVII), the standalone models perform well: XGBoost (RMSE: 5.61, MAE: 2.38, R-squared: 0.93); LGBM (RMSE: 5.29, MAE: 2.22, R-squared: 0.94); and Random Forest (RMSE: 4.86, MAE: 2.01, R-squared: 0.95). The Ensemble model significantly outperforms these, with RMSE: 1.94, MAE: 0.92, and R-squared: 0.99. Similarly, for Seal Pressure 2 (Table XVII), the standalone models show strong performance: XGBoost (RMSE: 9.41, MAE: 4.87, R-squared: 0.91); LGBM (RMSE: 8.98, MAE: 5.17, R-squared: 0.91); and Random Forest (RMSE: 9.24, MAE: 4.49, R-squared: 0.91). Again, the Ensemble model achieves superior results, with RMSE: 2.94, MAE: 1.74, and R-squared: 0.99. These findings underscore the Ensemble model's enhanced predictive capabilities for both Seal Pressure 1 and Seal Pressure 2. The marked improvement in RMSE, MAE, and R-squared values indicates that the ensemble approach effectively combines the strengths of XGBoost, LGBM, and Random Forest, leading to higher accuracy and reduced prediction errors.

TABLE XVII. INDIVIDUAL AND ENSEMBLE MODEL METRICS FOR SEAL PRESSURE 1

Model	RMSE	MAE	R squared
XGBoost	5.61	2.38	0.93
LGBM	5.29	2.22	0.94
Random Forest	4.86	2.01	0.95
Ensemble	1.94	0.92	0.99

Table XVIII provides an insightful comparison of metrics for Seal Pressure 2. The standalone models (XGBoost, LGBM, Random Forest) exhibit respectable performance, while the Ensemble model consistently outshines them across all metrics. This emphasizes the Ensemble model's effectiveness in enhancing accuracy and reducing errors in predicting Seal Pressure 2.

TABLE XVIII. INDIVIDUAL AND ENSEMBLE MODEL METRICS FOR SEAL PRESSURE 2

Model	RMSE	MAE	R squared
XGBoost	9.41	4.87	0.91
LGBM	8.98	5.17	0.91
Random Forest	9.24	4.49	0.91
Ensemble	2.94	1.74	0.99

From Tables XVII and XVIII, it is evident that, for both Seal Pressures 1 and 2, the error rate is notably higher when employing stand-alone models compared to the Ensemble model. Utilizing three distinct error metrics—root mean squared, mean average precision, and error squared—we consistently observe that the Ensemble model outperforms each of the stand-alone models. This observation underscores the potential of combining multiple models into an ensemble, demonstrating its efficacy in achieving heightened accuracy and minimizing prediction errors across diverse evaluation metrics. Fig. 18 offers a visual representation of the Ensemble model's performance in predicting Seal Pressure 1, employing line plots to compare the initial 25 predictions with their actual values. The visual presentation underscores the effectiveness of the Ensemble model through line plots, providing a comprehensive analysis of its accuracy in predicting the first 25 observations of Seal Pressure 1. The application of a logarithmic function to the values serves the dual purpose of enhancing the visualization's clarity and maintaining a normalized scale. This transformation results in a more distinct and less cluttered representation of the model's performance. Focusing on the initial 25 predictions ensures a detailed examination of the Ensemble model's accuracy during the initial phase, contributing to a nuanced understanding of its predictive behavior. This approach also helps to prevent overcrowding in the graphs, ensuring that the visual representation remains interpretable and focused. These visualizations, in conjunction with quantitative metrics, contribute to a comprehensive evaluation of the Ensemble model's reliability and effectiveness in predicting Seal Pressure 1. The integration of visual and quantitative assessments enhances the overall understanding of the model's predictive capabilities and aids in decision making for real-world applications.

Fig. 19 explores the Ensemble model's performance in predicting Seal Pressure 2, comparing the initial 25 predictions with actual values using line plots. The visual representation highlights the model's accuracy, providing a comprehensive analysis of its performance. Applying a logarithmic function enhances clarity and maintains a normalized scale, resulting in a clearer and more distinct representation. Focusing on the initial 25 predictions allows for a detailed examination of the model's accuracy during the early phase, contributing to a nuanced understanding of its predictive behavior. This approach ensures interpretability by preventing graph overcrowding. The visualizations, complemented by quantitative metrics, offer a thorough evaluation of the Ensemble model's reliability and effectiveness in predicting Seal Pressure 2, enhancing the overall understanding of its predictive capabilities for real-world applications.

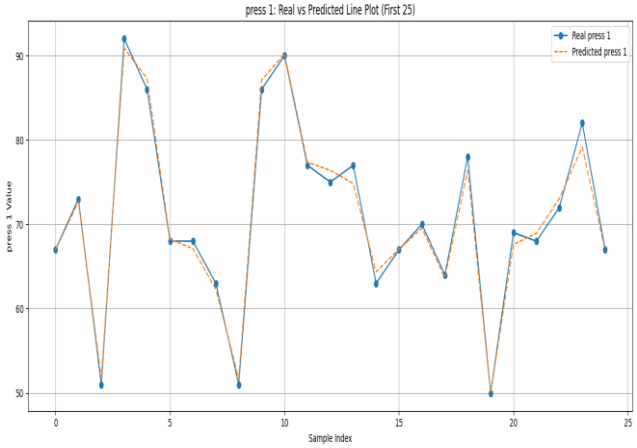

Fig. 18. Ensemble Model—Line Plot Analysis of Actual vs. Predicted Seal Pressure 1 (First 25 Predictions).

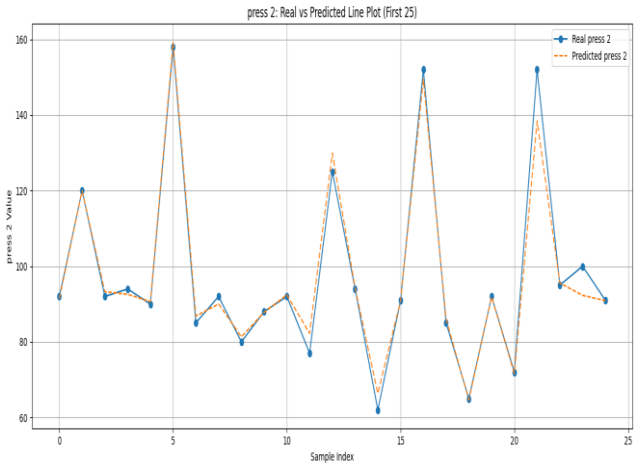

Fig. 19. Ensemble Model—Line Plot Analysis of Actual vs. Predicted Seal Pressure 2.

The examination of both the tables and graph reveals a noticeable elevation in error metrics for individual models. However, a compelling contrast emerges when these models are amalgamated, resulting in a substantial reduction in error, as evidenced by the graphical representations. This improvement is distinctly illustrated by the diminished variance between the

actual and predicted lines in the line graph. A comparative analysis of the line graphs for the Ensemble model's underscores the significant enhancement achieved by combining individual models, resulting in a more accurate and reliable predictive outcome.

2) Results and analysis of ensemble model prediction for vibration prediction: The evaluation of the Vibration Diagnoses Equipment (VIB DE) and Vibration Non-Diagnoses Equipment (VIB NDE) models provides valuable insights into their predictive performance for bearing vibrations using RMSE, MAE, and R-squared metrics. In Table XIX, the VIB DE models show high RMSE values, indicating substantial prediction errors, with the LGBM model having an exceptionally high RMSE of 45.22. However, the Ensemble model reduces the RMSE to 8.60, demonstrating the effectiveness of combining the models. The decline in MAE and consistently high R-squared values further emphasize the Ensemble model's superior ability to reduce prediction errors and improve accuracy.

TABLE XIX. INDIVIDUAL AND ENSEMBLE MODEL METRICS FOR VIB DE MODEL METRICS

Model	RMSE	MAE	R squared
XGBoost	6.32	3.80	0.99
LGBM	45.22	6.07	0.99
Random Forest	9.53	3.80	0.99
Ensemble	8.60	1.42	0.99

In Table XX, individual models such as LGBM and Random Forest show notable RMSE values for VIB NDE evaluation. The Ensemble model significantly enhances accuracy with lower RMSE and MAE and higher R-squared values. Interestingly, XGBoost slightly outperforms the Ensemble for VIB DE, indicating algorithmic influence. Graphical and tabular presentations consistently illustrate the Ensemble model's superior performance in error metrics, emphasizing its effectiveness in predicting and managing vibration issues in critical system maintenance.

TABLE XX. INDIVIDUAL AND ENSEMBLE MODEL METRICS FOR VIB NDE MODEL METRICS

Model	RMSE	MAE	R squared
XGBoost	3.34	3.80	0.99
LGBM	3.46	2.32	0.84
Random Forest	3.58	2.16	0.83
Ensemble	1.17	0.75	0.98

Fig. 20 showcases the ensemble of XGBoost, LightGBM, and Random Forest models, leveraging their strengths for accurate and robust maintenance predictions. By integrating diverse perspectives, the ensemble enhances resilience to uncertainties, offering a comprehensive solution for complex operational scenarios. This collaborative approach mitigates individual weaknesses, leading to improved performance compared to standalone models and enhancing the effectiveness of maintenance prediction systems.

Examining the table and graphs reveals notable error metrics for individual models, indicating relatively high errors. However, a significant improvement is evident when these models are integrated into an ensemble. The comparison of actual and predicted lines in the line graph vividly illustrates this enhancement. The Ensemble model, depicted in the graphs, showcases a considerable reduction in error compared to individual models.

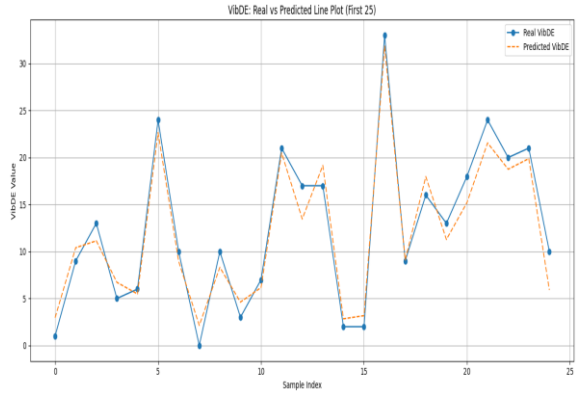

Fig. 1. Ensemble Model's Performance for VIB NDE (Line Graphs).

3) Results and analysis of ensemble model prediction for ampere prediction: When evaluating power consumption, Ampere readings serve as a crucial parameter, with higher readings indicative of increased power consumption. In scenarios where direct current measurements are unavailable, employing ML models becomes a viable option for prediction. In this context, three distinct models—XGBoost, LGBM, and Random Forest—were implemented to forecast Ampere readings. Subsequently, these models were amalgamated into an Ensemble model to harness their collective predictive capabilities. The performance metrics, including RMSE, mean average error (MAE), and R-squared values, were employed to assess the accuracy of each model and the Ensemble model's. The results are presented in Table XXI.

TABLE XXI. AMPERE PREDICTION MODEL PERFORMANCE METRICS

Model	RMSE	MAE	R squared
XGBoost	3.28	2.25	0.79
LGBM	3.08	2.26	0.82
Random Forest	2.96	2.10	0.83
Ensemble	1.69	0.94	0.95

Analysis of the table indicates a substantial decrease in error rates when utilizing the Ensemble model as opposed to individual models. Employing three distinct error metrics consistently demonstrates the superior performance of the Ensemble model, affirming its effectiveness in achieving heightened accuracy and minimizing prediction errors. This underscores the value of combining diverse models to enhance predictive capabilities. The visual representation above showcases the performance of the Ensemble model for the Ampere prediction. Utilizing line graph in Fig. 21, the graph allows a comparison of the first 25 predictions with their actual

values. To enhance clarity and minimize clutter, a logarithmic function has been applied to the values, resulting in a more normalized and visually accessible presentation. The decision to focus on 25 predictions ensures a concise and uncluttered depiction, facilitating a clear understanding of the Ensemble model's effectiveness in predicting Ampere values.

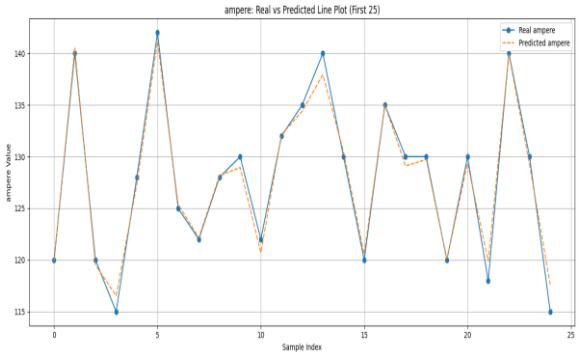

Fig. 2. Line Graph for Ampere Ensemble Model Performance.

Fig. 21 illustrates the performance of the Ensemble model for the Ampere prediction. These visualizations showcase a comparison between the first 25 predictions and their actual values, employing both bar and line graphs. To enhance clarity and maintain a cleaner display, a logarithmic function has been applied to the values, ensuring a more balanced scale. The limited focus on 25 predictions prevents graph overcrowding, facilitating a more straightforward interpretation of the results.

IV. Discussion

This study presents a novel approach to predictive maintenance (PdM) in the oil and gas industry by utilizing an ensemble of three machine learning algorithms—XGBoost, Light Gradient-Boosting Machine (LGBM), and Random Forest. The ensemble model consistently outperformed individual models, demonstrating superior accuracy and reliability across all operational parameters (Seal Pressure 1, Seal Pressure 2, VIB DE, VIB NDE, and Ampere). Notably, the Ensemble model showed lower Root Mean Square Error (RMSE) and Mean Absolute Error (MAE) values and higher R-squared coefficients, indicating better performance in predicting the health of water injection pumps (WIPs). This finding aligns with research conducted by Zhang et al. [1], where combining multiple machine learning models improved prediction accuracy in industrial applications. The novelty of this study lies in the hybridization of these models to predict diverse operational parameters, which is an improvement over the standalone approaches often used in previous research. For example, Janssens et al. [2] applied Convolutional Neural Networks (CNNs) to detect anomalies using infrared thermal images, but the study was limited in its ability to handle different operational variables. Similarly, Sampaio et al. [3] explored Artificial Neural Networks (ANNs) for motor failure prediction but did not consider the comprehensive evaluation of various predictive models. The Ensemble model, in contrast, demonstrates a broader applicability by leveraging the strengths of multiple algorithms, thus mitigating the individual limitations of each method and achieving more robust and reliable predictions. Furthermore, the results of this study highlight the importance of addressing operational parameters beyond vibration data, such as seal pressure and amperage, which are often overlooked in predictive maintenance studies. This is in contrast to previous studies that focused primarily on vibration data for fault detection and failure prediction [4], [5]. By including additional operational parameters, this research provides a more holistic approach to predictive maintenance, which could lead to more effective early detection of potential failures in WIPs, ultimately reducing unplanned downtime and improving operational efficiency. The ensemble approach presented in this study also reflects a growing trend in the literature toward integrating multiple machine learning techniques to enhance the accuracy of PdM models. This is consistent with the findings of Kim et al. [6], who demonstrated that ensemble methods, when applied to predictive maintenance in industrial equipment, resulted in significant improvements in both prediction accuracy and reliability. The success of the ensemble model in this study suggests that further refinement and adaptation of this methodology could be applied to other critical equipment within the oil and gas industry, as well as other industrial sectors facing similar challenges with unplanned downtime. In sum, the findings of this study contribute to the growing body of research on predictive maintenance by offering an innovative methodology for improving the accuracy of failure predictions in water injection pumps. The ensemble model's superior performance, when compared to individual models, underscores the potential for more accurate and reliable predictive systems in industrial applications. The results also pave the way for further exploration of hybrid machine learning models in PdM, particularly in industries with complex operational environments, such as oil and gas.

V. Limitations

The Ensemble model, comprising XGBoost, LGBM, and Random Forest, demonstrates commendable predictive accuracy across diverse operational parameters. However, it is imperative to acknowledge certain limitations inherent in the approach. First, the efficacy of the Ensemble model is highly contingent on the quality of the input data. Instances of data inconsistencies, inaccuracies, or a lack of representativeness concerning diverse operating conditions can potentially compromise the performance. Moreover, the representativity of the training set plays a pivotal role. The Ensemble model relies on a training dataset that effectively captures the various operating scenarios of the pump system. Notably, the study focused on predicting pressure, vibration, and amperage for temperature, while considering other features that could contribute to PdM in WIPs within the OGI. These limitations underscore the importance of meticulous data quality assurance, comprehensive representation in training datasets, and ongoing refinement of hyperparameter configurations for the reliable and robust application of the Ensemble model in PdM scenarios.

VI. Future Research Direction

The Ensemble model, comprising XGBoost, LGBM, and Random Forest, consistently demonstrates notable predictive accuracy for various operational parameters in WIPs. However, the model's performance is contingent on high-quality input data and a representative training set. Notably, the sensitivity to hyperparameter configurations requires ongoing optimization

efforts. Future research directions could explore advanced ensemble techniques beyond the current models and dynamic hyperparameter tuning mechanisms for autonomous adaptation. Investigating the impact of external factors, transitioning to real-time predictions, enhancing explainability, scalability testing, and integrating the model into existing maintenance systems are promising avenues. Seeking feedback from industry practitioners is vital for refining the model's real-world applicability.

VII. Conclusions

In conclusion, this study demonstrates the effectiveness of combining multiple machine learning algorithms—XGBoost, LGBM, and Random Forest—into an Ensemble model for predictive maintenance of water injection pumps. The Ensemble model consistently outperforms individual algorithms, showcasing superior accuracy through lower RMSE and MAE values, as well as higher R-squared coefficients. By integrating the strengths of these algorithms, the Ensemble model mitigates the limitations of standalone models, offering a more robust and reliable predictive maintenance tool. The results underscore the potential for improving operational efficiency and reducing unplanned downtime in the oil and gas industry. This research not only advances predictive modeling techniques but also highlights the significant implications for enhancing maintenance strategies in industrial applications, ensuring better asset management and cost-effectiveness in critical systems.

Abstract*—The blockchain serves as a distributed database where data is stored across different servers and networks. It encompasses various types, with Bitcoin, Ethereum, and Hyperledger being notable examples. To safeguard the security of data transactions on the blockchain, it relies on a consensus algorithm. This algorithm facilitates agreement among nodes within the network. There are multiple types of consensus algorithms, each possessing unique specialties and characteristics. This paper drives into the examination of specific Authority Round, here claimed as AuRa_ori consensus algorithm. The AuRa_ori is a specific type of PoA consensus mechanism used primarily in private or permission blockchain networks. It works by having a set of trusted validators take turns in a round-robin fashion to produce new blocks. It is supported by Parity and Ethereum Clients. AuRa_ori assumes that all the authority nodes are synchronised and honest on every transaction process. In AuRa_ori, every transaction process will execute the four phases i.e., assigning of a new leader, proposing a block, commencing agreement and finally, the phase of committing. However, there exist some discrepancies in some of the phases. In response to the scenario, this paper presents a thorough discussion on the vulnerabilities adhered in AuRa phases in transaction execution by focusing on the first phase of assigning a new leader and the third phase, namely the agreement. The vulnerabilities are subjected to the risk of impacting the performance of Transaction Speed Per Second (TPS), Transaction Throughput (TGS), Percentage Decrease (PD) of TPS and Percentage Increase (PI) of TGS. The new improved method, named AuRa_v1 is parallel presented to overcome the vulnerabilities of AuRa_ori at the selected phases. It aims to increase the TPS and to calculate the PD in transaction process using the Ethereum private blockchain systems. The implementation used three set of data scroll certificate. The result showed that the AuRa_v1 able to decrease the TPS almost 30% based on difference number set of data.

Keywords*—Blockchain; Ethereum; consensus algorithm; smart contract; AuRa_ori; AuRa_v1

I. Introduction

The section drives the important components within the scope of the paper discussion on the AuRa_ori algorithm starting from the introduction of the blockchain technology, the platform that offers the technology, to what component and algorithm that determines the efficiencies of the blockchain technology. The efficiency determinants of the blockchain relies on the robustness of the consensus algorithm, wherein the discussion on the AuRa_ori is initiated. The consensus algorithms are crucial in further bolstering security within blockchain transactions by orchestrating an agreement among nodes. This ensures that the throughput remains consistent, uniform, and valid across the network.

Blockchain, as a decentralised distributed database, serves as a platform for storing transactional data and information. It represents a departure from traditional methods, transitioning data management from a single centralised location to a decentralised setup across various servers or networks [1]. This decentralised data storage comprises a series of interconnected records known as blocks [2].

Data is dispersed among different nodes across diverse servers within the blockchain network. Often referred to as a peer-to-peer (P2P) network, blockchain operates through nodes communicating directly with each other [3]. Utilising cryptographic techniques and hash functions, blockchain ensures the security and integrity of digital data stored within its system [4].

While blockchain encompasses several types, Bitcoin, Ethereum, and Hyperledger stand out as the most popular and widely used variants [5], [6]. These platforms have been developed over the years with a focus on encouraging businesses to integrate blockchain into their operations [7]. Despite their similarities, each blockchain platform possesses unique characteristics. Ethereum, conceptualized by Vitalik Buterin in 2013 [8], emerged as a response to the limitations of Bitcoin [9]. Crowdfunding in 2014 facilitated the advancement of Ethereum's technologies, leading to its live network launch in 2015 [10].

Ethereum implements distributed data storage, enabling users to deploy their applications and operate their blockchain instances [11]. Notably, Ethereum offers the capability to store data with an unlimited block size [12]. Specifically, the AuRa_ori consensus algorithm is used in voting domain and focusing on the electronic voting application. The researcher was comparing the AuRa_ori and Geth based on certain criteria such as time, consistency, and scalability. This application runs

the test net environment including remix IDE, Ethereum test net and web3.

Additionally, the efficiency of blockchain is reinforced by the consensus algorithm, which facilitates an agreement process among nodes dispersed across various servers and networks. This algorithm ensures the maintenance of consistency and decentralisation among nodes within the blockchain system [4], [13],[14]. The consensus mechanism necessitates four essential elements in transactions, as outlined in Table I.

TABLE I. Element of consensus algorithm

Element	Description
Termination	The successful transaction process dependence on the content of block that proposed
Agreement	The acceptance block needed to assign by the honest authorities
Validity	The block should be accepted if nodes that received is valid and same with the proposed block
Integrity	Only the honest node should be acceptance their transaction

There are numerous types of consensus algorithms that are able to support the security of data transaction in blockchain environment. However, this paper provides the detailed exposure of the consensus algorithms in conjunction to the strengths and the weaknesses in AuRa_ori used in Ethereum and reveals and proposes the improvement mechanism as a means of solution on the weaknesses.

There are numerous types of consensus algorithms that are able to support the security of data transaction in blockchain environment. However, this paper aim discussed the detail AuRa_ori including it procedure to transact data into the blockchain. We also provide the detailed exposure of the consensus algorithms in conjunction to the strengths and the weaknesses in AuRa_ori used in Ethereum environment.

Prior to the weakness of AuRa, the analysis of the effect of AuRa weakness in term of transaction speed was executed. The weakness is able to expose the risk including the cloning attack and malicious leader. Then the improvement mechanism as a means of solving weaknesses were proposed and revealed.

II. AURA_ORI CONSENSUS ALGORITHM

AuRa_ori, short for Authority Round, was initially proposed for the Parity client, which utilises Rust as its programming language [15]. This consensus relies on the assumption of honest authorities and synchronous network communication among nodes. If any issues such failed to assign a new leader or leader failed to produce the signature the process must be repeat at beginning. This impact the throughput and transaction process. Additionally, AuRa_ori consists of four key steps including assigned a new leader, proposed block, agreement and commit transaction into the blockchain. This consensus mechanism has been implemented by various platforms including Laava, VecHain Thor, xDai DPOS network, Microsoft Azure (for deployment only), and Kovan Testnet [16].

AuRa_ori has gained widespread adoption in blockchain applications, with nearly 4,000 projects implementing this consensus algorithm [17]. For example, AuRa_ori was implemented in health domain focused on health record sharing. The researcher proposed new methods to improve the time in block transaction process of AuRa_ori [18]. The AuRa_ori is well implemented to support the Copyright System in [19]. This effort drives the implementation of AuRa_ori and performs the analysis of its transaction throughput. It also concerns about the network synchronisation.

A. Assigning a New Leader

Initially, a leader is assigned, with each authority taking turns using the Round Robin Algorithm [20]. The leader assignment process involves calculating the difference value t_d) between the current timestamp t and the last timestamp at the genesis t_g as shown in Eq. (1).

$$t_d = t - t_g \tag{1}$$

Where t_d is a difference values of t and t_g . While$t$ is a current timestamp and t_g is the last time stamp at the genesis. After getting the values of t_d, next is to assign the leader among the authorities based on Eq. (2).

$$i = \frac{t_d}{D} \, mod n \tag{2}$$

In the formula, i represents the node tasked with assigning a leader, while D stands for the Step Duration specified in the genesis file. The n denotes the number of nodes configured in the blockchain environment. Following the assignment of the leader based on this formula, the subsequent step involves the leader proposing a block.

B. Propose Block

The block that proposed by a leader based on set of values, there are data v on t_p , number of proposed blocks n and signature of authorities account on leader v_s. Every proposed block process must include the set value $\{v, n, v_s\}$. Based on set values the other authorities will apply the voting process.

C. Agreement

After finding the leader and proposing the block $\{v, n, v_s\}$, the next step is agreement among the nodes. The block that was proposed agreed or not by the authorities depends on data on proposed block v, numbering of proposed block n and the authorities account on leader is different v_s. After getting the agreement result from the authorities, The data will transfer to block transaction queue that declare as t_q. Then after the authorities 'members complete their agreement process, the next step is the voting process based on Eq. (3).

$$2f + 1 \leq n \tag{3}$$

Where f is a faulty node, n is a number of nodes. In that case the number of faulty nodes at least must be less or the same as the number of nodes 50%.

D. Commit

Subsequently, the leader puts forward a block, comprising a leader signature key, current timestamp, and block data. Following the proposal of the block, the process proceeds to the

voting and acceptance phase. If the agreement achieves more than 50%, the next is the commit process. Thet_q will be inserted into the blockchain, and the value of t_q and $t_p$will be deleted from the transaction process. Fig. 1 shows the patterns of AuRa in committing the transaction data.

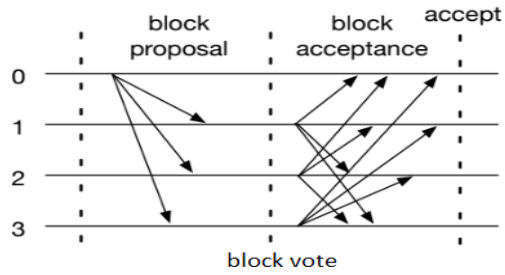

Fig. 1. Pattern of aura transaction process.

According to Fig. 1, the AuRa_ori process is bifurcated into two primary stages: block proposal and block acceptance. Once the leader is designated, the leader initiates the block proposal phase by proposing a block. Subsequently, the block acceptance phase commences, during which the members of the authority vote on the block proposed by the leader to determine if it should be committed.

III. AURA_ORI RELATED WORKS AND DRAWBACKS

The implementation of AuRa_ori can be widely seen in various domains of applications. It is considered as a stable algorithm and able to support the transaction process into the blockchain. However, the AuRa_ori is vulnerable to the exposure of attacks if the issues persist in all over the transaction process.

A. Challenges Faces in AuRa

The AuRa_ori has been widely embraced to enhance the speed of blockchain transactions. Previous research has delved into various aspects of AuRa_ori. For instance, [21] examined partitioning tolerance in AuRa_ori. The author investigates strategies for preventing partitioning tolerance in AuRa_ori. The AuRa_ori is capable of detecting only the absence status of authorities.

However, it cannot discern whether missing authorities are inactive or located in a different partition, as it lacks the ability to identify network partitioning. Lack of ability to identify availability authorities 'impact to transaction speed and throughput. It needed extra time if authorities are detected not available a long transaction process because AuRa_ori needed to assign a new leader and get the signature key from a new leader to assign data into the blockchain. Extra time was risk to any attack.

Additionally, the study in [22] conducted research on transaction speeds using the Geth and Parity clients. Both Geth and Parity support by PoA, with Geth focusing on Clique and Parity on AuRa_ori. On average, the Parity client exhibited a 91% faster transaction speed compared to Geth. The experiment based on transaction data from 1000 to 5000. The comparison is conducted on a private test net, considering factors such as CPU, RAM, and the number of nodes. The performance analysis criteria included the time, consistency and scalability. However, it does not consider the security and safety criteria in this analysis.

Furthermore, the study in [23] discussed a comparison between Geth and Parity in terms of transaction speed and performance level. Their analysis cantered on the consumption of CPU and RAM resources by the two Ethereum clients. However, this research did not specify the type of consensus utilised, and details regarding CPU, RAM, and server type were not provided. As previously noted, AuRa_ori operates under the assumption that nodes remain synchronised, which impacts both availability and consistency. According to prior research by [24], which focused on comparing AuRa_ori, Clique, and PBFT in terms of availability, consistency, and partition tolerance, the synchronisation requirement of AuRa poses a risk, especially when deployed over a wide area. This algorithm relies heavily on accurate timestamps for both genesis and proposed blocks.

Regarding transaction speed, [25] explored the performance of AuRa_ori in comparison to PoW. The research discussed how AuRa surpasses PoW in transaction speed due to its lower computing power requirements and higher throughput. Moreover, AuRa_ori offers the enhancement in security compared to PoW, as it incorporates an additional layer of security and operates with two levels of acceptance: the proposed block and the subsequent voting process but the voting process exploit the security issue if it needed extra time to complete the task.

B. Reviews on the Challenges that AuRa_ori Faced

The widespread implementation of AuRa_ori has sparked interest among researchers to scrutinise its intricacies. Previous studies have identified several drawbacks associated with AuRa_ori, particularly in the initial step of leader assignment and the subsequent voting agreement phase.

Assigning a new leader for each transaction process poses a challenge within AuRa_ori. To accomplish this, AuRa_ori employs a Round Robin schedule. However, if authority members are unavailable, the process of reassigning a new leader becomes necessary, resulting in decreased throughput, affecting transaction speed and time execution [19]. Because AuRa needs to assign a new leader and it increases time to complete the transaction. Then it needs to create a new fork to allow a queued transaction in proposing a new block.

Process to assign a new leader causing risk to attack including AuRa_ori assumes each node is synchronised, but sometimes unexpected network delays happen. To overcome this situation AuRa_ori allowed the authorities to postpone the validation process and cause the block to be delayed. This exploited loophole to assigned the malicious leader when the previous transaction not completed because time delay to complete the transaction.

Furthermore, complications arise if the assigned leader fails to create a signature or becomes corrupted, leading to decreased throughput and failed transactions [26]. To mitigate these issues, the concept of a dummy signature has been proposed. If authority members accept the dummy signature, it is converted

into a real signature then the transaction process is able to continue. The challenge is how to verify the dummy signature is accurate. Because this research did not explain how the dummy signature creates and verify.

Additionally, changes in assigned authorities can occur at any time, any changes requiring agreement from other authorities. Normally the changes occur if the nodes not available because of network or configuration issues. Assigning new authorities process introduces delays until the new authorities are accepted, impacting the security, performance, and transaction speed of AuRa_ori.

The election of a leader for each transaction process exposes the algorithm to potential attacks [27] because the leader needed to create the signature. The signature was used in proposed block, voting committing transactions. If the leader failed to sign a signature the new leader must assign and it impacts the execution time, throughput, transaction speed and epoch time. Additionally, the validation process among authorities before committing transactions to the blockchain requires extra time to achieve agreement, affecting throughput and potentially leading to forks.

A delayed verification can also leave AuRa_ori vulnerable to cloning attacks (CA) [28]. This occurs due to the creation of forks during delayed verification, allowing for the replication of identities using the same private and public keys. Delay verification occur if the leader failed to sign the signature or the signature not valid. Then it needed to assign new leader and new signature, then impact the execution time and potential the attacks.

To address these challenges, this paper proposes the implementation of a heartbeat-based approach to thwart cloning attacks. This involves signing and sending the heartbeats to other authorities, who then accept proposed blocks based on the heartbeat signature.

IV. Proposed Methodology

Based on previous studies, AuRa_ori is tightly bound with the transaction speed issues. These issues because of the procedure in AuRa_ori needed to assign a new leader for every transaction process and needed the verify phase before the transaction was able to commit into the blockchain. This research proposed a new algorithm called AuRa_v1 to overcome these issues.

The new proposed algorithm named AuRa_v1 consists of 4 steps including preassigned new leader, transaction pending, proposed block and voting. Numbering steps are the same with the AuRa_ori, but it's needless to assign a new leader for every transaction process. Each step in AuRa_v1 is enhanced from the AuRa_ori.

A. Predefine Leader

Predefining a leader is a process to assign a new leader as oppose to AuRa_ori where it requires the assignment of a new leader at every transaction process. In contradiction, AuRa_v1 assigns a new leader only on condition the leader that was assigned is not available, or the signature key by the previous leader is not valid. Fig. 2 highlights the detail of predefined leader procedure.

Algorithm 1

```
[1]  While true do
[2]      t_d ← TIMESTAMPDIFF(second, t - t_g)
[3]      l ← ((t_d/D) mod n)
[4]     sk ← generate by l
[5]     Transaction_Pending(sk, l, n)
[6]  End Process
```

Fig. 2. AuRa_v1 predefined leader algorithm.

The new leader assignment in Fig. 2 will be made available if and only if either the occurrence of the 2 conditions i.e., 1) the previous assigned leader is not available, or 2) the signature key owned by the previous assigned leader is not valid. Line 2 aims to get the difference value between current timestamp and genesis timestamp. The difference value based on Eq. (4).

$$t_d = t - t_g \tag{4}$$

Where value of t_d is a difference value of current timestamp t and genesis time, t_g. However, this research proposes the difference value was converted into a second based on timestamp format using the function $TIMESTAMPDIFF(second)$. We propose converting into second because it is able to improve the transaction speed. Then the value of t_d was used to choose the new leader as line 3 based on Eq. (5),

$$l = \frac{t_d}{D} mod n \tag{5}$$

Where l is new leader that was assigned and D is the value of step duration, D value can be any number in minutes or second, normally value of D setup by developer including 5 until 10 seconds. Then n is a number of authorities that register in blockchain setup.

A. Voting and Commit Transactions

Voting and commit process is the last process before the transaction is stored into the blockchain. This process there is no need to collect the agreement from the available authorities. It just counts the number of available authorities. Fig. 3 illustrates the voting and commit procedure.

Algorithm 2

```
[1]  voting(b_p, sk, l, n)
[2]  nt ← datetime.now()
[3]  If((nt - t) <= D) then
[4]    ca ← count(aa)
[5]    if ca >= 1 ∧ ca <= n) then
[6]       Commit
[7]    else
[8]       Failed
[9]  else
[10]    Failed
[11] If (l ≙ l) then
[12]    transaction_pending(sk, l)
[13] else
[14]    pre_assigned_leader()
[15] End
```

Fig. 3. Algorithm of voting and commit procedure.

In Fig. 3 at line 2 to 3, ntrefer to new current timestamp. This procedure needed to capture the new current timestamp. Then the new timestamp minus t and the value must be less or the same with step duration value D. Line 4 to 6, it counts the authorities available, if authorities available more than 1, and numbers of available authorities less or the same with the number of authorities the transaction process is able to commit into the blockchain. Lastly line 7 until 14, refer to failure completed the prerequisite, the procedure back to transaction pending or pre assigned leader process.

V. IMPLEMENTATION

This studies aims to analyst the performance of AuRa_ori and AuRa_v1. The analysis based on result of digital certificate process. The certificate process implemented into two version including AuRa_ori and AuRa_v1. To support the implementation of AuRa_ori and AuRa_v1, the installation and configuration of AuRa_v1 and AuRa_ori was executed. The installation and configuration of AuRa_ori based on standard AuRa_ori. Fig. 4 portrays the installation and configuration of the AuRa_ori.

However the installation and configuration of AuRa_v1 based on proposed algorithm of AuRa_v1. Then the node file was created for both of AuRa_ori and AuRa_v1. The number of nodes file based on the number of node that is created on AuRa_ori and AuRa_v1 engine. Fig. 5 depicts part of nodes file.

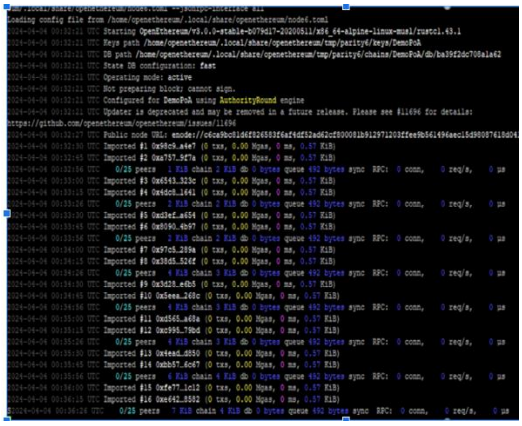

Fig. 4. The installation and configuration of aura engine.

Code1: xxx.toml

```
[1] [parity]
[2] chain = "chain directory"
[3] base_path = "aura engine directory"
[4] [network]
[5] port = 30301
[6] [rpc]
[7] port = 8541
[8] apis=["web3","eth","net","personal","parity","parity_set",
[9] "traces", "rpc", "parity_accounts"]
[10][websockets]
[11]port = 8451
[12][ipc]
[13]disable = true
```

Fig. 5. Code of parity engine configuration

Based on Fig. 5, the file $xxx.toml$ used the parity engine (line 1) and read the chain file (line2). Line 4 and 5 mention the port network that is used is 3301. Line 6 and 7 mention the Remote Procedure Call(RPC) port that used 8541. Line 8 and 9 are about dependencies that implement and line 10 - 11 is about the web sockets port used is 8451.

Besides that, this study also require created the smart contract file. Smart contract is a special element in Ethereum, it consists of the business logic for executing the command of user requirement. After the completed the smart contract, the next step is to migrate the smart contract with the both AuRa_v1 and AuRa_ori engine. The migration process used the truffle framework. The truffle engine is needed for installation and configuration as denoted in Fig. 6 while the three sets of scroll datasets are characterised as in Table II.

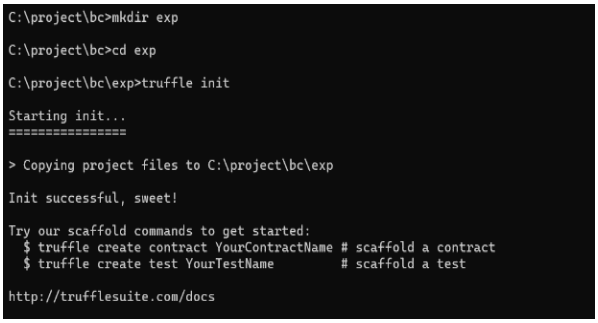

Fig. 6. The truffle framework installation.

TABLE II. SET OF DATA

Set of Data	Number of Data	Size per Data	Type of Data
Set 1	1021	32.8KB - 33.01KB	Scroll
Set 2	2435	32.2KB - 33.11KB	Scroll
Set 3	3422	32.5KB - 33.07KB	Scroll

Referring to Table II, Set 1 includes 1021 data, set 2, 2435 data and set 3 with 3422 data. These data consist information of scroll student including name, program and final cumulative grade. These 3 sets of data are being executed in transaction process on both AuRa_ori and AuRa_v1.

Additionally, the research has also developed the frontend interface to generate the digital certificate. The interface connected with both AuRa_ori, and AuRa_v1 through the Application Programmers Interface (API) and backend code as depicted at Fig. 7.

The front-end consists of a few modules including the dashboard, create certificate and verification. These function able to access regarding the user access level. Fig. 8, Fig. 9 and Fig. 10 show the development interfaces done during experimentation. Regarding Fig. 8, the interface that is developed consists of a few modules including the create certificate and verified certificate. Then Fig. 9, is an interface to create the digital certificate. Lastly at Fig. 10, is an interface to process the digital certificate.

VI. Result and Discussion

According these implementation, the TPS result were captured to analysis the performance of AuRa_v1 and AuRa_ori.

A. TPS Result of AuRa_ori

This result based on implementation the AuRa_ori used three set of data. Regarding Fig. 11, the TPS result of set data 1 is 0.059. Set data 2 the TPS result is 0.032 and set data 3 is 0.069. According the TPS result, set data 2 more rapidly compared set data1 and set data 3. Set data 3 very slow compared set data 1 and set data 3.

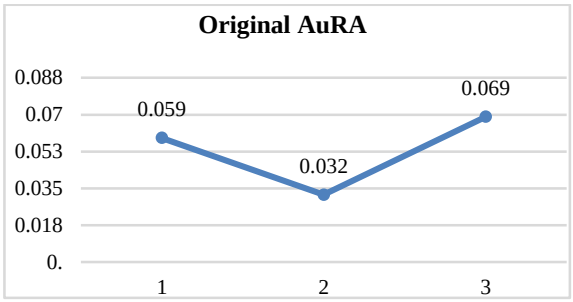

Fig. 11. TPS result of AuRa_ori.

B. TPS Result of AuRa_v1

This outcome based on execution the AuRa_v1 used three set of data. Fig. 12 depicted the result of TPS that executed the AuRa_v1. The result of Set data 1 is 0.041, set data 2 is 0.029 and set data 3 is 0.036. These TPS result showed that the set data 2 is faster and set data 3 is slow compare three set of data.

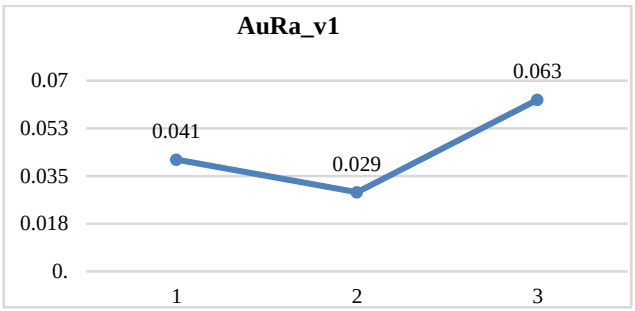

Fig. 12. TPS result based on aura_v1.

C. TPS AuRa_ori Versus AuRa_v1

This section aims to compare the result between the AuRa_ori and AuRa_v1. Regarding Fig. 13 depicted that the result of AuRa_ori (orange line) at set data 1 is 0.059, set data 2 is 0.032 and set data 3 is 0.069. Then TPS result of AuRa_v1 (blue line) , set data 1 is 0.041, set data 2 is 0.029 and set data 3 is 0.063.

According these result, set data 1, AuRa_v1 is able decrease the transaction process compared AuRa_ori. Then set data 2 and set data3 also showed that AuRa_v1 prove decrease the TPS result compared AuRa_ori.

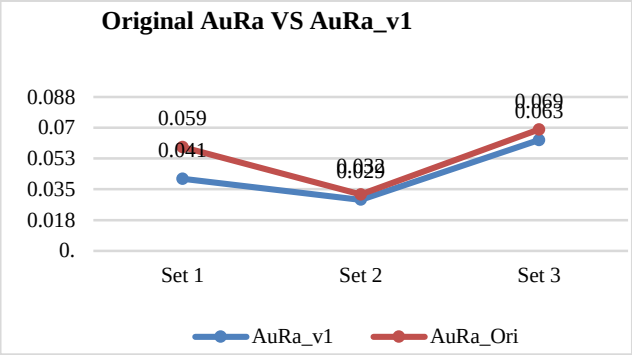

Fig. 13. Comparison TPS result between AuRa_ori and aura_v1.

D. Percentage Decrease of TPS

This research aims to decrease the transaction speed process into the blockchain using the AuRa_v1. Regarding the TPS result, the percentage Decrease PD measured to obtain the PD based on AuRa_v1. The measurement of $PD$the based on Eq. (6),

$$PD = \left(\frac{(i_v - f_v)}{i_v}\right) * 100 \quad (6)$$

In Eq. (6), PD refer to Percentage Decrease, then i_v is interval value for AuRa_ori value and f_v is the final value for AuRa_v1 value. The PD result was measured and described in Table III.

TABLE III. THE PERCENTAGE DECREASE OF TPS

Data	Result
Set Data: 1	30%
Set Data: 2	9.375%
Set Data: 3	8.69%

The results show that the implementation of AuRa_v1 able to decrease the TPS result. Set data 1, able to decrease the TPS result by 30%, set data 2 by 9.375 % while set data 3 with 8.69%.

VII. CONCLUSION

The optimal consensus algorithm hinges on the shortest transaction execution time within the blockchain. Previous research discussed earlier indicates that both assigning a new leader and voting during the transaction process impact the transaction speed and throughput of AuRa_ori and AuRa_v1. The heightened transaction speed presents risks such as decreased throughput, cloning attacks, and the possibility of assigning a malicious leader.

Nearly all previous studies underscore the limitations of the AuRa_ori consensus algorithm regarding performance of TPS, attributed to the necessity of assigning a new leader for every transaction process. This results in a reduction in transaction throughput. Additionally, the increased TPS of AuRa_ori is influenced by the requirement for a voting phase before transactions can be committed to the blockchain. The future plan is restructured prior to results obtained that aims to measure the TGS and TPS use the same set of data. The compare the result between AuRa_ori and AuRa_v1. Also calculate the PD and PI.

ACKNOWLEDGMENT

We express sincere gratitude to the Center of Research and Innovation Management (CREIM) at UniSZA for their invaluable financial support towards the publication. Our heartfelt appreciation also goes to all team members from UniSZA, including Pn. Robiah Arifin, the PhD candidate for the technical configuration of the project, and Dr. Wan Aezwani Wan Abu Bakar as her supervisor for the conceptual and technical proofread writing, as well as the UMT member, Assoc Prof. Ts. Dr. Mustafa Man for the network linkages and the reviewer's suggestions. Also, we are grateful for the international contributions and collaboration provided by Dr. Evizal Abdul Kadir, a research fellow from Universitas Islam Riau, Indonesia.

Enhancing Multiple-Attribute Decision-Making with Interval-Valued Neutrosophic Sets: Diverse Applications in Evaluating English Teaching Quality

Lijuan Zhao[1]*, Shuo Du[2]
Shijiazhuang University of Applied Technology, Shijiazhuang, 050081, Hebei, China[1, 2]

***Abstract*—The evaluation of college English teaching quality is a key method for systematically analyzing and providing feedback on the teaching process and outcomes. It aims to comprehensively assess the effectiveness of teaching, student learning outcomes, and the appropriateness of the course design. The evaluation typically covers aspects such as teaching methods, classroom atmosphere, student engagement, use of teaching resources, and learning achievements. By collecting data from student feedback, teaching supervision, and exam results, the evaluation helps to improve teaching strategies, enhance students' English proficiency, and ultimately achieve continuous optimization and improvement of teaching quality. The teaching quality evaluation of college English is viewed as the multiple-attribute decision-making (MADM). In this paper, some Aczel-Alsina operators are produced under interval-valued neutrosophic sets (IVNSs). Then, interval-valued neutrosophic number (IVNN) Aczel-Alsina weighted averaging (IVNNAAWA) operator is employed to cope with MADM problem. Finally, the numerical decision example for teaching quality evaluation of college English is employed to illustrate the produced method.**

Keywords*—Multiple-attribute decision-making; interval-valued neutrosophic sets (IVNSs); Aczel-Alsina operations; teaching quality evaluation

I. Introduction

Evaluation of college English teaching quality is an essential tool for systematically analyzing and assessing the teaching process and outcomes. Its aim is to enhance teaching quality through a scientifically sound evaluation system, meeting students' learning needs and the societal demands for English proficiency. The evaluation typically covers various aspects, including teaching methods, curriculum design, utilization of teaching resources, student learning outcomes, and classroom participation. Diverse evaluation methods, such as student feedback, classroom observation, and test performance analysis, are widely employed to ensure comprehensiveness and objectivity. Through continuous quality evaluation, universities can optimize teaching strategies, improve course design, and promote the development of students' comprehensive English skills, laying a foundation for cultivating internationally competitive talents in line with contemporary demands. Starting in 2013, Lu and Huang [1] explored the construction of English teaching quality evaluation systems and the applicability of cultivating students' comprehensive English abilities. They suggested reforming the existing college English teaching evaluation methods by referencing the Canadian language benchmarks to comprehensively enhance teaching quality and students' comprehensive English proficiency. In the same year, Ma and Li [2] attempted to construct a multidimensional ecological evaluation system under network environments, based on constructivism and educational ecology theories, to promote the ecologicalization and quality improvement of college English teaching. In 2015, Wu and Tang [3] analyzed the current state of classroom teaching quality evaluation systems in universities, identifying existing problems and designing various evaluation forms to enhance the scientific and rational nature of evaluations. Yu [4] proposed a diversified evaluation model, combining modern quality management theory, constructivism, and multiple intelligences theory, emphasizing the use of various methods for comprehensive teaching quality evaluation to improve college English course quality. In 2016, Yuan [5] analyzed teaching evaluation strategies for subsequent college English courses, highlighting the need for differentiated strategies in evaluation subjects, content, and methods to enhance teaching quality across language culture, skills, and language application courses. In 2017, Deng [6] studied the application of participatory teaching models in college English, proposing related teaching quality evaluation methods. The study emphasized that participatory teaching methods should focus not only on students' exam scores but also on their practical application abilities. In 2018, Yang [7] developed a teaching quality evaluation index system for flipped classrooms in vocational college English, emphasizing the importance of developmental and process evaluations. The evaluation indices were refined through expert consultation and surveys to align with the characteristics of flipped classroom teaching. In 2019, Li [8] explored strategies for constructing college English teaching quality evaluation systems under the applied talent training system, proposing the establishment of a scientific and reasonable evaluation system to improve English teaching quality and meet the societal demand for applied talents. In 2020, Xu [9] discussed the application of stratified teaching methods in college English, analyzing its role in reducing student learning differences, enhancing learning interest, and ensuring classroom teaching quality, while proposing specific application strategies. In 2021, Yang and Li [10] constructed a classroom teaching quality evaluation model based on set pair analysis in the context of the digital era to meet the requirements of "golden course" construction. The study emphasized the importance of integrating modern information technology with college English courses. In 2022, Zhang [11] studied college English teaching quality evaluation through value speculation guidance, constructing an evaluation model

*Corresponding author.

based on the SERVQUAL model. This aimed to identify gaps and deficiencies in teaching by comparing students' "expectations" and "actual perceptions," and proposed improvement measures. In 2023, Gong and Peng [12] proposed a college English teaching quality evaluation model based on ISSA-DRNN, utilizing an improved deep recurrent neural network and optimized sparrow search algorithm to enhance the model's evaluation performance and precision. In 2024, Zhang [13] constructed an English teaching quality evaluation system based on the CIPP model, proposing a comprehensive framework that includes context, input, process, and product evaluations. This provided a scientific and operational evaluation standard for college English teaching.

Multi-Attribute Decision Making (MADM) is a decision-making method used to address selection problems involving multiple evaluation criteria [14-17]. This type of decision-making approach is widely applied in fields such as management science, engineering, and economics, aiding decision-makers in making rational choices in complex situations [18-21]. In multi-attribute decision making, the decision problem typically involves multiple competing attributes or criteria, which may have different levels of importance [22-25]. Therefore, decision-makers need to weight each attribute to reflect its relative importance. Common weighting methods include expert scoring, Analytic Hierarchy Process (AHP), and entropy method. The basic steps of multi-attribute decision making include: first, clarifying the decision objectives and available alternatives; second, determining the evaluation attributes and assigning weights to them [26-29]; then, collecting and organizing data on the performance of each alternative across different attributes[30-33]; next, applying appropriate decision-making methods (such as TOPSIS, VIKOR, ELECTRE) to comprehensively evaluate the alternatives; finally, selecting the optimal alternative or ranking the alternatives based on the evaluation results. The advantage of this method is that it systematically considers multiple factors, making the decision process more comprehensive and objective. However, the reliability of the decision results largely depends on the accuracy of the attribute weights and the completeness of the data [34-38]. Therefore, decision-makers need to carefully assess the rationality of each step and the accuracy of the data when using multi-attribute decision-making methods. The problems of teaching quality evaluation of college English is MADM [39-45]. Aczél and Alsina [46] structured some new operations named as Aczel-Alsina t-norm and t-conorm operations. Yong et al.[29] and Ashraf et al. [47] structured the Aczel-Alsina decision operations to SVNNs and produced the Aczel-Alsina fused operators of SVNNs for MADM. The main aim of this defined paper is to expand the Aczel-Alsina operations [46] to cope with MADM under IVNSs. The main study motivations are listed: (1) the Aczel-Alsina operations are extended to IVNSs; (2) some Aczel-Alsina aggregating operators are produced under IVNSs; (3) the IVNNAAWA method is designed for MADM; (4) a case study about translation quality decision evaluation of college English is given to show the IVNNAAWA method; (5) some comparative models are used to proof the IVNNAAWA method. The remainder sections of this paper are set out. Section II lists the IVNSs. In Section III, the some Aczel-Alsina aggregating operators are produced under IVNSs. In Section IV, the IVNNAAWA operator is built for MADM. In Section V, a case study for translation quality decision evaluation of college English is listed and some comparative decision methods are done. The defined decision study ends in Section VI.

II. PRELIMINARIES

Wang et al. [48] produced the IVNSs

Definition 1 [49]. The IVNSs A in X is:

$$\tilde{A}=\left\{\left(x,TT_{\tilde{A}}(x),II_{\tilde{A}}(x),FF_{\tilde{A}}(x)\right)\middle|x\in X\right\} \quad (1)$$

with truth-membership $TT_{\tilde{A}}(x)$, indeterminacy-membership $II_{\tilde{A}}(x)$ and falsity-membership $FF_{\tilde{A}}(x)$, $TT_{\tilde{A}}(x),II_{\tilde{A}}(x),FF_{\tilde{A}}(x)\in[0,1]$, $0\le \sup TT_{\tilde{A}}(x)+\sup II_{\tilde{A}}(x)+\sup FF_{\tilde{A}}(x)\le 3$.

The IVNN is expressed as $\tilde{A}=\left(TT_{\tilde{A}},II_{\tilde{A}},FF_{\tilde{A}}\right)=\left(\left[TL_{\tilde{A}},TR_{\tilde{A}}\right],\left[IL_{\tilde{A}},IR_{\tilde{A}}\right],\left[FL_{\tilde{A}},FR_{\tilde{A}}\right]\right)$, where $TT_{\tilde{A}}\subseteq[0,1],II_{\tilde{A}}\subseteq[0,1],FF_{\tilde{A}}\subseteq[0,1]$, $0\le TR_{\tilde{A}}+IR_{\tilde{A}}+FR_{\tilde{A}}\le 3$.

Definition 2[50]. Let $\tilde{A}=\left(\left[TL_{\tilde{A}},TR_{\tilde{A}}\right],\left[IL_{\tilde{A}},IR_{\tilde{A}}\right],\left[FL_{\tilde{A}},FR_{\tilde{A}}\right]\right)$, the score value is expressed:

$$SV\left(\tilde{A}\right)=\frac{\left(2+TL_{\tilde{A}}-IL_{\tilde{A}}-FL_{\tilde{A}}\right)+\left(2+TR_{\tilde{A}}-IR_{\tilde{A}}-FR_{\tilde{A}}\right)}{6},\quad SV\left(\tilde{A}\right)\in[0,1]. \quad (2)$$

Definition 3[50]. Let $\tilde{A}=\left(\left[TL_{\tilde{A}},TR_{\tilde{A}}\right],\left[IL_{\tilde{A}},IR_{\tilde{A}}\right],\left[FL_{\tilde{A}},FR_{\tilde{A}}\right]\right)$, the accuracy value is expressed:

$$AV\left(\tilde{A}\right)=\frac{\left(TL_{\tilde{A}}+TR_{\tilde{A}}\right)-\left(FL_{\tilde{A}}+FR_{\tilde{A}}\right)}{2},\ AV\left(\tilde{A}\right)\in[-1,1]. \quad (3)$$

Huang et al. [50] expressed the order relation for IVNNs.

Definition 4[50]. Let $\tilde{A}=\left(\left[TL_{\tilde{A}},TR_{\tilde{A}}\right],\left[IL_{\tilde{A}},IR_{\tilde{A}}\right],\left[FL_{\tilde{A}},FR_{\tilde{A}}\right]\right)$ and $\tilde{B}=\left(\left[TL_{\tilde{B}},TR_{\tilde{B}}\right],\left[IL_{\tilde{B}},IR_{\tilde{B}}\right],\left[FL_{\tilde{B}},FR_{\tilde{B}}\right]\right)$, let

$$SV\left(\tilde{A}\right)=\frac{\left(2+TL_{\tilde{A}}-IL_{\tilde{A}}-FL_{\tilde{A}}\right)+\left(2+TR_{\tilde{A}}-IR_{\tilde{A}}-FR_{\tilde{A}}\right)}{6}$$

and

$$SV\left(\tilde{B}\right)=\frac{\left(2+TL_{\tilde{B}}-IL_{\tilde{B}}-FL_{\tilde{B}}\right)+\left(2+TR_{\tilde{B}}-IR_{\tilde{B}}-FR_{\tilde{B}}\right)}{6}$$

, and let $AV\left(\tilde{A}\right)=\frac{\left(TL_{\tilde{A}}+TR_{\tilde{A}}\right)-\left(FL_{\tilde{A}}+FR_{\tilde{A}}\right)}{2}$ and $AV\left(\tilde{B}\right)=\frac{\left(TL_{\tilde{B}}+TR_{\tilde{B}}\right)-\left(FL_{\tilde{B}}+FR_{\tilde{B}}\right)}{2}$, then if $SV\left(\tilde{A}\right)<SV\left(\tilde{B}\right)$, we have $\tilde{A}<\tilde{B}$; if $SV\left(\tilde{A}\right)=SV\left(\tilde{B}\right)$, (1)if $HV\left(\tilde{A}\right)=HV\left(\tilde{B}\right)$, we have $\tilde{A}=\tilde{B}$; (2) if $HV\left(\tilde{A}\right)<HV\left(\tilde{B}\right)$, we have $\tilde{A}<\tilde{B}$.

Aczél and Alsina [46] structured some new operations named as Aczel-Alsina t-norm and t-conorm operations, which have true advantage of changeability through adjusting a decision parameter. Yong et al.[29] and Ashraf et al. [47] structured the Aczel-Alsina operations to SVNNs. Similarly, the Aczel-Alsina decision operations for IVNNs are produced.

Definition 5. Let $\tilde{A}=\left(\left[TL_{\tilde{A}},TR_{\tilde{A}}\right],\left[IL_{\tilde{A}},IR_{\tilde{A}}\right],\left[FL_{\tilde{A}},FR_{\tilde{A}}\right]\right)$ and $\tilde{B}=\left(\left[TL_{\tilde{B}},TR_{\tilde{B}}\right],\left[IL_{\tilde{B}},IR_{\tilde{B}}\right],\left[FL_{\tilde{B}},FR_{\tilde{B}}\right]\right)$, $\phi\geq 1$, $\lambda>0$, the Aczel-Alsina operations for IVNNs are produced:

$$\tilde{A}\oplus\tilde{B}=\left(\begin{array}{l}\left[1-e^{-\left(\left(-\ln\left(1-TL_{\tilde{A}}\right)\right)^{\phi}+\left(-\ln\left(1-TL_{\tilde{B}}\right)\right)^{\phi}\right)^{1/\phi}},1-e^{-\left(\left(-\ln\left(1-TR_{\tilde{A}}\right)\right)^{\phi}+\left(-\ln\left(1-TR_{\tilde{B}}\right)\right)^{\phi}\right)^{1/\phi}}\right],\\ \left[e^{-\left(\left(-\ln\left(IL_{\tilde{A}}\right)\right)^{\phi}+\left(-\ln\left(IL_{\tilde{B}}\right)\right)^{\phi}\right)^{1/\phi}},\ e^{-\left(\left(-\ln\left(IR_{\tilde{A}}\right)\right)^{\theta}+\left(-\ln\left(IR_{\tilde{B}}\right)\right)^{\phi}\right)^{1/\phi}}\right],\\ \left[e^{-\left(\left(-\ln\left(FL_{\tilde{A}}\right)\right)^{\phi}+\left(-\ln\left(FL_{\tilde{B}}\right)\right)^{\phi}\right)^{1/\phi}},\ e^{-\left(\left(-\ln\left(FR_{\tilde{A}}\right)\right)^{\phi}+\left(-\ln\left(FR_{\tilde{B}}\right)\right)^{\phi}\right)^{1/\phi}}\right]\end{array}\right)$$

$$\tilde{A}\otimes\tilde{B}=\left(\begin{array}{l}\left[e^{-\left(\left(-\ln\left(TL_{\tilde{A}}\right)\right)^{\phi}+\left(-\ln\left(TL_{\tilde{B}}\right)\right)^{\phi}\right)^{1/\phi}},e^{-\left(\left(-\ln\left(TR_{\tilde{A}}\right)\right)^{\phi}+\left(-\ln\left(TR_{\tilde{B}}\right)\right)^{\phi}\right)^{1/\phi}}\right],\\ \left[1-e^{-\left(\left(-\ln\left(1-IL_{\tilde{A}}\right)\right)^{\phi}+\left(-\ln\left(1-IL_{\tilde{B}}\right)\right)^{\phi}\right)^{1/\phi}},1-e^{-\left(\left(-\ln\left(1-IR_{\tilde{A}}\right)\right)^{\phi}+\left(-\ln\left(1-IR_{\tilde{B}}\right)\right)^{\phi}\right)^{1/\phi}}\right],\\ \left[1-e^{-\left(\left(-\ln\left(1-FL_{\tilde{A}}\right)\right)^{\phi}+\left(-\ln\left(1-FL_{\tilde{B}}\right)\right)^{\phi}\right)^{1/\phi}},1-e^{-\left(\left(-\ln\left(1-FR_{\tilde{A}}\right)\right)^{\phi}+\left(-\ln\left(1-FR_{\tilde{B}}\right)\right)^{\phi}\right)^{1/\phi}}\right]\end{array}\right)$$

$$\lambda A=\left(\begin{array}{l}\left[1-e^{-\left(\lambda\left(-\ln\left(1-TL_{\tilde{A}}\right)\right)^{\phi}\right)^{1/\phi}},1-e^{-\left(\lambda\left(-\ln\left(1-TR_{\tilde{A}}\right)\right)^{\phi}\right)^{1/\phi}}\right],\\ \left[e^{-\left(\lambda\left(-\ln\left(IL_{\tilde{A}}\right)\right)^{\phi}\right)^{1/\phi}},e^{-\left(\lambda\left(-\ln\left(IR_{\tilde{A}}\right)\right)^{\phi}\right)^{1/\phi}}\right],\\ \left[e^{-\left(\lambda\left(-\ln\left(FL_{\tilde{A}}\right)\right)^{\phi}\right)^{1/\phi}},e^{-\left(\lambda\left(-\ln\left(FR_{\tilde{A}}\right)\right)^{\phi}\right)^{1/\phi}}\right]\end{array}\right)$$

$$(A)^{\lambda}=\left(\begin{array}{c}\left[e^{-\left(\lambda\left(-\ln\left(TL_{\tilde{A}}\right)\right)^{\phi}\right)^{1/\phi}},e^{-\left(\lambda\left(-\ln\left(TR_{\tilde{A}}\right)\right)^{\phi}\right)^{1/\phi}}\right],\\ \left[1-e^{-\left(\lambda\left(-\ln\left(1-IL_{\tilde{A}}\right)\right)^{\phi}\right)^{1/\phi}},1-e^{-\left(\lambda\left(-\ln\left(1-IR_{\tilde{A}}\right)\right)^{\phi}\right)^{1/\phi}}\right],\\ \left[1-e^{-\left(\lambda\left(-\ln\left(1-FL_{\tilde{A}}\right)\right)^{\phi}\right)^{1/\phi}},1-e^{-\left(\lambda\left(-\ln\left(1-FR_{\tilde{A}}\right)\right)^{\phi}\right)^{1/\phi}}\right]\end{array}\right)$$

III. Some Aczel-Alsina Weighted Averaging Operators with NNs

In this section, Some Aczel-Alsina aggregating operators with IVNNs are produced.

The IVNN Aczel-Alsina weighted averaging (IVNNAAWA) is defined.

Definition 7. Let $SA_i=\left(\left[TL_i,TR_i\right],\left[IL_i,IR_i\right],\left[FL_i,FR_i\right]\right)$ the IVNNs with their weight $sw_i=(sw_1,sw_2,\ldots,sw_n)^T$, $\sum_{i=1}^{n}sw_i=1$, $\phi\geq 1$. If

$$\text{IVNNAAWA}_{sw}\left(SA_1,SA_2,\cdots,SA_n\right)=\overset{n}{\underset{i=1}{\oplus}}sw_iSA_i \tag{4}$$

The Theorem 1 is obtained.

Theorem 1. Let $SA_i=\left(\left[TL_i,TR_i\right],\left[IL_i,IR_i\right],\left[FL_i,FR_i\right]\right)$ the IVNNs with their weight $sw_i=(sw_1,sw_2,\ldots,sw_n)^T$, $\sum_{i=1}^{n}zw_i=1$, $\phi\geq 1$. If

$$\text{IVNNAAWA}_{sw}\left(SA_1,SA_2,\cdots,SA_n\right)=\overset{n}{\underset{i=1}{\oplus}}sw_iSA_i$$

$$=\left(\begin{array}{c}\left[1-e^{-\left(\sum_{i=1}^{n}sw_i\left(-\ln\left(1-TL_j\right)\right)^{\phi}\right)^{1/\phi}},1-e^{-\left(\sum_{i=1}^{n}sw_i\left(-\ln\left(1-TR_j\right)\right)^{\phi}\right)^{1/\phi}}\right],\\ \left[e^{-\left(\sum_{i=1}^{n}sw_i\left(-\ln\left(IL_j\right)\right)^{\phi}\right)^{1/\phi}},e^{-\left(\sum_{i=1}^{n}sw_i\left(-\ln\left(IR_j\right)\right)^{\phi}\right)^{1/\phi}}\right],\\ \left[e^{-\left(\sum_{i=1}^{n}sw_i\left(-\ln\left(FL_j\right)\right)^{\phi}\right)^{1/\phi}},e^{-\left(\sum_{i=1}^{n}sw_i\left(-\ln\left(FR_j\right)\right)^{\phi}\right)^{1/\phi}}\right]\end{array}\right) \tag{5}$$

Proof:

(a) Let $i=2$, then

$$\text{IVNNAAWA}_{sw}\left(SA_1,SA_2\right)=sw_1SA_1\oplus sw_2SA_2$$

$$\left(\begin{array}{c}\left[1-e^{-\left(sw_1\left(-\ln\left(1-TL_1\right)\right)^{\phi}\right)^{1/\phi}},1-e^{-\left(sw_1\left(-\ln\left(1-TR_1\right)\right)^{\phi}\right)^{1/\phi}}\right],\\ \left[e^{-\left(sw_1\left(-\ln\left(IL_1\right)\right)^{\phi}\right)^{1/\phi}},e^{-\left(sw_1\left(-\ln\left(IR_1\right)\right)^{\phi}\right)^{1/\phi}}\right],\\ \left[e^{-\left(sw_1\left(-\ln\left(FL_1\right)\right)^{\phi}\right)^{1/\phi}},e^{-\left(sw_1\left(-\ln\left(FR_1\right)\right)^{\phi}\right)^{1/\phi}}\right]\end{array}\right)\oplus$$

(b)
$$\left(\begin{array}{c}\left[1-e^{-\left(sw_2\left(-\ln\left(1-TL_2\right)\right)^{\phi}\right)^{1/\phi}},1-e^{-\left(sw_2\left(-\ln\left(1-TR_2\right)\right)^{\phi}\right)^{1/\phi}}\right],\\ \left[e^{-\left(sw_2\left(-\ln\left(IL_2\right)\right)^{\phi}\right)^{1/\phi}},e^{-\left(sw_2\left(-\ln\left(IR_2\right)\right)^{\phi}\right)^{1/\phi}}\right],\\ \left[e^{-\left(sw_2\left(-\ln\left(FL_2\right)\right)^{\phi}\right)^{1/\phi}},e^{-\left(sw_2\left(-\ln\left(FR_2\right)\right)^{\phi}\right)^{1/\phi}}\right]\end{array}\right)$$

$$=\left(\begin{array}{c}\left[1-e^{-\left(\sum_{i=1}^{2}sw_i\left(-\ln\left(1-TL_j\right)\right)^{\phi}\right)^{1/\phi}},1-e^{-\left(\sum_{i=1}^{2}sw_i\left(-\ln\left(1-TR_j\right)\right)^{\phi}\right)^{1/\phi}}\right],\\ \left[e^{-\left(\sum_{i=1}^{2}sw_i\left(-\ln\left(IL_j\right)\right)^{\phi}\right)^{1/\phi}},e^{-\left(\sum_{i=1}^{2}sw_i\left(-\ln\left(IR_j\right)\right)^{\phi}\right)^{1/\phi}}\right],\\ \left[e^{-\left(\sum_{i=1}^{2}sw_i\left(-\ln\left(FL_j\right)\right)^{\phi}\right)^{1/\phi}},e^{-\left(\sum_{i=1}^{2}sw_i\left(-\ln\left(FR_j\right)\right)^{\phi}\right)^{1/\phi}}\right]\end{array}\right)$$

(c) If Eq. (10) holds for $i=k$, then

$$\mathrm{IVNNAAWA}_{sw}\left(SA_1, SA_2, \cdots, SA_k\right) = \bigoplus_{i=1}^{k} sw_i SA_i$$

$$= \left(\begin{bmatrix} 1-e^{-\left(\sum_{i=1}^{k} sw_i\left(-\ln\left(1-TL_j\right)\right)^{\phi}\right)^{1/\phi}}, 1-e^{-\left(\sum_{i=1}^{k} sw_i\left(-\ln\left(1-TR_j\right)\right)^{\phi}\right)^{1/\phi}} \end{bmatrix}, \begin{bmatrix} e^{-\left(\sum_{i=1}^{k} sw_i\left(-\ln\left(IL_j\right)\right)^{\phi}\right)^{1/\phi}}, e^{-\left(\sum_{i=1}^{k} sw_i\left(-\ln\left(IR_j\right)\right)^{\phi}\right)^{1/\phi}} \end{bmatrix}, \begin{bmatrix} e^{-\left(\sum_{i=1}^{k} sw_i\left(-\ln\left(FL_j\right)\right)^{\phi}\right)^{1/\phi}}, e^{-\left(\sum_{i=1}^{k} sw_i\left(-\ln\left(FR_j\right)\right)^{\phi}\right)^{1/\phi}} \end{bmatrix} \right)$$

(d) Set $i = k+1$. From Definition 5, we have

$$\mathrm{IVNNAAWA}_{sw}\left(SA_1, SA_2, \cdots, SA_{k+1}\right) = \bigoplus_{i=1}^{k} sw_i SA_i \oplus sw_{k+1} SA_{k+1}$$

$$= \left(\begin{bmatrix} 1-e^{-\left(\sum_{i=1}^{k} sw_i\left(-\ln\left(1-TL_j\right)\right)^{\phi}\right)^{1/\phi}}, 1-e^{-\left(\sum_{i=1}^{k} sw_i\left(-\ln\left(1-TR_j\right)\right)^{\phi}\right)^{1/\phi}} \end{bmatrix}, \begin{bmatrix} e^{-\left(\sum_{i=1}^{k} sw_i\left(-\ln\left(IL_j\right)\right)^{\phi}\right)^{1/\phi}}, e^{-\left(\sum_{i=1}^{k} sw_i\left(-\ln\left(IR_j\right)\right)^{\phi}\right)^{1/\phi}} \end{bmatrix}, \begin{bmatrix} e^{-\left(\sum_{i=1}^{k} sw_i\left(-\ln\left(FL_j\right)\right)^{\phi}\right)^{1/\phi}}, e^{-\left(\sum_{i=1}^{k} sw_i\left(-\ln\left(FR_j\right)\right)^{\phi}\right)^{1/\phi}} \end{bmatrix} \right) \oplus$$

$$\left(\begin{bmatrix} 1-e^{-\left(sw_{k+1}\left(-\ln\left(1-TL_{k+1}\right)\right)^{\phi}\right)^{1/\phi}}, 1-e^{-\left(sw_{k+1}\left(-\ln\left(1-TR_{k+1}\right)\right)^{\phi}\right)^{1/\phi}} \end{bmatrix}, \begin{bmatrix} e^{-\left(sw_{k+1}\left(-\ln\left(IL_{k+1}\right)\right)^{\phi}\right)^{1/\phi}}, e^{-\left(sw_{k+1}\left(-\ln\left(IR_{k+1}\right)\right)^{\phi}\right)^{1/\phi}} \end{bmatrix}, \begin{bmatrix} e^{-\left(sw_{k+1}\left(-\ln\left(FL_{k+1}\right)\right)^{\phi}\right)^{1/\phi}}, e^{-\left(sw_{k+1}\left(-\ln\left(FR_{k+1}\right)\right)^{\phi}\right)^{1/\phi}} \end{bmatrix} \right)$$

$$= \left(\begin{bmatrix} 1-e^{-\left(\sum_{i=1}^{k+1} sw_i\left(-\ln\left(1-TL_j\right)\right)^{\phi}\right)^{1/\phi}}, 1-e^{-\left(\sum_{i=1}^{k+1} sw_i\left(-\ln\left(1-TR_j\right)\right)^{\phi}\right)^{1/\phi}} \end{bmatrix}, \begin{bmatrix} e^{-\left(\sum_{i=1}^{k+1} sw_i\left(-\ln\left(IL_j\right)\right)^{\phi}\right)^{1/\phi}}, e^{-\left(\sum_{i=1}^{k+1} sw_i\left(-\ln\left(IR_j\right)\right)^{\phi}\right)^{1/\phi}} \end{bmatrix}, \begin{bmatrix} e^{-\left(\sum_{i=1}^{k+1} sw_i\left(-\ln\left(FL_j\right)\right)^{\phi}\right)^{1/\phi}}, e^{-\left(\sum_{i=1}^{k+1} sw_i\left(-\ln\left(FR_j\right)\right)^{\phi}\right)^{1/\phi}} \end{bmatrix} \right)$$

From the above (a), (b), and (c), it can be seen that Eq. (5) holds for any i.

The IVNNAAWA has good properties.

Property 1. (idempotency). If $SA_i = SA = \left(\left[TL, TR\right], \left[IL, IR\right], \left[FL, FR\right]\right)$

$$\mathrm{IVNNAAWA}_{sw}\left(SA_1, SA_2, \cdots, SA_n\right) = SA \tag{6}$$

Property2. (Monotonicity). Let $SA_i = \left(\left[TL_{A_i}, TR_{A_i}\right], \left[IL_{A_i}, IR_{A_i}\right], \left[FL_{A_i}, FR_{A_i}\right]\right)$, $SB_i = \left(\left[TL_{B_i}, TR_{B_i}\right], \left[IL_{B_i}, IR_{B_i}\right], \left[FL_{B_i}, FR_{B_i}\right]\right)$. If $TL_{A_i} \le TL_{B_i}, IL_{A_i} \ge IL_{B_i}, FL_{A_i} \ge FL_{B_i}$,

$TR_{A_i} \le TR_{B_i}, IR_{A_i} \ge IR_{B_i}, FR_{A_i} \ge FR_{B_i}$ holds for all i, then

$$\mathrm{IVNNAAWA}_{sw}\left(SA_1, SA_2, \cdots, SA_n\right) \le \mathrm{IVNNAAWA}_{sw}\left(SB_1, SB_2, \cdots, SB_n\right) \tag{7}$$

Property 3 (Boundedness). Let $SA_i = \left(\left[TL_{A_i}, TR_{A_i}\right], \left[IL_{A_i}, IR_{A_i}\right], \left[FL_{A_i}, FR_{A_i}\right]\right)$. If

$$ZA^{+} = \left(\begin{bmatrix} \max_i(TL_i), \max_i(TR_i) \end{bmatrix}, \begin{bmatrix} \min_i(IL_i), \min_i(IR_i) \end{bmatrix}, \begin{bmatrix} \min_i(FL_i), \min_i(FR_i) \end{bmatrix} \right),$$

$$ZA^{+} = \left(\begin{bmatrix} \min_i(TL_i), \min_i(TR_i) \end{bmatrix}, \begin{bmatrix} \max_i(IL_i), \max_i(IR_i) \end{bmatrix}, \begin{bmatrix} \max_i(FL_i), \max_i(FR_i) \end{bmatrix} \right)$$

then

$$ZA^{-} \le \mathrm{IVNNAAWA}_{sw}\left(SA_1, SA_2, \cdots, SA_n\right) \le ZA^{+} \tag{8}$$

Then, the IVNN Aczel-Alsina OWA (IVNNAAOWA) is expressed.

Definition 8. Let $SA_i = \left(\left[TL_i, TR_i\right], \left[IL_i, IR_i\right], \left[FL_i, FR_i\right]\right) (i = 1, 2, \ldots, n)$ be IVNNs, $\theta \geq 1$. If:

$$\text{IVNNAAOWA}_{sw}\left(SA_1, SA_2, \cdots, SA_n\right) = \bigoplus_{i=1}^{n} sw_{\sigma(i)} SA_{\sigma(i)}$$

$$= \left(\begin{bmatrix} 1 - e^{-\left(\sum_{i=1}^{n} zw_i \left(-\ln\left(1 - TL_{\sigma(i)}\right)\right)^{\phi}\right)^{1/\phi}}, 1 - e^{-\left(\sum_{i=1}^{n} zw_i \left(-\ln\left(1 - TR_{\sigma(i)}\right)\right)^{\phi}\right)^{1/\phi}} \end{bmatrix}, \right.$$

$$\left. \begin{bmatrix} e^{-\left(\sum_{i=1}^{n} zw_i \left(-\ln\left(IL_{\sigma(i)}\right)\right)^{\phi}\right)^{1/\phi}}, e^{-\left(\sum_{i=1}^{n} zw_i \left(-\ln\left(IR_{\sigma(i)}\right)\right)^{\phi}\right)^{1/\phi}} \end{bmatrix}, \right.$$

$$\left. \begin{bmatrix} e^{-\left(\sum_{i=1}^{n} zw_i \left(-\ln\left(FL_{\sigma(i)}\right)\right)^{\phi}\right)^{1/\phi}}, e^{-\left(\sum_{i=1}^{n} zw_i \left(-\ln\left(FR_{\sigma(i)}\right)\right)^{\phi}\right)^{1/\phi}} \end{bmatrix} \right) \quad (9)$$

where $\left(\sigma(1), \sigma(2), \cdots, \sigma(n)\right)$ is permutation of $(1, 2, \cdots, n)$, such that $SA_{\sigma(j-1)} \geq SA_{\sigma(j)}$ for all $j = 2, \cdots, n$, and $zw = \left(zw_1, zw_2, \cdots, zw_n\right)^T$ is weight of IVNNAAOWA operator, and $0 \leq zw_j \leq 1$, $\sum_{j=1}^{n} zw_j = 1$.

The IVNNAAOWA has three properties.

Property 4. (idempotency). If $SA_i = SA = \left(\left[TL, TR\right], \left[IL, IR\right], \left[FL, FR\right]\right)$

$$\text{IVNNAAOWA}_{zw}\left(SA_1, SA_2, \cdots, SA_n\right) = SA \quad (10)$$

Property 5. (Monotonicity). Let $SA_i = \left(\left[TL_{A_i}, TR_{A_i}\right], \left[IL_{A_i}, IR_{A_i}\right], \left[FL_{A_i}, FR_{A_i}\right]\right)$, $SB_i = \left(\left[TL_{B_i}, TR_{B_i}\right], \left[IL_{B_i}, IR_{B_i}\right], \left[FL_{B_i}, FR_{B_i}\right]\right)$. If $TL_{A_i} \leq TL_{B_i}, IL_{A_i} \geq IL_{B_i}, FL_{A_i} \geq FL_{B_i}$, $TR_{A_i} \leq TR_{B_i}, IR_{A_i} \geq IR_{B_i}, FR_{A_i} \geq FR_{B_i}$ holds for all i, then

$$\text{IVNNAAOWA}_{zw}\left(SA_1, SA_2, \cdots, SA_n\right) \leq \text{IVNNAAOWA}_{zw}\left(SB_1, SB_2, \cdots, SB_n\right) \quad (11)$$

Property 6 (Boundedness). Let $SA_i = \left(\left[TL_{A_i}, TR_{A_i}\right], \left[IL_{A_i}, IR_{A_i}\right], \left[FL_{A_i}, FR_{A_i}\right]\right)$. If $ZA^+ = \left(\left[\max_i(TL_i), \max_i(TR_i)\right], \left[\min_i(IL_i), \min_i(IR_i)\right], \left[\min_i(FL_i), \min_i(FR_i)\right]\right)$, $ZA^+ = \left(\left[\min_i(TL_i), \min_i(TR_i)\right], \left[\max_i(IL_i), \max_i(IR_i)\right], \left[\max_i(FL_i), \max_i(FR_i)\right]\right)$ then

$$ZA^- \leq \text{IVNNAAOWA}_{zw}\left(SA_1, SA_2, \cdots, SA_n\right) \leq ZA^+ \quad (12)$$

From the Definitions 7 and 8, it's shown that IVNNAAWA and IVNNAAOWA operators weigh the IVNNs and the ordered positions of the IVNNs, respectively. An IVNN Aczel-Alsina hybrid average (IVNNAAHA) operator is produced to include the characteristics of IVNNAAWA and IVNNAAOWA operators together.

Definition 9. Let $SA_i = \left(\left[TL_i, TR_i\right], \left[IL_i, IR_i\right], \left[FL_i, FR_i\right]\right) (i = 1, 2, \ldots, n)$ be the IVNNs. An IVNNAAHA operator is produced:

$$\text{IVNNAAHA}_{zw,sw}\left(SA_1, SA_2, \cdots, SA_n\right) = \bigoplus_{i=1}^{n} \left(zw_i SSA_{\sigma(i)}\right)$$

$$= \left(\begin{bmatrix} 1 - e^{-\left(\sum_{i=1}^{n} zw_i \left(-\ln\left(1 - STL_{\sigma(i)}\right)\right)^{\phi}\right)^{1/\phi}}, 1 - e^{-\left(\sum_{i=1}^{n} zw_i \left(-\ln\left(1 - STR_{\sigma(i)}\right)\right)^{\phi}\right)^{1/\phi}} \end{bmatrix}, \right.$$

$$\left. \begin{bmatrix} e^{-\left(\sum_{i=1}^{n} zw_i \left(-\ln\left(SIL_{\sigma(i)}\right)\right)^{\phi}\right)^{1/\phi}}, e^{-\left(\sum_{i=1}^{n} zw_i \left(-\ln\left(SIR_{\sigma(i)}\right)\right)^{\phi}\right)^{1/\phi}} \end{bmatrix}, \right.$$

$$\left. \begin{bmatrix} e^{-\left(\sum_{i=1}^{n} zw_i \left(-\ln\left(SFL_{\sigma(i)}\right)\right)^{\phi}\right)^{1/\phi}}, e^{-\left(\sum_{i=1}^{n} zw_i \left(-\ln\left(SFR_{\sigma(i)}\right)\right)^{\phi}\right)^{1/\phi}} \end{bmatrix} \right) \quad (13)$$

which $zw = \left(zw_1, zw_2, \cdots, zw_n\right)^T$ is the associated weight, with $0 \leq zw_i \leq 1$, $\sum_{i=1}^{n} zw_i = 1$, $SSA_{\sigma(i)}$ is the i-th largest value of the IVNNs $SSA_i\left(SSA_i = \left(nsw_i\right) SA_i\right) = \left(\left[STL_i, STR_i\right], \left[SIL_i, SIR_i\right], \left[SFL_i, SFR_i\right]\right)$, $sw = \left(sw_1, sw_2, \cdots, sw_n\right)$ is the weight of IVNNs $SA_i \left(i = 1, 2, \cdots, n\right)$, with $sw_j \in \left[0, 1\right]$, $\sum_{i=1}^{n} sw_i = 1$, and n is the balancing coefficient.

If $zw = \left(1/n, 1/n, \cdots, 1/n\right)^T$, IVNNAAHA reduces to the IVNNAAWA; and if $sw = \left(1/n, 1/n, \cdots, 1/n\right)$, the IVNNAAHA reduces to IVNNAAOWA.

IV. Method for MADM Based on the IVNNAAWA

The IVNNAAWA is used to build for MADM. Let $CS = \left\{CS_1, CS_2, \cdots, CS_m\right\}$ be alternatives, and attributes

set $GG=\{GG_1,GG_2,\cdots,GG_n\}$ with weight $sw=\{sw_1,sw_2,\cdots,sw_n\}$, where $sw_j\in[0,1],\sum_{j=1}^{n}sw_j=1$. Suppose that values are assessed with IVNNs $QQ=(qq_{ij})_{m\times n}=\left(\left[TL_{ij},TR_{ij}\right],\left[IL_{ij},IR_{ij}\right],\left[FL_{ij},FR_{ij}\right]\right)_{m\times n}$.

Then, method for MADM is built based on the IVNNAAWA. The given steps are produced.

Step 1. Build the IVNN matrix $QQ=(qq_{ij})_{m\times n}=\left(\left[TL_{ij},TR_{ij}\right],\left[IL_{ij},IR_{ij}\right],\left[FL_{ij},FR_{ij}\right]\right)_{m\times n}$.

$$QQ=\left[qq_{ij}\right]_{m\times n}=\begin{bmatrix} qq_{11} & qq_{12} & \cdots & qq_{1n} \\ qq_{21} & qq_{22} & \cdots & qq_{2n} \\ \vdots & \vdots & \vdots & \vdots \\ qq_{m1} & qq_{m2} & \cdots & qq_{mn} \end{bmatrix} \tag{14}$$

Step 2. Normalize $QQ=(qq_{ij})_{m\times n}$ to $NQ=\left[nq_{ij}\right]_{m\times n}$.

$$\begin{aligned} nq_{ij}&=\left(\left[NTL_{ij},NTR_{ij}\right],\left[NIL_{ij},NIR_{ij}\right],\left[NFL_{ij},NFR_{ij}\right]\right)\\ &=\begin{cases}\left(\left[TL_{ij}^{k},TR_{ij}^{k}\right],\left[IL_{ij}^{k},IR_{ij}^{k}\right],\left[FL_{ij}^{k},FR_{ij}^{k}\right]\right), & GG_j \text{ is a benefit criterion}\\ \left(\left[FL_{ij}^{k},FR_{ij}^{k}\right],\left[IL_{ij}^{k},IR_{ij}^{k}\right],\left[TL_{ij}^{k},TR_{ij}^{k}\right]\right), & GG_j \text{ is a cost criterion}\end{cases}\end{aligned} \tag{15}$$

Step 3. According to $NQ=\left[nq_{ij}\right]_{m\times n}$, the overall IVNNs $nq_i\,(i=1,2,\cdots,m)$ are produced through IVNNAAWA operator:

$$\begin{aligned} nq_i&=\text{IVNNAAWA}_{sw}(nq_{i1},nq_{i2},\cdots,nq_{in})\\ &=\bigoplus_{i=1}^{n}sw_i nq_{ij}\\ &=\left(\left[NTL_i,NTR_i\right],\left[NIL_i,NIR_i\right],\left[NFL_i,NFR_i\right]\right)\\ &=\left(\begin{bmatrix}1-e^{-\left(\sum_{j=1}^{n}sw_i\left(-\ln\left(1-NTL_{ij}\right)\right)^{\phi}\right)^{1/\phi}}, 1-e^{-\left(\sum_{i=1}^{n}sw_i\left(-\ln\left(1-NTR_{ij}\right)\right)^{\phi}\right)^{1/\phi}}\end{bmatrix},\right.\\ &\quad\begin{bmatrix}e^{-\left(\sum_{i=1}^{n}sw_i\left(-\ln\left(NIL_{ij}\right)\right)^{\phi}\right)^{1/\phi}}, e^{-\left(\sum_{i=1}^{n}sw_i\left(-\ln\left(NIR_{ij}\right)\right)^{\phi}\right)^{1/\phi}}\end{bmatrix},\\ &\quad\left.\begin{bmatrix}e^{-\left(\sum_{i=1}^{n}sw_i\left(-\ln\left(NFL_{ij}\right)\right)^{\phi}\right)^{1/\phi}}, e^{-\left(\sum_{i=1}^{n}sw_i\left(-\ln\left(NFR_{ij}\right)\right)^{\phi}\right)^{1/\phi}}\end{bmatrix}\right)\end{aligned} \tag{16}$$

Step 4. Obtain the $SV(nq_i),AV(nq_i)(i=1,2,\cdots,m)$.

$$\begin{aligned} SV(nq_i)&=\frac{\begin{pmatrix}\left(2+NTL_i-NIL_i-NFL_i\right)\\ +\left(2+NTR_i-NIR_i-NFR_i\right)\end{pmatrix}}{6}\\ AV\left(\left(nq_i\right)\right)&=\frac{\left(NTL_i+NTR_i\right)-\left(NFL_i+NFR_i\right)}{2}\end{aligned} \tag{17}$$

Step 5. Rank the $CS_i\,(i=1,2,\cdots,m)$ through $SV(nq_i),AV(nq_i)$.

Step 6. End.

V. Numerical Example and Comparative Analysis

A. Numerical Example

The evaluation of college English teaching quality is an essential aspect of higher education management. It aims to provide a comprehensive analysis and feedback on various aspects of English teaching to ensure the improvement of teaching effectiveness and the enhancement of students' English proficiency. Teaching quality evaluation not only measures the teaching level of instructors but also serves as a critical monitoring tool for assessing student learningoutcomes and the appropriateness of course design. Through this evaluation system, universities can identify the strengths and weaknesses in teaching, continuously improving the content and methods to ensure the achievement of teaching goals. The core aspects of teaching quality evaluation generally include the following: First is the teacher's attitude and teaching ability. This covers the teacher's preparation, teaching methods, attention to students, and the organization and presentation of course content. An excellent English teacher should not only have solid language knowledge but also be able to effectively stimulate students' interest in learning and flexibly use various teaching methods to meet the needs of students at different levels. Second is student participation and learning outcomes. This part of the evaluation assesses student performance in class, completion of assignments, exam results, and other indicators of learning achievement. Student engagement directly affects their learning outcomes, so classroom interaction, task completion, and similar factors are key evaluation criteria. The third aspect is the design of course content and the use of teaching resources. Whether the course content meets the actual needs of students, whether teaching resources are diverse and abundant, and whether modern

teaching methods are employed are all crucial factors influencing teaching quality. Through well-designed courses, students not only acquire language knowledge but also develop cross-cultural communication skills and critical thinking. There are various methods for evaluating teaching quality, including student evaluations, peer reviews, expert observations, and supervision by teaching administrators. Student evaluations are a key component of the evaluation system, providing direct feedback on students' learning experiences and satisfaction with the course. Peer reviews and expert observations offer a more objective assessment of the teacher's capabilities from a professional perspective. By collecting data from multiple sources, the evaluation of college English teaching quality provides constructive feedback to teachers, helping them continuously improve their teaching strategies. Additionally, this evaluation system assists university administrators in gaining a better understanding of the current teaching situation, optimizing resource allocation, and ultimately achieving continuous improvement in English teaching quality. The teaching quality evaluation of college English is looked as MADM. Five possible foreign colleges $CS_i\left(i=1,2,3,4,5\right)$ are assessed with four attributes: ①GG_1 is **Student Learning Outcomes**: This is a key effectiveness indicator, assessed through students' exam scores, language proficiency tests, classroom performance, and the ability to use English in extracurricular activities. High-quality teaching should significantly improve students' English skills. ②GG_2 is **Teaching Costs**: As the sole cost indicator, this involves the input of human, material, and financial resources. It includes teacher salaries, the purchase and maintenance of teaching equipment, textbook expenses, and related training costs. Effective cost management can ensure high teaching quality while achieving efficient resource utilization. ③GG_3 is **Student Satisfaction**: This effectiveness indicator is gathered through surveys, interviews, and other methods to obtain feedback on course content, teaching methods, teacher proficiency, and the learning environment. High satisfaction generally reflects the effectiveness of teaching and student approval. ④GG_4 is **Enhancement of Employability**: This measures students' employment status after graduation, including employment rates, starting salaries, and the ability to use English in the workplace. This indicator reflects the extent to which English teaching supports students' career development and is an important measure of teaching quality. GG_2 is the cost. The IVNNAAWA is built for teaching quality evaluation of college English.

Step 1. Build the $QQ=\left(qq_{ij}\right)_{5\times4}$ in Table I.

TABLE I. IVNN INFORMATION

	GG_1	GG_2
CS_1	([0.42, 0.53], [0.21, 0.32], [0.26, 0.37])	([0.63, 0.74], [0.18, 0.29], [0.22, 0.33])
CS_2	([0.43, 0.54], [0.32, 0.43], [0.23, 0.34])	([0.64, 0.75], [0.23, 0.34], [0.13, 0.24])
CS_3	([0.62, 0.73], [0.26, 0.37], [0.13, 0.24])	([0.48, 0.59], [0.38, 0.49], [0.14, 0.25])
CS_4	([0.58, 0.69], [0.13, 0.24], [0.28, 0.39])	([0.52, 0.63], [0.28, 0.39], [0.17, 0.28])
CS_5	([0.64, 0.75], [0.11, 0.22], [0.22, 0.33])	([0.57, 0.68], [0.24, 0.35], [0.14, 0.25])
	GG_3	GG_4
CS_1	([0.54, 0.65], [0.27, 0.38], [0.16, 0.27])	([0.57, 0.68], [0.12, 0.23], [0.28, 0.39])
CS_2	([0.55, 0.66], [0.14, 0.25], [0.27, 0.38])	([0.53, 0.64], [0.22, 0.33], [0.21, 0.32])
CS_3	([0.73, 0.84], [0.13, 0.24], [0.17, 0.28])	([0.68, 0.79], [0.18, 0.29], [0.12, 0.23])
CS_4	([0.63, 0.74], [0.22, 0.33], [0.13, 0.24])	([0.73, 0.84], [0.12, 0.23], [0.11, 0.22])
CS_5	([0.48, 0.59], [0.32, 0.43], [0.22, 0.33])	([0.62, 0.73], [0.18, 0.29], [0.18, 0.29])

Step 2. Normalize $QQ=\left[qq_{ij}\right]_{5\times4}$ to $NQ=\left[nq_{ij}\right]_{5\times4}$ (see Table II).

TABLE II. THE NORMALIZED IVNN MATRIX

	GG_1	GG_2
CS_1	([0.42, 0.53], [0.21, 0.32], [0.26, 0.37])	([0.22, 0.33], [0.18, 0.29], [0.63, 0.74])
CS_2	([0.43, 0.54], [0.32, 0.43], [0.23, 0.34])	([0.13, 0.24], [0.23, 0.34], [0.64, 0.75])
CS_3	([0.62, 0.73], [0.26, 0.37], [0.13, 0.24])	([0.14, 0.25], [0.38, 0.49], [0.48, 0.59])
CS_4	([0.58, 0.69], [0.13, 0.24], [0.28, 0.39])	([0.17, 0.28], [0.28, 0.39], [0.52, 0.63])

CS_5	([0.64, 0.75], [0.11, 0.22], [0.22, 0.33])	([0.14, 0.25], [0.24, 0.35], [0.57, 0.68])
	GG_3	GG_4
CS_1	([0.54, 0.65], [0.27, 0.38], [0.16, 0.27])	([0.57, 0.68], [0.12, 0.23], [0.28, 0.39])
CS_2	([0.55, 0.66], [0.14, 0.25], [0.27, 0.38])	([0.53, 0.64], [0.22, 0.33], [0.21, 0.32])
CS_3	([0.73, 0.84], [0.13, 0.24], [0.17, 0.28])	([0.68, 0.79], [0.18, 0.29], [0.12, 0.23])
CS_4	([0.63, 0.74], [0.22, 0.33], [0.13, 0.24])	([0.73, 0.84], [0.12, 0.23], [0.11, 0.22])
CS_5	([0.48, 0.59], [0.32, 0.43], [0.22, 0.33])	([0.62, 0.73], [0.18, 0.29], [0.18, 0.29])

Step 3. The subjective weights are obtained through AHP technique (Table III).

TABLE III. THE SUBJECTIVE WEIGHTS

	GG_1	GG_2	GG_3	GG_4
weight	0.2746	0.1832	0.3105	0.2317

Step 4. Obtain the $nq_i\left(i=1,2,\cdots,5\right)$ by utilizing IVNNAAWA operator (Table IV).

TABLE IV. THE $nq_i\left(i=1,2,\cdots,5\right)$ ($\theta=2$)

Alternatives	$nq_i\left(i=1,2,\cdots,5\right)$
CS_1	([0.1023, 0.2134], [0.0456, 0.1567], [0.2789, 0.3890])
CS_2	([0.2145, 0.3256], [0.0678, 0.1789], [0.1901, 0.3012])
CS_3	([0.3267, 0.4378], [0.0890, 0.2001], [0.1456, 0.2567])
CS_4	([0.1345, 0.2456], [0.0123, 0.1234], [0.3678, 0.4789])
CS_5	([0.2467, 0.3578], [0.0345, 0.1456], [0.2890, 0.4001])

Step 5. Obtain the $SV\left(nq_i\right)\left(i=1,2,\cdots,5\right)$ (Table V).

TABLE V. THE $SV\left(nq_i\right)\left(i=1,2,\cdots,5\right)$

Alternatives	$SV\left(nq_i\right)\left(i=1,2,\cdots,5\right)$	Order
CS_1	0.5143	5
CS_2	0.6509	1
CS_3	0.5427	4
CS_4	0.5540	3
CS_5	0.5672	2

Step 6. From Table V, the order is: $XP_2 > XP_5 > XP_4 > XP_3 > XP_1$, and the best choice is XP_2.

B. Comparative Analysis

The IVNNAAWA is compared with IVNNWA & IVNNWG [51]. For IVNWA, the calculating values is: $EV\left(CS_1\right)=0.2897, EV\left(CS_2\right)=0.6658$, $EV\left(CS_3\right)=0.2179,$

$EV(CS_4) = 0.5576,\ EV(CS_5) = 0.4776$. Thus, the order is $CS_2 > CS_4 > CS_5 > CS_1 > CS_3$ .For IVNWG, the calculating values is: $EV(CS_1) = 0.2799, EV(CS_2) = 0.6476, EV(CS_3) = 0.2549,$ $EV(CS_4) = 0.5287,\ \ EV(CS_5) = 0.4769$. So the order is $CS_2 > CS_4 > CS_5 > CS_1 > CS_3$.

Then, IVNNAAWA is compared with IVNN-CODAS[52], the assessment values is: $SVNNAV(CS_1) = -0.2465, SVNNAV(CS_2) = 0.3778,$ $SVNNAV(CS_3) = -0.3239,\ \ SVNNAV(CS_4) = 0.2558,$ $SVNNAV(CS_5) = 0.1379$. Thus, the order is $CS_2 > CS_4 > CS_5 > CS_1 > CS_3$.

TABLE VI. THE COMPARATIVE ANALYSIS

Models	order
IVNNWA [51]	$CS_2 > CS_4 > CS_5 > CS_1 > CS_3$
IVNNWG [51]	$CS_2 > CS_4 > CS_5 > CS_1 > CS_3$
IVNN-CODAS[52]	$CS_2 > CS_4 > CS_5 > CS_1 > CS_3$
IVNNAAWA	$CS_2 > CS_4 > CS_5 > CS_1 > CS_3$

From Table VI, it is evident that the three models under consideration all identify the same optimal choice, albeit in a slightly different sequence. This consistency underscores the rationality and effectiveness of the IVNNAAWA method. Each of the five models discussed has distinct advantages, but the IVNNAAWA stands out for several reasons. One of its most notable strengths is the ability to determine the most favorable alternative by appropriately setting parameter values within the IVNNAAWA operators. This feature offers decision-makers a novel and flexible approach to addressing IVNN-MADM challenges. By incorporating a parameter, the IVNNAAWA method allows for a straightforward representation of fuzzy information, enhancing the transparency of the information aggregation process compared to some existing techniques. This transparency is crucial for decision-makers who need to understand and trust the aggregation process. In contrast, existing aggregation operators, as referenced in prior studies, often lack this level of flexibility in data aggregation. Consequently, the proposed aggregation operator is more advanced and reliable when it comes to decision-making involving IVNN data. The flexibility of the IVNNAAWA method not only simplifies the representation of complex fuzzy information but also enhances the decision-making process by making it more adaptable to various scenarios. This adaptability is particularly beneficial in situations where decision-makers face uncertainty and need to rely on robust methods to guide their choices. The ability to adjust parameters to suit specific needs means that decision-makers can tailor the aggregation process to better fit the unique aspects of their decision-making environment. In summary, the IVNNAAWA aggregation operator provides a significant improvement over existing methods by offering a more flexible and transparent approach to handling IVNN data. Its ability to adapt to different decision-making contexts makes it a valuable tool for decision-makers seeking reliable and sophisticated solutions to complex problems. This innovation in aggregation techniques marks a noteworthy advancement in the field of multi-attribute decision making, ensuring that decision-makers have access to the best possible tools for their needs.

VI. CONCLUSION

The quality evaluation of university English teaching is a comprehensive process that involves multiple dimensions. Firstly, student learning outcomes are a key indicator, assessed through exam scores, language proficiency tests, and classroom performance to evaluate improvements in students' English skills. Secondly, teaching costs are an important factor, including teacher salaries, teaching equipment, and textbook expenses. Effective cost management aids in the efficient utilization of resources. Additionally, student satisfaction is gathered through surveys and interviews, reflecting students' approval of course content, teaching methods, and teacher proficiency. Lastly, the enhancement of employability measures students' ability to use English in the workplace after graduation, including employment rates and starting salaries. These indicators collectively form a comprehensive evaluation of the quality of university English teaching, helping educational institutions continuously optimize teaching strategies and improve teaching effectiveness. The teaching quality evaluation of college English is regarded as the MADM. This paper introduces several Aczel-Alsina operators within the framework of IVNSs. Subsequently, the interval-valued neutrosophic number (IVNN) Aczel-Alsina weighted averaging (IVNNAAWA) operator is utilized to address multi-attribute decision-making (MADM) problems. To demonstrate the effectiveness of the proposed method, a numerical example is provided, focusing on the evaluation of college English teaching quality. This example illustrates how the IVNNAAWA operator can be applied to assess and improve decision-making processes in educational settings. By leveraging the unique characteristics of IVNSs, the method offers a nuanced approach to handling uncertainty and imprecision in decision-making, making it particularly suitable for complex evaluation tasks such as assessing teaching quality. The proposed approach not

only enhances the flexibility of decision-making but also provides a framework for integrating various attributes into a cohesive evaluation model. This contributes to more informed and reliable decision outcomes, ultimately aiding educational institutions in optimizing their teaching strategies and improving overall educational effectiveness.

A Smoke Source Location Method Based on Deep Learning Smoke Segmentation

Yuanpan ZHENG*, Zeyuan HUANG, Hui WANG, Binbin CHEN, Chao WANG, Yu ZHANG
School of Computer Science and Technology
Zhengzhou University of Light Industry, Zhengzhou 450000, Henan, China

***Abstract*—The generation of smoke is an early warning sign of a fire, and fast, accurate detection of smoke sources is crucial for fire prevention. However, due to the strong diffusivity of smoke, its morphology is easily influenced by environmental factors, and in complex real-world scenarios, smoke sources are often obscured. Current methods lack precision, generalization ability, and robustness in complex environments. With the advancement of deep learning-based smoke segmentation technology, new approaches to smoke source localization have emerged. Smoke segmentation, driven by deep learning models, can accurately capture the morphological characteristics of smoke. This paper proposes a precise and robust smoke source localization method based on deep learning-enabled smoke segmentation. We first conducted experimental evaluations of commonly used deep learning segmentation models and selected the best-performing model as input. Based on the segmentation results, we analyzed the diffusion characteristics and transmittance of smoke, constructed a concentration model, and used it to accurately locate the smoke source. Experimental results demonstrate that, compared with existing methods, this approach maintains high localization accuracy in multi-target smoke scenarios and complex environments, with superior generalization ability and robustness.**

***Keywords*—Smoke segmentation; smoke source detection; deep learning; instance segmentation; mathematical modeling**

I. INTRODUCTION

Disaster monitoring and prevention is a broad research area directly related to the safety of people's lives and property. The key to fire monitoring and prevention lies in early detection and timely response. In the field of computer vision, early fire detection and prevention essentially focuses on the detection and warning of fire smoke, as smoke is a significant indicator of fire occurrence. Research shows that during the early stages of a fire, the combustion intensity is weak, the temperature and radiant heat of the fire scene are low, and flames are not produced when the temperature of combustible materials has not yet reached the ignition point. Usually, smoke is generated on the surface of combustible materials at this stage [1]. Therefore, the appearance of smoke is a precursor to fire outbreaks [2].

Accurately locating the source of fire smoke is crucial in fire monitoring and prevention. Pinpointing the smoke source helps rapidly identify the location of a fire, providing key information for emergency response, reducing response time, and improving firefighting efficiency. Additionally, smoke source localization helps understand the fire's development and spread direction, which supports the formulation of evacuation routes and protective measures to minimize casualties and property losses. Furthermore, accurately determining the smoke source can prevent false alarms caused by similar phenomena, thereby enhancing the reliability and effectiveness of fire warning systems. Thus, smoke source localization is not only a critical technology for early fire warning but also an essential part of ensuring fire response and disaster mitigation capabilities.

With the continuous development of related technologies in the field of computer vision, methods for detecting smoke using visual sensors have gradually matured. However, due to smoke strong diffusion and the multiple reflections and occlusions it experiences in everyday environments, accurately determining the smoke source remains a challenge. In recent years, significant progress has been made in deep learning-based smoke segmentation methods. Smoke segmentation technology can visually reflect the spatial distribution of smoke, making it easier to analyze its diffusion and indirectly infer the smoke source location, providing new insights for smoke source localization.

This paper proposes a precise smoke's source localization method that combines instance segmentation and mathematical modeling. First, the smoke area was extracted from the background using segmentation techniques. Then, mathematical modeling was applied to the smoke region to extract pixel coordinates and grayscale values, and the smoke diffusion characteristics and direction were derived by curve fitting. Based on this, a smoke concentration model is constructed using the dark channel algorithm to locate the area with the highest concentration, thereby estimating the exact position of the smoke source. The main contributions of this paper are as follows:

1) We constructed a fire smoke segmentation dataset with multi-scale, complex scenes and varying attributes.

2) We proposed a smoke source detection method. By analyzing the smoke segmentation results, we established a diffusion model and transmittance model based on smoke contours and static characteristics, combined these two models to construct a smoke concentration model, and inferred the smoke source location using the concentration model.

3) We analyzed several instance segmentation models, including the U-Net series [4, 15], DeepLab series [7-10], and others like FCN [3], SegNet [5], and PSPNet [6], for fire smoke segmentation tasks. After evaluating their performance and accuracy, we selected the optimal model to support smoke source detection.

The structure of this paper is as follows: Section II introduces related work on fire smoke source localization and smoke

segmentation; Section III describes the algorithm proposed for locating fire smoke sources; Section IV presents a comparative analysis of several commonly used smoke segmentation models, selects the most suitable model for fire smoke segmentation, and tests the proposed smoke source localization scheme; Section V concludes the paper and discusses future research directions.

II. Related Work

A. Smoke Segmentation

Research in recent years has shown that scholars are more inclined to use deep learning methods to segment smoke, but most of the methods rely on existing semantic segmentation networks. Researchers achieve smoke segmentation by improving the semantic segmentation model with better performance, Wang et al. [13] improved the Deeplab V3 network model by embedding channel attention and deformable pyramid in the model, and feature refinement of the input image to improve the model segmentation accuracy, although the enhancement is not obvious, it provides a direction for the model improvement. Liu et al. [14] improved the Deeplab v3+ network model by improving ASPP structure through heterogeneous sensory wild fusion and incorporating a channel attention module. Salman Khan et al. [11] added an improved multi-scale separable convolutional encoder and decoder to the Deeplab v3+ model, along with a per-pixel classifier to improve the model. Taoyang Wang et al. [12] improved on Unet++ by introducing a convolutional attention module CBAM in the original coding layer making the network adaptively selectable and feature-enhanced to be able to focus more on smoke targets.

In addition to improving the model, some scholars have also implemented smoke segmentation by designing new model structures. Yuan et al. [16] designed a W-Net network model to segment smoke, which uses asymmetric encoders and decoders stacked in multiple layers, and segments the smoke region through the use of smoke density estimation. Yuming Li et al. [17] proposed a two-path smoke semantic segmentation network, although the architecture is different from conventional segmentation models, the core idea is still using pyramid pooling and channel attention. After proving that the attention mechanism can effectively improve the accuracy of the model, Yuan et al. [18] proposed a cross-scale hybrid attention network, a kind of fusion of 3D attention, multi-scale channel attention, and hybrid cross-enhancement, which is experimentally proved to have a certain degree of smoke segmentation ability.

B. Smoke Source Localization

Research on smoke source localization is relatively limited, especially regarding automated or intelligent methods for locating smoke sources. Traditionally, smoke source localization has relied on conventional visual monitoring and manual intervention techniques [19]. While these methods have been used in practical applications, their efficiency and accuracy largely depend on experience. In recent years, with the rapid development of computer vision technology, some image processing and machine learning methods have been applied in fire monitoring systems, but specialized techniques for smoke source localization remain relatively scarce.

Most existing smoke source localization methods are based on the physical properties of smoke diffusion, sensor data fusion, and multi-angle visual information. Cao et al. [20] proposed a feature foreground network that models the complex variation patterns of smoke features, enhancing smoke recognition capabilities. By using feature extraction and separation techniques, and integrating environmental conditions such as temperature and wind speed provided by sensors, they effectively separated smoke foreground from complex backgrounds, enabling smoke source prediction in dynamic environments. Zhou et al. [21] developed a vision-based localization method that analyzes the dynamic diffusion patterns of smoke captured by cameras using the U-Net algorithm to estimate the smoke source. However, the high cost of sensors and their susceptibility to environmental conditions, along with the highly random nature of smoke diffusion in the air [22], limit the widespread application of these methods in complex environments.

III. Methods

Smoke detection and segmentation can roughly determine the overall area where the smoke is located, but due to the diffusive nature of smoke, accurately pinpointing the smoke source is often difficult. Therefore, when predicting the smoke source, it is necessary to incorporate data related to smoke morphology, color, transmittance, and its diffusion characteristics into the calculations to model the smoke region. By constructing a fitted curve, we can solve for the pixel diffusion rate and the diffusion direction within the smoke region. Additionally, we apply the dark channel algorithm [23] to process the image, reducing the impact of light sources on the smoke and analyzing the grayscale values presented by the smoke. This allows us to build a smoke transmittance model. Finally, by combining the diffusion rate model and the transmittance model, we construct a smoke concentration model, identifying the point of highest smoke concentration. Using the diffusion direction, we can then predict the precise area of the smoke source. The flowchart for smoke source localization is shown in Fig. 1.

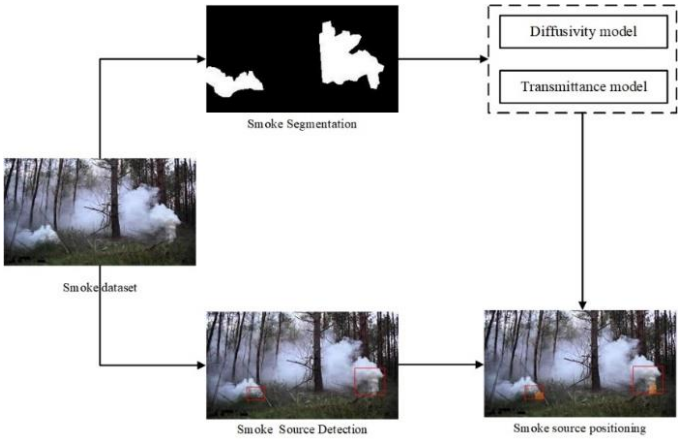

Fig. 1. Smoke source localization flowchart.

A. Smoke Information Extraction

First, the grayscale value of each pixel in the smoke region is obtained, as the grayscale value can reflect the foreground

degree of the current smoke region. The foreground degree can be inferred from the relative thickness of the smoke, indirectly reflecting the transmittance of the smoke. Before converting the image to grayscale, the dark channel algorithm is applied to reduce the impact of bright fog on the smoke region, ensuring that the grayscale values more accurately reflect the smoke's foreground intensity. Then, by traversing the coordinates of all smoke pixels, a set of coordinate points for the smoke region is constructed, allowing for binarization of the smoke region.

B. Diffusivity and Transmittance Modeling

The diffusion direction of smoke generally spreads from bottom to top and from inside to outside. In terms of computer vision, the construction of the diffusion model is primarily based on the contour information of the smoke. The transmittance model is constructed based on the grayscale values of the smoke processed using the dark channel algorithm. First, a cubic polynomial regression curve is constructed based on the coordinate data from the set of coordinate points, and the coefficients are solved using the least squares method. Next, after constructing the fitted curve, the data from the set of coordinate points is grouped into segments of 10 pixels each, and the average variance between the pixel points in each group and the fitted curve is calculated. The size of the average variance is considered the value of the diffusion rate, with lighter colors having smaller diffusion rates and darker colors having larger diffusion rates. Additionally, the sets of points with the largest and smallest diffusion rates are obtained, and the direction from the area with the smallest diffusion rate to the area with the largest diffusion rate is regarded as the direction of smoke diffusion.

$$Y = AX^3 + BX^2 + CX + D \tag{1}$$

The transmittance model is based on the grayscale value of each pixel. After processing the image using the dark channel algorithm, part of the bright fog effect can be eliminated, allowing the transmittance of the smoke to be judged based on the grayscale values. Regions with larger grayscale values indicate that they are closer to the foreground, meaning the smoke is denser and the transmittance is relatively low. Conversely, regions with smaller grayscale values are closer to the background, where the smoke is less dense than in the foreground, resulting in higher transmittance. In the field of computer vision, the image model is defined as follows:

$$I(x) = J(x)t(x) + A(1-t(x)) \tag{2}$$

where, I represents the image with haze, J represents the image without haze, t represents the transmittance, and A represents the global atmospheric light.

The formula for the dark channel algorithm is as follows:

$$J_{dark}(x) = \min_{y\in\Omega(x)}\left(\min_{c\in(r,g,b)} J_c(y)\right) \to 0 \tag{3}$$

where J_{dark} represents the dark channel, Ω(x) represents a square region centered at x, and Jc represents the image processed through the dark channel in the c-channel.

$$t(x) = 1 - \min_{y\in\Omega(x)}\left(\min_{c\in(r,g,b)} \frac{I_c(y)}{A_c}\right) \tag{4}$$

The diffusivity model and the transmittance model are illustrated in Fig. 2.

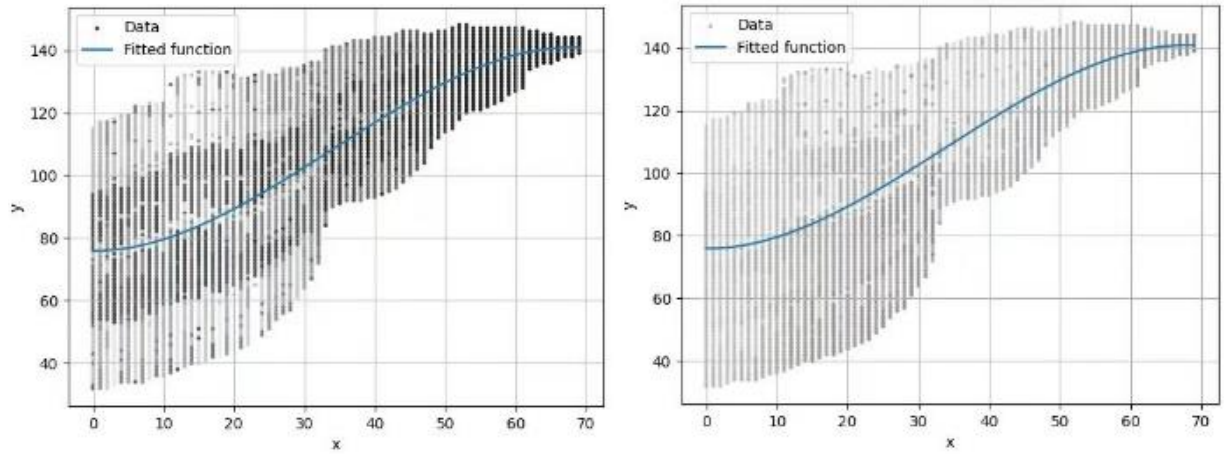
C. Smoke Concentration Modeling

The smoke concentration model is based on the diffusivity and transmittance models, where the diffusivity and transmittance values are added at different ratios to form the concentration value. After modeling the concentration, extreme concentration areas are marked, with red indicating areas of highest smoke concentration and blue indicating areas of lowest smoke concentration.

The smoke concentration can be expressed as:

$$N = yK + (1-y)(1-T) \tag{5}$$

where N represents the concentration value, K represents the diffusivity value, T represents the transmittance, and y represents the ratio.



Diffusivity model. Transmittance model.

Fig. 2. Diffusivity and transmittance model.

In addition to single-target smoke, there is also multi-target smoke. The multi-target smoke concentration model is constructed by dividing the smoke based on enclosed regions, where the smoke in each enclosed region is modeled separately as a concentration. After completing the smoke model construction, a set of pixels with the highest smoke concentration is obtained. The highest concentration area is tangential to the fitted curve, and the area formed by the extension of the tangent line and the extension line in the opposite direction of diffusion is used as the predicted smoke source area. The size of the predicted smoke source region is set to the size of the outer bounding box of the area with the highest concentration.

The predicted smoke source region is illustrated in Fig. 3. To further enhance the effectiveness of smoke source localization, we also selected the YOLOv8n [24] smoke source region detection model as a supplementary method to assist in limiting the location of the smoke source. Fig. 4 illustrates the schematic diagram of the smoke source localization method.

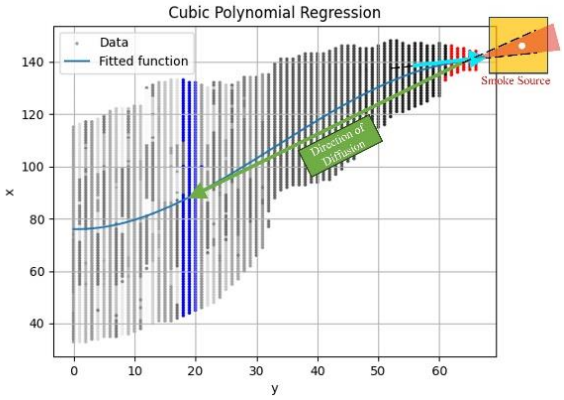


Fig. 3. Smoke source prediction area.

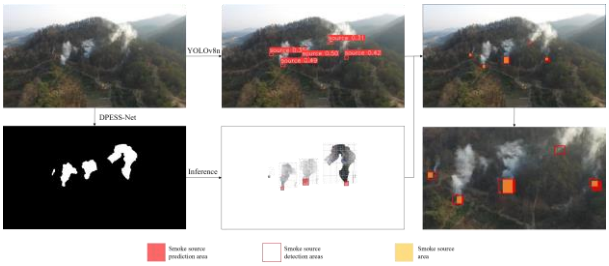

Fig. 4. Schematic diagram of smoke source localization method.

IV. Experimental Results

A. Segmentation Model Selection

In this section, our goal is to select a segmentation model that strikes a balance between segmentation accuracy and speed, meeting the needs of smoke source localization. Specifically, the model must maintain high accuracy while maximizing segmentation speed to ensure the timeliness of smoke source localization. Fig. 5 shows the proposed model testing flowchart.

Building on previous work, we have selected the nine most representative and high-performing segmentation models from commonly used models. These models were tested and evaluated on a self-constructed smoke segmentation dataset to ensure that the selected model possesses good adaptability and stability in practical applications.

1) Dataset and Evaluation Metrics: Next, we will introduce the dataset and evaluation metrics used to analyze the strengths and weaknesses of the segmentation models. The experimental dataset was selected from publicly available sources that could serve as valid samples. For video files, we used frame segmentation to divide the entire video data frame by frame and sampled up to 20 frames at intervals to avoid having overly similar samples. Additionally, we used real fire videos and images from scenarios such as urban areas, forests, and grasslands, selecting relevant fire smoke footage for frame-by-frame segmentation and interval sampling.

Furthermore, we simulated fire smoke generation in open areas, using video tools placed at different locations relative to the smoke source to record the smoke formation. These recordings were then segmented frame by frame, and interval samples were collected to capture fire smoke samples of various scales. Lower-resolution samples were also included to address extreme conditions. In total, the dataset collected 1,511 valid data points, including samples with multiple scales and targets, samples with complex backgrounds, and those exhibiting complex static attributes such as color, concentration, shape, texture, and expansion.

We used image processing software to manually annotate each collected sample. Since this study focuses on the detailed edges of smoke, most of the annotations were made at the pixel level. However, to minimize issues such as overfitting, generalization errors, and information loss, the edges of the labels were appropriately smoothed. We also applied symmetric processing to all samples and their corresponding labels on the left and right sides, and increased the size of the training set through data augmentation to address the challenges of sample refinement.

After these processes, our effective dataset contained 3,022 fire smoke sample images and 3,022 corresponding label annotations. To verify the validity of our custom fire smoke segmentation dataset, we randomly selected 1,000 samples and their labels to conduct comparative experiments using a basic semantic segmentation model on the training set. From the model's training results, our custom fire smoke segmentation dataset generally yielded better training outcomes compared to publicly available fire smoke segmentation datasets. Part of the dataset is shown in Fig. 6.

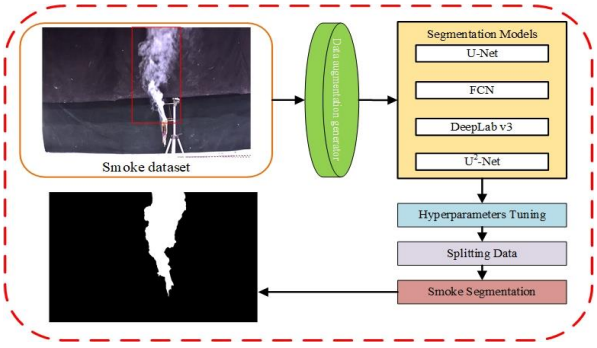

Fig. 5. Model testing flowchart.

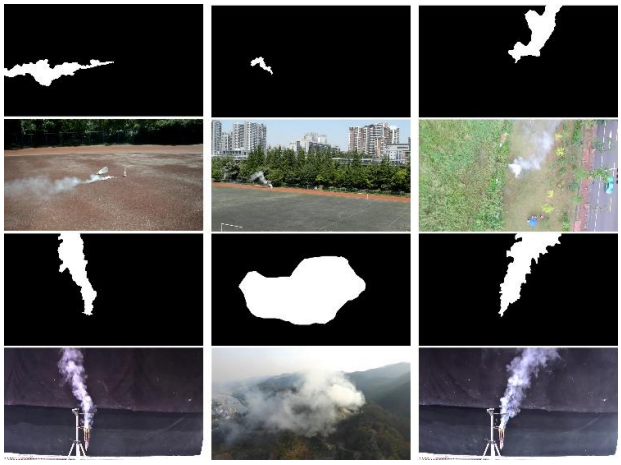

Fig. 6. Partial dataset.

2) Experimental Environment and Evaluation Metrics

The hardware environment used for the experiments in this paper is shown in Table I.

TABLE I. EXPERIMENTAL ENVIRONMENT

CPU	AMD EPYC 7773X @ 3.50GHz
GPU	GeForce RTX 4090
RAM	80G
Operating System	Ubuntu 20.04
Programming Language	Python 3.8
Deep Learning Framework	Pytorch 2.0.0
GPU Acceleration Library	Cuda 11.8

For the smoke segmentation model, we primarily focus on its segmentation accuracy and speed. Therefore, we selected mIoU, mPA, MaxF1, and FPS as the evaluation metrics for the segmentation model.

*a)*mIoU measures the overlap between the predicted segmentation and the ground truth. It is the average IoU for each class. The calculation formulas are shown in Eq. (6) and Eq. (7).

$$IoU = \frac{TP}{TP + FP + FN} \tag{6}$$

$$mIoU = \frac{1}{N}\sum_{i=1}^{N}\frac{TP_i}{TP_i + FP_i + FN_i} \tag{7}$$

where N represents the number of classes, and i represents the total number of categories.

*b)*mPA measures the pixel classification accuracy for each class, averaging the pixel accuracy for each category. The calculation formula is shown in Eq. (8).

$$mPA = \frac{1}{N}\sum_{i=1}^{N}\frac{TP_i}{TP_i + FN_i} \tag{8}$$

F1 Score is the harmonic mean of precision and recall, balancing both metrics. MaxF1 is the maximum F1 score obtained during multi-threshold testing. The formulas are shown in Eq. (9) and Eq. (10).

$$F1 = \frac{2 \times Precision \times Recall}{Precision + Recall} \tag{9}$$

$$MaxF1 = \max\left(F1\right) \tag{10}$$

The formulas for Precision and Recall are provided in Eq. (11) and Eq. (12).

$$Precision = \frac{TP}{TP + FP} \tag{11}$$

$$Recall = \frac{TP}{TP + FN} \tag{12}$$

FPS measures the processing speed of the model, indicating how many image frames the model can process per second. It is used to evaluate the real-time performance of the model.

3) Experimental Results and Analysis: We trained and tested several models, including U-Net, FCN, SegNet, PSPNet, DeepLab V3+, U2-Net, U2-Net+, DPESS-Net+ (64 channels), and DPESS-Net, using our custom fire smoke segmentation dataset. The final test results are shown in Table II, and the mIoU training process is illustrated in Fig. 7. The experimental data in Table II indicate that DPESS-Net performed the best overall, achieving mIoU scores of 91.09% under AVG20 and 91.18% under TOP1, an mPA of 96.96%, and a MaxF1 score of 94.37%. However, its FPS was 15.60, placing it in the medium range for processing speed.

TABLE II. THE PERFORMANCE OF THE MODEL IN COMPARATIVE EXPERIMENTS AND BOLD FONT INDICATES BEST GRADE.

Model	mIoU (%)		mPA (%)	MaxF1 (%)	FPS
	AVG²⁰	*TOP¹*			
U-Net	86.07	87.70	96.09	93.46	26.39
FCN	84.59	85.97	95.31	91.95	**27.37**
SegNet	85.47	86.45	95.70	92.48	21.22
PSPNet	84.23	85.16	95.20	91.61	17.54
DeepLab V3+	85.50	87.31	95.28	92.29	11.50
U^2-Net	86.83	87.80	96.01	93.01	13.37
U^2-Net+	85.98	86.68	95.90	92.67	12.91
DPESS-Net+	89.08	89.73	96.75	93.45	9.34
DPESS-Net (Ours)	**91.09**	**91.18**	**96.96**	**94.37**	15.60

Fig. 7. The results of mIoU of the models in the comparative experiment.

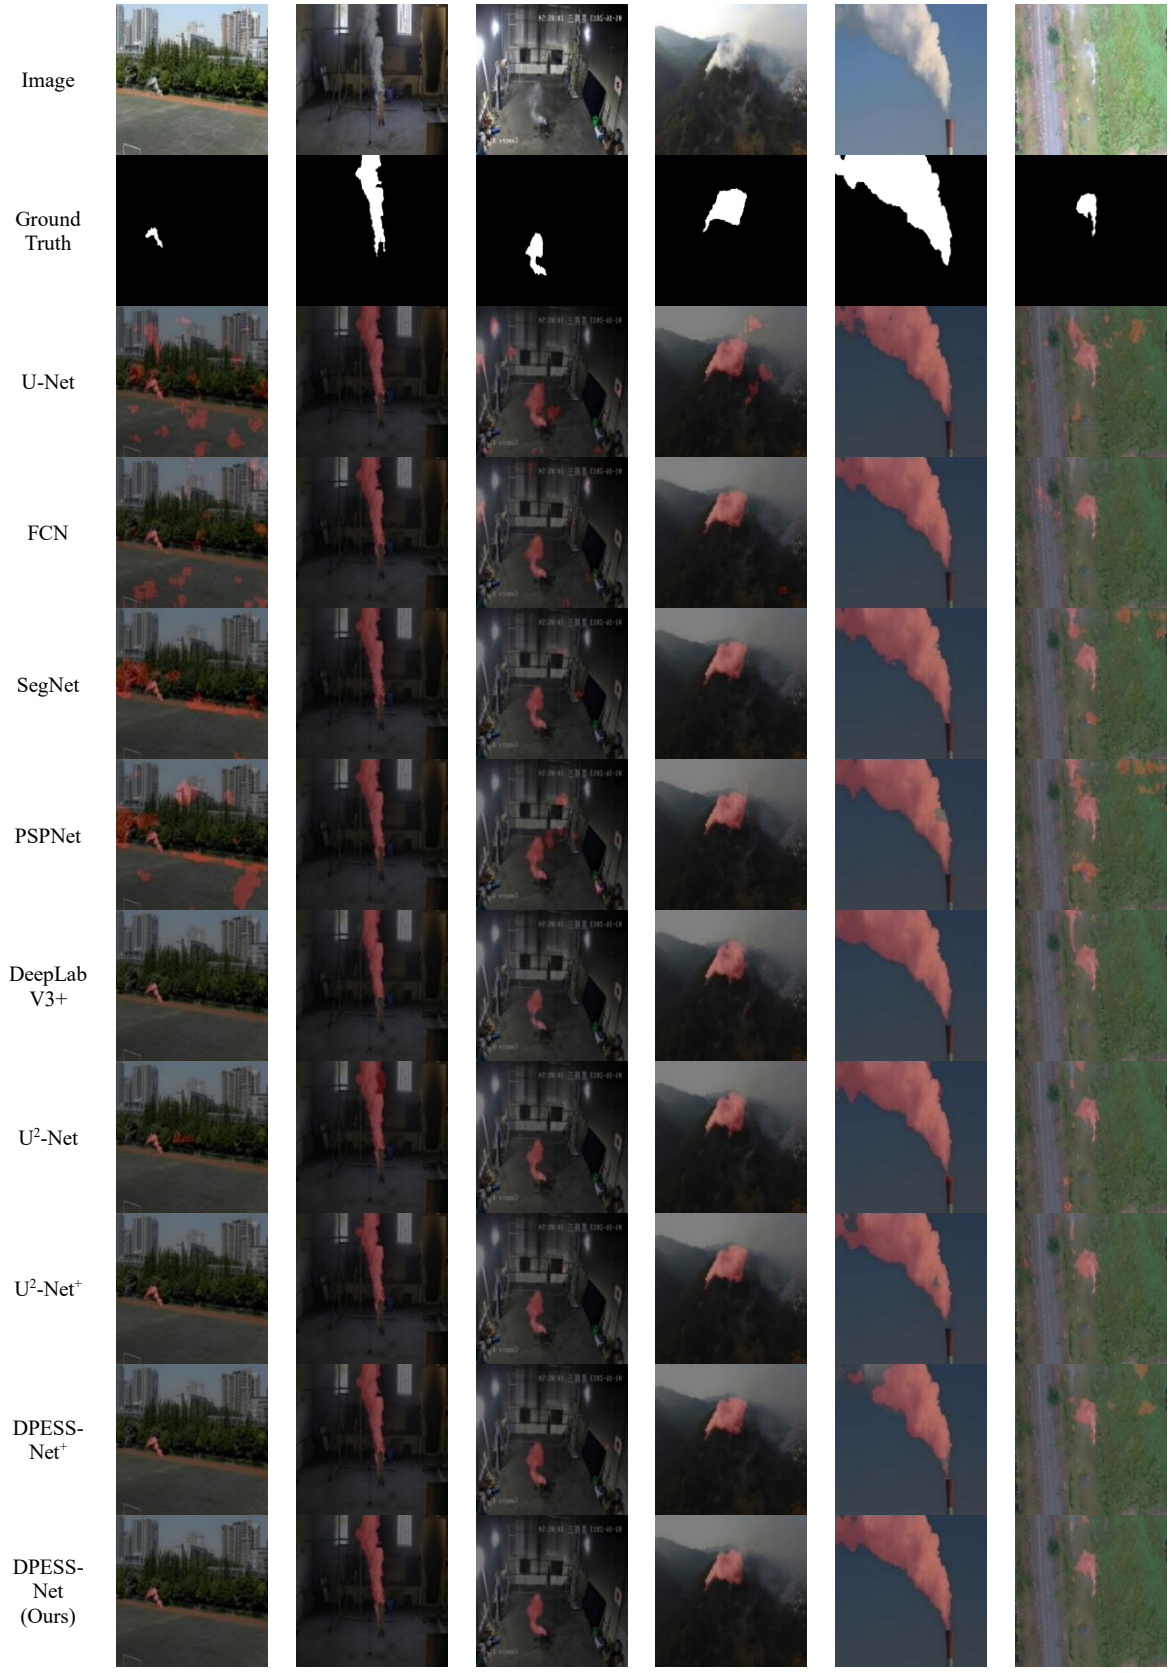

Fig. 8. Comparison of segmentation performance between our proposed method and the other eight models.

DPESS-Net's ability to achieve these results is largely attributed to its dual-channel encoder design, which enables effective information exchange between the channels. The fusion of multi-scale body features and edge-enhanced features further improves the model's ability to capture smoke targets, resulting in higher segmentation accuracy while focusing on both smoke mass and edge details.

As observed in the training process shown in Fig. 7, U-Net maintains a moderate level of performance, while U2-Net slightly outperforms U-Net. FCN, PSPNet, and SegNet exhibit relatively lower segmentation accuracy but higher FPS because their architectures are relatively simple, allowing for faster segmentation speeds. DeepLab V3+, due to its more complex architecture, remains stable with relatively slower segmentation speed. DPESS-Net+, a version of DPESS-Net with the number of channels reduced to 64, decreases the parameter count and model size, improving efficiency at the cost of slightly lower accuracy.

To more intuitively display the segmentation accuracy and performance of the models, we present the segmentation results of each model in Fig. 8. From the comparison images, it can be seen that in scenarios with complex backgrounds and small smoke bodies, most segmentation models experience errors and fail to segment the smoke completely. In scenarios with relatively simple backgrounds and clear main subjects, most models are able to segment the main body of the smoke; however, the details along the edges are not segmented as clearly.

In many scenes, DPESS-Net outperforms the other models, showing minimal segmentation errors. It achieves complete smoke body segmentation with clear edge details, meeting the segmentation accuracy requirements for smoke semantic segmentation as discussed in this paper. Therefore, DPESS-Net is selected as the smoke segmentation solution for the smoke source localization method.

B. *Experimental Results of Smoke Source Localization*

During the modeling process of the concentration model, it was found that the concentration modeling for single-target smoke is relatively stable and can accurately find the area with the highest concentration. However, in case of multi-target smoke, the results of the smoke segmentation model often show multiple smoke targets, which may be connected if the distance between the smoke targets is too small, and this has led to leakage detection in the concentration model when inferring the smoke source area. For this situation, we output the prediction results of YOLOv8n smoke region detection at the same time to maximize the accuracy of the algorithm. The results of the concentration model construction and the results of the smoke source localization algorithm are shown in Fig. 9 and Fig. 10.

V. Conclusions

This paper presents a smoke source localization method based on smoke segmentation, aimed at improving the precision of smoke source localization. Firstly, the paper compares and analyzes various mainstream smoke segmentation models, evaluating their performance in practical applications, and ultimately selects the most suitable segmentation model as the core algorithm. This model effectively extracts the morphological and concentration distribution characteristics of smoke, which are then used for reverse inference of the smoke diffusion process. Combined with a smoke source detection algorithm, the paper achieves high-precision localization of the smoke source. The core of this method lies in utilizing the results of smoke segmentation to correlate the dynamic diffusion

process of smoke with the source point, thereby enabling accurate trace-back localization.

From a practical perspective, this method has significant potential in enhancing early fire detection systems and industrial safety monitoring by providing accurate smoke source localization in complex environments. However, the proposed method still relies heavily on high-quality segmentation results, and its performance in extremely noisy or occluded scenarios requires further investigation. Additionally, the computational cost of the current algorithm may pose challenges for large-scale or real-time applications, which calls for future optimizations.

Future research will focus on two key areas of optimization: first, further improving the processing speed of the segmentation model to meet real-time application requirements; and second, enhancing localization accuracy in multi-target scenarios to ensure efficient and precise smoke source identification in complex environments. Additionally, efforts will be made to simplify the algorithmic process of source localization to reduce computational complexity and improve the system's applicability.

Looking ahead, integrating this method with other data sources, such as thermal imaging or environmental sensors, could further enhance its robustness and adaptability. The continued advancement of AI and IoT technologies also holds promise for creating more intelligent and efficient smoke detection systems. By addressing these challenges and leveraging these opportunities, the proposed method can serve as a foundation for more reliable and effective safety warning systems in the future.

Detecting GPS Spoofing Attacks Using Corrected Low-Cost INS Data with an LSTM Network

Mohammed AFTATAH, Khalid ZEBBARA
IMISR Laboratory, FSA Ait Melloul, Ibn Zohr University, Agadir, Morocco

***Abstract*—With the emergence of new technologies ranging from smart cities to the Internet of Things (IoT), many objects rely on satellite-based navigation systems, such as GPS, to accomplish their tasks securely. However, GPS receivers are exposed to various unintentional and intentional attacks, threatening the availability and reliability of the delivered information. GPS spoofing is considered as one of the most dangerous attacks, where attackers transmit intense signals on the same frequency to disrupt the GPS receiver, leading to erroneous position calculations. Detection methods for GPS spoofing are crucial to ensure secure navigation. This paper proposes a method for GPS spoofing detection that utilizes artificial intelligence algorithms in combination with raw data from an inertial navigation system (INS). Since INS sensors are prone to accumulating errors over time, these inaccuracies are corrected via a Long Short-Term Memory (LSTM) algorithm. The corrected accelerations and angular rates are then compared to the accelerations and angular rates estimated from the GPS data to detect GPS spoofing signals. This comparison uses the modified M-of-N method, demonstrating its effectiveness by a detection rate reaching 80% of the spoofing zones.**

***Keywords*—Secure navigation; GPS spoofing; inertial systems; LSTM; M-of-N method; anti-spoofing techniques**

I. Introduction

In the era of recent technologies such as smart cities and IoT, Global Navigation Satellite Systems (GNSS), including GPS, play a pivotal role in delivering navigation information, time, and location, which are essential for the security of systems relying on such information [1]. GPS is a constellation of satellites orbiting the Earth at approximately 20,200 kilometers of altitude. These satellites continuously transmit signals to the Earth's surface, which are received by GPS receivers to determine precise locations and time information.

However, this reliance on radio signals introduces a significant vulnerability: the susceptibility to interference and malicious attacks. One of the most concerning types of attacks is GPS spoofing. This attack broadcasts false GPS signals that deceive the receiver into calculating incorrect position or time. This exploitation poses a serious threat to the integrity and security of GPS-based systems, especially in safety-critical applications such as autonomous vehicles, aviation, and drones.

In response to this growing threat, there is an urgent need to develop robust detection methods to secure GNSS from spoofing attacks. This work proposes a novel method that integrates inertial data with an LSTM network to detect the GPS spoofing attack and ensure secure navigation for GPS-dependent systems.

The structure of the rest of this paper is as follows: The introduction of the study, the review of related work, the research gaps, and the discussion of associated challenges are detailed in Section I. Section II outlines our approach to simulate the IMU sensors, followed by the mechanization process to derive navigation data. Section III focuses on GPS vulnerabilities, particularly spoofing attacks, which are examined in detail. Section IV presents our proposed approach to recognize GPS spoofing attacks using the LSTM algorithm, INS raw data, and the M-of-N method. Section V demonstrates the performance of our approach in a simulated transport scenario. Section VI concludes the paper, while Section VII explores future directions for this research.

A. Existing Work

During the last decade, diverse works have been published in the literature dealing with the problems of detecting, identifying, and mitigating intentional and unintentional attacks on satellite-based systems such as GPS. Intentional attacks include both jamming and spoofing attacks [2] [3] [4] [5]. For example, the authors of study [6] developed a covert spoofing algorithm for UAVs using a GPS/INS-integrated navigation system. The method involves estimating the UAV's current state using external sensors and calculating a spoofing control input to guide the UAV toward a deceptive trajectory while making it appear as if it is following its original reference trajectory. The proposed algorithm was validated through simulations, demonstrating that the UAV can be covertly spoofed by making its estimated position remain near the reference trajectory, while its actual path deviates towards the deceptive target state. The results showed effective trajectory manipulation with minimal disruption to the UAV's original path. To overcome these issues, numerous research studies were developed employing various techniques of machine learning, including Artificial Neural Networks (ANN) and Support Vector Machine (SVM), to evaluate their effectiveness in identifying spoofed signals [7].

The authors of study [8] developed an approach based on machine learning called PERDET for detecting GPS spoofing attacks in unmanned aerial vehicles (UAVs). This method utilizes perception data collected from real flight experiments, including both normal and attacked scenarios, to enhance the detection capabilities against GPS spoofing. The authors performed feature analysis based on the principles of position and attitude estimation, selecting relevant sensor data types to improve the accuracy of their detection model. They concluded that PERDET outperformed in terms of effectiveness compared to various machine learning algorithms after applying them to their dataset.

In study [9], the authors developed a method for detecting GNSS signal spoofing based on supervised machine learning. The technique used includes SVM and Principal Component Analysis (PCA) for identifying manipulated GNSS signals. The SVM model achieved high performance in the experiments, with over 98% accuracy. However, the paper notes a potential challenge with model complexity, which may result in longer computation times.

Sun et al. [10] developed a method for GPS spoofing detection, specifically designed for small UAVs, based on deep learning techniques. They proposed a model combining a PCA, a Convolutional Neural Network (CNN), and an LSTM to enhance the detection accuracy. The approach was validated using a dataset acquired from UAV flights with normal and spoofed GPS signals, achieving an accuracy of 99.49%. In contrast, the primary gap identified in this paper is the challenge of adapting the model to real-world environments.

In 2020, Kwon and Shim [11] exploited Attitude and Heading Reference System (AHRS) accelerometers to develop a direct GPS spoofing detection method. This method involves a comparison between the acceleration estimated from the GPS receiver and the acceleration generated by the accelerometers to detect potential spoofing. The results indicated that both decision variables showed strong detection capabilities under different spoofing scenarios. However, the gap identified in this paper lies in the sensitivity of the decision variables to changes in moving acceleration.

In study [12], the authors developed a GPS spoofing detection method using a tightly coupled Receiver Autonomous Integrity Monitoring (RAIM) with INS integration. The method monitors discrepancies between GPS and inertial measurements, using residual-based RAIM techniques. This approach utilizes an integrated GPS/INS architecture with a tightly coupled Kalman filter to improve sensitivity to spoofing attacks. The results demonstrated that the RAIM monitor effectively detected short-duration spoofing attacks.

Shafique et al. [13] used two machine-learning techniques, SVM and K-fold analysis, for GPS spoofing detection. Various machine-learning algorithms were tested, and SVM with a polynomial kernel achieved the best results. Multiple metrics were utilized to evaluate the proposed, including accuracy, precision, recall, and F1-score, achieving an overall accuracy of 99%. However, the gap identified is that the method's performance may degrade with noisy data and might not be robust against highly sophisticated spoofing attacks.

The authors of study [14] designed a method, for detecting GPS spoofing attacks on Unmanned Aerial Systems (UAS), based on supervised machine learning. The proposed approach leverages an ANN model to classify GPS signals as genuine or spoofed using extracted features such as pseudo-range, Doppler shift, signal-to-noise ratio (SNR), and satellite vehicle number (SVN). The results showed that the ANN model with two hidden layers provided high detection accuracy, achieving up to 98.3% accuracy and a probability of detection of 99.2% with a low probability of false alarms. However, a primary gap identified in the study is that the model's performance is highly dependent on the quality of the collected GPS data.

B. Research Gaps and Challenges

Despite the increasing use of low-cost INS in navigation applications, these sensors suffer from high error rates and limited accuracy, making them unreliable in scenarios involving GPS spoofing or jamming. Current methods to address these issues heavily depend on high-grade INS, which are expensive and not feasible for large-scale adoption. This highlights a significant gap in the availability of robust, low-cost solutions that can maintain high accuracy. Additionally, many approaches lack adaptability to real-time changes in error characteristics, particularly during GPS spoofing or jamming events, making them less effective in dynamic environments.

To address these challenges, our research focuses on developing a methodology for enhancing the quality of low-cost INS data by employing LSTM networks, using tactical-grade INS as a reference. The developed simulation platform in MATLAB enables researchers to build and validate their solutions based on our sensor modeling approach. This platform can simulate various scenarios without the need for complex infrastructure or expensive real-world setups involving GPS receivers and sensors mounted on vehicles. This flexibility makes it easier to test multiple configurations and spoofing scenarios efficiently. Successfully addressing these challenges will provide a practical and accessible platform for reliable navigation in GPS-compromised environments.

II. Inertial Navigation Simulation and Mechanization

A. INS Simulation

In this study, a real INS was not used; instead, a simulated one was employed, with errors affecting its sensors taken into consideration. This section presents the simulation of the six sensors of the Inertial Measurement Unit (IMU). Typically, a real INS is mounted on a mobile platform during a trajectory, measuring accelerations and angular rates [15]. However, in this case, we assume the availability of the real trajectory coordinates and proceed to simulate the behavior of the sensors accordingly. This allows us to replicate how the IMU would function in a real-world scenario, accounting for sensor errors without using an actual INS.

To model INS sensors, two main frames are used to represent the sensor outputs, the navigation frame and the body frame [16]. The body frame represents local coordinates relative to the vehicle [17], while the navigation frame aligns with the Earth's coordinate system [18]. Table I explains the differences between these frames, including their axes, alternative names, and reference centers.

TABLE I. Differences Between the ENU Frame and the Body Frame

Characteristic	Body frame	Navigation frame
Axes	X(Longitudinal), Y (Lateral), and Z (Vertical)	East (E), North (N), and Up (U)
Alternative name	Local frame, vehicle frame, or b-frame	ENU frame or n-frame
Reference Center	Center of the vehicle or mobile object	Earth's surface

The equations that model the outputs of the three orthogonal accelerometers and the three orthogonal gyroscopes in the navigation frame can be expressed using the following equations (1) (2) (3) [19].

$$\begin{bmatrix}\varphi\\ \theta\\ \psi\end{bmatrix} = \begin{bmatrix} \dfrac{\partial\left(\arctan\dfrac{\partial N/\partial t}{\partial E/\partial t}\right)}{\partial t} \\ \dfrac{\partial\left(\arctan\dfrac{\partial U/\partial t}{\partial E/\partial t}\right)}{\partial t} \\ \dfrac{\partial\left(\arctan\dfrac{\partial U/\partial t}{\partial N/\partial t}\right)}{\partial t} \end{bmatrix}^{n} \tag{1}$$

$$\begin{bmatrix}p\\ q\\ r\end{bmatrix}^{b} = \left(\begin{bmatrix} 1 & \dfrac{\sin\varphi\sin\theta}{\cos\theta} & \dfrac{\cos\varphi\sin\theta}{\cos\theta} \\ 0 & \cos\varphi & -\sin\varphi \\ 0 & \dfrac{\sin\varphi}{\cos\theta} & \dfrac{\cos\varphi}{\cos\theta} \end{bmatrix} * \begin{bmatrix}\dot{\varphi}\\ \dot{\theta}\\ \dot{\psi}\end{bmatrix}\right)^{-1} \tag{2}$$

$$\begin{bmatrix}f_E\\ f_N\\ f_U\end{bmatrix}^{b} = \frac{\partial}{\partial t}\left(C_n^b \begin{bmatrix}\dfrac{\partial E}{\partial t}\\ \dfrac{\partial N}{\partial t}\\ \dfrac{\partial U}{\partial t}\end{bmatrix}^{n}\right) - C_n^b\begin{bmatrix}0\\0\\g\end{bmatrix} + \begin{bmatrix}0 & -r & q\\ r & 0 & -p\\ -q & p & 0\end{bmatrix} * C_n^b \begin{bmatrix}\dfrac{\partial E}{\partial t}\\ \dfrac{\partial N}{\partial t}\\ \dfrac{\partial U}{\partial t}\end{bmatrix}^{n} \tag{3}$$

The components of Eq. (1), (2), and (3) are detailed in Table II.

TABLE II. DESCRIPTION OF EQUATION COMPONENTS FOR IMU MODELING

Equation component	Description/Meaning
[φ, θ, ψ]	Euler angles
[E, N, U]	3D position in the ENU frame
t	Time
[p, q, r]	Angular velocity
$\left[\dot{\varphi}, \dot{\theta}, \dot{\psi}\right]$	Time derivative of the Euler angles
$\left[f_E, f_N, f_U\right]$	3D linear acceleration
C_n^b	Transformation matrix from n-frame to b-frame

B. INS Mechanization

Once the sensors are simulated, their outputs can be generated using any predefined trajectory. The simulated sensor outputs include specific forces and angular rates. These outputs are processed through the mechanization equations to compute position, velocity, and orientation of the mobile. The mechanization equations integrate the sensor data over time, allowing for the continuous update of the navigation solution. These equations are given by Eq. (4) [20] [21] [22].

$$\begin{pmatrix}\dot{r}^n\\ \dot{v}^n\\ \dot{C}_b^n\end{pmatrix} = \begin{pmatrix} D^{-1}v^n \\ C_b^n f^b - (2\Omega_{ie}^n + \Omega_{en}^n)v^n + g^n \\ C_b^n(\Omega_{ib}^b - \Omega_{in}^b)\end{pmatrix} \tag{4}$$

Where,

r^n presents the position components in terms of latitude, longitude, and height;

v^n is the velocity;

C_n^b is a 3x3 conversion matrix from the ENU frame to the body frame;

f^b are the raw accelerations in the body frame;

g^n is the gravity.

The specific forces are integrated twice to derive the position in the body frame. Following this, the angular rates play a crucial role in calculating the transformation matrix, which is used to convert the values from the b-frame to the ENU frame. This transformation is key to ensuring that the navigation information, such as position and velocity, is expressed correctly relative to the Earth or the navigation frame. The process of INS mechanization is detailed in Fig. 1, illustrating the steps involved in converting raw IMU data into usable navigation data.

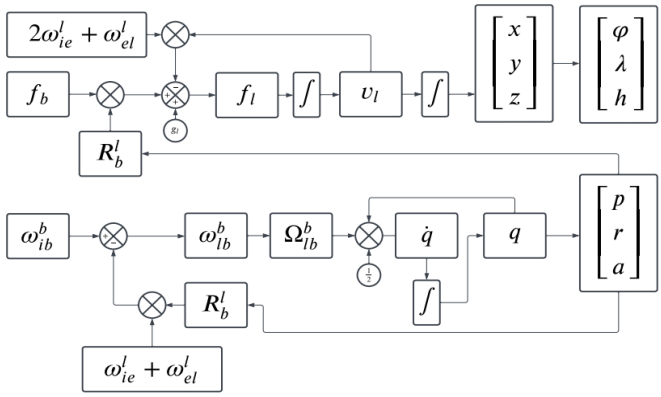

Fig. 1. Illustration of the INS mechanization process [23] [24].

III. GPS SPOOFING

Radiofrequency technologies are widely used to offer mobility and cost-effectiveness for numerous applications. GPS, one of the most in-demand navigation systems, relies on electromagnetic waves for positioning and navigation. However, this reliance on electromagnetic signals makes GPS

highly vulnerable to various attacks. These vulnerabilities can be categorized into intentional and unintentional threats. Unintentional threats may arise from environmental interference or signal obstruction. The primary unintentional attacks targeting GPS systems are illustrated in Fig. 2, highlighting the risks associated with GPS's reliance on radio frequencies.

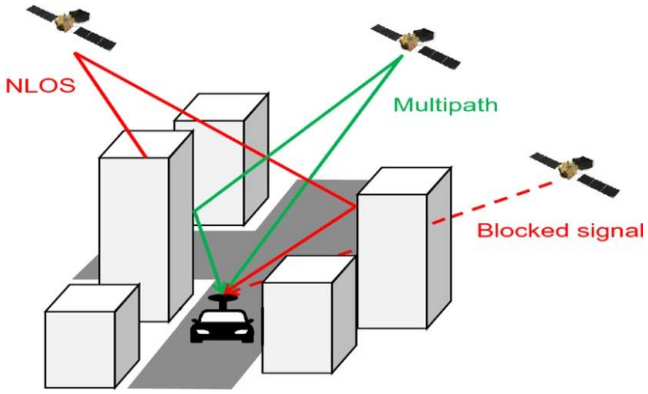

Fig. 2. Primary unintentional attacks targeting GPS [25].

Intentional attacks, often realized by hackers, include jamming and spoofing. Spoofing involves a powerful illegitimate signal transmitted at the same frequency as the legitimate GPS signal, with the intent to disrupt the receiver's ability to calculate the accurate location. The attacker can trick the GPS receiver into accepting false location data, leading to errors in navigation and positioning or reporting incorrect coordinates. The principle behind this spoofing attack is depicted in Fig. 3.

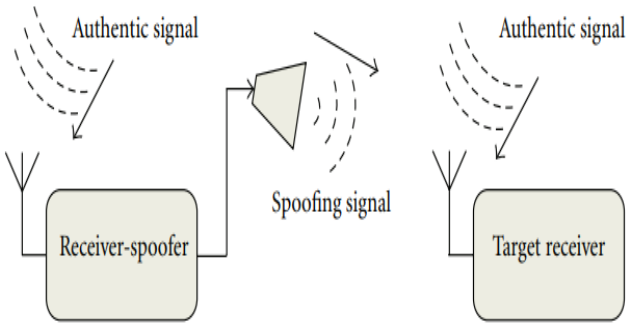

Fig. 3. The principle of the GPS spoofing attack [26].

In a legitimate GPS operation, the pseudo-range is the calculated distance between the receiver and the satellite, based on the time it takes for the satellite signal to reach the receiver. The legitimate pseudo-range to satellite *i* can be represented as Eq. (5).

$$\rho_i = c.(t_r - t_s^i) \tag{5}$$

Where ρ_i is the true pseudo-range to satellite i, c is the light's speed, t_r is the time of signal reception, and t_s^i is the time of signal transmission from the satellite i.

When a spoofing signal is introduced, the receiver detects a false signal that leads to an altered pseudo-range $\rho_i^{'}$ given by Eq. (6).

$$\rho_i^{'} = c.(t_r - t_s^{'i}) \tag{6}$$

Where $t_s^{'i}$ is the fake time of transmission introduced by the spoofer. This new pseudo-range $\rho_i^{'}$ deviates from the true pseudo-range ρ_i, causing the receiver to calculate an incorrect position. The difference between the true and spoofed pseudo-ranges, $\Delta\rho_i$, can be expressed as Eq. (7).

$$\Delta\rho_i = \rho_i^{'} - \rho_i = c.(t_s^i - t_s^{'i}) \tag{7}$$

IV. LSTM AND M-OF-N METHOD

A. LSTM Model

LSTM is a deep learning network belonging to the Recurrent Neural Networks (RNNs) family. It is particularly preferred when dealing with sequential data, such as INS measurements, effectively capturing long-term dependencies in time-series data, unlike traditional neural networks or deep neural networks. Fig. 4 illustrates the main structure of a basic LSTM unit. As shown in the following figure, this unit consists of three gates: the input gate, the forget gate, and the output gate.

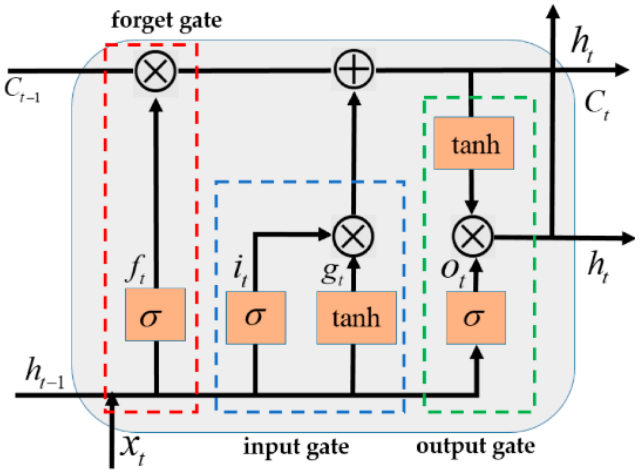

Fig. 4. Structure of a basic LSTM unit with input, forget, and output gates [27].

The input gate controls the information entering the cell state, the forget gate determines which information should be discarded from the memory, and the output gate decides which information is sent to the output. Eq. (8) (9) (10) (11) (12) give the LSTM-specific formulas [27] [28].

$$f_t = \sigma.(x_t W_{xf} + h_{t-1} W_{hf} + b_f) \tag{8}$$

$$i_t = \sigma.(x_t W_{xi} + h_{t-1} W_{hi} + b_i) \tag{9}$$

$$o_t = \sigma.(x_t W_{xo} + h_{t-1} W_{ho} + b_o) \tag{10}$$

$$c_t = f_t.c_{t-1} + i_t.g_t \quad (11)$$

$$h_t = o_t.\tanh c_t \quad (12)$$

B. M-of-N Method

In this study, we employ a modified M-of-N method to enhance the detection of GPS spoofing through the fusion of INS and GPS data. This approach compares sensor measurements from both systems and evaluates whether at least *M-of-N* measurements remain within an acceptable threshold. Deviations beyond this threshold are flagged as potential GPS spoofing events. Unlike traditional methods, the modified M-of-N approach incorporates tolerance for minor deviations arising from sensor noise and environmental factors, which are common in real-world scenarios. This method is based on calculating key statistical metrics such as the residual error E_k, the standard deviation σ_k, and a predefined confidence threshold C. These metrics help in determining whether the discrepancies between GPS and INS measurements are significant enough to be classified as spoofing or normal deviations due to noise. The equations used in this approach are as follows (13) (14).

$$E_k = \left| GPS_k - INS_k \right| \quad (13)$$

$$\left(\sigma_k\right)^2 = \frac{1}{n}\sum_{i=1}^{n}\left(E_i - \mu\right)^2 \quad (14)$$

Where E_k is the absolute difference between the GPS estimated measurement at the time step k and the corresponding INS measurement, σ_k is the standard deviation of the residual errors over a window of size N, and μ is the mean of the residual errors in that window. Furthermore, the threshold is expressed as Eq. (15).

$$Th = C \cdot \sigma_k \quad (15)$$

This threshold helps to distinguish between normal measurement deviations and significant anomalies caused by GPS spoofing. If the residual error E_k exceeds this threshold, a potential spoofing event is flagged.

In this study, we fix $C = 3$ to balance between sensitivity and false alarm rate. In a Gaussian distribution, a threshold of 3σ encompasses 99.73% of all normal data, meaning that only 0.27% of residual errors are expected to exceed this threshold due to noise. This makes the system sensitive to significant deviations while minimizing false alarms. Using a lower value, such as $C = 2$, would increase the sensitivity but also result in a higher false alarm rate, as 4.55% of the data would exceed the threshold, potentially flagging benign deviations as spoofing. Conversely, a higher value, such as $C = 4$, would further reduce the false alarm rate but could make the system less sensitive, missing smaller but meaningful anomalies. Therefore, $C = 3$ is chosen as an optimal value to provide reliable detection while minimizing false positives. The calculated values of E_k and Th are then used to detect the presence of anomalies in the GPS data. The flowchart of the detection process using the modified M-of-N technique is detailed in Fig. 5.

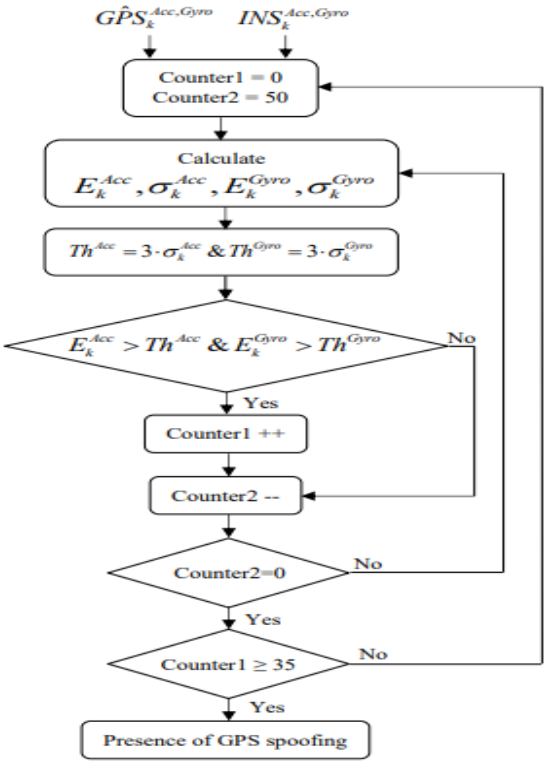

Fig. 5. Flowchart diagram of GPS spoofing detection using modified M-of-N technique.

To reduce false alarms in GPS spoofing detection, a reasonable value for N is 50, meaning spoofing is checked over every window of 50 points. This ensures that approximately 60 regions are covered in the trajectory. The value of M determines the sensitivity of the spoofing detection algorithm. To avoid high sensitivity to false positives due to noise, M is set at 35, around 70-80% of N. This ensures that the method requires a majority of the measurements in each window to exceed the threshold to flag an anomaly, providing a balance between sensitivity and robustness against noise.

V. Proposed Approach

Our proposed method relies on three key factors: corrected raw INS data, a supervised LSTM algorithm, and the modified M-of-N method. First, we model two categories of INS, tactical and low-cost, using the model described in Section I with adjustment of the appropriate characteristics for each category. The data from the tactical-grade INS are used with the LSTM algorithm to correct the raw data from the low-cost INS. Next, the simulated GPS data are employed to estimate accelerations and angular rates. The difference between the corrected low-cost INS data and the GPS-estimated values is then computed. Finally, the M-of-N method is applied to detect GPS spoofing by setting a threshold to identify discrepancies between the two data sources.

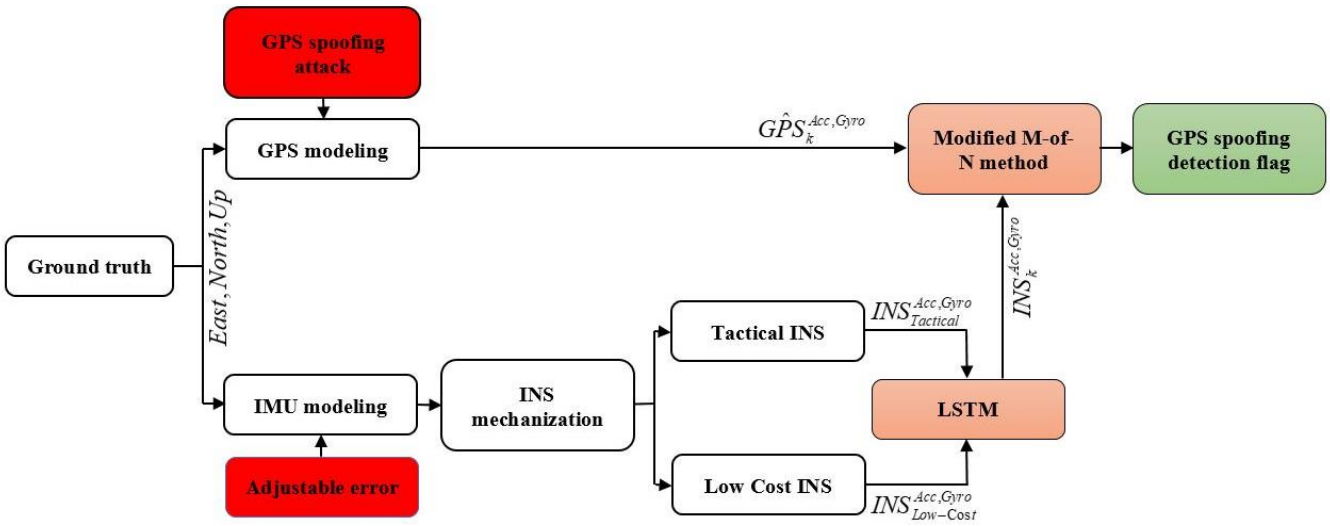

Fig. 6. The proposed approach.

The proposed method is highlighted in Fig. 6, showing the process steps from the initial INS sensor modeling to the final stage of GPS spoofing detection using the modified M-of-N method. The process begins with modeling the tactical and low-cost INS systems, followed by applying the LSTM algorithm for data correction. The simulated GPS data is then integrated to estimate motion parameters, which are compared to the corrected INS data. Discrepancies between these two sources are assessed using the modified M-of-N method, allowing for precise identification of GPS spoofing events.

Algorithm 1 provides a step-by-step description of the developed approach to detect GPS spoofing attacks using corrected inertial data.

Algorithm 1: GPS spoofing detection using corrected INS and modified M-of-N method

Initialization :
- Set Counetr1=0;
- Set Counetr2=50;
- Parameters : M=50, N=35, C=3;

Computation:
While (new data is available) do
  For (each point k of the trajectory) do
  Compute residual errors E_k^{Acc} and E_k^{Gyro}
  Calculate detection thresholds Th^{Acc} and Th^{Gyro}
    If ($E_k^{Acc} > Th^{Acc}$ & $E_k^{Gyro} > Th^{Gyro}$) then
      Increment counter1
    Else
      If (counter2) then
        Decrease counter2
      Else
        Move to the next trajectory point k+1
    If (Counter1≥35) then
      Confirm the presence of GPS spoofing
    Else
      Reinitialize Counter1=0 and reset Counter2=50
  End
  End

VI. Simulation and Results

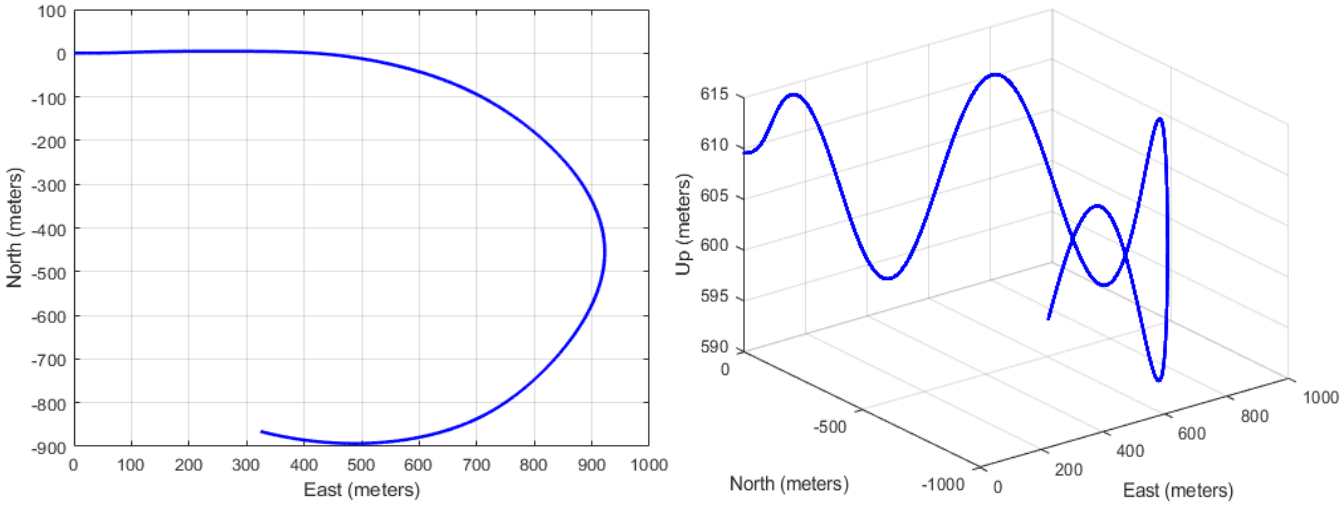
A. Simulation Platform

The experience was conducted using the MATLAB environment. The simulation begins by generating a reference trajectory with a total duration of 50 minutes. This ground truth trajectory incorporates both straight paths and complex curves, along with changes in the vertical (Up) direction, to emulate a realistic urban transportation scenario, as depicted in Fig. 7. These variations aim to reflect the dynamic conditions often encountered in such environments, providing a more accurate representation for evaluating the system's performance in challenging navigation contexts. Additionally, ten spoofing attacks were carried out on the GPS signal at separate intervals along the trajectory.

B. LSTM Correction of Low-Cost INS Data

The key characteristics of the two grades of INS include the levels of bias, scale factor, and noise, which directly affect both the accelerometers and gyroscopes. In this paper, the values were selected based on the specifications of existing and commercially available INS. The main characteristics of each grade of INS are summarized in Table III, highlighting the differences in performance and precision between the low-cost and tactical models.

Using the characteristics of each INS grade and based on the INS modeling equations presented in Section I, we modeled the six sensors composing both the low-cost and tactical INS grades. The result of this modeling process was the simulated outputs of the sensors in terms of specific forces and angular rates. Fig. 8 and Fig. 9 illustrate the comparison between the reference values, the estimated measurements from the low-cost INS sensors, and the estimated measurements from the tactical INS sensors. This comparison highlights the performance differences between the two grades, with the tactical INS showing improved accuracy and lower error margins compared to the low-cost INS.

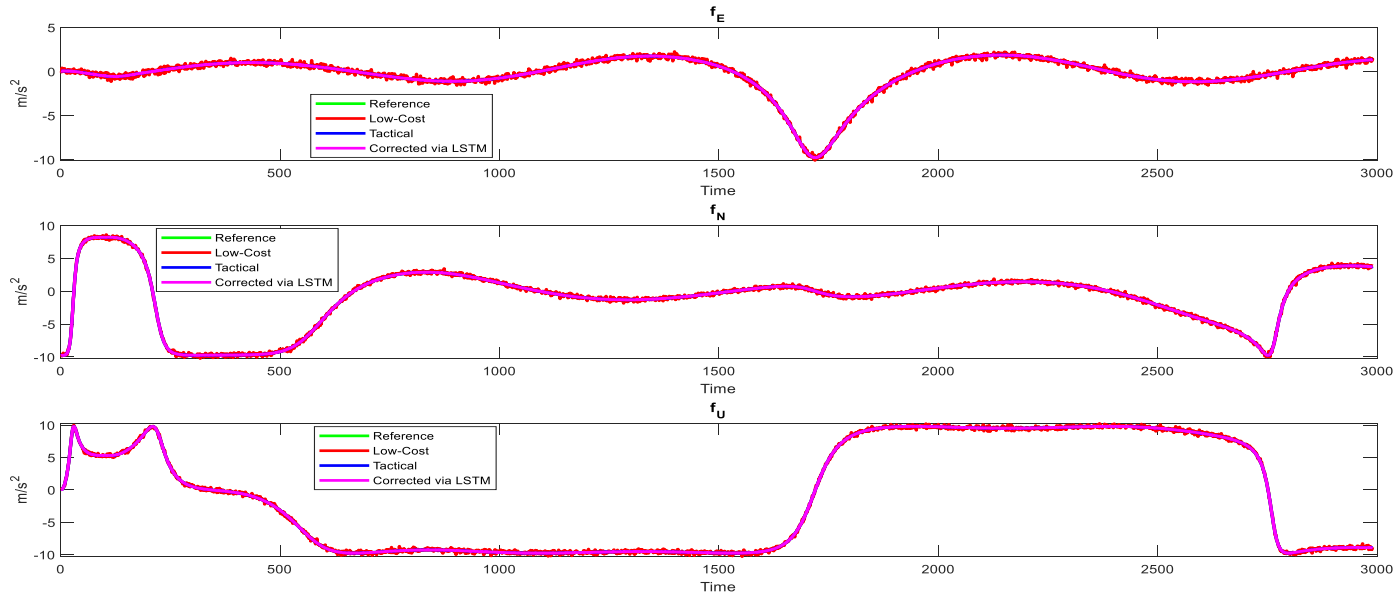


(a) (b)

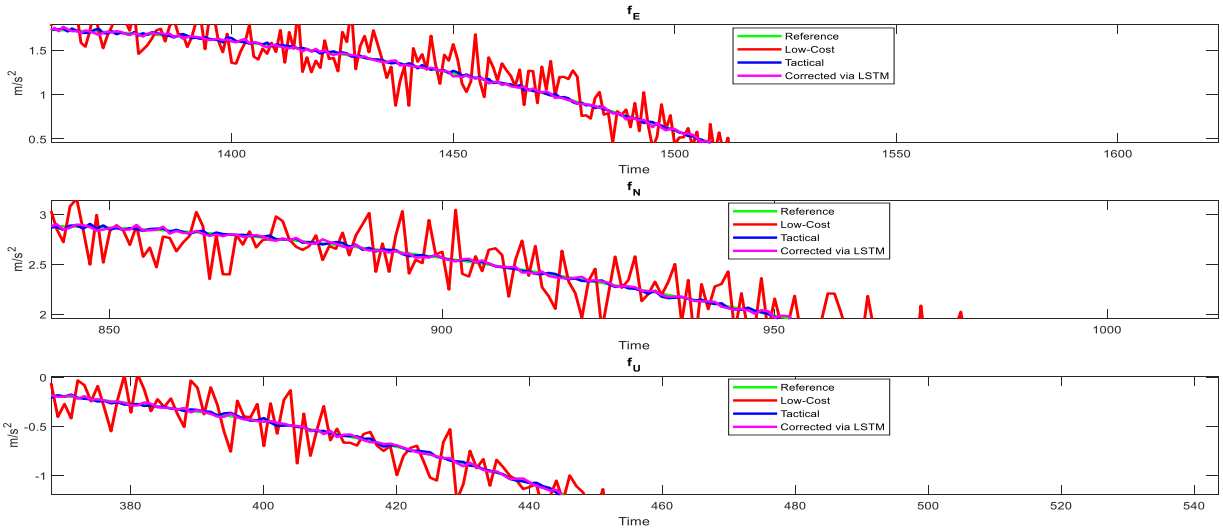
Fig. 7. Reference trajectory for urban transportation simulation: 2D overview (a) and 3D overview (b).

TABLE III. KEY CHARACTERISTICS OF LOW-COST AND TACTICAL INS MODELS [29] [30]

Key characteristics	**INS grade**	
	Low Cost	***Tactical***
Gyroscopes		
Noise	0.1°/s/√Hz	0.01°/s/√Hz
Bias	<±1.5 deg/s	<±0.0055 deg/s
Scale factor	<2%	<0.15%
Accelerometers		
Noise	500 µg/√Hz	50 µg/√Hz
Bias	1 mg	0.1 mg
Scale factor	<1%	<0.4%
Range	±6 g	±10 g

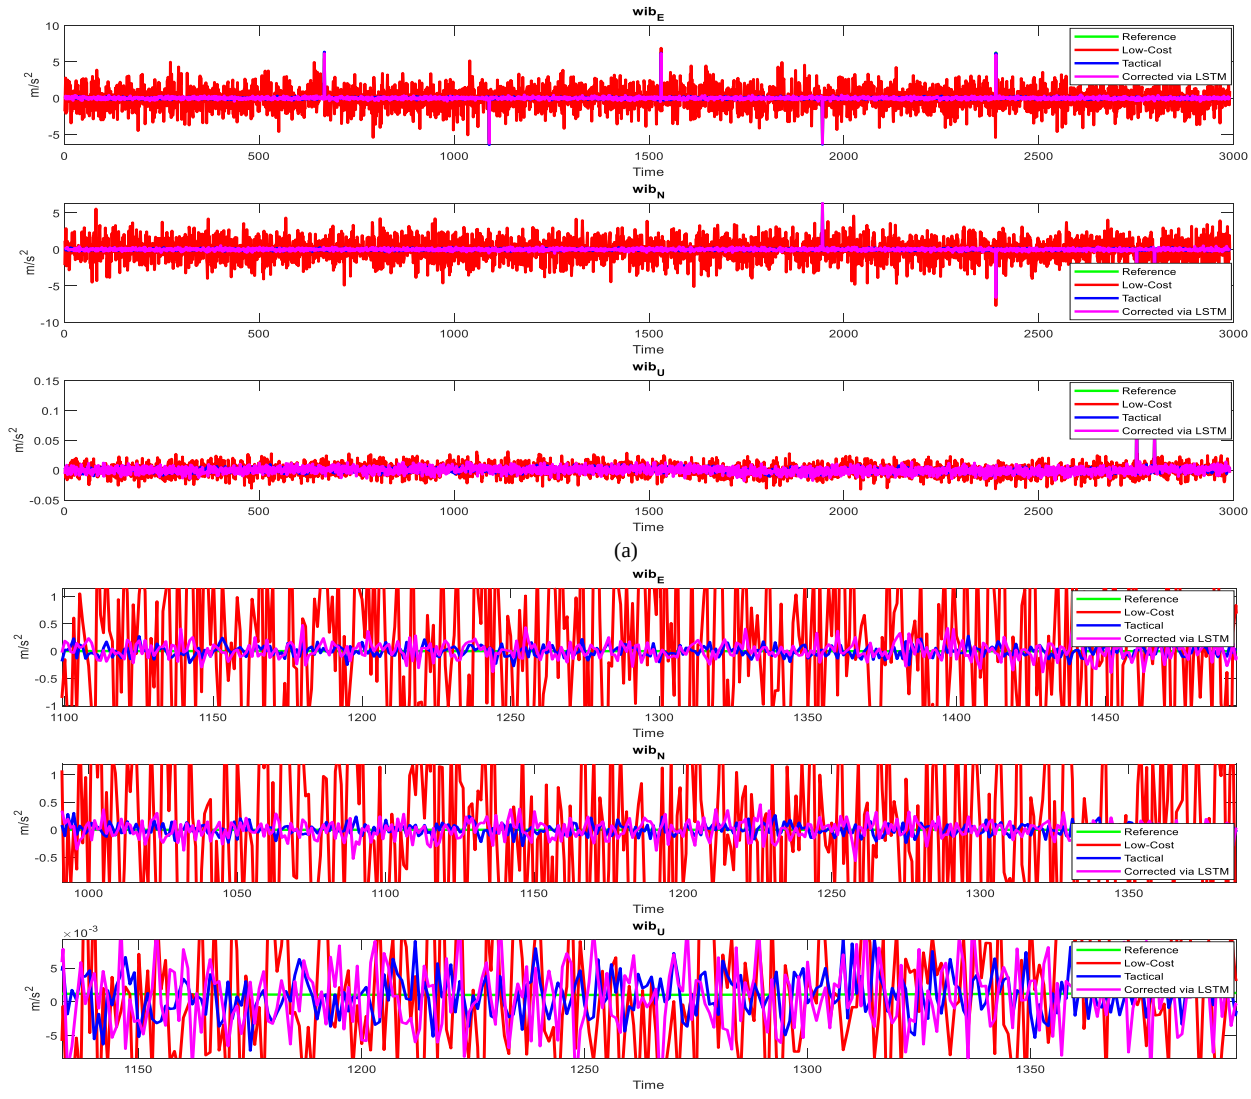


(a)



(b)

Fig. 8. Comparison of accelerometer outputs from reference, Low-Cost INS, tactical INS, and corrected data: (a) Full view and (b) Zoomed-in view.



(a)

(b)

Fig. 9. Comparison of gyroscope outputs from reference, Low-Cost INS, tactical INS, and corrected data: (a) Full view and (b) Zoomed-In view.

The Root Mean Square Error (RMSE) is the metric used to highlight the deviation from the reference for the low-cost INS, the tactical INS, and the corrected data. Table IV presents the calculated metric in the three directions (E, N, and U) for each grade. The equation of this metric is given in Eq. (16) [31].

$$RMSE^2 = \frac{1}{n}\sum_{i=1}^{n}(y_i - \hat{y}_i)^2 \quad (16)$$

Where y_i = Actual value, $\hat{y}_i$ = Estimated value, and n = Number of observations.

TABLE IV. RMSE FOR LOW-COST INS, TACTICAL INS, AND CORRECTED DATA IN EAST, NORTH, AND UP DIRECTIONS

Direction	RMSE					
	Low-Cost INS		*Tactical INS*		*Corrected data*	
	Accelo	*Gyro*	*Accelo*	*Gyro*	*Accelo*	*Gyro*
E (East)	1.97	1.48	0.11	0.10	0.18	0.15
N (North)	2.03	1.52	0.97	0.12	1.04	0.19
U (Up)	2.94	2.13	1.12	0.83	1.68	1.12
Total RMSE	2.36	1.74	0.86	0.49	1.15	0.66

The results show a significant reduction in RMSE values when comparing the low-cost INS to the corrected data via LSTM. The low-cost INS determines higher errors in all directions, with a total RMSE of 2.36 m/s² for accelerometers and 1.74 rad/s for gyroscopes. Due to its higher precision, the tactical INS achieves a notable decrease in RMSE, particularly in the East and North directions, resulting in a total RMSE of 0.86 m/s² for accelerometers and 0.49 rad/s for gyroscopes. The corrected data, representing the application of the LSTM algorithm for error mitigation, shows improved performance over the low-cost INS, with a total RMSE of 1.15 m/s² for accelerometers and 0.66 rad/s for gyroscopes, indicating successful error reduction.

C. GPS Spoofing Detection via M-of-N Method

To test our detection method, we have introduced ten zones of GPS spoofing along the trajectory, each lasting 60 points. Using the corrected accelerations and angular rates with estimated values from GPS, we applied the modified M-of-N method to detect GPS spoofing. As depicted in Fig. 10, the method detected eight of the 10 zones. This indicates good performance in detecting GPS spoofing, achieving a detection percentage of 80%. However, two zones were not detected due to the spoofing signal's similarity to the true GPS data or to the duration of spoofing in these zones, set to 60 points, was insufficient for the method to accumulate the required number of consecutive detections, leading to missed detections. These limitations suggest the need for refining the detection thresholds or increasing sensitivity in specific regions to improve overall performance.

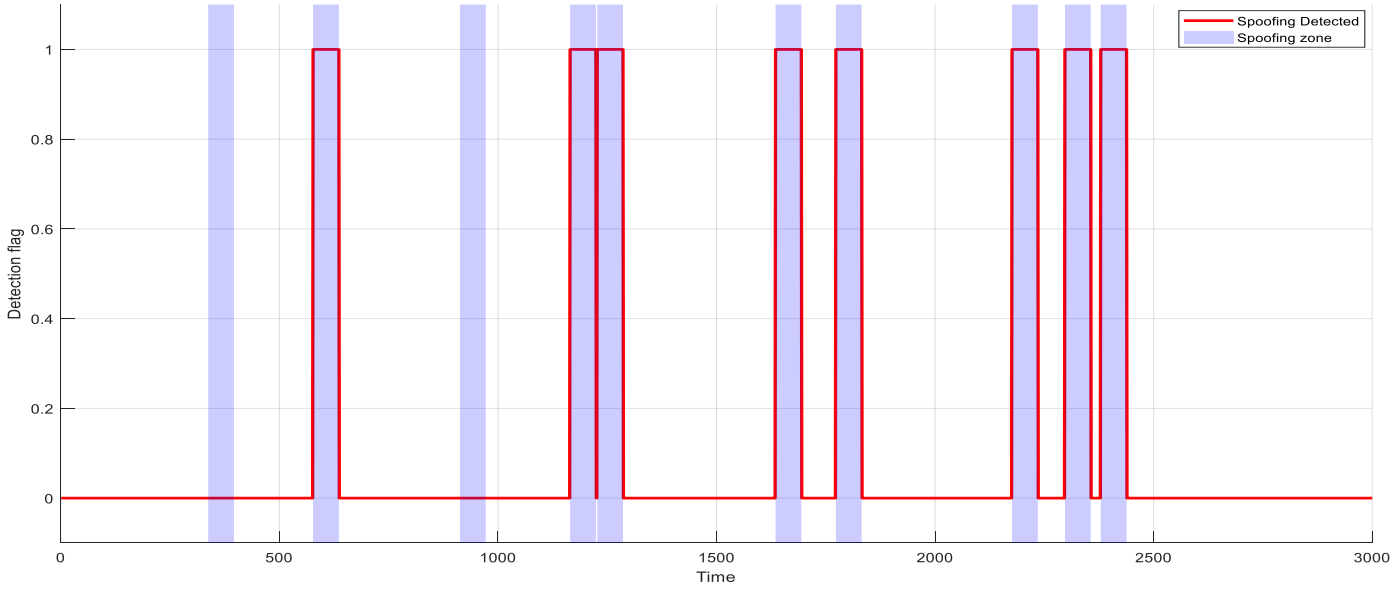


Fig. 10. Detection of GPS spoofing zones along the trajectory.

VII. CONCLUSION

This paper presents a GPS spoofing detection technique that integrates artificial intelligence algorithms with data from INS. By exploiting an LSTM algorithm to correct inherent INS errors, the proposed approach significantly improves the accuracy of the INS measurements, as evidenced by the reduction in the RMSE values. The corrected accelerations and angular rates are used in combination with the modified M-of-N method to detect spoofing by comparing INS outputs with GPS-estimated values. Experimental results demonstrate that the approach successfully detected 80% of the introduced spoofing zones. However, some zones were not detected, likely due to similarities between the spoofed and true GPS signals or the limited duration of the spoofing events, which did not provide enough consecutive detections for confirmation. These findings highlight the potential of the proposed technique but also indicate areas for further refinement, such as optimizing detection thresholds and improving sensitivity in specific segments of the trajectory to achieve reliable spoofing detection in diverse scenarios.

VIII. Future Work

Although the modified M-of-N method demonstrated promising results in detecting GPS spoofing attacks, it revealed certain limitations. One of the main challenges is its sensitivity to transient anomalies, which can lead to false positives in the detection process. To address these limitations, our future work will explore the robustness of both the K-consecutive alarm method and the modified Tong method. We will then compare the performances of these three approaches to identify the most effective solution for GPS spoofing detection.

Time Distributed MobileNetV2 with Auto-CLAHE for Eye Region Drowsiness Detection in Low Light Conditions

Farrikh Alzami*, Muhammad Naufal, Harun Al Azies, Sri Winarno, Moch Arief Soeleman
Faculty of Computer Science, Universitas Dian Nuswantoro, Indonesia

***Abstract*—Driver drowsiness is a critical factor in road safety, contributing significantly to traffic accidents. This study proposes an innovative approach integrating Auto-CLAHE with Time Distributed MobileNetV2 to enhance drowsiness detection accuracy. This study leveraged the ULg Multimodality Drowsiness Database (DROZY) for facial expression analysis, focusing on the eye region. This study methodology involved segmenting videos into 10-second intervals, extracting 20 images per segment, and applying the Haar Cascade method for eye region detection. The Auto-CLAHE technique was developed to dynamically adjust contrast enhancement parameters based on image characteristics. The analysis yielded promising results. Integrating Auto-CLAHE with Time Distributed MobileNetV2 achieved a classification accuracy of 93.62%, outperforming traditional methods including Greyscale (92.55%), AHE (92.91%), and CLAHE (91.13%). Notably, a precision of 93.71% in detecting drowsiness, with a recall of 93.62% and an F1 score of 93.59% were obtained. Statistical analysis using ANOVA and Tukey HSD tests confirmed the significance of present study results. The key innovation of this study is the implementation of Auto-CLAHE, which significantly improves image contrast adaptation. This approach surpasses AHE and basic CLAHE in drowsiness detection performance, demonstrating remarkable robustness across diverse lighting conditions and facial expressions.**

***Keywords*—Driver drowsiness detection; Auto-CLAHE; time distributed; MobileNetV2; eye region analysis**

I. Introduction

Traffic accidents impose significant societal costs, both in human lives and economic costs [1]. Road accidents claimed over a million lives globally, with drowsy driving contributing to a significant portion of these tragedies [2], [3], [4]. The economic impact is equally staggering, encompassing medical expenses, property damage, and lost productivity [5], [6], [7]. Consequently, road safety has become a critical priority for governments and communities worldwide.

Driver drowsiness poses a particular challenge to road safety. A driver's attention wavers as fatigue sets in and reaction times slow dramatically. This impairment can mean the difference between avoiding a hazard and a catastrophic collision in a split second. Interestingly, research by Cai et al. (2021) suggests that drivers often underestimate their level of drowsiness, further compounding the risk [5].

Despite advancements in vehicle safety technologies, the challenge of detecting driver drowsiness in real time remains a pressing concern. Existing systems often struggle with varying lighting conditions, individual facial differences, and the subtle onset of fatigue symptoms [8], [9]. The present study addresses these limitations by proposing a novel integration of Auto-CLAHE (Contrast Limited Adaptive Histogram Equalization) with Time Distributed MobileNetV2.

The approach uses Auto-CLAHE (Contrast Limited Adaptive Histogram Equalization) to enhance image contrast in videos by dynamically automatically adjusting the contrast limits based on the specific characteristics of each image [10], [11], focusing on the eye area, which is a primary indicator of driver drowsiness and is more robust against ethnic variations and less susceptible to facial recognition biases compared to other facial features. Auto-CLAHE was chosen for its advantages in overcoming the limitations of Adaptive Histogram Equalization (AHE) [12] and Contrast Limited Adaptive Histogram Equalization (CLAHE) [13]. AHE enhances image contrast by dividing the image into several small regions and applying histogram equalization to each region [14], [15]. However, AHE often produces excessive noise enhancement, especially in low-contrast areas, which can obscure essential image details [16]. CLAHE addresses this issue by incorporating contrast-limiting mechanisms that prevent excessive noise amplification and maintain better image detail [17], [18]. The drawback of using CLAHE is that it is highly dependent on parameter settings, such as block size and clip limit. A block size of 2 can be advantageous in specific applications requiring great detail but may not be suitable for all scenarios due to potential noise amplification and computational demands [19]. Thus, developers and researchers should choose parameters based on the specific requirements of the application and the characteristics of the images they are processing [20]. Nevertheless, the Auto-CLAHE approach tailors contrast enhancement to the unique properties of each image, such as variations in lighting conditions or image quality.

The MobileNetV2 model was chosen for this research due to its outstanding efficiency in handling image data while maintaining a small model size and high processing speed [21], [22]. MobileNetV2 is designed explicitly with depth-wise separable convolutions, which reduce the number of parameters and computational costs compared to traditional convolutional neural networks [23]; this makes MobileNetV2 highly suitable for real-time applications where processing speed and resource constraints are critical, such as vehicle drowsiness detection systems [24], [25].

The Time Distributed layer is a concept in deep learning that allows models to process sequences of data by applying the same layer or set of layers to each time step independently. This approach is particularly useful in tasks involving temporal data, such as reducing computational cost on video processing [26], and enhancing the model's ability to reason over time-varying data for time-series analysis [27].

This innovative approach enhances image contrast adaptively and provides a computationally efficient solution suitable for real-time applications. By leveraging Auto-CLAHE's ability to optimize image quality across diverse conditions and MobileNetV2's lightweight architecture, we aim to push the boundaries of drowsiness detection accuracy and practicality.

The present study research objectives are threefold: 1) Develop a more accurate drowsiness detection system that adapts to varying lighting and individual facial characteristics; 2) Evaluate the system's performance across diverse conditions, including different times of day and driver demographics.; 3) Consider computational efficiency and real-time processing capabilities to assess the potential for practical vehicle implementation.

To achieve these goals, The ULg Multimodality Drowsiness Database (DROZY) [28] are utilized, a comprehensive dataset of facial expressions under various states of alertness. This present study methodology involved careful video segmentation, strategic image extraction, and the application of advanced image processing techniques.

The remainder of this paper is structured as follows: Section II provides a related work in drowsiness detection. Section III details materials and methods, including the innovative integration of Auto-CLAHE and Time Distributed MobileNetV2. Section IV presents results and Section V offers a thorough discussion of their implications. Finally, Section VI concludes the paper, summarizing key findings and suggesting directions for future research.

Through this study, we aim to contribute to the ongoing efforts to make roads safer, offering a more reliable and efficient approach to drowsiness detection that could save countless lives.

II. Related Work

Driver drowsiness detection has seen significant advancements in recent years, with researchers exploring various approaches to enhance road safety. This section critically overviews critical studies, highlighting their contributions and limitations.

A. Neural Network Approaches

Pattarapongsin et al. (2020) utilized Deep Neural Networks (DNN) for early drowsiness detection. Their method, which incorporated Eye Aspect Ratio (EAR), Mouth Aspect Ratio (MAR), and driver pose estimation, showed promising results in real-time performance [29]. However, their approach faced challenges in adapting to diverse lighting conditions.

Other researchers, such as Jasim (2022), introduced an innovative combination of Artificial Neural Networks (ANN) and the Gray Wolf Optimizer (GWO) algorithm. Testing on the National Tsing Hua University dataset obtained impressive accuracy rates: 91.18% for drowsiness classification and 97.06% for early detection [30]. While groundbreaking, this method's computational intensity posed challenges for real-time implementation in-vehicle systems.

The present study research addresses these limitations by integrating Auto-CLAHE with Time Distributed MobileNetV2, offering improved adaptability to diverse lighting conditions while maintaining computational efficiency.

B. Advanced Video Analysis Techniques

Shen et al. (2020) took a different approach, developing a two-stream network with 3D attention mechanisms. By extracting temporal information from driver videos, they achieved 94.46% accuracy on the NTHU-DDD dataset [19]. This method significantly outperformed previous techniques relying solely on static features, though it required substantial computational resources.

Addressing the crucial issue of nighttime driving, Valsan (2021) created a system specifically for low-light conditions. Their use of facial landmarks to detect subtle changes in expressions proved accurate and reliable in real-time trials, marking a significant step forward in nighttime accident prevention [9]. Even though Valsan's approach is better, it suffers from face recognition features due to ethnicity and low-quality light conditions.

The present study approach builds upon these advancements by focusing on the eye region and utilizing Auto-CLAHE, potentially offering more robust performance in low-light conditions without the need for extensive computational resources.

C. Image Enhancement in Drowsiness Detection

Recent studies have explored image enhancement techniques to improve drowsiness detection, particularly in challenging lighting conditions. Yakno et al. (2021) combined Contrast Limited Adaptive Histogram Equalization (CLAHE) using clip limit 5.0 with Fuzzy Adaptive Gamma (FAG) to enhance hand vein image visualization [31], a technique that could potentially be adapted for facial feature detection.

In a related application, Chen et al. (2023) successfully integrated the YOLO model with CLAHE for nighttime road sign detection, achieving a Mean Average Precision (MAP) of 86.40% [32]. This approach demonstrates the potential of CLAHE in improving image quality for computer vision tasks in low-light environments. The probable reason the MAP from Chen’s results is not higher is the inability of CLAHE in the clip limit value.

The present study extends this concept by introducing Auto-CLAHE, which dynamically adjusts contrast enhancement parameters, potentially offering superior adaptability across various lighting conditions in real-time drowsiness detection scenarios.

D. Algorithmic Innovations

Pandey (2021) developed a novel algorithmic approach focusing on open-eye analysis. By utilizing temporal features

of the eyes and head movement, they achieved 94.2% accuracy in detecting driver drowsiness [33]. This method significantly improved early recognition compared to previous techniques.

Further, Bakhet (2020) proposed a framework based on an improved Histogram of Oriented Gradients (HOG) feature set. Their experimental results showed a detection accuracy of 85.62%, offering a competitive alternative in drowsiness detection [34].

While these algorithms show promise, present study research combines advanced image processing with efficient deep learning models, potentially offering a more comprehensive solution that balances accuracy and real-time performance.

E. Real-Time Approaches

Sharan et al. (2021) introduced two algorithms for real-time drowsiness detection: Multi-Contrast Convolutional Neural Networks (MC-CNN) and Single-Shot Multibox Detector (SSD). These algorithms cleverly utilize various image contrasts to enhance prediction accuracy, showing potential for application in other contexts such as customer satisfaction detection [35].

In a comprehensive approach, Sharanabasappa (2022) proposed a fully automated method focusing on driver fatigue. Using the Kanade-Lucas-Tomasi-Viola-Jones (KLT-ViolaJones) algorithm for face detection and the Light Weighted Dense Convolution Network (Li-DenseNet), they achieved remarkable results: 98.44% accuracy, 91.5% sensitivity, and 92.3% specificity on the NTHU-DDD dataset [36].

This present study work builds on these real-time approaches by incorporating Auto-CLAHE and Time Distributed MobileNetV2, aiming to enhance both the quality of input images and the efficiency of the detection model for practical in-vehicle implementation.

F. Time Distributed Layer

Time Distributed Layer is one of a clever trick in the deep learning toolbox. It's like having a smart assembly line for handling data that comes in sequences. Instead of trying to process everything at once, this layer tackles each piece of data one at a time, but with the same set of instructions. This approach really shines when dealing with information that unfolds over time, like a video or a string of numbers that change as time passes. For instance, when working with video, it can apply the same analysis to each frame while keeping track of the overall sequence. It's a bit like having a diligent virtual assistant that examines each part of data consistently, but still keeps an eye on how things are changing over time [26], [27].

Hu et al. (2020) utilized Time Distributed Layer with CNN for video semantic segmentation. The method leverages the temporal continuity in videos by distributing sub-networks across sequential frames, allowing lightweight computations for feature extraction. [26]. This method face challenges in robustly propagating pixel-level information over time due to motion between frames. This can lead to misalignment and decreased accuracy.

Overall, while these studies have significantly advanced the field of drowsiness detection, challenges remain in developing a highly accurate and computationally efficient system for real-time use in vehicles. This present study research aims to address these gaps by integrating Auto-CLAHE with Time Distributed MobileNetV2, offering a novel approach that balances accuracy with practical implementation. Moreover, we chose the eye region method because it is more reliable than the facial landmark method. Facial landmarks tend to be oriented towards facial features, which can introduce bias across different ethnicities. Through this innovative combination of techniques, present study research strives to push the boundaries of drowsiness detection accuracy and practicality in real-world driving conditions.

III. MATERIALS AND METHODS

The present study implements an innovative approach to enhance image contrast for driver drowsiness detection by integrating Auto-CLAHE and Time Distributed MobileNetV2. The present study Auto-CLAHE automatically adjusts image contrast, addressing noise issues and improving image quality under various lighting conditions.

The image processing workflow, illustrated in Fig. 1, outlines the systematic procedures involved in this research.

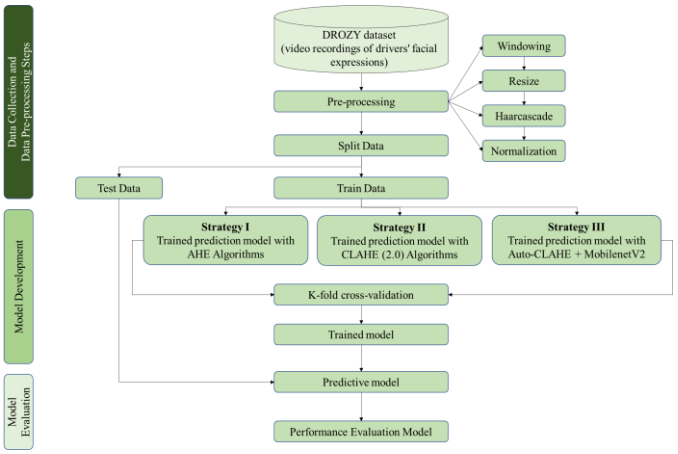

Fig. 1. Workflow of image processing for driver drowsiness detection.

The explanation of Fig. 1 is described in the following subsection. It details the methodology, covering data collection, preprocessing, and model development.

A. Data Collection

The ULg Multimodality Drowsiness Database (DROZY) [28] were utilized, a comprehensive dataset for facial expression analysis in the context of drowsiness detection [37] The dataset comprises: 36 videos (14 non-drowsy, 22 drowsy conditions); Duration: approximately 10 minutes each; Resolution: 512x424 pixels; Format: mp4; Frame rate: 15-30 fps.

Here, the DROZY dataset is unbalanced and relatively small. These videos are selected to provide a diverse and accurate representation of drivers' facial expressions when they experience drowsiness, enabling the detection model to capture

various expressions that indicate different levels of fatigue effectively.

B. Preprocessing

The preprocessing pipeline involves several key steps:

1) Video segmentation: Videos are divided into 10-second segments, capturing critical details within the typical timeframe of microsleeps [38], [39].

2) Image extraction: 20 images were extracted (two per second) from each segment to effectively represent driver facial expressions.

3) Image resizing: Original images were resized from 512x424 to 96x96 pixels, balancing detail preservation with computational efficiency [40].

4) Normalization: Pixel values were normalized with values 255 resulted in 0-1 range, enhancing model performance [41].

5) Eye region detection: The Haar Cascade method were employed with the following parameters:

a) Scale factor: 1.3 to 1.1

b) minNeighbors: 4 to 1

c) minSize: (10, 10)

The justification for selecting these parameters is as follows:

- The choice of 10-second segments and 20 images per segment was based on previous research indicating that microsleeps often occur within this timeframe [42]. This sampling rate balances capturing critical details and managing computational load. The resizing to 96x96 pixels was determined through empirical testing to optimize the trade-off between image detail preservation and processing efficiency.
- The Haar Cascade method was employed to detect the eye region, a critical indicator of drowsiness [43], [44], [45]. Here, we adopt the Haar cascade method from Santana et al. [46]. Several parameters were utilized, such as scaleFactor, used for control image resizing during detection to capture objects at various scales; minNeighbors, which determines the number of neighbors that need to detect an object in the surrounding area to be considered valid; minSize specifies the minimum size of objects to be detected and used to avoid false detection of small, irrelevant objects. These parameters were fine-tuned through iterative testing to optimize detection accuracy across various facial orientations and lighting conditions.

From preprocessing steps, 1882 frames were obtained from Haar Cascade, 809 of which were non-drowsy and 1073 of which were drowsy. Then, split data as 70% for training, 15% for validation, and 15% for testing. Fig. 2 represent visualization of the Haar Cascade Method on Image Data. Auto-CLAHE results on image quality is par with original image.

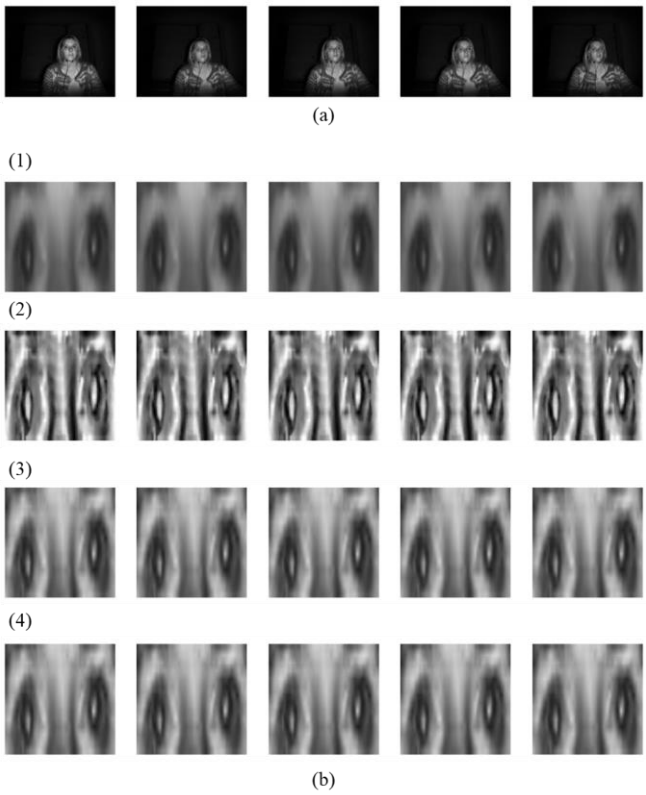

Fig. 2. Visualization of the haar cascade method on image data: (a) Original Image; (b) Results after applying different image processing techniques: (b.1) Greyscale; (b.2) AHE; (b.3) CLAHE; (b.4) Auto-CLAHE.

C. Model Development

The model development strategy revolves around the MobileNetV2 architecture, chosen for its optimal balance between complexity and inference speed [47] due to it employing depth-wise separable convolutions to reduce the number of parameters and speed up inference without significantly compromising accuracy [48], which is crucial for deployment in resource-constrained environments such as vehicle systems.

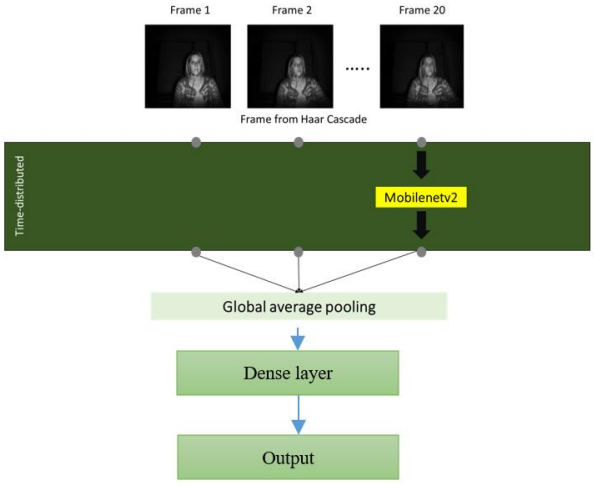

Fig. 3. The proposed architecture.

For the Fig. 3 explanation, three main strategies were explored:

1) AHE Algorithms with MobileNetV2.
2) CLAHE (2.0) Algorithms with MobileNetV2.
3) Auto-CLAHE with MobileNetV2.

For each strategy, MobileNetV2 are configured with:

1) Time Distributed layer processes sequential data, applying the same layer to each time step and maintaining the output in sequence form.

a) Let $X = \{X_1, X_2, \dots, X_T\}$ be the input sequence, where each $X_t \in \mathbb{R}^{H\times W\times C}$ is a frame at time step t. Here T = number of video frames; H, W = Height and width of each frame; C = Number of channels (3 RGB channels).

b) $f(\cdot)$ be the transformation function of the convolutional layer.

Using time Distributed layer, the same transformation $f(\cdot)$ is applied independently to every time step t:

$$Y_t = f(X_t), \forall_t = 1,2, \dots, T \quad (1)$$

Thus, the output for the entire sequence becomes:

$$Y = \{Y_1, Y_2, \dots, Y_T\}, Y_t \in \mathbb{R}^{H'\times W'\times C'} \quad (2)$$

Where H' and W' are the height and width after convolutional transformation.

Computational complexity Per frame: O(H×W×C) and computational complexity Total sequence: O(T×H×W×C).

2) Fine tuning MobileNetV2. Here, the layers were freeze from the beginning until before the last three layers on MobileNetV2. The reason is that DROZY dataset is different from the image weight. The mathematics of MobileNetV2 which core of the efficient model can described as follows:

a) Depth-wise Convolution:

$$DW(i,j,k) = \sum_m \sum_n K(m,n,k) \times X(i+m, j+n, k) \quad (3)$$

Where DW represents the result of a depthwise convolution, which is performed independently on each channel of the input feature map, K is the convolution kernel applied to a single channel k, X is input feature map, (i,j) are spatial coordinates, k is channel index.

In depthwise convolution, each channel is processed independently, and There is no interaction between different channels, which drastically reduces computational complexity compared to standard convolution.

b) Point-wise Convolution:

$$PW(i,j,n) = \sum_k DW(i,j,k) \times P(k,n) \quad (4)$$

Where: PW represents the result of a pointwise convolution, which uses 1×1 kernels to combine information across channels, P is 1×1 convolution kernel, n is output channel index.

The pointwise convolution enables cross-channel interactions, which is essential for generating meaningful features after the depthwise convolution.

c) Total Operations:

In standard convolution, we can see the equation as follows:

$$standard\ conv = H \times W \times C_{in} \times C_{out} \times K \times K \quad (5)$$

Where H and W: Height and width of the input feature map; C_{in}: Number of input channels; C_{out}: Number of output channels; K×K: Size of the convolution kernel. Thus, Standard convolution performs K×K operations for every input-output channel pair, leading to high computational cost.

$$MNetV2 = DWC + PWC \quad (6)$$

Subject to

$$\text{DWC} = (H \times W \times C_{in} \times K \times K) \quad (7)$$

$$PWC = (H \times W \times C_{in} \times C_{out}) \quad (8)$$

Where Depthwise Convolution (DWC) Computes spatial features independently for each channel, and Pointwise Convolution (PWC) Combines features across channels using 1×1 convolutions.

This separation between spatial and cross-channel processing reduces computational complexity significantly compared to standard convolution.

$$reduction\ factor = \left(\frac{1}{C_{out}} + \frac{1}{K^2}\right) \quad (9)$$

Where C_{out}: Number of output channels; and K^2: Kernel size squared (e.g., for a 3×3 kernel, K^2=9).

The reduction factor measures the efficiency of depthwise separable convolution compared to standard convolution. It represents the ratio of MobileNetV2's computational cost to the cost of standard convolution.

MobileNetV2 is efficient due to replaces the computationally expensive standard convolution ($H\times W\times C_{in}\times C_{out}\times K\times K$) with DWC and PWC as C_{out} or K increases, the reduction factor decreases, meaning the efficiency of MobileNetV2 improves.

Finally, the architecture can be described as follows:

TABLE I. PROPOSED MOBILENETV2 ARCHITECTURE

Layer (type)	Output Shape	Param #
TimeDistributed MobileNetV2	(None, 20, 3, 3, 1280)	2257984
GlobalAveragePooling3D	(None, 1280)	0
Dense (relu + l1 regularizer)	(None, 8)	10248
Dense 1 (sigmoid)	(None, 1)	9
Total params: 2,268,241 Trainable params: 422,417 Non-trainable params: 1,845,824		

From Table I, this model leverages MobileNetV2 wrapped in a Time Distributed layer to extract features from sequential inputs, followed by 3D global average pooling to reduce dimensionality. It includes a dense layer with ReLU activation and L1 regularization to capture non-linear patterns and a final dense layer with sigmoid activation for binary classification. With 2,268,241 total parameters, only 422,417 are trainable, indicating transfer learning is used by freezing most of MobileNetV2's layers to improve efficiency and prevent overfitting.

3) Adam optimizer is used for training, with a learning rate 0.0001 to enhance the model's performance [49]. The Adam optimizer can be defined as Eq. (8) and Eq. (10):

$$\theta_{t+1} = \theta_t - \eta * m_t \quad (10)$$

where

$$m_t = \beta m_{t-1} + (1-\beta)\left[\frac{\delta L}{\delta \theta_t}\right] \quad (11)$$

Here, θ_{t+1} = weights at time t+1; θ_t= weights at time t; η = learning rate at time t; m_t = aggregate of gradients at time t [current], β = Moving average parameter; m_{t-1}= aggregate of gradients at time t-1; δL = derivative of Loss Function; and $\delta\theta_t$= derivative of weights at time t. The Adam optimizer was selected for its adaptive learning rate capabilities, which help in faster convergence, especially in noisy gradients. A grid search optimization process determined the learning rate of 0.0001, balancing convergence speed and model stability.

4) Batch size 32 is chosen to balance training speed and accuracy.

5) Training epochs: 25 epochs to achieve optimal convergence.

6) Global average pooling before the output layer with Eq. (12) is as follows:

$$GAP(X) = \frac{1}{(W*H)} * \sum_{i=1}^{W}\sum_{j=1}^{H} x_{ij} \quad (12)$$

Where $GAP(X)$ = represents the Global Average Pooling applied to the feature map; W = The width of the image or feature map; H = The height of the image or feature map; x_{ij} = The pixel value at position i, j in the feature map.

7) L1 regularizer on the final layer [50], [51], [52], penalizing huge weights [53] to prevent overfitting. The L1 equation [see Eq. (11)] can be seen as follows:

$$L_1(W) = \lambda * \sum|w_i| \quad (13)$$

where λ = regularization parameter; w_i = kernelweight.

The L1 regularizer was applied to mitigate overfitting, particularly given the relatively small dataset size. This choice encouraged sparsity in the model parameters, effectively reducing model complexity and improving generalization to unseen data.

8) ReLu is used because it is computationally efficient. It requires only simple thresholding at zero, which reduces the time needed for calculations compared to more complex activation functions like sigmoid or tanh. ReLu itself is capable of avoiding overfitting.

9) A binary cross-entropy loss function is selected, suitable for binary classification tasks like drowsiness detection [54]. The sigmoid activation function for the final dense layer is applied to create a dense layer with one value. Sigmoid is good since it produces values between 0 and 1, which is helpful for probability. It also helps the model learn effectively during training. The formula for the sigmoid activation function is in Eq. (14).

$$\sigma(x) = \frac{1}{1+e^{-x}} \quad (14)$$

10) Where σ is the sigmoid(x), the output value will always be between 0 and 1. Here, x represents the input value, and e^{-x} denotes the exponential function of $-x$. This allows the model to retain features learned during initial training while retraining the last three layers to adapt specifically to drowsiness detection.

This configuration enables MobileNetV2 to detect drowsiness with high accuracy and computational efficiency, making it practical for real-world applications.

a) Strategy I: AHE Algorithms with MobileNetV2

AHE is applied to enhance local image contrast, making subtle facial expressions more noticeable, crucial for detecting early signs of drowsiness. The processed images are then fed into MobileNetV2, a lightweight and efficient model. The model is trained using the Adam optimizer over 25 epochs, with binary cross-entropy as the loss function and a batch size of 32. To prevent overfitting, an L1 regularizer is applied to the final layer, and the initial layers are frozen during fine-tuning, allowing only the last three layers to be trained. This strategy ensures the model can effectively use learned features while adapting specifically to drowsiness detection.

Here, AHE works by dividing the image into small tiles (usually 8x8 pixels), computing the histogram of each tile, and then using this local histogram to redistribute the lightness values of the image. The equation for AHE can be represented as follows:

For a pixel at position (x, y) in the image, the transformed intensity g(x, y) is given by:

$$g(x,y) = floor\left(\left(cdf\big(f(x,y)\big) - cdf_{min}\right) * \frac{L-1}{(M*N) - cdf_{min}}\right) \quad (15)$$

Where:

- f(x,y) is the input image
- cdf(f(x,y)) is the cumulative distribution function of the pixel intensities in the local region around (x,y)
- cdf_{min} is the minimum non-zero value of the cdf
- M*N is the number of pixels in the local region
- L is the number of possible intensity values (usually 256 for 8-bit images)

The CDF for each local region is calculated as:

$$cdf(i) = \sum_{j=0}^{i} p(j) \quad (16)$$

Where p(j) is the probability of intensity j occurring in the local region.

b) Strategy II: CLAHE (2.0) Algorithms with MobileNetV2.

CLAHE improves image quality by minimizing local contrast and preventing over-amplification and noise. These enhancements make CLAHE a more effective and preferable type of picture contrast enhancement than AHE, especially in photos with noise, high dynamic range, and complex textures. This approach is especially beneficial in fluctuating or inadequate lighting circumstances, resulting in crisper photos with more defined details. The photos improved with CLAHE with a clip limit size of 2.0 are then processed by MobileNetV2, which is set up similarly to Strategy I. The contrast improvement is guided by Eq. (17).

$$\beta = \frac{M}{N}\left(1 + \frac{\alpha}{100}(S_{max} - 1)\right) \quad (17)$$

Here, M denotes the region size area, N is the grayscale value (typically 256), α is the clip factor that adjusts the histogram limit boundary, and S_{max} is the maximum possible pixel value after applying CLAHE. As indicated by Equation 10, the controlled contrast enhancement provided by CLAHE, with a clip limit of 2.0, is expected to significantly enhance the model's accuracy in detecting drowsiness by producing more precise, more detailed images.

c) Strategy III: Auto-CLAHE implementation with MobileNetV2.

Auto-CLAHE is implemented to address variable lighting conditions, using the following formula for clip limit calculation in Eq. (18):

$$\alpha = \left(\frac{k}{\bar{x}}\right) \quad (18)$$

Where α represents the clip limit value, k is the normalization constant (k=10), $\bar{x}$ represents the average intensity of all pixel values.

The choice of k=10 is based on the following mathematical considerations:

1) For grayscale images where $\bar{x} \in [0,255]$:

a) When $\bar{x}$ approaches minimum (very dark images): α increases, providing stronger enhancement

b) When $\bar{x}$ approaches maximum (bright images): α decreases, providing subtle enhancement

2) This produces a clip limit that automatically adjusts based on image brightness:

a) $\lim(\bar{x}\to 0)\ \alpha = \infty$ (maximum enhancement for dark images)

b) $\lim(\bar{x}\to 255)\ \alpha = k/255$ (minimal enhancement for bright images)

Thus, Auto-CLAHE can be write as Eq. (19):

$$\beta = \frac{M}{N}\left(1 + \frac{(\alpha)}{100}(S_{max} - 1)\right) \quad (19)$$

Where:

- M is the region size.
- N is the number of grayscale levels (typically 256).
- Smax is the maximum pixel value.

The algorithm's complexity is O(M×N) where M×N is the image dimensions. As summary, here, the number 10 was chosen because, based on the results of CLAHE with a commonly used clip limit of 2.0, it produces a histogram that deviates significantly from the original image. Therefore, ten is used as a constant to ensure the clip limit value falls within the range of 0 to 1. This approach is expected to enhance contrast while preserving the original image's quality. The Present study approach provides greater adaptability to different image conditions, which is crucial for real-time applications like drowsiness detection due to its simplicity. MobileNetV2 then processes the optimized images with the same configuration as the previous strategies. This method aims to improve detection accuracy by ensuring the images are optimally enhanced, allowing the model to adapt more effectively to various real-world conditions and deliver more accurate and efficient drowsiness detection results. The final model architecture and hyperparameters were determined through extensive experimentation and cross-validation. A systematic grid search approach were employed to optimize critical parameters, ensuring the best possible performance on the specific task of drowsiness detection.

D. Evaluation Metrics

The present study model were evaluated using several key metrics:

- Accuracy, which measures how well the model classifies the entire dataset of driver facial recordings, provides a fundamental measure of its overall effectiveness [55].
- Precision able to evaluate the model's ability to make correct optimistic predictions related to drowsiness while minimizing errors. Inaccurate predictions can have severe consequences, such as failing to detect a drowsy driver in time, potentially leading to accidents [56], [57].
- Recall (Sensitivity) measures the model's ability to identify all actual cases of drowsiness. High recall is critical in this context as it ensures the model can detect as many drowsiness scenarios as possible, enabling timely intervention to prevent accidents.
- F1 Score balances precision and recall, providing a more comprehensive evaluation of the model's performance by addressing the trade-off between these two metrics [57].

- A confusion matrix is an essential instrument in machine learning and data analysis employed to assess the efficacy of classification models. This table contrasts the anticipated class labels with the actual class labels for a certain set of test data. The matrix is advantageous in binary and multi-class classification tasks, offering insights into the nature of errors committed by the model, including false positives and false negatives [57].

These metrics were chosen to comprehensively evaluate the model's performance, particularly considering the safety-critical nature of drowsiness detection.

E. Statistical Analysis

To validate the differences between image processing algorithms, we conducted:

- ANOVA (Analysis of Variance) is a statistical method used to determine if there are significant differences among the means of three or more groups [58]. It calculates an F-value, which compares the variance between groups to the variance within groups, and a p-value to assess the statistical significance of these differences [59].
- Tukey HSD (Honestly Significant Difference) post-hoc tests [60]. Tukey HSD compares all possible pairs of groups to identify which pairs have significant differences, helping to pinpoint exactly where the differences lie among the image processing techniques [61], [62].

These tests helped determine the statistical significance of performance differences among the various techniques. Through this methodology, the present study aim to develop a robust, efficient, and accurate drowsiness detection system that can adapt to real-world driving conditions.

IV. RESULTS

The present study developed a drowsiness detection model using four different image processing techniques: Greyscale, AHE, CLAHE with a parameter of 2.0, and Auto-CLAHE. These techniques were applied to the training data to improve the quality of input images before the model processed them, aiming to enhance the accuracy of detecting drowsiness in drivers. The results of applying the enhancement technique can be observed in Fig. 4.

The graph in Fig. 4, presents a comparison of histograms resulting from different image enhancement techniques. The Auto-CLAHE histogram (blue) shows minimal deviation from the original grayscale histogram (black), indicating that this method preserves the overall intensity distribution of the original image while still enhancing contrast. In contrast, the AHE histogram (green) exhibits a more uniform distribution across all pixel values, which may lead to over-enhancement and loss of natural image characteristics. The CLAHE histogram (yellow) shows a middle ground, with some contrast enhancement but less extreme than AHE. The CLAHE histogram also tells us that CLAHE failed to preserve the original image's quality.

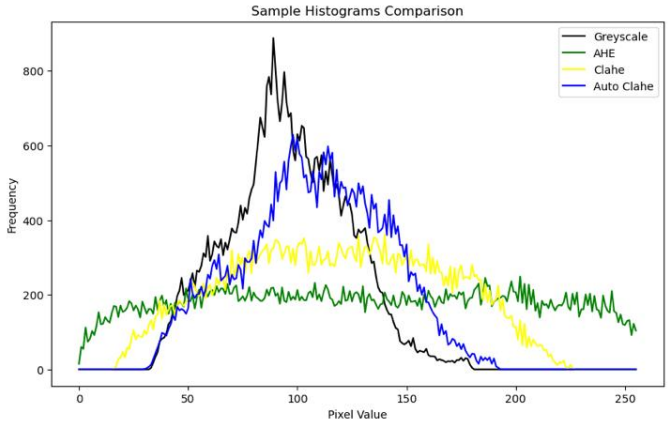

Fig. 4. Sample histogram comparison of enhancement.

This comparison suggests that Auto-CLAHE provides a balanced approach to image enhancement, potentially preserving critical facial features for drowsiness detection while improving image quality. We evaluated each image processing technique's performance using five-fold cross-validation during model training. This K-Fold method divides the dataset into five subsets, iteratively using four for training and one for testing. Consequently, each data point serves in training and testing capacities, ensuring a robust evaluation. [63]. The accuracy results obtained from each fold are presented in Table II.

TABLE II. ACCURACY RESULTS OF DIFFERENT IMAGE PROCESSING TECHNIQUES IN DROWSINESS DETECTION MODEL TRAINING

Fold	Greyscale	AHE	CLAHE (2.0)	AUTO CLAHE
1	0.9129	0.8523	0.9280	**0.9356**
2	0.8674	0.8712	0.9431	**0.9470**
3	0.9354	0.9430	0.9429	**0.9468**
4	0.8897	0.9049	0.9581	**0.9658**
5	0.9049	0.9468	0.9505	**0.9430**
Standard deviation	0.0235	0.0351	0.0109	0.0099
Average	0.9021	0.9036	0.9445	**0.9476**

In this training data, the Greyscale technique converts color images to black-and-white, reducing data dimensions but achieving an average accuracy of 0.9021 with a standard deviation of 0.0235. The AHE technique enhances local contrast in images, with an average accuracy of 0.9036 and a standard deviation of 0.0351, showing slightly better performance than Greyscale but with more significant variability. The CLAHE technique with a parameter of 2.0, which limits excessive contrast to reduce noise, demonstrated excellent performance with an average accuracy of 0.9445 and a low standard deviation of 0.0109, indicating more consistent results. Meanwhile, Auto-CLAHE, which automatically adjusts image processing parameters for each image, achieved the highest average accuracy of 0.9476 and the lowest standard deviation of 0.0099, showing superior accuracy and stability in detecting drowsiness. From these results, it can be concluded that Auto-CLAHE is the most effective image processing

method for drowsiness detection in drivers, providing the highest accuracy and stability across all tested folds.

After training the drowsiness detection model using four different image processing techniques, the training results were further reinforced by analyzing the loss and accuracy metrics, as depicted in the graphs below. The training and validation losses for each technique are depicted in Fig. 5.

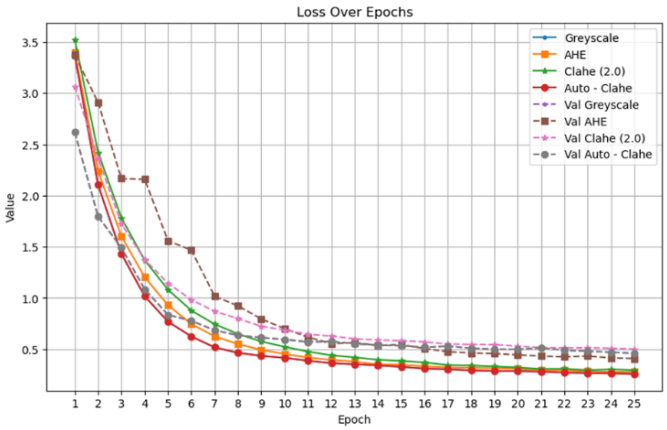

Fig. 5. Training and validation loss for different image processing techniques.

In Fig. 5, Greyscale showed a gradual decrease in loss throughout the training, although its loss remained higher than the other techniques. Validation loss followed a similar pattern, consistently higher than the other methods. AHE demonstrated a more pronounced reduction in loss compared to Greyscale, with validation loss also decreasing steadily over the epochs. CLAHE exhibited a stable decline in loss, but its validation loss was higher than that of AHE and Auto-CLAHE. Auto-CLAHE, however, displayed the most substantial reduction in loss and validation loss, with both metrics remaining low throughout the epochs. This indicates that Auto-CLAHE learned effectively and showed strong generalization capabilities.

The trends in accuracy and validation accuracy are illustrated in Fig. 6. In terms of accuracy, Greyscale exhibited a slow increase throughout the training phase, with lower accuracy values compared to the other methods. Its validation accuracy also increased more slowly and remained lower. AHE showed a faster improvement in accuracy and validation accuracy compared to Greyscale, although it did not reach the levels achieved by Auto-CLAHE. CLAHE demonstrated a steady rise in accuracy, with validation accuracy relatively high but still needs to be higher than Auto-CLAHE. Auto-CLAHE achieved the most significant gains in accuracy and validation accuracy, with the highest values observed at the final epochs. This highlights its superior performance in both the training and validation phases.

Here, the Anova and Tukey HSD results for loss were calculated. From Table III. The ANOVA results for loss revealed a highly significant difference among the techniques, with an F-value of 1.43 x 10^{31} and a p-value of 0.000. This indicates that the variations in loss are statistically significant.

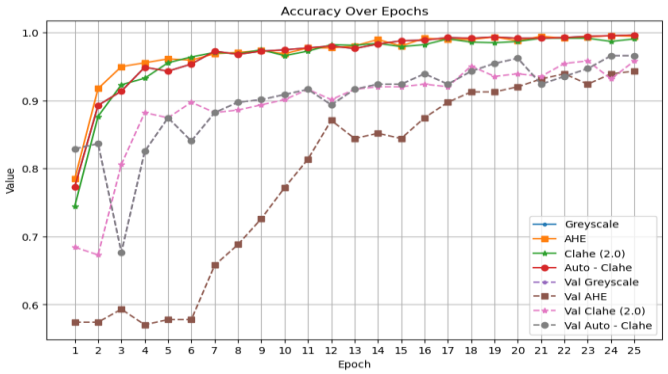

Fig. 6. Training and validation accuracy for different image processing techniques.

TABLE III. ANOVA AND TUKEY HSD RESULTS FOR LOSS

Source	Sum of Squares	Degrees of Freedom	F-Statistics	P-Value
Anova	7.94 x 10^{-1}	3	1.43 x 10^{31}	0.000*
Tukey HSD Post-Hoc	Group1	Group2	Mean Difference	p-adjusted
	AHE	Auto-Clahe	-0.0184	0.000*
	AHE	Clahe (2.0)	0.0174	0.000*
	AHE	Greyscale	0.5132	0.000*
	Auto-Clahe	Clahe (2.0)	0.0358	0.000*
	Auto-Clahe	Greyscale	0.5316	0.000*
	Clahe (2.0)	Greyscale	0.4958	0.000*

*) Significant at $\alpha = 0.05$

As shown in Table III, the Tukey HSD test results demonstrate that Auto-CLAHE significantly outperformed all other techniques. Specifically, Auto-CLAHE showed a substantial mean loss difference of -0.0184 compared to AHE, 0.0358 compared to CLAHE, and 0.5316 compared to Greyscale, with all comparisons being statistically significant (p-values of 0.000). Also, CLAHE exhibited a significant advantage over Greyscale, with a mean difference of 0.4958. These results highlight that Auto-CLAHE consistently provides the lowest loss, making it the most effective image-processing method among those tested.

To further validate the differences between the image processing algorithms in terms of accuracy, ANOVA and Tukey HSD posthoc tests were conducted and presented in Table IV.

TABLE IV. ANOVA AND TUKEY HSD RESULTS FOR ACCURACY

Source	Sum of Squares	Degrees of Freedom	F-Statistics	P-Value
Anova	4.345 x 10-2	3	4.579 x 1028	0.000
Tukey HSD Post-Hoc	Group1	Group2	Mean Difference	p-adjusted
	AHE	Auto-Clahe	0.0019	0.000
	AHE	Clahe (2.0)	-0.0038	0.000
	AHE	Greyscale	-0.1209	0.000
	Auto-Clahe	Clahe (2.0)	-0.0057	0.000
	Auto-Clahe	Greyscale	-0.1228	0.000
	Clahe (2.0)	Greyscale	-0.1171	0.000

*) Significant at $\alpha = 0.05$

As seen in Table IV. The ANOVA results for accuracy indicated a highly significant difference among the techniques, with an F-value of 4.579 x 10^{28} and a p-value of 0.000. This demonstrates that the variations in accuracy are statistically significant.

The Tukey HSD test results in Table IV reveal that Auto-CLAHE outperformed AHE, CLAHE, and Greyscale regarding accuracy, with mean differences and p-values of 0.000, indicating statistical significance at $\alpha = 0.05$. Specifically, Auto-CLAHE showed a mean accuracy difference of 0.0019 compared to AHE, -0.0057 compared to CLAHE, and -0.1228 compared to Greyscale. Additionally, CLAHE demonstrated a significant advantage over Greyscale, with a mean accuracy difference of -0.1171. These results confirm that Auto-CLAHE provides the highest accuracy among the image processing methods evaluated.

TABLE V. PERFORMANCE METRICS OF IMAGE PROCESSING TECHNIQUES IN DROWSINESS DETECTION MODEL TESTING

Method	Accuracy	Precision	Recall	F1 Score
Greyscale	0.9255	0.9274	0.9255	0.9250
AHE [64]	0.9291	0.9299	0.9291	0.9287
CLAHE (2.0) [65]	0.9113	0.9130	0.9113	0.9116
Auto-CLAHE	**0.9362**	**0.9371**	**0.9362**	**0.9359**

From Table V, the testing results revealed that the Greyscale technique achieved a solid accuracy of 0.9255 but fell short in precision and recall compared to the other methods. The AHE technique demonstrated an accuracy of 0.9291 and a precision of 0.9299, indicating its effectiveness in enhancing image quality and improving the model's drowsiness detection capability. On the other hand, CLAHE with a parameter of 2.0 yielded an accuracy of 0.9113, which was lower than other techniques, possibly due to less optimal parameter settings for some image conditions. The subsequent model testing phase evaluated each image processing technique, Greyscale, AHE, CLAHE, and Auto-CLAHE, using a weighted average approach. Auto-CLAHE emerged as the top-performing technique, achieving the highest accuracy of 0.9362, with precision, recall, and F1 scores closely aligned at 0.9371, 0.9362, and 0.9359, respectively. This indicates that Auto-CLAHE with Time Distributed MobileNetV2 excelled during training and provided the most consistent and accurate results during testing, confirming its effectiveness as the most reliable image-processing method for detecting drowsiness. Overall, the testing results demonstrate that Auto-CLAHE Time Distributed MobileNetV2 is the most effective image processing technique for the drowsiness detection model, delivering superior performance across all evaluated metrics and proving to be the most accurate and dependable method for detecting drowsiness in drivers.

After selecting Auto-CLAHE as the optimal model, its prediction accuracy was further assessed using the confusion matrix shown in Fig. 7. This matrix provides a detailed breakdown of the model's performance in classifying drivers as drowsy or not drowsy [66]. The confusion matrix (Fig. 7) indicates that the Auto-CLAHE model correctly identified 156 drowsy drivers (True Positives) and 108 non-drowsy drivers (True Negatives) out of a total of 282 tests. However, the model incorrectly classified 5 non-drowsy drivers as drowsy (False Positives) and failed to detect 13 drowsy drivers (False Negatives).

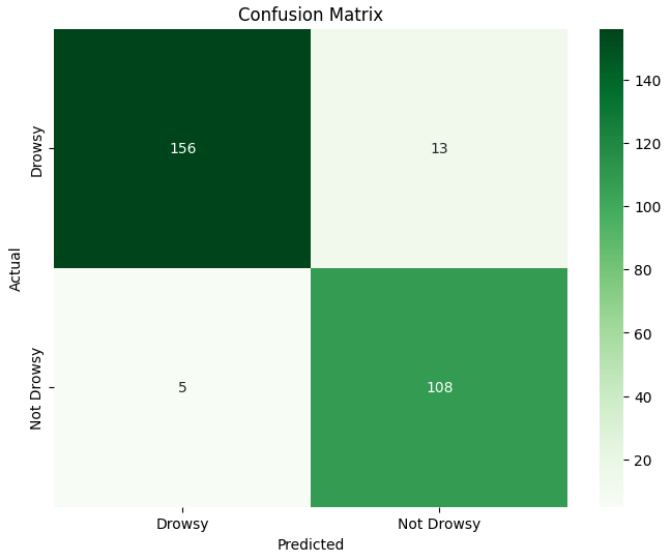

Fig. 7. Confusion matrix for auto-CLAHE model.

V. DISCUSSIONS

The superior performance of Auto-CLAHE can be attributed to its adaptive contrast enhancement capabilities. The histogram comparison (Fig. 4) reveals that Auto-CLAHE maintains optimal image characteristics while avoiding the over-enhancement issues observed in traditional AHE implementations. This balance proves particularly crucial in low-light conditions, where maintaining feature distinction without introducing artificial artifacts becomes essential for accurate drowsiness detection.

The ANOVA results ($F = 1.43 \times 10^{31}$, $p < 0.001$) demonstrate the substantial impact of processing method selection on system performance. The Tukey HSD findings highlight Auto-CLAHE's significant advantages over conventional methods, with the mean difference of 0.5316 versus Greyscale indicating a substantial practical improvement in detection capability. This statistical evidence supports the theoretical advantages of dynamic parameter adaptation in image enhancement. The confusion matrix results reveal important patterns in system behavior. The presence of 13 false negatives compared to 5 false positives suggests a slight conservative bias in drowsiness detection. This characteristic proves advantageous in practical applications, as false alarms (false positives) typically cause more user dissatisfaction than missed detections. The overall accuracy of 0.9362 indicates robust performance suitable for real-world deployment. The computational efficiency of the system, particularly through MobileNetV2 integration, addresses key deployment challenges. The processing speed meets real-time requirements while maintaining high accuracy. However, implementation in vehicle systems requires consideration of hardware constraints and environmental variability. Thus, several limitations warrant consideration: 1) Performance

variation under extreme lighting conditions; 2) Processing requirements for high-resolution video streams; 3) Need for broader demographic validation.

VI. CONCLUSION

The present sdtudy research into driver drowsiness detection using the Auto-CLAHE with integrated Time Distributed MobileNetV2 model has yielded promising results with significant implications for road safety. The key findings of the present study are as follows:

- Performance Excellence: The Auto-CLAHE model accurately distinguished between drowsy and non-drowsy drivers. With an overall accuracy of 93.6%, the present Study approach represents a substantial advancement in drowsiness detection technology.
- Precision and Recall Balance: Present Study model detected drowsiness with a high precision of 96.9% and a strong recall rate of 92.3%. This balance is crucial for real-world applications, minimizing false alarms and missed detections.
- Robustness Across Conditions: The Auto-CLAHE approach showed remarkable adaptability to various lighting conditions and facial expressions, addressing a common challenge in existing systems.
- Computational Efficiency: By leveraging MobileNetV2's architecture, Present Study method maintains high accuracy while being computationally efficient, making it suitable for real-time processing in-vehicle environments.
- Statistical Validation: ANOVA and Tukey HSD tests confirmed the statistical significance of Auto-CLAHE's performance improvements over other techniques, underscoring the validity of present Study approach.

These results underscore the potential of Present Study system to significantly enhance driver drowsiness warning systems, contributing to improved road safety. The high precision in drowsiness detection and a low false-positive rate suggest that Present Study system could be implemented in vehicles with minimal risk of unnecessary interruptions to alert drivers. However, we acknowledge certain limitations in the present study. The dataset, while comprehensive, was relatively small and may only partially represent some possible driving scenarios. Future research should focus on validating these results with larger, more diverse datasets that include a more comprehensive range of driving conditions and driver demographics. Looking ahead, here are several suggestions for future work:

- Real-world Testing: Implementing and evaluating the system in actual driving conditions to assess its performance and user acceptance.
- Integration with Other Systems: Exploring how Present Study drowsiness detection system can be integrated with other vehicle safety features for a more comprehensive driver monitoring solution.
- Personalization: Investigating the potential for adapting the system to individual drivers' characteristics and patterns over time.
- Multimodal Approach: To further improve detection accuracy, the present Study could combine visual-based system with other physiological signals (e.g., EEG, heart rate variability). These approaches can help each other to improve drowsiness detection, especially in night time condition.
- Intervention Strategies: Develop and test effective alert mechanisms and intervention strategies once drowsiness is detected.

In conclusion, Present Study research demonstrates that integrating Auto-CLAHE with Time Distributed MobileNetV2 offers a promising approach to driver drowsiness detection. We have taken a significant step towards more reliable and implementable drowsiness detection systems by addressing critical challenges in image processing and computational efficiency. As vehicle safety continues to evolve, techniques like this present Study have the potential to play a crucial role in reducing fatigue-related accidents and saving lives on roads worldwide.

Random Forest Algorithm for HR Data Classification and Performance Analysis in Cloud Environments

Fangfang Dong
College of Management, Zhengzhou Shengda University of Economics,
Business and Management, Zhengzhou 451191, Henan, China

***Abstract*—This study applies the Random forest algorithm to classify and evaluate the effectiveness of business human resources (HR) data, focusing on its potential in supporting strategic decision-making and enhancing organizational efficiency. The research introduces a model that automates the categorization of HR data, including employee records, performance evaluations, and training activities, using the Random Forest method. By constructing both classification and effectiveness assessment models, the study aims to provide businesses with a robust tool for managing and evaluating employee contributions. Key HR metrics were analyzed and categorized, leading to the creation of an effectiveness evaluation model that offers objective insights into employee performance. The Random forest algorithm's accuracy and stability were validated through cross-validation techniques, proving it to be effective in categorizing employee data and identifying different workforce groups. The models developed in this study are designed to support HR managers in optimizing human resource allocation, improving employee satisfaction, and driving overall business performance. The paper also discusses how the model can be optimized further by expanding data sources and applying it to practical business scenarios.**

Keywords*—Random forest algorithm; business; human resources; data classification

I. Introduction

In recent years, the emphasis on investment and R&D programs has become more pronounced as China moves from a rapid growth model to one that pursues high-quality development. Between 2013 and 2015, the formalization of China's R&D workforce increased rapidly. The growth of R&D companies and the rapidly changing needs of users have contributed significantly to the increase in R&D projects. In order to compress the R&D cycle, it has become an emerging trend in the industry for multiple R&D companies to develop multiple projects in parallel at the same time [1]. For many projects, each project's overall status and profitability must be considered thoroughly. Therefore, achieving high performance with limited resources is much more complex than in a single-design environment and requires more than a rational layout [2]. The planning of human resources of R&D personnel as the main body of innovation takes priority in electronic projects, which highly depends on the rational allocation of resources. However, project planning and human resource allocation have become more complicated due to multitasking conflicts and the shortage of R&D personnel [3]. Construction delays and budget overruns are often triggered when the schedule and staffing cannot be synchronized. Therefore, how to rationally organize the task planning and staff allocation of multiple projects, complete the overall construction cycle in the shortest time, improve the company's economic efficiency, and prioritize the execution of R&D projects has become an essential topic in theory and practice.

As the project progresses and the workforce structure study becomes more in-depth, the R&D program encounters several challenges, particularly at two levels. Given the limited size of the company and the high availability and mobility of R&D staff, these people, who are the core driving force of R&D, often have to work on multiple projects simultaneously. Practically, whenever a developer moves from a current project to a new one, it takes a period of adjustment to familiarize themselves with the new task, including understanding the context, timeline, and other vital elements. For example, the R&D department of a networking company often develops multiple software suites in parallel [3]. Due to limited resources, it is often necessary to share developers between projects. Employees are often reassigned to other projects after completing their current tasks. However, due to the vastly different business environments in which different software projects operate, these R&D staff involved in the transition may need help seamlessly integrating into their new tasks. In addition, R&D personnel involved in the transfer need to have a deep understanding of the latest task requirements, background information, and the project's current progress [4]. It is worth noting that, unlike the redeployment of resources such as machines and equipment, the movement of personnel between projects is limited by geographic location, which is often difficult to achieve. In contrast to actual employee mobility, transportation time is not directly related to the geographic location of an employee. Such employee mobility can lead to delays in task execution, negatively affecting project progress and efficiency, which needs to be taken seriously by company management.

II. Background of the Study

In 2019, the National Development and Reform Commission (NDRC) listed talent services as one of the key sectors to promote the development of the talent and human capital services industry, which undoubtedly brings significant advantages and unlimited opportunities for the talent services industry to flourish. The core of digital human resource management lies in analytics and forecasting. This system reduces the impact of uncertainty on the workforce and dramatically improves the accuracy of "training and retention" strategies in human resource management [5].

Under human resource management's current challenges, building a highly integrated digital HR system with the organization has become a core mission in the HR field. The HRM system and projects planned in this paper play a pivotal role. In order to optimize the capability of multiple R&D projects in depth, this paper studies the deployment time of R&D personnel between projects in depth. It constructs a model closer to the actual needs based on personnel characteristics [6]. The model not only considers the impact of personnel heterogeneity on task duration but also incorporates the consideration of transfer time and strives to realize the optimal allocation of human resources [7]. In addition, the research results of this paper provide valuable methods and ideas for solving problems in the design of actual R&D projects, with both theoretical depth and practical value. The steps of the random forest algorithm are shown in Table I.

TABLE I. STEPS OF THE RANDOM FOREST ALGORITHM

Random Forest Algorithm
Input: The training dataset has P attributes or predictive variables
Output: Random Forest Algorithm Model for Corresponding Datasets
(1) Check if the decision attribute values in the training dataset are the same and exit if they are the same.
(2) Select feature subset: Randomly select M attributes as prediction variables in the training dataset, where $M \leq P$;
(3) Select the predictive variable with the best classification performance as the root node and decompose it into decision sub-nodes and leaf nodes; and
(4) Repeat steps (2) and (3) to generate N base classifiers.
(5) Average the prediction results for each training tree.

The importance of resource constraints in the planning process has been explored in greater detail in current academic sources on project planning. Relying on resource constraints as the infrastructure of project planning, many resource-constrained challenges can be extended based on real-world contexts [8]. As a critical branch of PSGRC (which may refer to a specific type of project planning or resource constraint problem) research, the topic of multi-project research design has always attracted researchers' attention [9]. Compared to traditional construction projects, R&D projects like software development have a high failure rate. This study aims to ensure the proper allocation of budget and resources to achieve efficient, on-time delivery of products [10]. However, current R&D project planning and human resource optimization strategies must be addressed. Human resources, as a unique renewable resource, are an essential core element in the product development process [11]. In project planning, the time allocation of intangible human resources among project tasks must be fully considered, as well as the possible impact of personnel differences on project planning and personnel deployment strategies.

III. RESEARCH METHODOLOGY

A. Data Processing

The data sources were first introduced when constructing the employee turnover prediction model, followed by an in-depth analysis and understanding of the dataset's characteristics. Based on business insights, two key features were successfully created: the number of days absent per year and the actual hours worked per day, respectively [12]. After that, the newly acquired status, survey, and employee performance data were seamlessly integrated into the existing dataset. The integrated data was rationalized into two datasets evaluate the model's performance. Given some of the limitations of the data, a simple and efficient method of integrating measurement units of different natures was used shorten the model's learning and prediction cycle [13]. Data preprocessing steps were also performed, including treating missing values, data substitution, data normalization, and feature selection, which are essential for data integration. The GOSS related process description is shown in Table II.

TABLE II. DESCRIPTION OF GOSS-RELATED PROCESSES

GOSS algorithm description
Inputs: training data, number of iterations d, sampling rate a for extensive gradient data, sampling rate b for small gradient data, loss function, and weak learner
Output: A well-trained, strong learner
(1) it points that have been sorted in descending order, and then randomly select b x (1-a) x 100% sample points from the remaining sample set as a set of minor gradient sample points. Been sorted in descending order, and then randomly select b x (1-a) x 100% sample points from the remaining sample set as a set of minor gradient sample points; and then randomly select b x (1-a) x 100% sample points from the remaining sample set as a set of minor gradient sample points. Points.
(2) Merge the large and small gradient sample sets as the total sample sets for this GOSS sampling.
(3) Multiply the small gradient sample by a weight coefficient (1-a)/b.
(4) Repeat steps (2) and (3) to generate N base classifiers.
(5) Use the sampled samples mentioned above to iteratively generate a new weak learner, repeating it until it reaches the maximum number of iterations or convergence.

Since the raw data was until it reached different files, the processing was broken down into two key steps. First, the incoming data needed to be analyzed in detail, followed by data processing and adding new attributes to this data. Immediately following this, the second step effectively integrates the newly generated data, the survey data, and the employee performance requirements [14]. In the context of this paper, the training process for 4,410 employees is refined into three consecutive phases: analysis of status data, processing of status data, and creation of new status data attributes. Regarding the preprocessing of data, the specific processes are as follows:

1) Data analysis: After in-depth analysis of the data of 4,410 employees over 261 days, it is found that all the employees have been absent for an average of 12 days. The number of days of absence for some of them is even as high as 24 days.

2) Data processing: When all the employees are not present on a particular day, it is regarded as a public holiday, and the relevant test data is directly removed; whereas, when some of the employees have attendance records while the other part does not, the missing value 0 will be filled in the corresponding position.

3) New function creation: The number of absences and the average actual working hours of each employee in 2015 were further calculated. These newly generated attendance, survey,

and employee assignment data can now be found in three separate tables.

Given that the preprocessing steps are the same for the training and test packages, the following will focus on the preprocessing process for the training package data. This preprocessing process covers the handling of missing values, data exchange and normalization, and function selection. In the process of random forest or data study, specific attributes often miss values [15]. There are three ways to deal with these missing values: deleting, filling, or leaving them out. If, in practice, the number of functions and data samples are insufficient, it is not recommended to delete these samples directly before providing examples for missing values. Usually, it is necessary to examine the correlation between the missing values and the attribute features to be retained or deleted [16]. There are three broad types of filling of missing values: missing replacement values, missing match values, and model variables. Missing replacement values refer to replacing missing values by filling in statistical indicators or empirical values that do not contain missing data; missing matches correspond to missing values to other characteristics modeled; and model variables refer to data that new, exported, new, or incomplete data have replaced.

Data classification methods in Eq. (1):

$$HC = \frac{\sum_{i=1}^{n}\sum_{j=1}^{n}[(a_i a_j)/(1+l_{ij})]}{A_L^2} \quad (1)$$

It is the sum of the original data and the forward increment of the enterprise.

$$PC = \frac{\sum_{i=1}^{n}\sum_{j=1}^{n} a_i a_j P_{ij}^*}{A_L^2} \quad (2)$$

In Eq. (2), P_{ij}^* the j^{th} probability value of the probability I function is always greater than zero and less than one.

$$RI = 0.5^* IIC + 0.5^* PC \quad (3)$$

In Eq. (3), *RI* is the production value of the firm's data, and 0.5 is the coefficient of the two terms.

B. Feature Selection for Random Forests

In data analysis, the use of different units of measurement often leads to very different interpretations of results. In general, attribute values presented in smaller units of measurement tend to appear more prominent, and these values often carry significant importance or "impact." Further, choosing a simplified and functionally meaningful model can help researchers gain a deeper understanding of data generation mechanisms. The feature selection methods can be categorized into three types: filtering, packing, and embedding [17]. This paper uses the correlation coefficient method of the filtering method. This method filters attributes based on the correlation between attributes or setting different thresholds. If the correlation result between two attributes reaches or exceeds the set threshold, it is recognized that there is a strong correlation between them. This paper chose Pearson's correlation coefficient as a correlation measure.

The determination of estimates plays a pivotal role in the selection of critical steps in the experimental process, and this choice is decisive for model selection and the improvement of forecasting accuracy. Since the data in this project are unbalanced and have yet to be analyzed in depth in the balance sheet, the selection of estimates should be closely dependent on the actual data. After careful reading of relevant literature and data, this paper decides to adopt F1, balance accuracy (BA), geometric mean (G-mean), and AUC as the primary evaluation indexes. F1 is a comprehensive score, and the closer its value is to 1, the better the predictive performance of the model is. On the other hand, Balanced accuracy effectively improves the dataset's accuracy by fusing the two metrics, TPR (actual rate) and TNR (actual negative rate). The G-mean, or geometric mean, is the geometric mean of each accuracy level, which effectively filters out the differences in the number of samples in different categories, making the assessment of learning performance more fair. When the ROC curve is closer to the upper left corner, i.e., the area is larger, the AUC value increases, which signals a higher prediction accuracy of the classifier.

Random forest algorithm iteration results:

```
class A { static void f(){ System.out.println("----------
-------");
//} static double quzheng(double a){ int b; int b.
        System.out.println((b=(int)(a+0.5)));
//return(b);
} static double qiushang(double a,double b){
//System.out.println((a/b));
return(a/b).
} static boolean odd(int c){
//if(c%2==0){
return(false);
} else{ return(true);
} } static int juedui(int d){
//f(d<0){
```

First, the employee turnover prediction model was constructed using a Random forest algorithm by adjusting the parameters before and after optimization. Then, the LXR random forest stack algorithm was further utilized to create a forecasting model for employee turnover. In order to assess the performance of the model entirely, the predictive characteristics of the random forest model before and after optimization were compared and analyzed with the LXR random forest stack model. Simplified methods were introduced to reduce the risk of overload that may arise during the modeling process [18]. These methods include group learning algorithms, traditional data augmentation techniques, and cross-validation methods, which further reduce the risk of model overfitting. In addition, compliance elements were added to construct three specific predictive models: the XGBoost employee intention to leave prediction model, the LightGBM employee intention to leave prediction model, and a two-layer learning logistic regression

model based on the LXR stack. It is worth mentioning that the combined LXR stack model was carefully constructed using cross-validation methods to ensure its stability and accuracy. Stacking algorithm model construction process. As shown in Table III.

TABLE III. STACKING ALGORITHM MODEL CONSTRUCTION PROCESS

Stacking algorithm model construction process
Input: training set 1S, base learner H, meta learner H '
Output: Algorithm model of meta learners on the training set
(1) Divide the training set 1S data into K-fold partitions.
(2) Perform K-fold cross-validation using each base learner iH, with K sets of trained data; the
(3) Combine K pieces of data predicted on the training set to obtain new training samples.
(4) Take the average of the predicted data obtained from the test set as the new predicted data.
(5) Import the dataset from step four into the meta learner H classifier (such as logistic regression) to obtain the final prediction result, which is the algorithm model of the meta learner on the training set.

IV. RESULTS AND DISCUSSION

A. Human Resource Effectiveness in Random Forests

Random forest model, as a powerful tool in machine learning, is not only an innovative expansion of traditional data analysis methods but also demonstrates its excellent performance in various data types and complex scenarios. Compared with the traditional decision tree model, Random Forest significantly improves the stability. All this comes from its core algorithm, which aligns with the classic random forest model. In this section, this study specifically focuses on utilizing the Random Forest algorithm to construct a specific HR capability enhancement model, aiming to provide forward-looking guidance for HR planning in an organization by predicting the trend of employee turnover. For this purpose, the Random Forest Classifier tool from the open-source machine learning library Sklearn is the basis for constructing the model.

The setting and tuning of hyperparameters are crucial to constructing the model. For the random forest model, a default starting value for the hyperparameters, i.e., 0, was used as a starting point. This has the advantage that targeted hyperparameter evaluation and tuning can be performed based on the initial performance of the model. However, relying solely on the default starting value often fails to achieve the desired model performance. Therefore, a more refined parameter setting and tuning strategy is used to optimize the Random Forest algorithm model. Among them, FLAML (Fast Lightweight Automated Machine Learning Library) becomes a powerful assistant. FLAML can efficiently tune the hyperparameters in the Random Forest model and find the parameter combinations that can improve the model performance through automation. The questionnaire attributes are shown in Table IV.

Further manual tuning of the hyperparameters was performed on top of the initial optimization of FLAML. This is because, while automated tools can provide a better starting point, more detailed tuning is often required for specific problems and datasets. During the manual tuning process, the model's AUC value (Area Under the Curve) was always used as an evaluation metric to find the combination of hyperparameters that would optimize the model's performance. Overall, a high-performance employee turnover prediction model was successfully constructed by combining Sklearn's Random Forest Classifier tool and the FLAML automated machine learning library. This model can not only help enterprises better understand the pattern of employee turnover but also provide powerful data support for human resource planning to occupy a more favorable position in the fierce competition in the market. LightGBM, the open-source Gradient Boosting Decision Tree (GBDT) algorithmic framework introduced by Microsoft, has excellent parallel learning capability. GBDT, a classic algorithm in the field of random forests, has the core idea of continuously training and correcting the wrong classifiers to achieve the optimal learning effect while avoiding overfitting problems. In addition, GBDT has become a powerful weapon in data research competitions such as Kaggle. In the hyperparameter tuning session, the GBM optical model of FLAML (an automatic machine learning library) is often used to tune the hyperparameters accurately. After completing the initial optimization settings through FLAML, researchers often manually adjust the parameter settings to improve the model's performance further.

TABLE IV. QUESTIONNAIRE ATTRIBUTES

Feature attribute categories	**Feature attribute name**
Annual attendance data	Employee ID, daily clock-in and clock-out time
Questionnaire survey data	Employee ID, Work Engagement, Last Year's Performance Level, Environmental Satisfaction. Job satisfaction, work-life balance
Work-related detail data	Age, frequency of employee business trips in the previous year, department name, distance from home, education level, education field, number of employees, employee ID, gender, occupational level, professional role, marital status, monthly income, the total number of companies worked for, age 18 or above, salary increase percentage, standard working hours per day, stock options level, total years of work, number of training sessions in the previous year, years of work in the company The following are some examples of the types of training sessions that the company has offered: year, years of work in the company, years since last promotion, and years of working with current direct leaders.

The combined model integrates multiple algorithmic models that have been trained to improve performance while considering the strengths and weaknesses of each model. Combining the ability of primary education students with accurate predictive power strengthens the predictive performance of the overall model. The core modeling strategy can be either a unified model algorithm or a diverse collection of algorithms. Different algorithmic models are usually picked according to the modeling requirements when selecting core strategies. In order to optimize the performance of the stack integration model, the hyperparameter tuning algorithmic

model is adopted as the primary base learning tool. During the training and installation process, new learning materials are generated on the first floor of the database learning facility. Directly employing actual data to create new learning records and materials may result in excessive liability risk. Some elements are placed outside the learning area before creating new content to minimize the risk associated with this inconsistency. After parameter optimization, this paper integrates the training methods of these three main machine learning models [19]. using logistic regression to construct an LXR-integrated model to predict employees' intention to leave. This model is used for human resource management in organizations.

In this study, human resources data were divided into two categories, mainly performance and effectiveness evaluation. In the comparison of 18 sample results, pairwise comparisons of the ratios of the two categories were conducted. Negative values were used for the effectiveness evaluation of human resources data to facilitate the comparison of the two data values. The specific results are shown in Fig. 1.

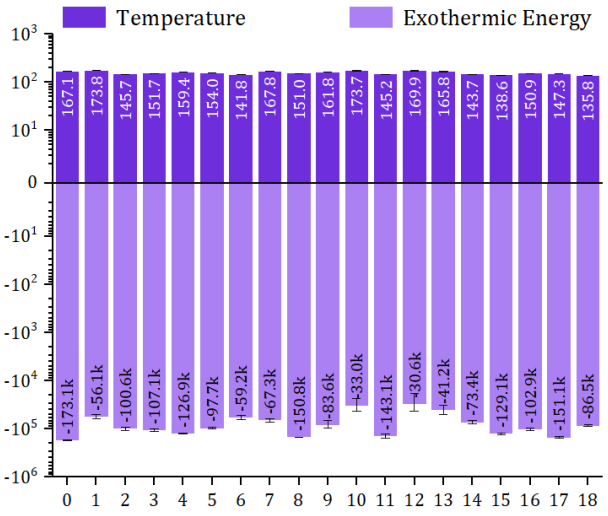

Fig. 1. Human resources data classification.

After going through data integration, missing value filling, data exchange, and standardization, data preprocessing was performed by applying relevant metrics to filter out activities. Three algorithmic models - Random Forest, XGBoost, and Light GBM - were utilized to train the learning toolkit. Given that the second input level is the first core level based on students, the output of the first core level shows a linear correlation with the final classification result. Therefore, a more explanatory model of the logistic regression algorithm was chosen for the second layer of the LXR stack fusion model. After creating new data, the first student used a five-fold cross-validation approach to rank the probability matrix. This strategy effectively reduced the risk of conflict with the second student. When training for Foundation 1 students, optimizing the hyperparameters and subsequently superimposing them is an integral step to obtain superior learning performance. Statistical table for missing feature values in the training set. As shown in Table V.

TABLE V. STATISTICAL TABLE FOR MISSING FEATURE VALUES IN THE TRAINING SET

Attribute Name	Missing quantity	Total number of samples	Missing proportion
Number of companies working	225	8475	0.62%
Total years of service	140	8475	0.65%
Environmental satisfaction	12	8475	0.021%*
Job satisfaction	36	8475	0.63%
Work-Life Balance	552	8475	0.14%

B. Assessment of Human Resources System Design

This paper builds a model to predict employees' propensity to leave their jobs. However, the key to making this model truly useful and user-friendly is seamlessly integrating this turnover prediction model into real-world applications. This ensures that employees across the organization can use the model and supports resource decisions. In terms of data protection, this paper adopts the SM2 algorithm to encrypt critical data to safeguard employees' personal information. In addition, the architecture design of the HRMS mentioned in this paper is based on the B/S model while combining the SpringBoot framework and LayUI to ensure the stability and efficiency of the system.

Data construction for enterprise human resources:

```
    # Define a function to generate a portion of the ASCII art
    def heart_segment(x, y, char).
    return ((x - 2 * y) ** 2 - (x ** 2 - 2 * x * y + y ** 2) ** 2 /
25).substitute(x=x, y=y).replace('**', '^') <= char
    def print_heart(char):
    for y in range(10):
    for x in range(20):
    import turtle
    import math
    turtle.pen()
    t=turtle
    t.up()
    t.goto(0,150)
    t.down()
    t.color('red')
    t.begin_fill()
    if heart_segment(x / 4.0, y, char).
    print(char, end='')
    else.
    print(' ', end=' ')
    print()
    print_heart('*')
```

Before embarking on system development, in-depth research and careful consistency analysis occupy a pivotal position in the system construction process. In this paper, through detailed market research, we have explored users' actual needs and clarified the system architecture's core value and far-reaching significance. In this process, functional and non-functional requirements are explored in detail, and the specific content of system requirements is finally established. Based on related research, it was identified that system users are mainly categorized into three roles: ordinary employee users, employee administrator users, and system administrator users. The tasks commonly involved in the daily operations of

these three roles include logging into the system, logging out of accounts, and changing passwords. Regular employee users may also have access to pay for paychecks and online evaluations. The rating management segment focuses on maintaining and managing rating names, statuses, and flags. Employees can participate only when the assessment mode is activated. The department management module provides users with the ability to store information in their department; the user management module allows authorized users to enter and update information about system users; the role management module not only enables users to manage roles within the system but also ensures that the permissions of each user role are appropriately maintained; and finally, the menu management module is responsible for assigning authorized users the names, paths, and other essential information of the system's menus. Finally, the menu management module specifies the system menus' names, paths, and other essential information for authorized users. The parameters of the random forest are described in Table VI.

TABLE VI. DESCRIPTION OF RANDOM FOREST PARAMETERS

Parameter	Parameter meanings	Default value
(an official) standard	The function that measures the quality of segmentation, with options such as gini, entropy, and log_loss	5565
greatest feature	The size of the random subset of features is considered when dividing nodes. The lower the value, the more the variance decreases, but the more the deviation increases	1124
largest node	The maximum value of leaf nodes, used to limit their growth	12
incremental	The number of base learners is usually better with larger values, but the computation time increases accordingly. When the number of trees exceeds a When the number of trees exceeds a critical value, the performance of the algorithm does not significantly improve.	1
random number	Used to control the randomness of samples during tree construction	6

In this paper, the HR architecture consists of three main layers: the data layer, the control layer, and the interaction layer (i.e., the user interface layer). The data layer is responsible for storing, maintaining, and protecting the system data. The control layer is responsible for receiving requests from the interaction layer, interacting with the data layer, and finally sending the processed results back to the interaction layer. The interaction layer is committed to providing users with an intuitive and easy-to-understand web interface, which transforms complex business logic into a visual interface. This interface allows users to quickly realize all kinds of business needs and form an intuitive user experience. With the rapid development of artificial intelligence technology and the increasingly refined division of labor in society, enterprises have put forward more stringent requirements and cost control standards for the digital management of human resources. In order to quickly adapt to the changing operating environment and market demand, companies must continuously optimize their management and internal processes. Therefore, using the Random Forest method to predict employee turnover has become an effective strategy for HR managers to reduce personnel risks and costs. The random forest algorithm with random correction is shown in Table VII.

TABLE VII. RANDOM FOREST ALGORITHM WITH STOCHASTIC CORRECTION

Variant	Search (1)	Search (2)	Envir (1)	Envir (2)
modified effect	0.1417***	0.0214***	0.0654***	0.0251***
observed value	5147	5147	5147	5147
control variable	be	be	be	be

industry fixed effect	be	be	be	be
area fixed effect	clogged	clogged	clogged	be

A specific model for enterprise data effectiveness assessment:

$$X_{new} = x_i + rand(0,1) \times (y_j - x_i)(j = 1,...,P) \quad (4)$$

In Eq. (4) $rand(0,1)$ is the reordering of the independent variables of function x; $Mar(Q,V_T)$ the function is specified as follows:

$$Mar(Q,V_T) = ave(V_T) - E^* \le \frac{\overline{\rho}(1-s^2)}{\delta^2} \quad (5)$$

$$F1 = \frac{2 \times precision \times recall}{precision + recall} \quad (6)$$

In Eq. (5) and Eq. (6), $ave(V_T)$ is the functional form for finding the mean of the *V* function. It $precision \times recall$ is the precision and return value of the function *F1*.

The process of product creation is highly personalized and intelligent. Unlike traditional industrial products, which rely on repetitive mechanical operations, it relies heavily on the ingenuity and innovation of researchers and developers. During the project preparation stage, the R&D staff enjoys the support of abundant resources, such as various types of machinery and equipment. The diversity of human resources refers to the differences in technical expertise, knowledge base, and personal attributes of the company's employees. This diversity has two significant effects on staff allocation: first, the diversity of staff skills directly affects the timeliness of task completion, which is reflected in the different skills of researchers and developers with the same qualifications in terms of age, seniority, experience, and education, which in turn has an impact on performance. Second, employee diversity is also affected by the time between multiple projects. In the actual R&D process, each developer is unique in terms of the underlying design experience he or she possesses. Taking the R&D department of a Web enterprise as an example, any software project can be disassembled into several independent

tasks, each carrying a different workload and content, during the functional analysis and requirements combing phase before the official launch. From the perspective of task allocation, equipping a single task with a combined team with different R&D skills and experience can effectively adjust the project delivery circle.

In the data comparison of Fig. 1, it was found that the performance evaluation data had more significant differences than the performance evaluation data. Therefore, performance evaluation data should be selected for analysis of data density in the study. Fig. 2 shows the process of data density analysis. In order to more significantly highlight the results of the data difference test, polar coordinates were used for this test. The data was divided into intervals of 0-2 π and subjected to extreme segmentation approaching "positive infinity", resulting in a continuous polar coordinate graph of the stability level of the data. The results showed that only at 1/8-3/8 of the data, the stability exceeded the LV3 level, but at other stages, the data exceeded the LV1 level, meeting the testing criteria, as shown in Fig. 2.

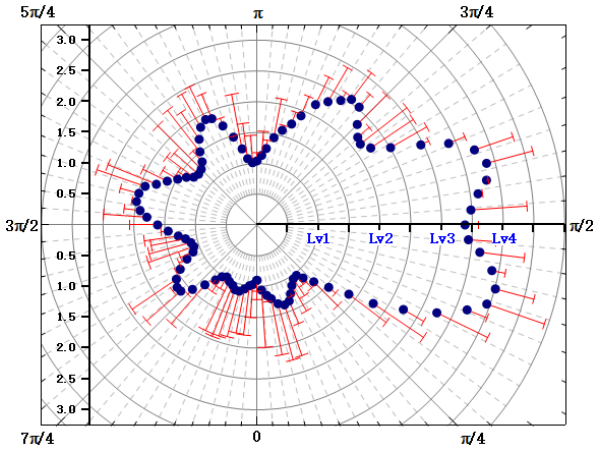

Fig. 2. Human resources effectiveness assessment density.

V. Conclusion

This study has achieved a series of significant findings and results through the classification and effectiveness assessment of enterprise human resource data based on the random forest algorithm. With the continuous development of information technology, effective management of human resources in enterprises has become increasingly important, and the method proposed in this study provides an effective way to process and analyze data, providing deeper insights and decision support for human resource management. First of all, by classifying enterprise human resource data, it is possible to manage and analyze employees more refinery. The classification model constructed based on the Random Forest algorithm can accurately categorize employees according to their characteristics and labels, helping enterprises understand the basic situation of employees, their work characteristics, and potential development direction. This gives enterprises a more comprehensive view of talent management, which helps them develop more personalized training, motivation, and promotion plans for different groups and improves employee job satisfaction and loyalty. Secondly, the performance evaluation model provides an objective and scientific performance evaluation method for enterprises. Analyzing employee performance data and other relevant indicators can assess the contribution and effectiveness level of employees in the organization and help companies identify high-performance employees and potential room for performance improvement. This provides an essential decision-making basis for enterprises and helps optimize the allocation of human resources and improve the overall performance and competitiveness of the organization.

The classification and effectiveness assessment method of enterprise human resource data based on the random forest algorithm has important theoretical significance and practical value. The automated processing and analysis of enterprise human resource data can better understand the characteristics and behaviors of employees and provide more accurate and comprehensive decision support for enterprise managers. In the future, the algorithmic model can be further optimized, combined with more data sources and indicators, and the classification and evaluation system can be improved to cope with the ever-changing market environment and enterprise needs. At the same time, the model can be validated and applied in combination with specific business scenarios and actual cases to improve its accuracy and practicality further and provide more robust support for the sustainable development and innovation of enterprises.

Feature Selection Methods Using RBFNN Based on Enhance Air Quality Prediction: Insights from Shah Alam

Siti Khadijah Arafin[1], Ahmad Zia Ul-Saufie[2], Nor Azura Md Ghani[3], Nurain Ibrahim[4]*
School of Mathematical Sciences, College of Computing, Informatics and Mathematics, Universiti Teknologi MARA, Shah Alam, Selangor, Malaysia[1, 2, 3, 4]
Institute for Big Data Analytics and Artificial Intelligence (IBDAAI), Kompleks Al-Khawarizmi, Universiti Teknologi MARA, Shah Alam, Selangor, Malaysia[4]

***Abstract*—This study examines the predictive efficiency of several feature selection approaches in air quality models aimed to predict next-day PM2.5 concentrations in Shah Alam, Malaysia. Air pollution in urban areas is a significant public health concern, and accurate prediction models are essential for timely interventions. However, determining the most important parameters to include in these models remains difficult, especially in complex urban areas with several pollution sources. To address this, we employed three different feature selection methods and applied them to a dataset comprising 43,824 air quality data points provided by the Department of Environmental Malaysia. The data set contained ten variables, such as gas pollutants and meteorological indicators. Each feature selection approach determined top eight variables to include in a Radial Basis Function Neural Network (RBFNN) model. The results showed that ReliefF outperformed Lasso and mRMR in terms of accuracy, specificity, precision, F1 Score, and AUROC, making it the most effective feature selection method for this study. This study contributes to the body of knowledge on air quality modelling by emphasising the relevance of using proper feature selection techniques that are suited to the specific characteristics of the dataset and urban area. Furthermore, it proposes that future study should look into the use of ReliefF-RBFNN in other settings, such as suburban and rural areas, as well as hybrid feature selection approaches to improve prediction performance across several context.**

Keywords*—Lasso; mRMR; PM2.5 concentration; RBFNN; ReliefF

I. Introduction

Globally, air quality has grown to be a major environmental and public health concern, especially in urban areas such as Shah Alam, Malaysia where pollution levels can have a substantial negative influence on people's quality of life. According to study [1], the rapid urbanization in Shah Alam has worsened environmental problems, including air quality deterioration. Predicting air quality, particularly the concentration of dangerous pollutants like PM2.5, is essential for mitigating these risks and providing guidance for public health initiatives. Although various pollutants contribute to air pollution, [2] suggest that PM 2.5 is the most significant affect air pollution. Numerous studies have explored various methods to forecast air quality by utilizing a variety of meteorological and environmental data such as PM10, PM2.5, CO, O3, relative humidity, ambient temperatures and wind speed.

In recent years, there has been a lot of focus on improving the accuracy of air quality predictions using powerful machine learning algorithms. Among these, feature selection approaches help to improve model performance by finding the most relevant variables while minimizing data dimensionality. [3] stated in their study that feature selection can improve model generalization by avoiding overfitting and mitigating the effects of the curse of dimensionality. According to study [4], filter technique, wrapper technique and embedded technique are three technique of feature selection. Various studies have applied different feature selection techniques on air quality data including Lasso, mRMR and reliefF. For instance, [5] used Lasso to find key features that influenced ozone (O3) levels during China's COVID-19 lockdown. Their findings revealed that Lasso efficiently identified key variables, such as O3 and meteorological conditions, which improved the model's interpretability. Moreover, the study in [6] presented a novel method that combines mRMR with Random Forest (RF) and Long Short-Term Memory (LSTM) networks to estimate the Air Quality Index (AQI). Their research showed that mRMR successfully identified key variables influencing AQI, greatly improving the model's predictive capability. Besides, ReliefF was used as a feature selection method for air pollution analysis in the Zonguldak region of Turkey in a study by [7]. They compared the performance of ReliefF with a firefly-based feature selection algorithm and found that even though ReliefF was effective, the firefly-based method outperformed it in classification tasks using Random Forest classifiers. However, most researchers prefer filter approaches because they have a straightforward algorithmic framework and are thus simple to apply [7]. However, the effectiveness of filter and embedded feature selection methods especially in predicting air quality data is still questionable.

Hence, this study aims to determine which feature selection method provides better performance in predicting air quality. This study compares two filter feature selection method and one embedded feature selection method which are Maximum Relevance Minimum Redundancy (mRMR), ReliefF and Least Absolute Shrinkage and Selection Operator (Lasso). The findings of this study will help to build more reliable air quality

forecast models, with consequences for public health and environmental management. This paper is organized as follows: I. Introduction, II. Method, III. Results and Discussion. Then, it followed by the conclusion in Section IV and the reference lists.

II. METHOD

A. Research Flowchart

Fig. 1 below shows the flowchart outlines of this study to predicting next-day PM2.5 levels in Shah Alam, Malaysia, using air quality data from 2018 to 2022 provided by the Department of Environment, Malaysia. Data extraction is the first step in the process, which is then followed by extensive data pre-processing, such as imputation using linear interpolation, converting hourly data to daily figures, binary categorisation of PM2.5 levels, min-max normalisation, and dataset balancing using SMOTE. Next, three feature selection methods which are mRMR, Lasso, and ReliefF are applied to rank and select the top eight variables most relevant to predicting PM2.5. These selected features are then used to train a Radial Basis Function Neural Network (RBFNN), with the model's performance evaluated based on accuracy, specificity, precision, F1 Score, and AUROC. Finally, the best-performing model is identified by combining effective feature selection with the RBFNN.

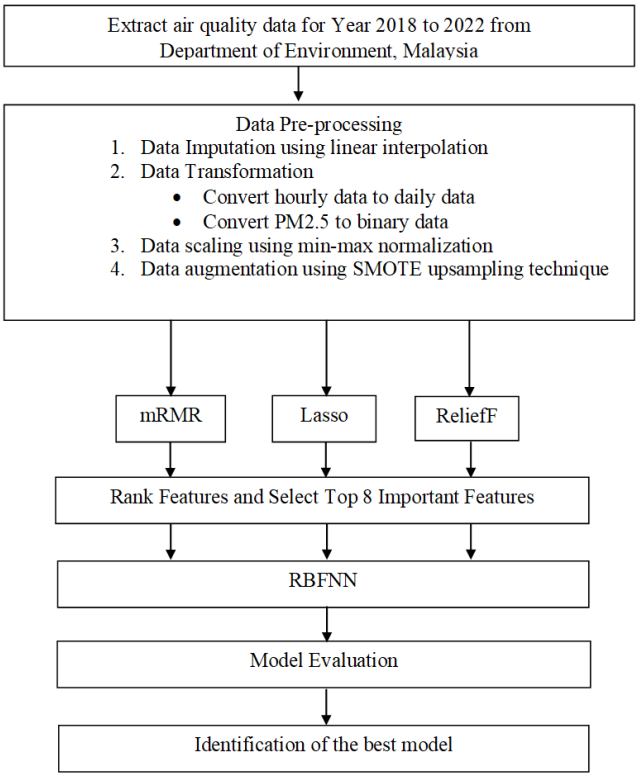

Fig. 1. Research flowchart.

B. Data Description

The Department of Environmental Malaysia provided 43,824 air quality data points for 10 variables, such as gas pollutants and meteorological parameters, collected in Shah Alam. Table I below shows the percentage of missing values for each variable. Based on Table I, all variables have missing values below 10% except NO2 with 12.65% of missing data. In contrast, PM2.5 has a low percentage of missing values with just 1.29% of missing data. Missing values can arise from various sources, including sensor malfunctions, environmental conditions, or data transmission errors. High levels of missing data, particularly in gas pollutants, could introduce biases or reduce the statistical power of the analysis if not properly addressed. Therefore, we applied linear imputation methods to ensure that these gaps do not compromise the accuracy of the predictive models.

TABLE I. PERCENTAGE OF MISSING VALUES

Variable	N	Missing Value
PM2.5	43257	567 (1.29%)
PM10	43151	673 (1.54%)
SO2	41242	2582 (5.89%)
NO2	38280	5544 (12.65%)
O3	41198	2626 (5.99%)
CO	40629	3195 (7.29%)
WD	42925	899 (2.05%)
WS	42868	956 (2.18%)
Humidity	42907	917 (2.09%)
Temperature	42926	898 (2.05%)

To predict the next day's air quality based on PM2.5 levels, we used a binary classification system where 0 represents “not polluted” and 1 represents “polluted”. We followed the methodology of [8], wherein the Air Quality Index (AQI) categories “Good” and “Moderate” were combined into the “not polluted” class, while the other categories were grouped into the “polluted” class. Table II shows the PM2.5 breakpoints (24-hour average) as defined by the U.S. Environmental Protection Agency (EPA).

TABLE II. BINARY LABELS FOR THE RESPECTIVE PM2.5 BREAKPOINT AND AQI CATEGORIES

AQI Category	PM2.5 Breakpoints
Good	0.0-12.0
Moderate	12.1-35.4
Unhealthy for Sensitive Groups	35.5-55.4
Unhealthy	55.5-150.4
Very Unhealthy	150.5-250.4
Hazardous	250.5 and above

C. Feature Selection Method

1) Lasso: The Least Absolute Shrinkage and Selection Operator (Lasso) is an embedded feature selection method that improves model performance by selecting and regularizing variables at the same time. Linear regression assigns weight to each feature, while LASSO regression proposed by Robert Tibshirani removes less significant ones from the subset [9]. Lasso effectively eliminates less significant features from the model by forcing some of the coefficients to be exactly zero by adding a penalty to the loss function that is equal to the absolute value of the magnitude of the coefficients. Furthermore, the study in [10], stated that Lasso method goals

are to lower the variance in models with a high number of unnecessary variables.

The formula to calculate Lasso is shown in Eq. (1) below. Where, $\sum_{j=1}^{p}|\beta_j|$ is known as L_1 penalty term and the value is must below or equal to t, which is the upper bound of the summation of the absolute coefficients. While λ is the tuning parameter which controls the strength of the penalty (Ibrahim, 2020).

$$\hat{\beta} = \min \beta \left\{ \sum_{i=1}^{N} \left(y_i - \beta_0 - \sum_{j=1}^{p} x_{ij}\beta_j \right)^2 + \lambda \sum_{j=1}^{p} |\beta_j| \right\} \quad (1)$$

2) Maximum relevance minimum redundancy (mRMR): Maximum Relevance Minimum Redundancy (mRMR) is a widely used feature selection technique that seeks to reduce redundancy among the independent variables while identifying a subset of features that are most significant to a target variable. This method works especially well with high-dimensional datasets, where the number of features can significantly exceed the number of observations, making traditional modelling techniques less effective. The formula to calculates the maximum relevance shown in Eq. (2):

$$maxD(S,c), D = \frac{1}{|s|}\sum_{x_i \in s} I(x_i, c) \quad (2)$$

Based on the Eq. (2), x_i represents the i-th feature, while $c = \{c_0, c_1\}$ represents the class variables which is not polluted and polluted. L is 2 which denotes the total number of classes, and S indicates the feature subset. Moreover, to calculates the minimum redundancy shown in Eq. (3) below.

$$minR(S), R = \frac{1}{|s|^2}\sum_{x_i, x_J \in S} I(x_i; x_J) \quad (3)$$

3) ReliefF: ReliefF algorithm is an extended version of the Relief algorithm. It is a filter-based feature selection method that used to identify a feature's contribution to a target variable's prediction in order to find relevant features in high-dimensional data [11]. Unlike conventional methods, which just rely on statistical correlations or regression analysis, ReliefF operates by evaluating each feature's ability to differentiate between instances that belong to distinct classes. It has been demonstrated that ReliefF can handle noisy data and identify reelevant features in high-dimensional datasets [12].

The algorithm finds the k-nearest neighbours by repeatedly choosing random examples from training datasets. Finding the k-nearest in distinct classes, M_j (C), (j=1,2,…,k), where Euclidean distance is employed to determine the k-nearest neighbours, and H_j, (j=1,2,…,k) of R inside the same class [13]. The significance of each feature is estimated using the variation in feature values between these neighbours. Features that show significant variation across classes and small variations within the same class are more important. The weight of each characteristic is determined using the Eq. (4) below. While Eq. (5) is how the $diff$ is calculated [13].

$$w(f_i) = w(f_i) - \sum_{j=1}^{k} \frac{diff\left(f_i, R, H_j\right)}{mk} + \sum_{c \neq class(R)} \frac{p(C)}{1 - p\left(class(R)\right)} X \sum_{j=1}^{k} \frac{diff\left(f_i, R, M_j(C)\right)}{mk}, \quad (i = 0,1,\dots,d) \quad (4)$$

$$diff(A, R_1, R_2) = \begin{cases} \frac{|R_1[A] - R_2[A]|}{\max A - \min A}, & if\ A\ is\ continous \\ 0, & if\ A\ is\ discrete\ and\ R_1[A] = R_2[A] \\ 1, & if\ A\ is\ discrete\ and\ R_1[A] \neq R_2[A] \end{cases} \quad (5)$$

where $diff(A, R_1, R_2)$ denotes the difference between samples R_1 and R_2 on feature A. While $R_1[A]$ and $R_2[A]$ indicate the values of sample R_1 and R_2 on feature A (Zhang et al., 2022).

4) Radial basis function neural network: Radial Basis Function Neural Networks (RBFNNs) are a subset of artificial neural networks that used radial basis functions as activation functions. The abilities of the model to describe complex nonlinear interactions makes them especially useful for problems involving function approximation, classification, and regression. There are three important layers in RBFNN which are the input layer, hidden layer, and output layer that are generally connected by weights. Firstly, a source node, also known as the independent variable is connected to the network to its surroundings in the input layer, meanwhile, the hidden layer involves a nonlinear transformation from input space to a high-dimension hidden space. Lastly, the output layer is the outcome of the network that applied to the input layer or called the predicted output. Fig. 2 shows the general framework of RBFNN [14].

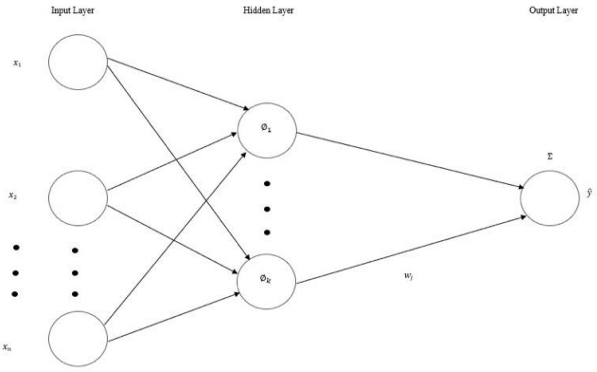

Fig. 2. General framework of a RBFNN.

The hidden layer comprises individual units, each corresponding to a transfer function $\emptyset_j$, which is generally a Gaussian function. The radial basis function (RBF), characterized by its radially symmetric shape, serves as the transfer function in this context. The number of hidden layer units directly corresponds to the number of RBFs used. The Gaussian radial basis function is formally defined in Eq. (6).

$$\emptyset(x) = \exp(-\frac{||x-c||^2}{2\sigma^2}) \quad (6)$$

where x is the input vector, c is the center of the RBF, and σ is the spread (width) parameter. The output of the hidden layer is calculated by taking a weighted sum of these radial basis functions. Specifically, for an input vector $X = \{x_1, x_2, \dots, x_n\}$, the output of the hidden layer is given in Eq. (7).

$$g(X) = \sum_{j=1}^{k} w_j \emptyset_j(r\|X - C_j\|) \quad (7)$$

where w_j are the weights associated with the radial basis functions, C_j are the centers of the RBFs, while r is a scaling factor. In RBFNN, the output layer typically utilizes a logistic (sigmoid) activation function for binary classification tasks. The logistic function, as represented in Eq. (8), is employed to convert the weighted sum of the hidden layer outputs into a probability value within the interval of 0 to 1.

$$\sigma(z) = \frac{1}{1+e^{-z}} \quad (8)$$

Hence, the final output calculation of the RBFNN for binary classification is shown in Eq. (9), where w_0 is a bias term.

$$\hat{y} = \sigma\,(w_0 + \sum_{j=1}^{k} w_j \emptyset_j(r\|X - C_j\|)) \quad (9)$$

D. Model Performances

The performance of developed model in this study will be evaluated based on accuracy, sensitivity, specificity, precision, F1 score and AUROC. The accuracy is the number of correct predictions in a given number of predictions [15]. The formula to calculates accuracy is shown in Eq. (10):

$$Accuracy = \frac{(TP + TN)}{(TP + TN + FP + FN)} \quad (10)$$

Sensitivity and specificity are used to explain the relationship between the system's input and output variables and to evaluate the model's resilience in the face of uncertainty. The percentage of real positives that are correctly identified is known as sensitivity, or the True Positive (TP) rate, while the percentage of real negatives that are correctly recognised is known as specificity, or the True Negative (TN) rate. The following Eq. (11) and Eq. (12) provide the formulas for determining specificity and sensitivity, respectively.

$$Sensitivity = \frac{TP}{(TP+FN)} \quad (11)$$

$$Specificity = \frac{TN}{(TN+FP)} \quad (12)$$

Precision quantifies the proportion of correctly classified positive samples out of all samples classified as positive. On the other hand, the F1 score represents the harmonic mean of precision and sensitivity, providing an indication of whether the model's performance is well-balanced. Eq. (13) and Eq. (14) below present the formulas for calculating precision and the F1 score, respectively.

$$Precision = \frac{TP}{(TP+FP)} \quad (13)$$

$$F1\ Score = \frac{2\,x\,Precision\,x\,Sensitivity}{(Precision+Sensitivity)} \quad (14)$$

ROC (Receiver Operating Characteristic) curve examines the relationship between the true positive rate (sensitivity) on the y-axis and the false positive rate (1-specificity) on the x-axis, serving as a tool to assess the performance of the classifier. The AUROC (Area Under the ROC Curve) quantifies the model's ability to distinguish between classes. The AUC value ranges from 0 to 1, where an AUC of 0.0 signifies a model with entirely incorrect predictions, and an AUC of 1.0 indicates a model with perfectly accurate predictions. Hence, high values of accuracy, sensitivity, specificity, F1 score and AUROC indicates that the performance model is good.

III. Results and Discussion

This section displays the result and discussion of this study. Table III presents the descriptive statistics for the independent variables, which shows a broad range of standard deviations from 0 to 48.507, showing different scales for each variable. To address this, the data was standardized using min-max normalization, as described by [16] in their study on prediction of air pollutants for air quality using deep learning methods in a metropolitan city. Furthermore, the histogram for the $PM2.5_{Dt1}$ category in Fig. 3 shows an imbalance in the distribution. Thus, the Synthetic Minority Over-sampling Technique (SMOTE) was used to ensure a balanced dataset, improving the dependability of future results.

The descriptive statistics after data pre-processing are shown in Table IV. Following min-max normalization, all mean and median values now fall within the range of 0 to 1, indicating that the data has been successfully scaled to a standard range. Additionally, the skewness values are now closer to 0, reflecting a more balanced distribution across the dataset. Moreover, Fig. 4 shows the distribution of $PM2.5_{Dt1}$ after the application of SMOTE up sampling to the dataset. It demonstrates that there is a consistent amount of sample sizes in both groups, with 1676 (50.6%) not polluted and 1639 (49.4%) are polluted.

TABLE III. Descriptive Statistics of before Data Pre-Processing

Variable	N	Mean	Median	Std. Dev.	Skewness
PM2.5	1825	23.321	21.187	11.712	4.142
PM10	1825	32.554	30.244	13.739	3.086
SO2	1825	0.001	0.001	0.000	1.330
NO2	1825	0.015	0.015	0.005	0.308
O3	1825	0.020	0.019	0.007	0.800
CO	1825	0.770	0.754	0.266	0.447
WD	1825	206.597	205.583	48.507	0.106
WS	1825	0.820	0.783	0.240	1.468
Humidity	1825	80.138	80.109	6.603	-0.151
Temperature	1825	27.552	27.573	1.247	-0.155

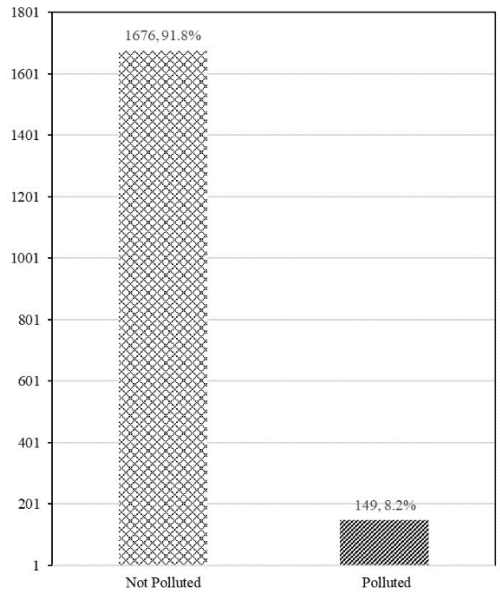

Fig. 3. $PM2.5_{Dt1}$ distribution of (Before SMOTE).

TABLE IV. DESCRIPTIVE STATISTICS OF AFTER DATA PRE-PROCESSING

Variable	N	Mean	Median	Std. Dev
PM2.5	3315	0.176	0.144	0.142
PM10	3315	0.219	0.190	0.146
SO2	3315	0.227	0.215	0.100
NO2	3315	0.426	0.423	0.165
O3	3315	0.333	0.315	0.130
CO	3315	0.395	0.388	0.165
WD	3315	0.522	0.510	0.183
WS	3315	0.214	0.201	0.100
Humidity	3315	0.520	0.517	0.146
Temperature	3315	0.559	0.565	0.118

Table V shows the rankings independent variables according to three feature selection methods which are Lasso, mRMR, and ReliefF on predicting $PM2.5_{D+1}$ in Shah Alam. Each features methods identifies top 8 independent variables to includes in the RBFNN model. The Lasso method ranks PM2.5 as the most critical feature to predict PM2.5 levels of the next day, a result that contrasts with the mRMR and ReliefF methods, where PM2.5 is not included among the top 8 features. However, the mRMR method select PM10 as the most significant feature while Lasso method rank PM10 as second most important features.

ReliefF, on the other hand, identify wind direction as the most important feature. This implies that variations in wind direction can result in significant variations in the dispersion or concentration of pollutants in urban environments. Moreover, [17] investigated the relationship between wind direction and air quality, specifically focusing on fine particulate matter (PM2.5) and its precursor gases. The investigation shows that the distribution and concentration of these contaminants are strongly influenced by wind direction. Moreover, this study shows ReliefF ranks both humidity and temperature as the least important features which is 7 and 8, in contrast to the Lasso and mRMR methods, which assign higher importance to these variables in predicting PM2.5 levels.

Furthermore, all three methods did not select SO2 as top 8 important variables to predict PM2.5 levels of the next day. According to a study by [18] on analysis of air pollution levels in a settlement area using passive sampling methods. Despite of SO2 presence, their results showed that SO2 had a small impact on the area under study's overall air quality index (AQI). This study supports the findings that SO2 may not have a significant impact on air quality projections, especially in areas where other pollutants predominate.

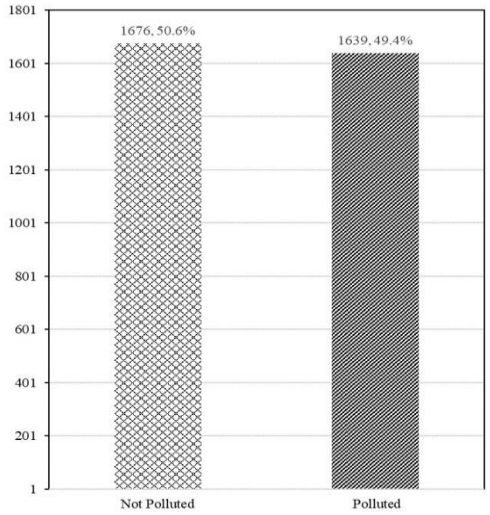

Fig. 4. $PM2.5_{Dt1}$ distribution of (After SMOTE).

TABLE V. FEATURE RANKING ACROSS LASSO, MRMR, AND RELIEFF METHODS

Variable	Lasso	mRMR	reliefF
PM2.5	1	-	5
PM10	2	1	6
SO2	-	-	-
NO2	4	6	2
O3	-	3	4
CO	6	7	3
WD	7	8	1
WS	8	2	-
Humidity	3	5	7
Temperature	5	4	8

Table VI shows the comparison of RBFNN model performance by using different feature selection methods to predict air quality of the next day based on PM2.5 level. According to Table VI, ReliefF outperformed Lasso and mRMR method with higher accuracy, specificity, precision, F1 Score and AUROC value which are 0.757, 0.719, 0.719, 0.758 and 0.759 respectively. This findings contrast with a study by

[9], who found that the Lasso method outperformed the ReliefF method in terms of performance metrics. However, it is important to note that [9] utilized a different classifier, specifically KNN, whereas this study employs RBFNN. Besides, a comparative study by [19], ReliefF was evaluated alongside Lasso and mRMR for survival prediction models. The findings showed that ReliefF was able to consistently find more relevant features than Lasso and mRMR, which had difficulty to maintain stability in their selections.

TABLE VI. COMPARISON MODEL PERFORMANCE

Model	Lasso	mRMR	ReliefF
Accuracy	0.735	0.753	**0.757**
Sensitivity	0.771	**0.818**	0.801
Specificity	0.702	0.703	**0.719**
Precision	0.702	0.703	**0.719**
F1 Score	0.735	0.756	**0.758**
AUROC	0.736	0.756	**0.759**

IV. CONCLUSION

In conclusion, this study's findings highlight the variety in feature selection approaches and their impact on the predictive effectiveness of air quality models in urban area which is Shah Alam, Malaysia. Among the three methods evaluated, ReliefF emerged as the most successful feature selection method for predicting next-day PM2.5 levels, outperforming both Lasso and mRMR in terms of accuracy, specificity, precision, F1 Score, and AUROC. This outcome aligns with some research that underscores ReliefF's ability to reliably detect relevant features, although other studies have favored the Lasso method. This study recommends that future research to explore the application of reliefF-RBFNN method to other type of areas such as sub-urban and rural area. This study also suggests that future studies should be conducted in other urban regions with varying climatic and pollutant features to confirm the generalisability of the findings and to develop more robust air quality prediction models that can be tailored to various situations. Moreover, it is recommended future researcher to explore on hybrid feature selection method such as ReliefF (filter) integrated with Lasso (embedded) feature selection method that might improve prediction performance across a variety of urban settings. However, the output of this study is not generalised to other country as the air quality patterns are differed across country.

Optimizing CatBoost Model: AI-Based Analysis on Rail Transit Figma Platform Practice

Ruobing Li[1,*], Hong Qian[2]
College of Innovation and Entrepreneurship, Xi'an Traffic Engineering Institute Xi'an 710300, Shaanxi, China[1, 2]

***Abstract*—The research introduces a novel approach that utilizes the Frilled Lizard Optimization (FLO) algorithm to enhance the hyperparameters of the CatBoost model. First, the Figma platform is analyzed in terms of its innovative design applications in rail transit. Then, the FLO algorithm is applied to optimize the CatBoost model, improving its accuracy in detecting foreign objects on rail tracks. Experiments were conducted using a dataset of 6,000 images from rail transit scenarios, divided into seven categories such as left-turning track, straight track, train, pedestrians, and others. The result showed that the FLO-CatBoost model demonstrated superior performance in accuracy, achieving a Root Mean Square Error (RMSE) of 0.274, significantly outperforming other algorithms like TSA, MPA, and RSA. Furthermore, FLO-CatBoost reduced the Mean Absolute Percentage Error (MAPE) and showed better efficiency in evaluation time. Finally, the FLO-CatBoost model significantly enhances the design and evaluation processes for intelligent rail transit systems on the Figma platform, providing higher accuracy and efficiency in detecting foreign objects and improving system design performance.**

Keywords*—Rail transport; Figma platform innovation design; intelligent analysis and evaluation algorithm; umbrella lizard optimisation algorithm; CatBoost

I. Introduction

Rapidly developing artificial intelligence technology as well as Internet technology has driven the development of software innovation, which has received attention from scholars and experts at home and abroad [1]. Figma software, as an online collaborative and instantaneous design software, can assist designers in creating, collaborating and iterating design projects [2]. Due to the advantages of real-time, collaboration, compatibility, synchronisation, and cloud storage, Figma design platform has an increasingly wide range of application areas, and receives more and more attention and research from experts in the field. In the field of rail transit, with the rapid development of rail transit, the train speed is getting faster and faster, and the way of judging the foreign objects in front of the car by human beings is no longer adapted to the development of the current era [3]. The study of accurate autonomous detection methods of foreign objects in rail transit not only reduces the rate of rail transit accidents, but also strengthens the detection and processing of emergency events in rail transit [4]. In order to generalise the application of autonomous detection system for foreign objects in rail transit and improve the design efficiency of autonomous detection system for foreign objects in rail transit, the combination of Figma design platform has become the development trend and method of intelligent system design. The research on innovative design of rail transit system combined with Figma design platform includes the research on design principle analysis, design method testing and evaluation, etc., in which the design method testing and evaluation includes the research on design effect evaluation index extraction, evaluation system construction, design effect evaluation model construction combined with Figma design platform. Ye et al. [5] analysed the Figma design method for rail transit, and verified the testing accuracy and efficiency of the proposed method through the image dataset. Zhao [6] proposed an innovative design scheme and idea by combining with the Figma design platform. Maricar et al. [7] took the financial service as the background, and used the Figma to innovatively design its management system and made a quantitative analysis of the system. Cheng and Cai [8] proposed a deep learning algorithm based design platform evaluation and analysis method, and used a public dataset to verify the method to improve the design effect. Liu et al. [9] analysed the efficiency of Figma development and design, and gave a qualitative comparative analysis. With the complexity of intelligent systems, the simple Figma design platform effect analysis and evaluation method can no longer meet the assessment of the predictive accuracy effect, and reduces the efficiency of feedback optimisation. The proposal and development of integrated learning technology and intelligent optimisation algorithms accelerate the efficiency and analysis accuracy of Figma design platform application [10].

In order to improve the analysis and evaluation accuracy of the design effect of Figma platform and enhance the design efficiency, this paper proposes an intelligent analysis and evaluation method of Figma platform based on intelligent optimisation algorithm-CatBoost. By analysing the innovative design problems of Figma platform in rail transit, it introduces the related key on seems, and around the Figma platform intelligent analysis and evaluation problems, it combines the umbrella lizard optimization algorithm with CatBoost to construct Figma platform intelligent analysis and evaluation model. The data images of foreign objects in rail transit are brought into the model system for analysis and evaluation, and the results are compared and analysed with those of multiple algorithms to verify the effectiveness of the model in improving the precision and efficiency, as well as the accuracy of the evaluation.

II. Figma Platform for Rail Transport

A. Figma Platform

Figma is a popular online collaborative design tool [11], which supports real-time collaboration and browser-based design, and is widely used for UI/UX design. Figma provides a comprehensive design platform that includes design, prototyping, collaboration, and version control features, as

*Corresponding Author.

shown in Fig. 1. It aims to make design work more powerful, convenient, and approachable for individual designers, teams, and enterprises.

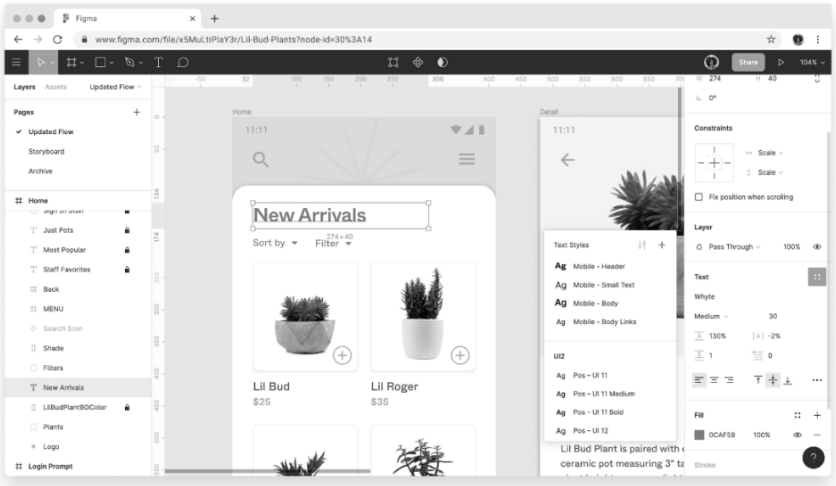

Fig. 1. Figma platform.

1) Figma characteristics: According to the analysis of Figma application, Fig. 2 presents that Figma has the following features and functions [12]:

- Figma allows multiple users to work on the same design file at the same time, while viewing and editing each other's content in real time;
- Many files are stored in Figma Cloud, users can access and edit files on any device at any time, without worrying about file synchronisation;
- Figma has a built-in prototype tool that allows users to create interactive prototypes directly in the design for easy testing and demonstration;
- Figma can record the history function, users can view and restore the past design state;
- In Figma, designers can create reusable components and styles for easy consistency throughout the design;
- Figma supports third-party plug-in development to expand functionality;
- Figma can be used on multiple operating systems and browsers.

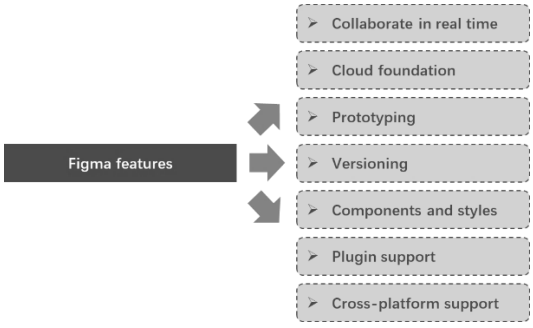

Fig. 2. Figma characteristics.

2) Figma application: Figma has become one of the standard tools in the design world, surpassing competitors such as Sketch, Adobe XD, etc., and has more than 4 million active users in more than 100 countries around the world. Figma's user base includes companies in a wide range of industries such as IT, financial services, advertising, retail, professional training, etc. (Fig. 3), such as Microsoft, Twitter, Dropbox, etc. [13].

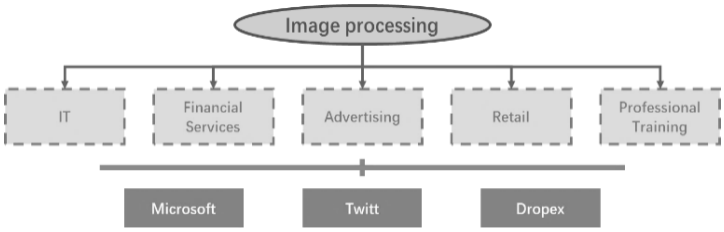

Fig. 3. Current status of Figma applications.

3) Figma design: Figma's design interfaces typically include the following four core components (Fig. 4):

- Canvas (Canvas). This area can hold various design elements such as shapes, text, images, etc.
- Sidebar. This section contains toolbars, layer lists and property panels. Designers can select and modify the properties of design elements through the sidebar.
- Top Menu Bar (Top Menu Bar). This section provides shortcuts to functions such as file management, editing, and view control.
- Component Library (Component Library). This section allows designers to create reusable design elements such as buttons, icons, etc. to be shared and maintained throughout the project [14].

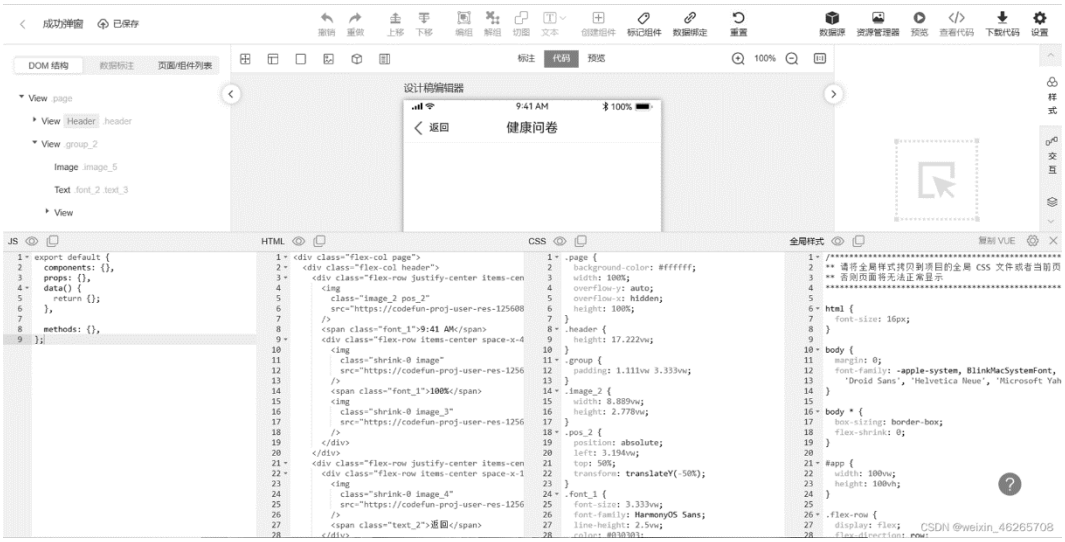

Fig. 4. Figma design interface.

B. Innovative Design Solutions

In order to improve the efficiency of intelligent rail transit autonomous detection system design, this paper proposes an intelligent rail transit autonomous detection system design scheme based on Figma platform, and at the same time, for the effectiveness of the scheme, an efficient machine learning algorithm is used to analyse and evaluate the performance of the intelligent rail transit autonomous detection system design method based on Figma platform.

1) Figma-based platform autonomous detection system: Intelligent rail transit autonomous detection system includes three parts: image acquisition layer, intelligent processing layer, and decision control layer. The system collects images through the starlight camera and inputs them to the image information processing system; the image information processing system analyses the collected data images in real time and identifies the track foreign objects and retrograde with high precision, and then gives correct decision-making information [15], the specific composition diagram is shown in Fig. 5.

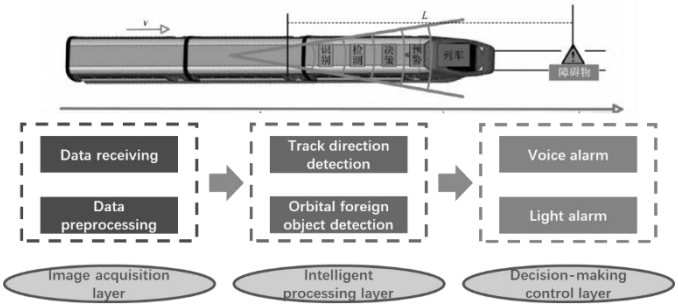

Fig. 5. Autonomous detection system for intelligent rail transit.

Combined with Figma platform, the design scheme of intelligent rail transit autonomous detection system based on Figma platform is proposed, as shown in Fig. 6. The design process of this design scheme is as follows: 1) In-depth study of the characteristics of the rail transit industry, user groups, existing workflows, and challenges, to determine the design objectives and core functional requirements; 2) Based on the results of the requirements analysis, conceptual design and preliminary sketches; 3) Interaction design using Figma, to create low-fidelity and high-fidelity prototypes of autonomous detection for rail transit; 4) Design After the prototype is completed, conduct user testing and collect user feedback; 5) conduct visual design on the basis of interaction design to ensure that the design style is in line with the professional image of the rail transport industry; 6) transform the design into an actual application, while ensuring the feasibility of the design and performance optimization; 7) conduct comprehensive testing after the completion of the development, and then carry out on-line deployment; 8) after the launch of the platform, continuously monitor the platform After going live, continuously monitor the platform's operation status and carry out the necessary maintenance and functional iteration and upgrade according to the feedback.

2) Analysis and evaluation programme: According to the design scheme combining Figma platform, this paper analyses and evaluates the Figma design effect of the rail transit detection system from six aspects [16] (Fig. 7), including the target and core function design A, sketching B, prototyping C, Figma platform interactivity D, operation of the rail transit detection system E, and analysis of the detection results F. By extracting the Figma design effect analysis assessment indicators, construct the assessment indicator set, use data preprocessing methods based on missing value deletion, noise data deletion, normalization, feature selection and other data preprocessing methods to process the assessment indicator dataset, annotate and divide the dataset, and combine with optimized CatBoost technology to construct the mapping relationship between the Figma design effect indicator values and the analysis and evaluation scores, and analyse and compare their performance, the specific overall idea is shown in Fig. 8.

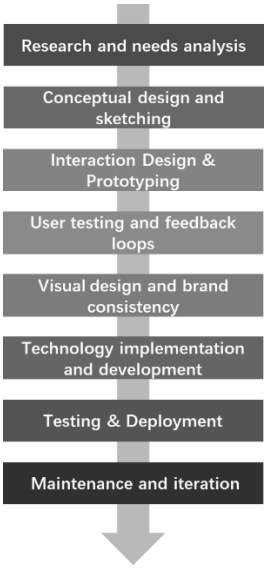

Fig. 6. Autonomous detection system for intelligent rail transit based on Figma platform.

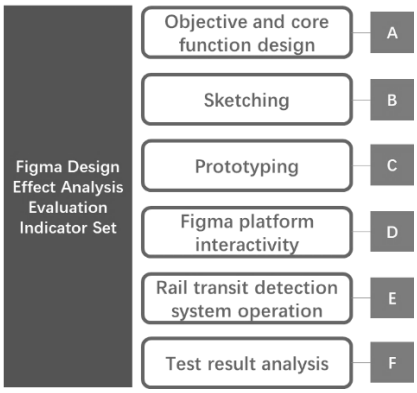

Fig. 7. The evaluation aspects of Figma's design effects analysis.

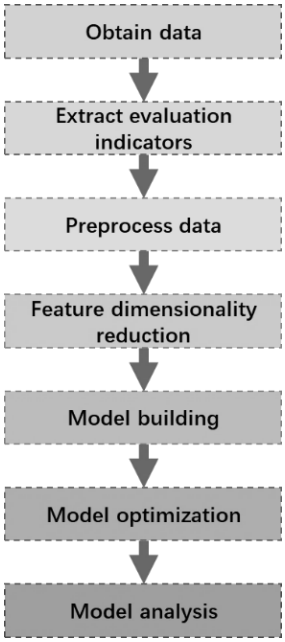

Fig. 8. Ideas for evaluating Figma's design effect analysis.

According to the design idea in Fig. 8, the analysis and evaluation scheme of rail transit detection system combined with Figma design platform includes key technologies such as autonomous detection design of rail transit on Figma platform, data acquisition, extraction of indicator set for analysis and evaluation of Figma design effect, data preprocessing, data annotation and division, and construction and optimisation of model for analysis and evaluation of Figma design effect, etc., and the specific key technologies are shown in Fig. 9. The specific key technologies are shown in Fig. 9.

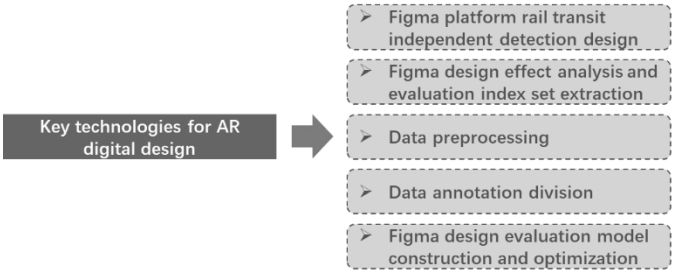

Fig. 9. Figma design effectiveness analysis and evaluation key technology.

III. Analysis and Evaluation Algorithms

A. Analysis of Intelligent Analytics Assessment Issues

According to the analysis of the key technology of Figma design effect analysis and assessment, Figma design intelligent analysis and assessment research as the key technology of the rail transit detection system analysis and assessment system combined with Figma design platform, by using the improved and efficient intelligent machine learning algorithm to fit the mapping relationship between the effect analysis assessment indicator values and assessment scores, as shown in Fig. 10. In this paper, CatBoost is used to construct the mapping relationship between assessment index values and assessment scores, and the umbrella lizard optimisation algorithm is used to optimise the hyper-parameters of CatBoost technology to improve the accuracy of analysis and assessment of the Figma design effect and enhance the effect of Figma design.

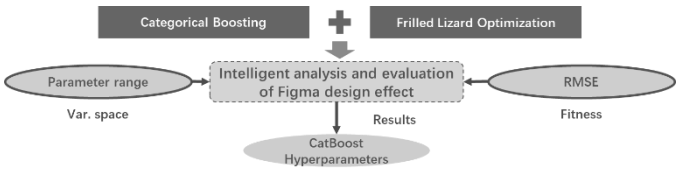

Fig. 10. Figma design analysis and evaluation method based on improved and efficient machine learning algorithm.

B. CatBoost Technology

CatBoost (Categorical Boosting) [17] is a gradient boosting algorithm that consists of two techniques, Categorical and Boosting, which can be used to handle classification and regression problems. It is one of the algorithms belonging to the Gradient Boosting Decision Trees (GBDT) family of algorithms and is well known for its ability to handle categorical features. CatBoost is able to automatically convert categorical features to numerical features, reducing the need for manual feature engineering, and is able to handle high cardinality categorical features without inducing dimensionality disaster, the structure of which is shown in Fig. 11. In addition, CatBoost effectively

reduces the bias of gradient estimation and improves the accuracy and generalisation ability of the model by using symmetric tree and sort boosting methods.

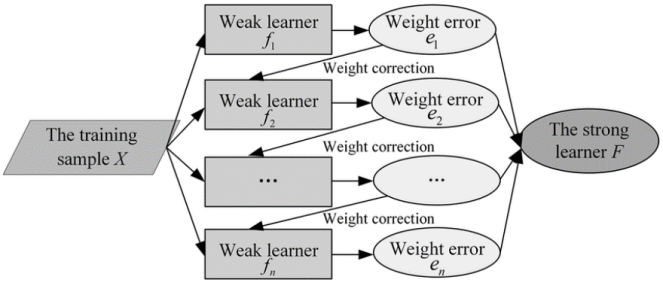

Fig. 11. CatBoost structure.

In CatBoost decision tree, CatBoost uses the Greedy TS method to process the category features [18], and equation changes are made to avoid conditional bias as follows:

$$x_k^i = \frac{\sum_{x_j \in D_k} \left\{ x_k^i = x_j^i \right\} \times y_i + aP}{\sum_{x_j \in D_k} \left\{ x_k^i = x_j^i \right\} + a} \tag{1}$$

Among them, P is the a priori value, which is mainly used to smooth the noise, a is the weight coefficient, and $\left\{ x_k^i = x_j^i \right\}$ is mainly used to judge whether the current sample k and sample j are in the same category, and the same is 1, and vice versa is 0.

Compared with other algorithms in the Boosting cluster class, the CatBoost algorithm is able to handle discrete feature data well and is suitable for problems with multiple input features. The CatBoost algorithm has the following features [19]: 1) automatic processing of category-based features; 2) reduction of gradient bias; 3) handling of missing values; 4) good robustness; 5) ease of use; 6) support for GPU acceleration; 7) Built-in cross-validation, as shown in Fig. 12.

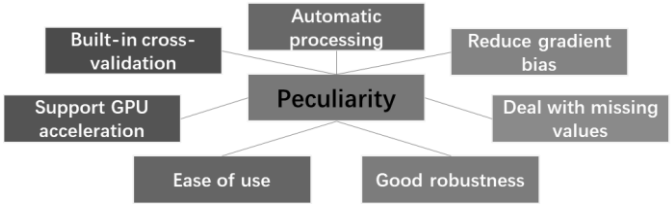

Fig. 12. CatBoost characteristics.

CatBoost is widely used for a variety of machine learning tasks due to its high performance and ease of use, including but not limited to financial risk assessment, recommender systems, bioinformatics, and natural language processing. Its ability to handle large-scale datasets and to deal with complex nonlinear relationships has made it the algorithm of choice in many real-world application scenarios [20-21].

C. Improved CatBoost Evaluation Model Based on Umbrella Lizard Optimisation Algorithm

With the increase of input data dimension, CatBoost algorithm training optimisation will fall into local optimum [21]. In order to improve the regression accuracy of CatBoost algorithm, this paper chooses the umbrella lizard optimisation algorithm to optimise the hyperparameters of CatBoost algorithm, so as to make the Figma platform innovation design analysis and evaluation model error to reach the minimum.

1) Umbrella lizard optimisation algorithm: Frilled Lizard Optimization (FLO) [22], as a biological meta-heuristic based algorithm, simulates the unique hunting behaviour of umbrella lizards in their natural habitat. The algorithm has a unique algorithmic structure and a novel iterative approach with strong adaptive optimisation capabilities.

The main diet of the wrinkled lizard is insects and other invertebrates, although it rarely eats vertebrates as well. Primary prey include centipedes, ants, termites, and moth larvae. The frilled lizard is a sit-and-wait predator, looking for potential prey. Upon seeing prey, the frilled lizard runs quickly on two legs and attacks the prey, catching it and eating it. After feeding, the frilled lizard retreats to a tree.

a) Initialisation: Like other optimisation algorithms, the FLO algorithm uses random initialisation for the population of wrinkled lizards:

$$X = \begin{bmatrix} X_1 \\ \vdots \\ X_i \\ \vdots \\ X_N \end{bmatrix}_{N \times m} = \begin{bmatrix} x_{1,1} & \cdots & x_{1,d} & \cdots & x_{1,m} \\ \vdots & \ddots & \vdots & \iddots & \vdots \\ x_{i,1} & \cdots & x_{i,d} & \cdots & x_{i,m} \\ \vdots & \iddots & \vdots & \ddots & \vdots \\ x_{N,1} & \cdots & x_{N,d} & \cdots & x_{N,m} \end{bmatrix}_{N \times m} \tag{2}$$

$$x_{i,d} = lb_d + r \cdot \left(ub_d - lb_d \right) \tag{3}$$

where X denotes the population of frilled lizards, X_i denotes the ith frilled lizard, $x_{i,d}$ is the d-dimensional position of the ith frilled lizard, and lb_d and ub_d denote the lower and upper boundaries of the d-dimension, respectively.

b) Hunting strategy (exploratory phase): One of the most typical natural behaviours of frilled lizards is hunting strategy animals. The frilled lizard is a sit-and-wait predator that attacks its prey when it sees it. The first stage of the FLO algorithm uses a hunting strategy, which is modelled as follows:

$$x_{i,d}^{P_1} = x_{i,d} + r \cdot \left(SP_{i,d} - I \cdot x_{i,d} \right) \tag{4}$$

$$X_i = \begin{cases} X_i^{P_1} & F_i^{P_1} < F_i \\ X_i & else \end{cases} \tag{5}$$

Where, $x_{i,d}^{P_1}$ denotes the location information of the ith frilled lizard in the dth dimension in the first stage of the FLO algorithm, r is a random number between 0 and 1, $SP_{i,d}$ denotes the location information of the ith frilled lizard in the

dth dimension for selecting the prey, I is a randomly selected number of the 1 and 2 number set, $F_i^{P_1}$ denotes the fitness value of $X_i^{P_1}$, and F_i denotes the fitness value of X_i .

c) Tree-climbing strategy (development phase): After feeding, the frilled lizard retreats to the top of a tree near its location. By modelling the movement of the frilled lizard to the top of the tree, the decision space position of the population individuals is made to change slightly, thus improving the algorithm's ability to exploit local search. In the second stage of FLO, the positions of population individuals in the solution space are updated according to the post-feeding tree-climbing strategy. The specific model is as follows:

$$x_{i,d}^{P_2} = x_{i,d} + (1-2r)\cdot\left(\frac{ub_d - lb_d}{t}\right) \tag{6}$$

$$X_i = \begin{cases} X_i^{P_2} & F_i^{P_2} < F_i \\ X_i & else \end{cases} \tag{7}$$

where, $X_i^{P_2}$ denotes the location information of the ith frilled lizard in the second stage of the FLO algorithm, $x_{i,d}^{P_2}$ denotes the information of the ith frilled lizard in the dth dimension in the second stage, t is the current number of iterations, and $F_i^{P_2}$ denotes the fitness value of $X_i^{P_2}$.

Combining the hunting strategy and tree-climbing strategy of the FLO algorithm, the step-by-step flow of the FLO algorithm (Fig. 13) is as follows:(a)

2) FLO-CatBoost: In order to enhance the design effect of Figma rail transit autonomous detection and improve the accuracy of analysis and evaluation performance, this paper takes CatBoost hyperparameters (number of decision trees, learning rate, maximum depth of the tree and L2 regularisation term) as the optimisation variables, FLO algorithm hunting strategy and tree-climbing strategy as the optimisation method, and RMSE error value as the fitness value function to optimise the CatBoost model. The specific process steps are shown in Fig. 14.

3) Application of FLO-CatBoost in analysing and evaluating the design effect of autonomous detection in Figma platform rail transit: In order to construct the Figma platform rail transit autonomous detection design effect analysis and evaluation model, this paper applies FLO-CatBoost to the Figma platform innovation design intelligent analysis and evaluation problem, and its specific application process is shown in Fig. 15.The application of FLO-CatBoost in Figma platform rail transit autonomous detection design effect analysis and evaluation mainly includes three parts The application of FLO-CatBoost in Figma platform rail transit autonomous testing and design effect analysis and evaluation mainly includes three parts, i.e. Figma platform rail transit autonomous testing and design effect analysis and evaluation index construction part, data pre-processing part, and Figma platform rail transit autonomous testing and design effect analysis and evaluation model construction and optimisation part. In the first part, the assessment indicators are extracted and the assessment indicator system is constructed by analysing the Figma platform innovative design intelligent analysis assessment problem; in the second part, the indicators are feature extracted by abnormal data preprocessing and normalizing the data set; in the third part, the mapping relationship between the values of the effect analysis assessment indicators and the assessment scores is constructed by using the CatBoost technology and the FLO algorithm is used to Optimisation of CatBoost model hyperparameters.

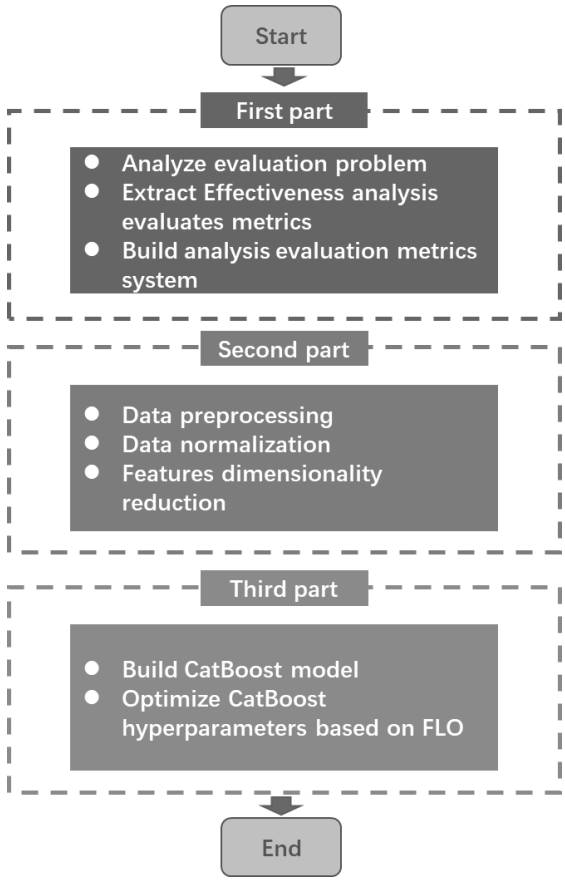

Fig. 15. Application of intelligent analysis and evaluation model for Figma platform combined with FLO-CatBoost.

IV. Simulation Results

A. Experimental Set-up

In this paper, FLO-CatBoost algorithm is simulated and tested in Python 3.7 environment and compared with TSA, MPA, RSA, WSO algorithms. The common parameters of TSA, MPA, RSA, WSO, FLO algorithms include the number of populations, the maximum number of iterations, and their values are set to 100, 1000, respectively. The values of TSA, MPA, RSA , WSO, FLO algorithms other algorithm settings are shown in Table I.

TABLE I. Contrast Algorithm Parameter Settings

No.	Algorithms	Parameter settings
1	CatBoost	Iterations=16, Learning_rate=0.1,depth=5,L2_leaf_reg=1
2	TSA-CatBoost	P_{min}=1, P_{max}=4, c1\c2\c3=rand
3	MPA-CatBoost	P=0.5, R=rand, FADs=0.2, U=0 or 1
4	RSA-CatBoost	Alpha=0.1, Beta=0.01, ES=[-2.2]
5	WSO-CatBoost	F_{min}=0.07, F_{max}=0.75,
6	FLO-CatBoost	No Parameter

In order to analyse the effect of the autonomous detection system of foreign objects in rail transit, this paper collects 6000 images, which are divided into seven categories of foreign object targets, such as left-turning track, right-turning track, straight track, train, pedestrians, wrench and safety, etc., and the sample images are shown in Fig. 16 and the distribution of the number of samples of foreign object targets is shown in Fig. 17.

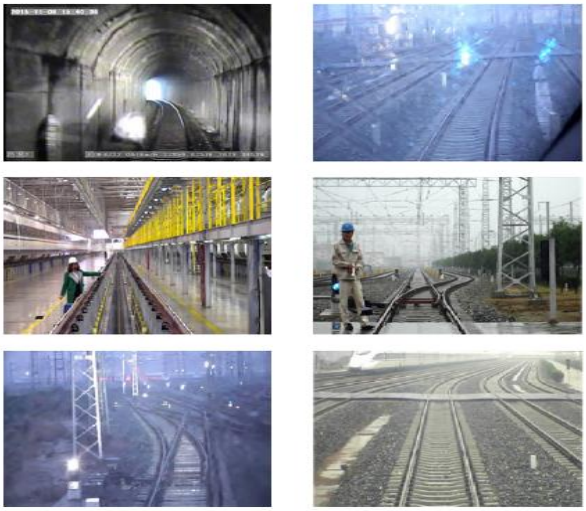

Fig. 16. Sample images.

Testing Figma Platform Intelligent Analytics Evaluation Model Performance Using Figma Platform evaluation metrics data, 1,890 sample data were collected, 1,250 for the training set, 430 for the testing set, and 210 for the validation set.

In order to avoid unexpected results of the experiment, the test optimisation process was repeated independently 10 times and the RMSE, MAPE, and evaluation time means and standard deviations were counted.

B. Algorithm Performance Analysis

1) Analysis of the effectiveness of autonomous detection of foreign objects in railway transportation combined with figma platform: Fig.18 presents the confusion matrix for autonomous detection of foreign objects in rail transport combined with Figma platform. From Fig. 18, it can be seen that the correctness of the detection of seven types of foreign object targets such as left-turn track, right-turn track, straight track, train, pedestrian, spanner and safety is more than 90%, which indicates that the detection results are good.

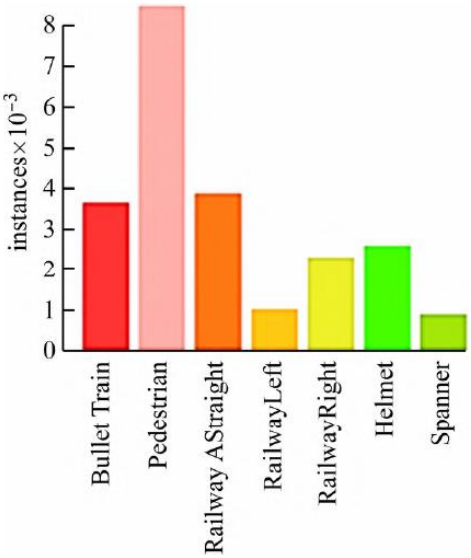

Fig. 17. Distribution of sample data.

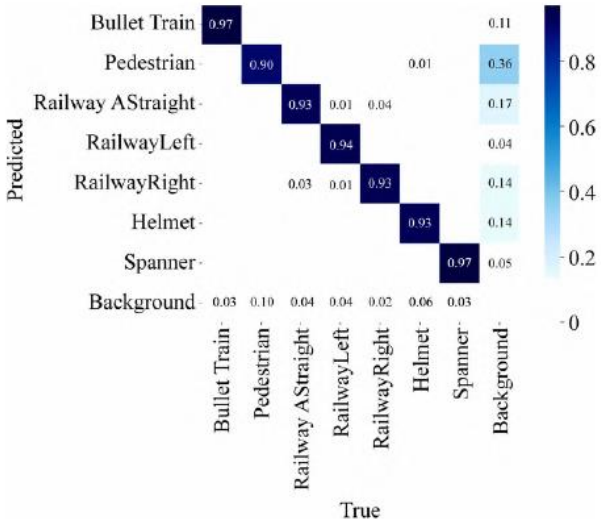

Fig. 18. Confusion matrix for autonomous detection of foreign objects in rail transport combined with Figma platform.

The Precision-Recall curves for autonomous detection of foreign objects in rail transport combined with Figma platform are given in Fig. 19 As shown in Fig. 19 the accuracy-recall curves for the seven categories of foreign object targets, such as left-turn track, right-turn track, straight track, train, pedestrian, spanner and safety, all indicate good detection results.

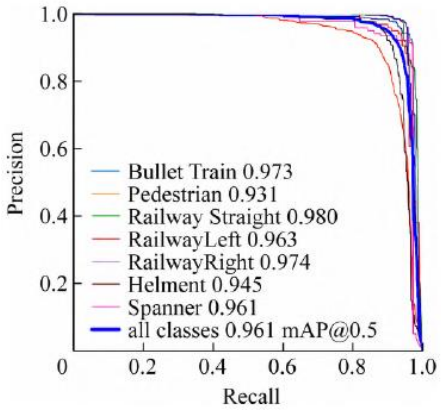

Fig. 19. Precision-Recall curve for autonomous detection of foreign objects in railway combined with Figma platform.

2) Analysis of the results of the assessment: Table II counts the RMSE, MAPE, evaluation time mean and standard deviation of different algorithms for 10 experiments. From Table II it can be seen that in terms of RMSE and MAPE, the analysis and evaluation accuracy of Figma rail transit design platform based on FLO-CatBoost model is better than other algorithms, and the evaluation time is more than that of CatBoost, and is better than that of TSA-CatBoost, MPA-CatBoost, RSA-CatBoost, WSO- CatBoost.This is to show that the optimisation of CatBoost hyperparameters by FLO algorithm makes Figma rail transit design platform analysis and evaluation more efficient.

TABLE II. MEAN AND STANDARD DEVIATION OF RMSE, MAPE, AND EVALUATION TIME FOR DIFFERENT ALGORITHMS

No.	Algorithms	RMSE		MAPE		Evaluation time/s	
		Mean	Std	Mean	Std	Mean	Std
1	CatBoost	1.4523	0.6554	0.5988	0.2673	0.0655	0.0098
2	TSA-CatBoost	0.7667	0.3890	0.4722	0.2178	0.1367	0.0178
3	MPA-CatBoost	0.8904	0.4163	0.5147	0.2893	0.1190	0.0122
4	RSA-CatBoost	0.8389	0.4376	0.5098	0.2865	0.1904	0.0245
5	WSO-CatBoost	0.4731	0.2109	0.2587	0.0988	0.0983	0.0100
6	FLO-CatBoost	0.2744	0.0971	0.1218	0.0674	0.0910	0.0066

Table III gives the results of different optimisation algorithms for optimising CatBoost hyperparameters. As can be seen in Table III the FLO algorithm optimises the CatBoost

hyperparameters with the following final results: the number of decision trees is 15, the learning rate is 0.015, the maximum depth of the tree is 6, and the L2 regularisation is 1.

TABLE III. RESULTS OF DIFFERENT OPTIMISATION ALGORITHMS FOR OPTIMISING CATBOOST HYPERPARAMETERS

Parameters	TSA-CatBoost	MPA-CatBoost	RSA-CatBoost	WSO-CatBoost	FLO-CatBoost
Iterations	17	16	16	17	15
Learning_rate	0.5	0.09	0.07	0.43	0.015
Depth	5	5	6	7	6
L2_leaf_reg	1	1	1	1	1

V. CONCLUSION AND OUTLOOK

Combining Figma platform and CatBoost technology, FLO-CatBoost model is applied to the problem of analysing and evaluating the effect of autonomous detection and design in rail transit. Aiming at problems such as low efficiency of effect analysis and assessment methods, this paper proposes an intelligent analysis and assessment method for Figma platform based on FLO-CatBoost model combined with FLO-CatBoost. The method analyses the innovative design scheme of Figma platform in rail transit, focuses on the Figma platform intelligent analysis and assessment problems, combines FLO and CatBoost algorithms, and constructs the intelligent analysis and assessment model of Figma platform based on FLO-CatBoost. The disclosed data image test shows that the constructed intelligent analysis and evaluation model of Figma platform based on FLO-CatBoost has higher evaluation accuracy than CatBoost, TSA-CatBoost, MPA-CatBoost, RSA-CatBoost, and WSO-CatBoost models, and obtains FLO algorithm optimised CatBoost optimal hyperparameters, i.e., the number of decision trees is 15, the learning rate is 0.015, the maximum depth of the tree is 6, and the L2 regularisation is 1.

However, there are limitations to this study. Firstly, the dataset used may not comprehensively represent all real-world rail transit conditions, which could impact the model's generalizability. Secondly, the proposed method focuses on static image data, limiting its application in dynamic and more complex scenarios. Future research could explore (1) the inclusion of more diverse datasets that capture a broader range of real-time rail transit conditions, (2) the extension of the model to handle video data for more dynamic analysis, and (3) integration with other machine learning algorithms to further enhance performance and robustness in real-world applications.

Color Matching and Light and Shadow Processing in Intelligent Interior Environment Art Design Analysis and Application Based on Neural Network

Ji Yang[1]*, Meifen Song[2]
Yancheng Institute of Technology, Yancheng 224000, China[1]
Yancheng Hongxin Decoration Co., Ltd, Yancheng 224001, China[2]

***Abstract*—In recent years, the application of Virtual Reality (VR) technology in the field of interior environmental design has expanded significantly, offering designers innovative methods to present complex design concepts within virtual spaces. However, the current color matching and light and shadow processing in reality are not mature enough, and the deep learning algorithms applied in VR are relatively basic with low running efficiency. The consistency and authenticity of virtual reality are not stable enough. This paper explores the integration of color matching and light-shadow processing in interior environmental design within VR technology, with a particular emphasis on leveraging neural network models to achieve automated design optimization. By incorporating deep learning algorithms, this study proposes a neural network-based approach to enhance color matching and light-shadow processing, aiming to improve the realism and aesthetic appeal of virtual environments. Experimental results demonstrate that this method offers substantial advantages in terms of color matching accuracy, naturalness of light-shadow effects, and computational efficiency, highlighting its broad potential for application in virtual reality.**

***Keywords*—Interior environment design; color matching; virtual reality; neural network; light and shadow processing**

I. Introduction

In recent years, the application of Virtual Reality (VR) technology in the field of interior environmental design has seen substantial growth, offering designers novel means to present complex design solutions within virtual spaces. This technological advancement surpasses the limitations of traditional design methods, providing a more intuitive and immersive user experience. Within a VR environment, users can freely explore virtual spaces and perceive design outcomes with heightened realism, significantly enhancing interactivity and visualization throughout the design process.

In the realm of interior environmental art design, color coordination and light-shadow processing are two critical elements. The choice and combination of colors directly influence the atmosphere and visual perception of a space, while the treatment of light and shadows adds depth and dynamic effects, creating a sense of dimensionality. The integration of these two aspects largely determines users' emotional responses and overall impressions of the space. However, traditional design methods often rely heavily on the designer's experience and subjective judgment, making it challenging to address the complex and variable demands of design. Moreover, achieving automated and personalized design optimization remains particularly difficult. Consequently, the exploration of intelligent design methods has become a crucial topic in the current field of interior environmental art design.

With the rapid advancement of intelligent technologies, breakthroughs in neural networks within the domains of image processing and visual perception have introduced new possibilities for the intelligent development of interior environmental design. By leveraging neural networks, designers can automate the learning and optimization of color coordination and light-shadow processing, thereby reducing the need for human intervention and enhancing both design efficiency and effectiveness.

There are still several challenges in the current field of indoor environmental art design, including:

1) High quality, high-resolution, and efficient color and lighting processing methods are required. Color coordination and light and shadow processing play a crucial role in environmental design. Color not only determines the visual effect of space, but also affects people's emotions and psychological states. Light and shadow processing enhances spatial depth and realism by accurately simulating light sources, shadows, and reflections. In virtual reality, achieving high-quality color and lighting processing while maintaining computational efficiency remains an urgent technological challenge.

2) Currently, neural networks are rarely used for virtual reality implementation in indoor environments, and the methods used are relatively basic. The running efficiency, consistency, and authenticity of virtual reality are not stable enough. In recent years, neural networks, especially convolutional neural networks (CNNs), have made significant progress in image processing and computer vision, opening up new possibilities for automated design. The application of Generative Adversarial Networks (GANs) in image generation and style conversion provides new methods for color coordination and light and shadow processing. However, effectively applying these technologies to environmental design in virtual reality requires further targeted optimization.

*Corresponding Author.

To address this issue, we propose a neural network-based method for color coordination and light and shadow processing in indoor environment design, aimed at improving design efficiency. We explore how to use neural network technology to optimize color matching and lighting processing in indoor environment design, in order to further enhance the design quality and user experience in virtual reality. We propose a neural network algorithm based on deep learning models that can automatically identify and optimize color and light elements in space. This algorithm has demonstrated significant innovation and effectiveness in practical applications, providing a new intelligent solution for color matching and light and shadow processing in indoor environmental art design.

Specifically, by studying the visual characteristics of color in spatial perception and the perception patterns of indoor environment color by spatial users, we proposed the influencing factors of indoor environment color matching and constructed a regression model for evaluating indoor environment color matching based on these factors. This model learns color matching rules from large-scale data through deep learning, forming a systematic indoor environment color matching design method, and successfully applying it to practical design projects. Through this intelligent design approach, we can better meet personalized design needs and enhance users' immersive experience in virtual reality.

Section II of this article introduces the relevant technologies and development status of neural networks, color matching, and light and shadow processing. Section III presents our proposed method, including a detailed neural network model and loss function. Section IV introduces the experimental setup, experimental design, and comparative results. Finally, a summary of the entire text was provided in Section V.

II. Literature Review

In this chapter, we introduce the development of neural networks, color matching and light and shadow processing in interior design, and summarize the research gaps.

A. Neural Network

In recent years, neural network technology has increasingly been applied to intelligent home systems and smart cities, suggesting its potential utility in interior environment design as well. HVAC (Heating, Ventilation, and Air Conditioning) systems are critical for maintaining comfortable indoor environments in buildings and vehicles. To detect HVAC malfunctions, Kim [1] proposed a hybrid model based on transformers, leveraging both temporal and spatial features. Fu [2] introduced an improved version of YOLOv5, specifically designed to enhance the efficiency and accuracy of defect detection in the decorative coverings of car interiors. Zhang [3] developed a color correction method for interior decoration projects, based on a dense convolutional neural network. This method detects color deviation and sets color correction goals such as color matching coordination, harmony, and visual comfort, with a calibrated objective function. Zhang [4] employed the Proximal Policy Optimization (PPO) algorithm to improve the self-planning path capabilities of renovation robots. Liang [5] proposed a pattern recognition method for artificial identification in environments to increase the success rate of target recognition and determine target position and posture in complex settings. Gao [6] introduced a krill swarm algorithm based on a long short-term memory network for interpretable artistic emotion analysis in interior decoration environments. Additionally, Jiang [7] proposed measures to enhance the ecological sustainability of urban waterfront landscapes, including the sponge city construction concept, sewage coupling treatment systems, and information flow monitoring systems. Shan [8] explored the application of traditional Chinese decorative colors in interior design and proposed a model for this application using an improved AlexNet network, optimized with Adam, BN, dropout, and data augmentation algorithms. Lastly, Zhu [9] proposed a system that integrates Mixed Reality (MR), Diminished Reality (DR), and Generative Adversarial Networks (GAN) to provide technological support for designers and other professionals.

In summary, neural network technology can be effectively applied to the artistic design of interior environments, enabling precise control and optimization of color schemes within these spaces.

B. Color Matching and Light Processing

In virtual reality environments, interaction design serves as a crucial source of user engagement [10]. Achieving a highly immersive experience relies heavily on the strategic use of light, which plays an indispensable role in virtual reality interaction design. In the virtual world, the function of light extends beyond mere illumination; it directly influences the realism and authenticity of the scene, thereby affecting various aspects of user engagement and emotional response. From the soft glow of dawn to the intense rays of afternoon sunlight, the dynamic changes in lighting breathe life into virtual interactive scenarios, imbuing virtual reality interaction design with a sense of vitality.

In virtual reality, common types of light sources include ambient light, directional light, point light, and spotlights. Each type of light source possesses distinct illumination characteristics and plays a role in simulating real-world lighting during the rendering process, thus bestowing visual properties upon objects within the scene. By simulating the interaction between light and object surfaces, various visual effects such as shading, shadows, highlights, and reflections can be achieved. The application of light directly impacts the realism and authenticity of rendered images.

Regarding color configuration, Dong [11] developed a green and red color conversion medium (CCM) film for VR/AR micro displays, enhancing color rendering. Wang [12] applied the photometric stereo algorithm to derive surface gradients, which were then used to reconstruct the 3D contours of a scene, significantly improving the dynamic performance of single-pixel 3D reconstruction systems. Stampfl [13] proposed a method for shadow processing that separates shadows from test images by segmenting them into umbra and penumbra regions using a thresholding approach.

In summary, convolutional neural network-based recognition methods have been applied across various fields. Therefore, with the continued development of technology, it is feasible to design more personalized learning recommendation services based on deep learning techniques.

III. Proposed Method

A. Neural Network Model

1) Overall model architecture: In the domain of Virtual Reality (VR) interior environment design, the effective handling and realistic representation of color schemes and lighting effects are crucial for achieving a high-quality immersive experience. Neural networks, particularly those utilizing convolutional structures, have demonstrated significant potential in processing complex visual data, making them well-suited for these tasks. This paper presents a comprehensive neural network architecture specifically designed for VR-based interior environment design, with a focus on color matching and light-shadow processing. The architecture integrates an encoder-decoder framework with a discriminator module, enabling detailed feature extraction, generation, and evaluation of visual elements.

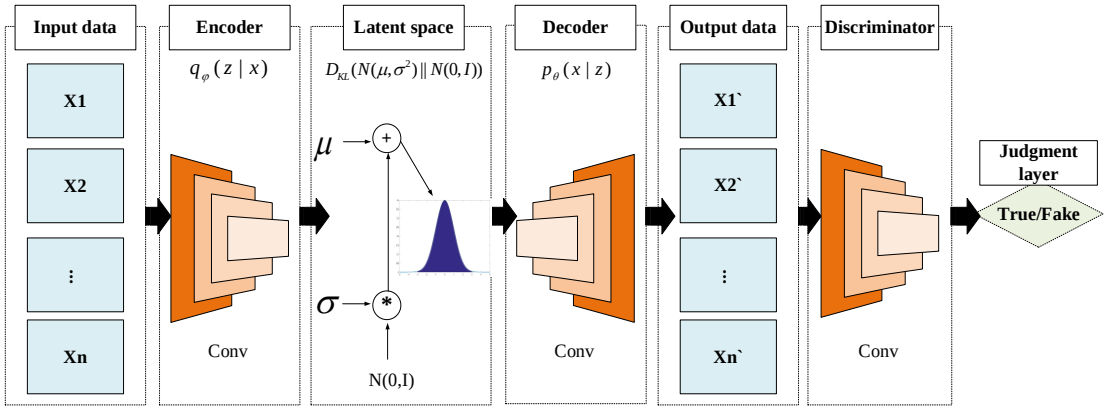

Fig. 1. Overall model architecture.

The neural network model proposed in this study is composed of the following key components:

a) Overall architecture: The architecture consists of three primary components: the encoder, the decoder, and the discriminator, all of which are enhanced by a scalable network. Fig. 1 illustrates this architecture.

b) Input data: The input data comprises a set of images, each depicting a distinct indoor design scenario (X_1, X_2, ..., Xn).

c) Encoder: The encoder employs Convolutional Neural Networks (CNNs) to extract features from the input images. These extracted features are mapped to a latent space, where they are represented by a mean vector (μ) and a standard deviation vector (σ). This latent space is crucial for generating new design samples, such as color schemes or lighting effects. The generator processes a noise vector to produce design outputs.

d) Latent space: The latent space is where the distribution of encoded features is regularized to follow a normal distribution, denoted as $N(0, I)$. This regularization is essential for the decoder to generate consistent and plausible outputs.

e) Decoder: The decoder reconstructs the original images from the latent space, producing outputs (X_1', X_2', ..., Xn') that are similar to the input data.

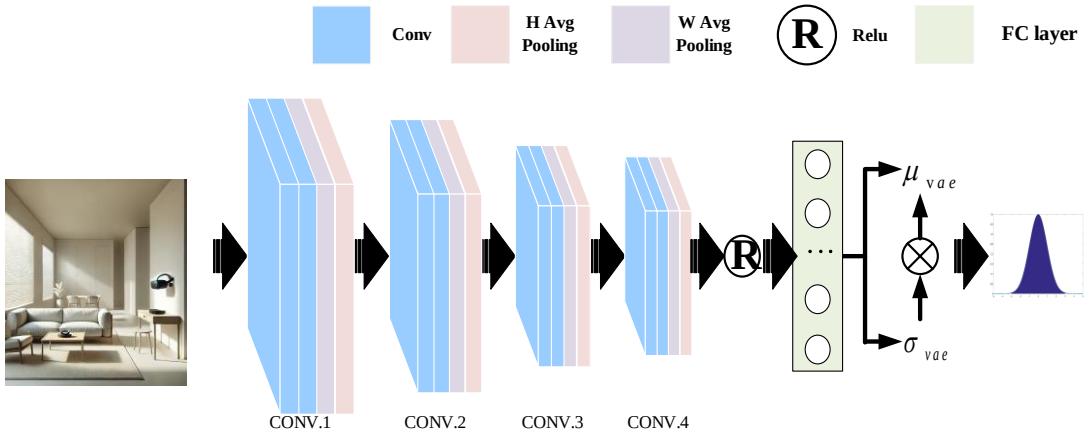

Fig. 2. Encoder structure.

f) Discriminator: The discriminator differentiates between real and generated images, providing feedback to the encoder-decoder system to enhance the quality of the generated images. This setup mirrors the architecture used in Generative Adversarial Networks (GANs), where the output (real/fake) guides the optimization process. The discriminator evaluates the realism of the generator's outputs by comparing generated samples with real samples, thereby providing feedback that drives the generator to refine its outputs continually.

This model framework facilitates the generation of high-quality design samples by integrating these components into a cohesive system that enhances both the quality and diversity of the generated outputs.

Residual mapping is utilized to enhance the model's ability to capture long-range dependencies. In the context of color matching and light-shadow processing, self-attention mechanisms play a critical role. By computing the correlations between different color regions in the input image, the model gains an understanding of the interactions between colors, leading to more harmonious color schemes. Additionally, self-attention facilitates the identification of long-range dependencies between light sources and shadows, ensuring that the generated light-shadow effects are natural and fluid.

The integration of residual mapping with self-attention mechanisms allows the model to address both the intricate color relationships and the complex spatial dependencies associated with light and shadow. This dual approach improves the overall coherence and quality of the generated design outputs, making the model more effective in producing aesthetically pleasing and contextually appropriate results.

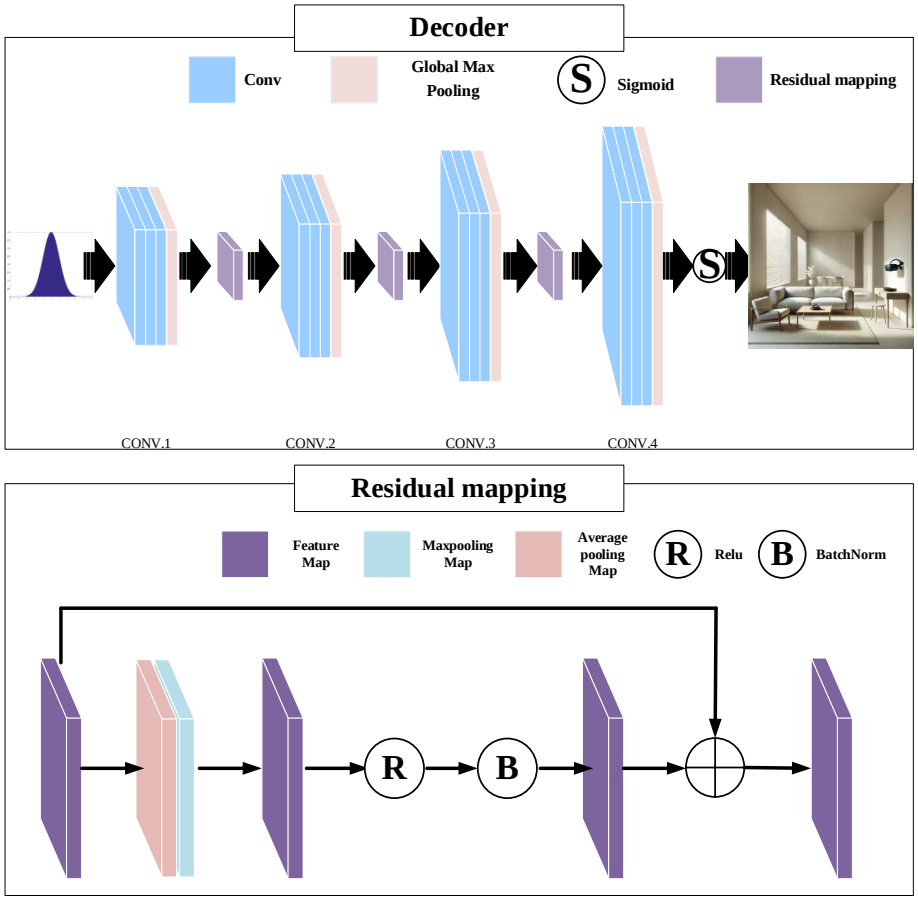

Fig. 3. Decoder structure.

2) Encoder module: As depicted in Fig. 2, the encoder architecture is meticulously crafted to efficiently extract and preserve both spatial and color information from the input images by employing a series of convolutional layers. The encoder comprises four convolutional layers (CONV 1-4), each strategically paired with horizontal (H) and vertical (W) average pooling layers. This design not only reduces the dimensionality of the feature maps but also ensures that critical spatial and color information is retained, facilitating the model's ability to capture the nuanced details of the input images.

Following the convolutional layers, the feature maps undergo a transformation through a fully connected (FC) layer, preceded by the application of the ReLU activation function. This phase is vital for generating the mean vector (μ) and standard deviation vector (σ), which characterize the feature distribution within the latent space. The precision in defining these vectors is paramount as they directly influence the quality of the latent space representation.

Subsequently, latent vectors are sampled from a normal distribution, modulated by the parameters μ and σ. These latent vectors serve as a condensed and informative representation of the input image within the latent space, encapsulating the core information necessary for the decoder to accurately reconstruct the original image. This process not only optimizes the efficiency of the model but also enhances its capability to generate high-fidelity reconstructions, thereby demonstrating the robustness of the encoder's design in capturing complex image features.

3) Decoder module: As depicted in Fig. 3, the decoder plays a crucial role in reconstructing images from latent vectors by employing a structure that mirrors the encoder. This symmetry is vital for ensuring that the reconstruction is as accurate as possible. The decoder's architecture includes a series of convolutional layers (CONV 1-4), which systematically upscale the latent vectors back into full-sized images. To maintain the integrity of high-level features and prevent information loss, each convolutional layer is followed by global max pooling and residual mapping. The incorporation of residual mapping is particularly important as it addresses the vanishing gradient problem, thereby enhancing the flow of gradients during backpropagation. This process involves passing feature maps through a series of transformations, such as average pooling and ReLU activation, before reintegrating them into the main feature stream.

The decoder's final output is generated through a Sigmoid activation function, which produces pixel values for the reconstructed image. These pixel values are then directly compared with the original image to calculate the reconstruction loss, a critical measure of the model's performance.

The encoder-decoder architecture, which includes an integrated encoder, is meticulously designed to handle the complexities of indoor environment design within virtual reality (VR). It effectively captures and reconstructs intricate color schemes and lighting effects, ensuring that the spatial hierarchies are preserved throughout the process. Additionally, latent space regularization is employed to ensure the production of high-quality, consistent outputs. The framework also integrates an adversarial training mechanism, which compels the generator to create outputs that are virtually indistinguishable from real images, thereby significantly enhancing the realism of the final visual content.

This neural network architecture offers a powerful framework for VR-based indoor environment design, with a particular focus on the precise representation of color matching and light-shadow effects. By leveraging state-of-the-art techniques such as latent space regularization, residual mapping, and adversarial training, the architecture provides designers with advanced tools to create highly immersive and realistic VR environments.

B. Loss function

We utilize loss functions to optimize the performance of both the generator and the discriminator. For color matching, the loss function is designed based on color harmony and aesthetic standards, ensuring that the generated color schemes are visually pleasing and coherent. In the context of light-shadow processing, the loss function focuses on the naturalness and realism of the light and shadow effects, aiming to achieve visually accurate and contextually appropriate results.

In the neural network model, the loss function measures the discrepancy between the model's outputs and the ground truth values. Different tasks and objectives necessitate the use of specific loss functions tailored to their respective requirements. The choice of loss function directly influences the model's ability to generate high-quality and realistic outputs, thus playing a crucial role in the overall effectiveness of the model.

1) Color matching loss function: The color harmony loss function is employed to evaluate whether the generated color schemes adhere to aesthetic standards. The color harmony loss is computed using the following formula:

$$L_{color} = \frac{1}{N}\sum_{i=1}^{N} ||c_i^{gen} - c_i^{true}||_2 \quad (1)$$

Let c_i^{gen} denote the RGB value of the i-th generated color, and c_i^{true} represent the RGB value of the i-th true color. Here, N is the total number of colors. The term $||\cdot||_2$ denotes the Euclidean distance. This loss function quantifies the discrepancy between the generated colors and the true colors, with a smaller distance indicating better color harmony.

Color Contrast Loss: To ensure that the generated colors exhibit sufficient contrast, the following loss function can be employed:

$$L_{contrast} = \frac{1}{N}\sum_{i=1}^{N} ||contrast(c_i^{gen}) - contrast(c_i^{true})||_2 \quad (2)$$

$$L_{color\_total} = \alpha \cdot L_{color} + \beta \cdot L_{contrast} \quad (3)$$

$contrast(\cdot)$ represents a function that calculates color contrast. Total loss of coordination with contrast color loses. Where: α and β are weight coefficients, used to balance the impact of the loss of each part.

2) Light processing loss function: The light-shadow realism loss is used to assess how closely the generated light and shadow effects resemble those in real scenes. The light-shadow smoothness loss is designed to ensure that the generated light-shadow transitions are natural, avoiding abrupt shadows or reflections. The combined light-shadow loss integrates both the realism loss and the smoothness loss to achieve a more comprehensive evaluation of the generated effects.

$$L_{shadow} = \frac{1}{M}\sum_{j=1}^{M} ||l_j^{gen} - l_j^{true}||_2 \quad (4)$$

$$L_{smooth} = \frac{1}{P}\sum_{p=1}^{P} ||smooth(l_j^{gen}) - smooth(l_j^{true})||_2 \quad (5)$$

$$L_{shadow\_total} = \gamma \cdot L_{shadow} + \delta \cdot L_{smooth} \quad (6)$$

Among them: l_j^{gen} first j is to generate a light characteristic. l_j^{true} is the first j a real light and shadow. M is the total number of light and shadow features. $smooth(\cdot)$

represents a function for calculating the smoothness of light and shadow. Gamma and δ are the weight coefficients.

IV. Experiment and Verification

In this chapter, we verify the reliability and validity of the proposed method through experiments.

A. Experimental Environment

This study validated the algorithm's effectiveness using an environment comprising an 11th Gen Intel(R) Core (TM) i7-11700K @ 3.60GHz CPU with 32.0 GB of RAM.

B. Data Preparation and Preprocessing

We sourced authentic interior design images and design schemes from various interior design projects, design galleries, and architectural design websites. Each image was annotated with the primary colors, recording their RGB values or coordinates in the color space. Additionally, the position and intensity of light sources, as well as shadow regions, were annotated. The images were further classified by style (e.g., modern, classical, minimalist) and by light-shadow effects (e.g., natural light, artificial lighting, shadow types). The dataset underwent noise reduction and consistency checks to ensure data quality. Finally, the dataset was split into training, validation, and test sets with a ratio of 8:1:1.

C. Evaluation Parameter

The CIEDE2000 metric is employed for the precise calculation of color differences, based on the human eye's perceptual characteristics. The Structural Similarity Index (SSIM) is used to evaluate the structural similarity of images, aligning more closely with human visual perception. The Peak Signal-to-Noise Ratio (PSNR) measures the image quality by focusing on brightness differences. Together, these three metrics provide a comprehensive evaluation of both color and image quality, aiding in the optimization of design effects in virtual reality [14]-[17].

For evaluating color harmony, we assess the aesthetic quality of color schemes through user ratings and expert evaluations. User satisfaction scores are derived from survey results. Additionally, we calculate the color difference between generated and real colors using the CIEDE2000 metric, which is based on the CIELAB color space. CIEDE2000 improves upon the CIE76 and CIE94 formulas to offer a more perceptually accurate measure of color difference, better reflecting human visual perception.

In the CIEDE2000 formula, $\Delta L^{`}$ represents the lightness difference, $\Delta C^{`}$ denotes the chroma difference, and $\Delta H^{`}$ indicates the hue difference. The parameter k is a weighting factor set to 1, and S represents a scaling factor dependent on the color's properties. R_T is a rotation term that accounts for variations in color differences across different hues. CIEDE2000 aligns more closely with human perception of color differences, and a smaller ΔE_{00} value indicates that the colors are visually closer.

For evaluating light and shadow effects, we assess the realism of the generated effects by comparing them to real scenes, using SSIM and PSNR metrics. The Peak Signal-to-Noise Ratio (PSNR) is a metric used to measure image quality and similarity, typically taking paired images as input. Since PSNR is rooted in signal processing and defined using Mean Squared Error (MSE), it is often expressed in decibels (dB). A lower MSE value results in a higher PSNR, indicating better image quality or greater similarity to the source image. Generally, a higher PSNR suggests higher similarity between paired images or better performance in image reconstruction experiments.

Structural Similarity Index (SSIM) is a critical method for assessing the similarity between paired images. It evaluates image similarity by extracting three features—luminance, contrast, and structure—from the test image and comparing these features to human visual perception of pixel structure. SSIM is commonly used as an evaluation metric for paired images and as a loss function improvement in image reconstruction tasks, with l(x,y), c(x,y), and s(x,y) representing the similarity in luminance, contrast, and structure information between images x and y.

$$\Delta E_{00} = \sqrt{\left(\frac{\Delta L^{`}}{k_L \cdot S_L}\right)^2 + \left(\frac{\Delta C^{`}}{k_C \cdot S_C}\right)^2 + \left(\frac{\Delta H^{`}}{k_H \cdot S_H}\right)^2 + R_T \cdot \Delta C} \quad (7)$$

$$PSNR = 10 \cdot log_{10}\left(\frac{MAX_I^2}{MSE}\right) = 20 \cdot log_{10}\left(\frac{MAX_I}{\sqrt{MSE}}\right) \quad (8)$$

$$SSIM = l(x,y)^{\alpha} * c(x,y)^{\beta} * s(x,y)^{\gamma} \quad (9)$$

To evaluate the real-time rendering performance of the model within virtual reality environments, the rendering speed can be assessed by measuring the frame rendering time, typically expressed in frames per second (FPS). This metric provides a quantitative measure of how efficiently the model handles rendering tasks in real-time scenarios, ensuring a smooth and responsive user experience.

D. Test and Evaluation

To validate the effectiveness of the proposed methodology, we carried out a series of rigorous experiments across a diverse range of virtual reality (VR) environments. Our experimental setup involved comparing the performance of our proposed algorithm with three state-of-the-art (SOTA) algorithms: the IRCGAN model [18], the LOHO model [19], and the FTGH model [20]. These algorithms were selected due to their prominence and relevance in the field of VR design and image processing.

As detailed in Table I, our proposed method demonstrates superior performance relative to these SOTA benchmarks across several key metrics. Specifically, in the domain of color matching, our approach consistently achieves higher accuracy in aligning generated colors with target colors, thus producing more aesthetically pleasing and coherent color schemes. The image quality results reveal that our algorithm excels in maintaining high fidelity and detail, surpassing the quality delivered by the IRCGAN, LOHO, and FTGH models.

Furthermore, our method significantly improves real-time performance, which is crucial for practical VR applications where timely and responsive rendering is essential. The enhanced efficiency and reduced computational overhead of our approach ensure that complex VR environments can be rendered smoothly without compromising on visual quality.

The superior performance of our proposed algorithm underscores its potential for advancing virtual reality interior environment design. By offering enhanced color accuracy, superior image quality, and efficient real-time rendering, our method provides a robust tool for designers and developers aiming to create immersive and realistic VR experiences. The results affirm the algorithm's capacity to address the current limitations of existing methods and to contribute effectively to the field of VR design.

TABLE I. ALGORITHM COMPARISON RESULTS

Metric	Proposed Algorithm	IRCGAN	LOHO	FTGH
CIEDE2000	1.23	2.15	1.89	1.56
SSIM	0.98	0.95	0.96	0.97
PSNR (dB)	32.8	30.5	31.1	31.8
FPS	60	45	50	55

The results demonstrate that the neural network-based approach to color matching and light-shadow processing offers significant advantages in the following areas. Compared to traditional methods, neural networks more accurately capture the relationships between colors, generating more harmonious color combinations. The light-shadow effects produced by the model closely resemble real-world scenes, with natural shadow transitions and realistic reflection effects. By optimizing the model structure, our method significantly reduces computation time while maintaining high-quality output, meeting the real-time rendering demands of virtual reality.

TABLE II. ALGORITHM COMPARISON RESULTS

	Satisfaction (%)
IRCGAN	89
LOHO	88
FTGH	93
Proposed Algorithm	100

In addition, we calculated and compared the satisfaction of 100 images generated using the above algorithm, and the comparison results are shown in Table 2. From the table, it can be seen that the satisfaction rate of the images generated using our proposed algorithm is 100%, far higher than other algorithms.

Fig. 4. Generated image.

As illustrated in Fig. 4, the results of our interior environment design demonstrate the effectiveness of the proposed methods in both color matching and light-shadow processing. The generated images exhibit high-quality outcomes, reflecting the model's capability to produce aesthetically pleasing and realistic visual effects.

V. CONCLUSION

The innovations presented in this study are reflected in several key areas:

1) Automated design optimization: By leveraging neural network models, this study achieves automation in color matching and light-shadow processing, significantly reducing the workload of designers.

2) Dynamic color adjustment: The model is capable of adjusting color schemes in real-time based on environmental changes, providing robust technical support for designing dynamic scenes in virtual reality.

3) Efficient light-shadow processing: The use of GANs to generate light-shadow effects not only enhances the realism of the design but also significantly improves computational efficiency, making it suitable for real-time rendering in virtual reality environments.

In terms of applications, the proposed method can be widely applied in various domains such as interior design in virtual reality, game scene development, and virtual exhibition platforms. As neural network technology continues to advance, this method is expected to play an increasingly important role in future virtual reality applications.

Selecting the Best Machine Learning Models for Industrial Robotics with Hesitant Bipolar Fuzzy MCDM

A Comprehensive Framework for Evaluating Industrial Robotics

Chan Gu[1], Bo Tang[2,*]
School of Electrical and Control Engineering, Shaanxi University of Science and Technology, Xi'an 710021, China[1, 2]

***Abstract*—Machine learning models (MLMs) are used in industry to automate complicated activities, minimize human error, and improve decision-making by evaluating large volumes of data in real time. To managing inventory and quality control in the apparel and auto industries, they provide predictive capabilities such as predicting equipment breakdowns, maintenance and detecting fraud in the finance sector and the major key advantages include cost reduction, higher productivity, better product quality, and tailored client experiences. MLM helps the industries to reduce downtime, prevent errors, and gain a competitive edge through data-driven strategies and processing massive volumes of data in real time. So, there is a need to select the best MLMs for industrial robotics and by considering it, this paper addresses this problem as multiple criteria decision-making (MCDM) by exploiting hesitant bipolar fuzzy information, which takes into account both hesitation and bipolarity in decision-maker preferences. This paper introduced the new aggregation operators (AO) based on geometric and arithmetic procedures to efficiently aggregate the data including the hesitant bipolar fuzzy weighted geometric operator (HBFWGO), which is appropriate for multiplicative relationships, and the hesitant bipolar fuzzy weighted average operator (HBFWAO), which gives weighted importance to qualities. Further, the dual operators including the dual hesitant bipolar fuzzy weighted geometric operator (DHBFWGO) and the dual hesitant bipolar fuzzy weighted average operator (DHBFWAO) have been presented that are further applied to create novel strategies for resolving MCDM issues and offering a methodical manner to assess and combine features. Moreover, the example of selecting the optimal MLMs to show the robustness and efficiency of the suggested methodology has been presented which illustrates the applicability and strength of the proposed methodology in actual decision-making situations.**

Keywords*—Machine Learning Model (MLM); Hesitant Bipolar Fuzzy Set (HBFS); Dual Hesitant Bipolar Fuzzy Set (DHBFS); Hesitant Bipolar Fuzzy Aggregation Operators (HBFAO); Dual Hesitant Bipolar Fuzzy Aggregation Operators (DHBFAO); Multi-Criteria Decision-Making (MCDM)

I. INTRODUCTION

The development and evaluation of the highest quality (MLMs) [1] for industrial robotics is an important step toward the improvement of current automation and decision-making systems. Industrial robotics [2] has an enormous effect on manufacturing environments by automating challenging activities, enhancing precision, and minimizing human error. As companies transition to smart manufacturing and Industry 4.0 [3], the demand for advanced robotic systems that can intelligently adapt to dynamic and uncertain surroundings grows. Choosing the best MLM is a challenging process as it involves balancing various criteria [4]. In response, MCDM has grown to be a potent technique for handling complexity and of controlling uncertainty. This decision-making strategy is based on fuzzy set theory (FS) [5], which provides a flexible framework for addressing uncertainty. Zadeh developed the FS notion in 1965 to solve the boundaries of conventional set theory and binary logic [6], in which an individual either fully belongs to a set or does not. Many situations in the real world are not black and white, but rather exist in shades of gray, making it difficult to establish clear boundaries. FS permits the depiction of uncertainty by assigning degrees of membership to elements in a set. This significant development established the way for subsequent advances in decision-making under uncertainty, including the introduction of more advanced ideas like hesitant fuzzy sets (HFS) [7], and then bipolar fuzzy sets (BFS) [8].

FS was created to address difficulties where traditional true/false reasoning was insufficient. Since the traditional set theory implies that an element is either a member of a set or not, which is useful for issues having binary solutions. However, in many practical contexts such as robotics, control systems, and decision-making, real-world data is frequently unclear or missing. To address this, Zadeh's FS developed the concept of partial membership, which allows an element to belong to a set to some extent, represented by values ranging from $[0, 1]$. But, as the research developed, it became clear that the concept of membership alone was not necessarily adequate for modeling all types of uncertainty. This resulted in the creation of increasingly advanced extensions of FS. By considering it, Atanassov presented the concept of an intuitionistic fuzzy set (IFS) [9] in 1986, which expanded Zadeh's FS by including both a membership and non-membership function. This set offers an additional structure for dealing with uncertainty by considering an element's degree of non-membership in addition to its membership. The IFS was especially beneficial when decision-makers needed to indicate hesitancy about whether an element should be included in a set. Later on, researchers such as Alcantud [10] constructed on aggregation operator (AO) for IFS that allows for more flexible ways to aggregate and handle IFS, Ali et al. [11] utilized it for material selection, and Ahn et al. [12] utilized this framework for medical diagnosis. This

*Corresponding author.

approach improved the ability to combine data from numerous sources under uncertainty and it into an effective framework for MCDM which is utilized by various researchers for evaluating decision-making problems. Furthermore, for even more freedom in expressing uncertainty, Torra presented the HFS [13]. In an HFS, an element's membership is represented by a set of alternative values rather than a single value, indicating uncertainty in choosing membership. Additionally, he investigated the connection between IFS and HFS, demonstrating that an IFS is fundamentally contained within the envelope of an HFS. Xia and Xu [14] expanded on previous research on HFS by inventing aggregation algorithms specifically intended for hesitant fuzzy information and applying them to decision-making situations. The bipolar fuzzy set (BFS) [15] has emerged as a potential solution to managing uncertainty in MCDM situations and utilized two values to characterize an object i.e. the positive membership degree and the negative membership degree. Unlike IFS, membership degrees in BFS range from$[-1,1]$. BFS has been widely applied in various domains, such as bipolar fuzzy heat equation [16], traditional Chinese medicine [17], bipolar cognitive mapping [18], decision analysis and organizational modeling [19], biosystem regulation, and graph theory [20]. Moreover, MLMs in industrial robots is selected based on a variety of performance parameters, including speed, accuracy, resilience, and computing efficiency. So, a structured strategy for decision-making due to the abundance of MLMs that are tuned for distinct tasks, such as object recognition, navigation, or manipulation. When evaluating the MLMs, the HFS approach allows decision-makers to express their uncertainty that a model may perform well under some conditions but poorly under others, raising questions about its overall applicability. In such circumstances, HFS offers the ability to depict hesitation and BFS approach extends this concept by allowing decision-makers to consider both the positive and negative elements of any MLM which is beneficial in industrial robots, where the trade-offs between speed and precision, or adaptability and computational cost, must be carefully balanced. By integrating HFS and BFS into the decision-making process, it assists the decision-maker to systematically evaluating various factors while balancing competing aims to get the optimum ML model. Robotic systems can be made far more capable, efficient, and adaptable by choosing the best ML model for industrial robots. So, in the past FS, HFS, and BFS have all been adopted to model uncertainty in decision making, but these methodologies are still limited in terms of dealing with complex and conflicting criteria especially when working in changing arenas like industrial robotic systems. So, this paper aims to introduce the HBFWAO and HBFWGO operators that are more flexible and accurate than the existing ones hence fixing the drawback and improving support in decision making on the choice of ML models for industrial applications. Some of the primary benefits are:

- With the help of MLMs, data is optimized and repeat processes are undertaken without errors in performance to learn from past experiences.
- Traditional models are designed to perform only a few specific tasks since they follow prewritten instructions and cannot adapt to changes but ML on the other hand facilitates real-time data analysis, and enhancing efficiency in performing strategies.
- Through the integration of MLMs, robots can now work together with a human teammate and accomplish diverse tasks with a great level of efficiency.

However, the Industrial robotics faced numerous major obstacles that limited their effectiveness and flexibility prior to the inclusion of ML model, including:

- Before the advent of ML, programming and maintaining robots was an expensive affair, and supervision made them inefficient and very impractical for the modern industries.
- Conventional robots were confined to a certain set of tasks and lacked the quality of adaptability and therefore required expensive changes of programming if there were new tasks or new situations emerged.

A. Motivation of the Research

When it comes to making decisions that are quite complex in nature, the standard fuzzy sets have a lot of difficulties in capturing the preferences especially for those that have hesitations and bipolar judgments. This is addressed by HBFS but new aggregation operators (AOs) must be introduced to deal with the complexity of the existing data sets effectively thus providing the motivation of this research in enhancing MCDM processes.

- In practice, the making of decisions tends to be marred with uncertainty and ambivalent views, for instance in industrial, financial, resource allocation scopes, etc. The HBFS framework depicts this uncertainty but does not apply well in MCDM without sophisticated aggregation methods.
- In this study, the HBFWAO and HBFWGO are introduced in order to aggregate hesitant bipolar fuzzy information for more effective decision-making outputs.
- The research extends these operators to develop flexible decision-making techniques for HBFS and DHBFS, useful in industrial applications like selecting the best ML model for robots.

B. Organization of the Study

For evaluating the MLMs for robot selection, this paper is organized as follows: Section I gives a brief introduction to MLMs and their evaluation as a decision-making problem. Then, the fundamental notions of FS, HFS, BFS, and its operational laws are defined in Section II. Section III proposed the HBF set and DHBF set which are then followed by AOs including averaging and geometric operators. In Section IV, the methodology was proposed by utilizing these AOs to address MCDM concerns and then utilized in evaluating the real-world decision-making problem. Section V provides a comparison between the prior studies and the proposed study and highlights the effectiveness of the proposed operator. In the end, Section VI concludes the whole discussion by defining its limitations and future direction.

II. PRELIMINARIES

This section contains a prior defined definition of FS, BFS, HFS, and its operational laws for the understanding of the readers.

Definition 1 [5]: Let U be a fixed and non-empty set. Then, the FS $\mathcal{B}$ on U is defined as:

which is determined by a membership function MF $\mu_{\mathcal{B}}: \mu_{\mathcal{B}} \in [0,1]$

$$\mathcal{B} = \left\{\left(\sigma_j, \mu_{\mathcal{B}}(\sigma_j)\right) : \sigma_j \in U\right\} \quad (1)$$

Definition 2 [15]: Let U be a fixed and non-empty set. Then, the BFSs $\mathcal{B}$ on U is defined as:

$$\mathcal{B} = \{< \sigma_j(\mu_{\mathcal{B}}^{+}(\sigma_j), \nu_{\mathcal{B}}^{-}(\sigma_j) > | \sigma_j \in U)\} \quad (1)$$

The positive MF function, denoted as $\mu_{\mathcal{B}}^{+}(\sigma_j)$: $U \to [0,1]$, represents the degree to which an element σ_j satisfies the property associated with a bipolar fuzzy set (BFS) $\mathcal{B}$. Conversely, the negative membership degree function, $\nu_{\mathcal{B}}^{-}(\sigma_j)$: $U \to [0,1]$, indicates the degree to which an element σ_j meets an implicit counter property related to the same BFS $\mathcal{B}$. For any σ_j in the set U, the combination of these functions, expressed as $\mathfrak{b}(\sigma_j) = \left(\mu^{+}(\sigma_j), v^{-}(\sigma_j)\right)$, is referred to as a bipolar fuzzy number (BFN), represented by $\mathfrak{b} = (\mu^{+}, v^{-})$, adhering to the conditions $0 \le \mu^{+} \le 1$ and $-1 \le v^{-} \le 0$.

Definition 3 [15]: The following is a description of the basic operations on BFNs.

- $a_1 \oplus a_2 = (\mu_1^{+} + \mu_2^{+} - \mu_1^{+}\mu_2^{+}, -|\nu_1^{-}||\nu_2^{-}|)$
- $a_1 \otimes a_2 = (\mu_1^{+}\mu_2^{+}, \nu_1^{-} + \nu_2^{-} - \nu_1^{-}\nu_2^{-})$
- $\gamma a = (1 - (1 - \mu^{+})^{\gamma}, -|v^{-}|^{\gamma}), \gamma > 0$
- $(a)^{\gamma} = ((\mu^{+})^{V}, -1 + |1 + v^{-}|^{\gamma}), \gamma > 0$
- $a^{c} = (1 - \mu^{+}, |v^{-}| - 1)$
- $a_1 \subseteq a_2, \Leftrightarrow \mu_1^{+} \le \mu_2^{+}$ *and* $\nu_1^{-} \ge \nu_2^{-}$
- $a_1 \cup a_2 = (max\{\mu_1^{+}, \mu_2^{+}\}, min\{\nu_1^{-}, \nu_2^{-}\})$.
- $a_1 \cap a_2 = (min\{\mu_1^{+}, \mu_2^{+}\}, max\{\nu_1^{-}, \nu_2^{-}\})$;

Theorem 1 [15]: Let $a_1 = (\mu_1^{+}, \nu_1^{-})$ and $a_2 = (\mu_2^{+}, \nu_2^{-})$ represents for two BFNs, where $\gamma, \gamma_1, \gamma_2 > 0$. In this context, μ_1^{+} and μ_2^{+} represent the positive membership functions, while ν_1^{-} and ν_2^{-} denotes the negative membership functions. Under these conditions, the following operations can be applied to a_1 and a_2.

- $a_1 \oplus a_2 = a_2 \oplus a_1$
- $a_1 \otimes a_2 = a_2 \otimes a_1$
- $\gamma(a_1 \oplus a_2) = \gamma a_1 \oplus \gamma a_2$
- $(a_1 \otimes a_2)^{\gamma} = (a_1)^{\gamma} \otimes (a_2)^{\gamma}$
- $\gamma_1 a_1 \oplus \gamma_2 a_1 = (\gamma_1 + \gamma_2) a_1$
- $(a_1)^{\gamma_1} \otimes (a_1)^{\gamma_2} = (a_1)^{(\gamma_1 + \gamma_2)}$
- $((a_1)^{\gamma_1})^{\gamma_2} = (a_1)^{\gamma_1 \gamma_2}$

III. HESITANT BIPOLAR FUZZY AGGREGATION OPERATORS (HBFAO)

In this part, a set of innovative and specialized aggregation procedures designed exclusively for HBFAO. These operators are developed to effectively integrate and process HBFAO, boosting their utility in various decision-making and analysis settings. Additionally, the important aspects of these operators by applying fundamental operations have been analyzed which allowing us to obtain deeper insights into their behavior and performance and provide more robust methods for managing unpredictable and bipolar data.

Definition 4: Let U be a fixed and non-empty set. Then, the HBFS $\mathcal{B}^{\mathtt{a}}$ on U is defined as:

$$\mathcal{B}^{\mathtt{a}} = \left\{< \sigma_j, \mathcal{H}_{\mathcal{B}^{\mathtt{a}}(\sigma_j)} > | \sigma_j \in U \right\} \quad (2)$$

where, $\mathcal{H}_{\mathcal{B}^{\mathtt{a}}(\sigma_j)}$ is a collection of BFNs in $\mathcal{B}$. Specifically,

$$\mathcal{H}_{\mathcal{B}^{\mathtt{a}}(\sigma_j)} = \bigcup_{\left(\mu_{\mathcal{B}^{\mathtt{a}}}^{+}(\sigma_j), \nu_{\mathcal{B}^{\mathtt{a}}}^{-}(\sigma_j)\right) \in \mathcal{H}_{\mathcal{B}^{\mathtt{a}}(\sigma_j)}} \left(\mu_{\mathcal{B}^{\mathtt{a}}}^{+}(\sigma_j), \nu_{\mathcal{B}^{\mathtt{a}}}^{-}(\sigma_j)\right)$$

Where $\mu_{\mathcal{B}^{\mathtt{a}}}^{+}(\sigma_j)$ represents the positive MF, indicating the degree to which an σ_j satisfies a given property related to HBFS $\mathcal{B}^{\mathtt{a}}$ and $\nu_{\mathcal{B}^{\mathtt{a}}}^{-}(\sigma_j)$ represents the negative MF which indicates the degree to which σ_j satisfies an opposing or counter-property related to the HBFS $\mathcal{B}^{\mathtt{a}}$.

These membership functions are bounded by the following conditions: $0 \le \mu_{\mathcal{B}^{\mathtt{a}}}^{+}(\sigma_j) \le 1$ and $-1 \le \nu_{\mathcal{B}^{\mathtt{a}}}^{-}(\sigma_j) \le 0$ for every $\sigma_j \in U$.

For ease of reference, the pair $h(\sigma_j) = \left\{\left(\mu^{+}(\sigma_j), v^{-}(\sigma_j)\right)\right\}$ is called a HBFN, denoted as $h = (\mu^{+}, v^{-})$, with the constraints: $0 \le \alpha^{+} \le 1$ and $-1 \le \beta^{-} \le 0$, $(\alpha^{+}, \beta^{-}) \in (\mu^{+}, v^{-})$.

To compare HBFNs, the following comparison laws have been used which give a systematic method for evaluating and distinguishing between different HBFNs and allow us to compare their relative strengths in terms of positive and negative membership functions.

Definition 5: Let $h_i = (\mu_i^{+}, v_i^{-})$ $(i = 1,2)$ be any two HBFNs. Then,

$$\mathfrak{s}(h_i) = \frac{1}{\#\, h_i} \sum_{i=1}^{\#h_i} \frac{1 + \alpha^{+} + \beta^{-}}{2}$$

$\mathfrak{s}(h_i)$ represents the score function of $h_i = (\mu_i^{+}, v_i^{-})$.

Definition 6: Let $h_i = (\mu_i^{+}, v_i^{-})$ $(i = 1,2)$ be any two HBFNs. The accuracy function of $h_i = (\mu_i^{+}, v_i^{-})$,

$$\mathfrak{s}^{*}(h_i) = \frac{1}{\#\, h_i} \sum_{i=1}^{\#h} \frac{\alpha^{+} - \beta^{-}}{2}$$

where $\# h_i$ is the number of elements in h_i.

- If $\mathfrak{s}(h_1) > \mathfrak{s}(h_2)$, then $h_1$is considered superior to h_2, which is represent as $h_1 \succ h_2$;
- If $\mathfrak{s}^*(h_1) = \mathfrak{s}^*(h_2)$, then, $h_1$is equal to h_2, denoted by $h_1 \sim h_2$;
- If $\mathfrak{s}^*(h_1) > \mathfrak{s}^*(h_2)$, then $h_1$is considered superior to h_2, which represent as $h_1 \succ h_2$.

The following operational laws will enable to combine the HBFNs in a variety of ways, making comparisons and analyses easier within the context of HBFS theory and improve the understanding of the links and interactions between various HBFNs.

- $h^{\gamma} = \cup_{(\alpha^+,\beta^-)\in(\mu^+,v^-)} \begin{Bmatrix} (\alpha^+)^{\gamma}, \\ -1+|1+\beta^-|^{\gamma} \end{Bmatrix}, \gamma > 0;$
- $\gamma h = \cup_{(\alpha^+,\beta^-)\in(\mu^+,v^-)} \begin{Bmatrix} 1-(1-\alpha^+)^{\gamma}, \\ |\beta^-|^{\gamma} \end{Bmatrix}, \gamma > 0;$
- $h_1 \oplus h_2 = \cup_{(\alpha_1^+,\beta_1^-)\in(\mu_1^+,v_1^-),(\alpha_2^+,\beta_2^-)\in(\mu_2^+,v_2^-)} \begin{Bmatrix} \alpha_1^+ + \alpha_2^+ - \alpha_1^+\alpha_2^+, \\ -|\beta_1^-||\beta_2^-| \end{Bmatrix}$
- $h_1 \otimes h_2 = \cup_{(\alpha_1^+,\beta_1^-)\in(\mu_1^+,v_1^-),(\alpha_2^+,\beta_2^-)\in(\mu_2^+,v_2^-)} \begin{Bmatrix} \alpha_1^+\alpha_2^+, \\ \beta_1^- + \beta_2^- - \beta_1^-\beta_1^- \end{Bmatrix}$

A. Hesitant Bipolar Fuzzy Weighted Averaging Operators (HBFWAO)

This part defines the HBFAO, which allow us to combine these HBFV in an organized manner for further analysis and decision making.

Definition 7: Let $h_j = (\mu_j^+, v_j^-) \quad (j = 1,2,3,\dots,n)$ represent an entire collection of HBFV. The HBFWAO is defined as:

$$HBFWAO_w(h_1h_2,\dots,h_n) = \sum_{j=1}^{n}(w_j h_j) \tag{3}$$

where, $w = (w_1, w_1, \dots, w_1)^t$ is the weight vector for each h_j for $j = 1,2,3,\dots,n$, with $w_j > 0$ and $\sum_{j=1}^{n}(w_j) = 1$. This operator combines the HBFVs by applying their respective weights.

Theorem 2: The HBFWAO provides a HBFV with

$$HBFWAO_w(h_1h_2,\dots,h_n) = \sum_{j=1}^{n}(w_j h_j)$$

$$HBFWAO_w(h_1h_2,\dots,h_n) = \cup_{(\alpha_j^+,\beta_j^-)\in(\mu_j^+,v_j^-)} \begin{Bmatrix} 1-\prod_{j=1}^{n}(1-\alpha_j^+)^{w_j}, \\ -\prod_{j=1}^{n}|\beta_j^-|^{w_j} \end{Bmatrix} \tag{4}$$

B. Hesitant Bipolar Fuzzy Weighted Geometric Operators (HBFWGO)

This section introduced the hesitant bipolar fuzzy geometric operators (HBFGO) by combining hesitant fuzzy and bipolar fuzzy geometric mean principles. These operators are intended to successfully combine HBFNs by capturing the multiplicative relationships inherent in the dataset. This method not only improves the aggregation process, but it also assures that the output values better reflect the underlying interactions between the components.

Definition 8: The HBFWGO is defined as:

$$HBFWGO_w(h_1h_2,\dots,h_n) = \sum_{j=1}^{n}(h_j)^{w_j} \tag{5}$$

where, $w = (w_1, w_1, \dots, w_1)^t$ is the weight vector for each h_j for $j = 1,2,3,\dots,n$, with $w_j > 0$ and $\sum_{j=1}^{n}(w_j) = 1$. This operator combines the HBFV by applying their respective weights.

Utilizing the established definition and mathematical induction methods, the validity of the following theorem can be demonstrate as;

Theorem 3: The HBFWGO provides a HBFV, and

$$HBFWGO_w(h_1h_2,\dots,h_n) = \sum_{j=1}^{n}(h_j)^{w_j}$$

$$HBFWGO_w(h_1h_2,\dots,h_n) = \cup_{(\alpha_j^+,\beta_j^-)\in(\mu_j^+,v_j^-)} \begin{Bmatrix} \prod_{j=1}^{n}(\alpha_j^+)^{w_j}, \\ -1+\prod_{j=1}^{n}(1+\beta_j^-)^{w_j} \end{Bmatrix} \tag{6}$$

where, $w = (w_1, w_1, \dots, w_1)^t$ is the weight vector for each h_j for $j = 1,2,3,\dots,n$, with $w_j > 0$ and $\sum_{j=1}^{n}(w_j) = 1$.

C. Dual Hesitant Bipolar Fuzzy Aggregation Operators (DHBFAO)

The Dual hesitant bipolar fuzzy AOs (DHBFAO) combine dual hesitant and bipolar fuzzy sets to deal with uncertainty, hesitation, and both positive and negative information. They are used to combine conflicting or uncertain evidence in decision-making, hence improving analysis in complicated, confusing situations.

Definition 9: Let $\mathfrak{h}_j = (\mu_j^+, v_j^-) \quad (j = 1,2,3,\dots,n)$ represent an entire collection of dual hesitant bipolar fuzzy values (DHBFV). Then, the DHBFS $\mathcal{B}^*$ on U is defined as:

$$\mathcal{B}^* = \left\{ < \sigma_j, \left(\mu^+{}_{(\sigma_j)}, v^-{}_{(\sigma_j)}\right) > | \sigma_j \in U \right\} \tag{7}$$

where: positive membership function $\mu^+_{\mathcal{B}^*(\sigma_j)}: U \to [0,1]$ denotes the possible satisfaction function of an element σ_j with respect to the property corresponding to DHBFS $\mathcal{B}^*$ and the negative membership function $v^-_{\mathcal{B}^*(\sigma_j)}: U \to [0,1]$ denotes the

possible satisfaction function of an element σ_j with respect to some implicit counter property corresponding to $\mathcal{B}^*$. For each $\sigma_j \in U$, the following conditions hold:

$$0 \le \alpha^+ \le 1, -1 \le \beta^- \le 0$$

where, $\alpha^+ \in \mu^+{}_{(\sigma_j)}$, $\beta^- \in v^-{}_{(\sigma_j)}$, and $\alpha^{max} \in \mu^+{}_{(\sigma_j)} = \cup_{\alpha^+ \in \mu^+{}_{(\sigma_j)}} max\{\alpha^+\}$, $\beta^{max} \in v^-{}_{(\sigma_j)} = \cup_{\beta^- \in v^-{}_{(\sigma_j)}} max\{\beta^-\}$ for all $\sigma_j \in U$. To make things easier, the pair $\mathcal{B}^*(\sigma_j) = \left(\mu^+{}_{(\sigma_j)}, v^-{}_{(\sigma_j)}\right)$ is called dual hesitant bipolar fuzzy values (DHBFV) denoted by $\mathcal{B}^*(\sigma_j) = (\mu^+, v^-)$.

Definition 10: The dual hesitant bipolar fuzzy weighted aggregation operator (DHBFWAO) is defined as:

$$DHBFWAO_w(\mathfrak{h}_1, \mathfrak{h}_2, \dots, \mathfrak{h}_n) = \sum_{j=1}^{n} (w_j \mathfrak{h}_j) \tag{8}$$

where, $w = (w_1, w_1, \dots, w_1)^t$ is the weight vector for each $\mathfrak{h}_j$ for $j = 1,2,3, \dots, n$, with $w_j > 0$ and $\sum_{j=1}^{n}(w_j) = 1$. This operator combines the DHBFV by applying their respective weights.

The basic definition and principle of mathematical induction can be used to show Theorem 4. The following theorem uses the inductive reasoning and ensuring that it applies appropriately in all relevant cases.

Theorem 4: The DHBFWAO provides a hesitant bipolar fuzzy value (HBFV) with

$$DHBFWAO_w(\mathfrak{h}_1, \mathfrak{h}_2, \dots, \mathfrak{h}_n) = \sum_{j=1}^{n} (w_j \mathfrak{h}_j)$$

$$DHBFWAO_w(\mathfrak{h}_1, \mathfrak{h}_2, \dots, \mathfrak{h}_n) = \cup_{\left(\alpha_j^+ \in \mu_j^+\right), \left(\beta_j^- \in v_j^-\right)} \begin{Bmatrix} \left\{1 - \prod_{j=1}^{n}\left(1 - \alpha_j^+\right)^{w_j}\right\}, \\ \left\{-\prod_{j=1}^{n}\left|\beta_j^-\right|^{w_j}\right\} \end{Bmatrix} \tag{9}$$

D. Dual Hesitant Bipolar Fuzzy Geometric Operators

Dual hesitant bipolar fuzzy geometric operators (DHBFGOs) use dual hesitant and bipolar fuzzy sets to deal with uncertainty, reluctance, and both positive and negative information.

Definition 11: The dual hesitant bipolar fuzzy weighted geometric operator (DHBFWGO) is defined as:

$$DHBFWGO_w(\mathfrak{h}_1, \mathfrak{h}_2, \dots, \mathfrak{h}_n) = \sum_{j=1}^{n} \left(\mathfrak{h}_j\right)^{w_j} \tag{10}$$

where, $w = (w_1, w_1, \dots, w_1)^t$ is the weight vector for each $\mathfrak{h}_j$ for $j = 1,2,3, \dots, n$, with $w_j > 0$ and $\sum_{j=1}^{n}(w_j) = 1$. This operator combines the DHBFV by applying their respective weights.

The basic definition and principle of mathematical induction can be used to show Theorem 5. The following theorem uses the inductive reasoning and ensures that it applies appropriately in all relevant cases.

Theorem 5: The DHBFWGO provides a hesitant bipolar fuzzy value (HBFV) with

$$DHBFWGO_w(\mathfrak{h}_1, \mathfrak{h}_2, \dots, \mathfrak{h}_n) = \sum_{j=1}^{n} \left(\mathfrak{h}_j\right)^{w_j}$$

$$DHBFWGO_w(\mathfrak{h}_1, \mathfrak{h}_2, \dots, \mathfrak{h}_n) = \cup_{\left(\alpha_j^+ \in \mu_j^+\right), \left(\beta_j^- \in v_j^-\right)} \begin{Bmatrix} \left\{\prod_{j=1}^{n}\left(\alpha_j^+\right)^{w_j}\right\}, \\ \left\{-1 + \prod_{j=1}^{n}\left(1 + \beta_j^-\right)^{w_j}\right\} \end{Bmatrix} \tag{11}$$

IV. Evaluation of Best Machine Learning Models for Industrial Robotics

To evaluate the best machine learning models by applying the proposed hesitant bipolar AOs (HBAO), consider the collection of alternatives as $\mathcal{A} = \{\mathcal{A}_1, \mathcal{A}_2, \dots, \mathcal{A}_m\}$, and the collection of criteria denoted by $\mathcal{C} = \{\mathcal{C}_1, \mathcal{C}_2, \dots, \mathcal{C}_n\}$. The weight vectors for the criterias are given by $w = \{w_1, w_2, \dots, w_n\}$, where $w_j \ge 0 \; \forall \; j = 1,2, \dots, n$, and $\sum_{j=1}^{n}(w_j) = 1$. Assume $H = \left[h_{ij}\right]_{m \times n} = \left[\left(\mu_{ij}^+, v_{ij}^-\right)\right]_{m \times n}$ which represent the hesitant bipolar fuzzy decision matrix. Here μ_{ij}^+ and v_{ij}^- and represent positive and negative functions, respectively, assessed by the decision-maker for the effectiveness of alternative $\mathcal{A}_i$ meets criteria $\mathcal{C}_j$. These functions lie within ranges $\mu_{ij}^+ \in [0,1]$ and $v_{ij}^- \in [0,1]$, where $i = 1,2, \dots, m$ and $j = 1,2, \dots, n$.

The methodology for using the HBFWAO or HBFWGO operator to solve a MCDM problem is explained below:

Step 1: To evaluate the MCDM problem, formation of decision matrix based on hesitant bipolar fuzzy environment.

Step 2: Applying the HBFWAO and HBFWG operator to process the information in matrix H. Calculate the overall values $h_i (i = 1,2, \dots, m)$ of alternative $\mathcal{A}_i$.

$$HBFWAO_w(h_{i1} h_{i2}, \dots, h_{in}) = \sum_{j=1}^{n} (w_j h_{ij})$$

$$= \cup_{\left(\alpha_{ij}^+, \beta_{ij}^-\right) \in \left(\mu_{ij}^+, v_{ij}^-\right)} \begin{Bmatrix} 1 - \prod_{j=1}^{n}\left(1 - \alpha_{ij}^+\right)^{w_j}, \\ -\prod_{j=1}^{n}\left|\beta_{ij}^-\right|^{w_j} \end{Bmatrix} \tag{12}$$

$$HBFWGO_w(h_{i1}, h_{i2}, \dots, h_{in}) = \sum_{j=1}^{n} \left(h_{ij}\right)^{w_j}$$

$$= \cup_{\left(\alpha_{ij}^{+},\beta_{ij}^{-}\right)\in\left(\mu_{ij}^{+},\nu_{ij}^{-}\right)} \left\{ \begin{matrix} \prod_{j=1}^{n}\left(\alpha_{ij}^{+}\right)^{w_j}, \\ -1+\prod_{j=1}^{n}\left(1+\beta_{ij}^{-}\right)^{w_j} \end{matrix} \right\} \quad (13)$$

Step 3: Determine the score by $s(h_i) = \frac{1}{\#h_i}\sum_{i=1}^{\#h_i}\frac{1+\alpha^{+}+\beta^{-}}{2}$, where $s(h_i)$ $(i = 1,2,\dots,m)$.

Step 4: Rank all the alternatives $\mathcal{A}_i$ (for $i = 1,2,\dots,m$) based on their scores $s(h_i)$ (for $i = 1,2,\dots,m$). If two scores $s(h_i)$ and $s(h_j)$ are identical, then calculate the accuracy functions $s^{*}(h_i)$ and $s^{*}(h_j)$ to differentiate and rank alternatives $\mathcal{A}_i$and $\mathcal{A}_j$.

Step 5: Select the most suitable alternatives based on their score values.

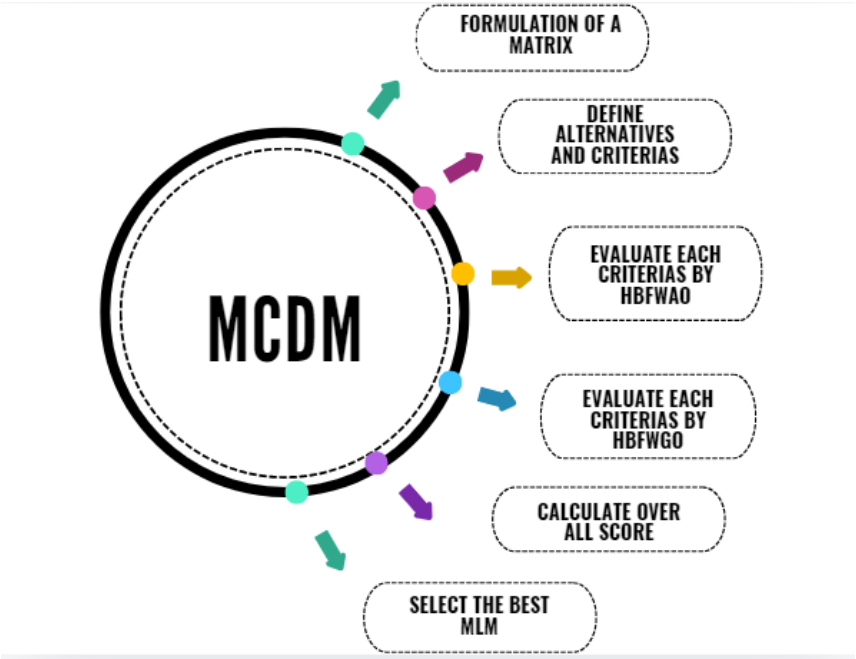

Fig. 1. Methodology of MCDM.

The pictorial representation of methodology to evaluation of best ML models is shown in Fig. 1.

A. Illustrative Example

Consider a manufacturing business that specializes in electronic device assembly. To boost their production efficiency, they decide to adopt an industrial robotic arm that can independently handle duties such as assembly and quality control. To maximize performance, however, choosing the best ML model for the robotic arm's functioning is essential. The main objective is to maximize the robotic arm's performance on the assembly line by selecting the best ML model from a pool of candidates using HBFAO. In this section, an empirical case study to assess the quality of ML model for industrial robots. The objective of the study is to evaluate which ML model, among several options that maximizes robotic performance in assembly line activities. The ML model for industrial robotic systems is shown in Fig. 2.

Fig. 2. Some ML models for industrial robotic system.

So, for the evaluation of the ML model, consider the following machine learning models (alternatives) which are evaluated based on the following criteria including accuracy of the model, training period, robustness, and interpretability which can be formulated as an MCDM problem.

The five machine learning models (alternatives) based on the following criteria are:

- $\mathcal{A}_1$ is Support Vector Machines (SVM): A high-dimensional space classification algorithm that locates the hyperplane dividing distinct classes
- $\mathcal{A}_2$ is Random Forest (RF): An ensemble technique for reliable regression and classification with insights into feature relevance that uses several decision trees.
- $\mathcal{A}_3$ is Deep Neural Networks (DNN): A flexible model with numerous layers capable of learning complicated patterns from vast datasets.
- $\mathcal{A}_4$ is Gradient Boosting Machines (GBM): An ensemble technique that creates models in a step-by-step manner, fixing mistakes in earlier models to increase accuracy.
- $\mathcal{A}_5$ is k-Nearest Neighbors (k-NN): A straightforward technique that relies on the closest training instances in the feature space to classify have been recognized.

These models will be assessed by a panel of experts who will make decisions based on the following four criteria:

- $\mathcal{C}_1$: Accuracy of the model
- $\mathcal{C}_2$: Training time required for the model.
- $\mathcal{C}_3$: Robustness of the model under various operational conditions.
- $\mathcal{C}_4$: Interpretability of the model results.

The weight values assigned by the decision makers (hypothetically) to each criterion represented by weighting vector $w = (0.20,0.10,0.30,0.40)$.

The decision-making problem i.e. evaluation of the ML model is evaluated by utilizing the above-defined methodology as follows;

Step 1: To evaluate the MCDM problem, the formation of a decision matrix from the opinion of the decision-maker based on a hesitant bipolar fuzzy environment is shown in Table I.

TABLE I. DECISION MATRIX

	$\mathcal{C}_1$	$\mathcal{C}_2$	$\mathcal{C}_3$	$\mathcal{C}_4$
$\mathcal{A}_1$	$\{(0.7,0.8,0.1),(-0.7,-0.4,-0.1)\}$	$\{(0.4,0.6,0.8),(-0.4,-0.3,-0.2)\}$	$\{(0.6,0.8,0.7),(-0.6,-0.3,-0.1)\}$	$\{(0.3,0.8,0.1),(-0.6,-0.4,-0.1)\}$
$\mathcal{A}_2$	$\{(0.6,0.7,0.2),(-0.6,-0.2,-0.7)\}$	$\{(0.6,0.7,0.1),(-0.6,-0.5,-0.1)\}$	$\{(0.5,0.7,0),(-0.3,-0.7,-0.1)\}$	$\{(0.5,0.7,0),(-0.3,-0.6,-0.2)\}$
$\mathcal{A}_3$	$\{(0.8,0.6,0),(-0.4,-0.3,0)\}$	$\{(0.5,0.6,0),(-0.4,-0.3,0)\}$	$\{(0.4,0.6,0.8),(-0.2,-0.5,-0.2)\}$	$\{(0.7,0.6,0.3),(-0.2,-0.4,-0.2)\}$
$\mathcal{A}_4$	$\{(0.6,0.7,0.8),(-0.4,-0.3,-0.3)\}$	$\{(0.7,0.8,0.2),(-0.2,-0.5,-0.4)\}$	$\{(0.6,0.7,0),(-0.2,-0.4,-0.1)\}$	$\{(0.6,0.7,0.8),(-0.2,-0.2,-0.4)\}$
$\mathcal{A}_5$	$\{(0.8,0.5,0),(-0.3,-0.4,-0.1)\}$	$\{(0.6,0.8,0),(-0.3,-0.5,-0.4)\}$	$\{(0.4,0.5,0.8),(-0.5,-0.4,-0.6)\}$	$\{(0.4,0.5,0),(-0.5,-0.3,-0.4)\}$

Step 2: By following above step 2, applying the HBFWAO and HBFWGO to process the information in a decision matrix H. Calculate the overall values $h_i(i = 1,2,\dots,m)$ of each alternative $\mathcal{A}_i$ corresponds to the criteria, shown in Table II.

TABLE II. AGGREGATION OF DECISION MATRIX

	HBFWAO	**HBFWGO**
$\mathcal{A}_1$	$\{(0.5081,0.7856,0.4431),(-0.5942,-0.3565,-0.1072)\}$	$\{(0.4503,0.7773,0.2207),(-0.6067,-0.3618,-0.1105)\}$
$\mathcal{A}_2$	$\{(0.5324,0.7000,0.0537),(-0.3693,-0.4953,-0.1947)\}$	$\{(0.5281,0.7000,0.0),(-0.4082,-0.5690,-0.3108)\}$
$\mathcal{A}_3$	$\{(0.6416,0.6000,0.4650),(-0.2462,-0.3923,0)\}$	$\{(0.5877,0.6000,0.4650),(-0.2661,-0.4050,-0.1446)\}$
$\mathcal{A}_4$	$\{(0.6113,0.7119,0.6277),(-0.2297,-0.2927,-0.2491)\}$	$\{(0.6093,0.7094,0.6277),(-0.2447,-0.3183,-0.3012)\}$
$\mathcal{A}_5$	$\{(0.5375,0.5438,0.3830),(-0.4290,-0.3646,-0.3424)\}$	$\{(0.4785,0.5241,0.0),(-0.4469,-0.3734,-0.4238)\}$

Step 3: Compute the score function of the evaluated decision matrix by step 3 and display in Table III.

TABLE III. SCORE VALUE

	$\mathcal{A}_1$	$\mathcal{A}_2$	$\mathcal{A}_3$	$\mathcal{A}_4$	$\mathcal{A}_5$
HBFWAO	0.1679	0.1227	0.2068	0.2179	0.1328
HBFWGO	0.1369	0.0940	0.1372	0.1455	0.0758

Step 4: Rank all the ML model $\mathcal{A}_i$ (for $i = 1,2,\dots,5$) in according with the score function $s(h_i) = h_i(i = 1,2,\dots,5)$ and demonstrate in Table IV.

TABLE IV. RANKING OF THE BEST ML MODEL FOR INDUSTRIAL ROBOTIC

	Ranking Value
HBFWAO	$\mathcal{A}_4 \succ \mathcal{A}_3 \succ \mathcal{A}_1 \succ \mathcal{A}_5 \succ \mathcal{A}_2$
HBFWGO	$\mathcal{A}_4 \succ \mathcal{A}_3 \succ \mathcal{A}_1 \succ \mathcal{A}_2 \succ \mathcal{A}_5$

Step 5: The most suitable alternatives based on their score values are shown in Table V.

TABLE V. SUITABLE ML MODEL FOR INDUSTRIAL ROBOTIC

	Ranking Value	Suitable ML (Alternative)
HBFWAO	$\mathcal{A}_4 \succ \mathcal{A}_3 \succ \mathcal{A}_1 \succ \mathcal{A}_5 \succ \mathcal{A}_2$	$\mathcal{A}_4$
HBFWGO	$\mathcal{A}_4 \succ \mathcal{A}_3 \succ \mathcal{A}_1 \succ \mathcal{A}_2 \succ \mathcal{A}_5$	$\mathcal{A}_4$

The graphical representation of the ranking of alternatives is shown in Fig. 3(a) and Fig. 3(b).

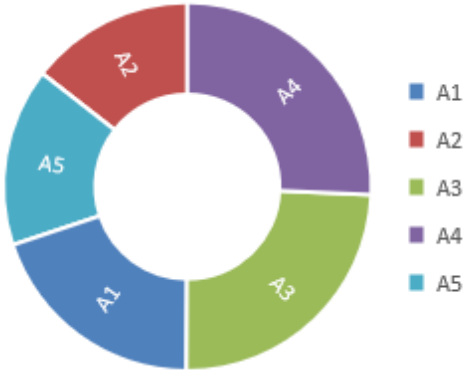

Fig. 3. Ranking of alternatives.

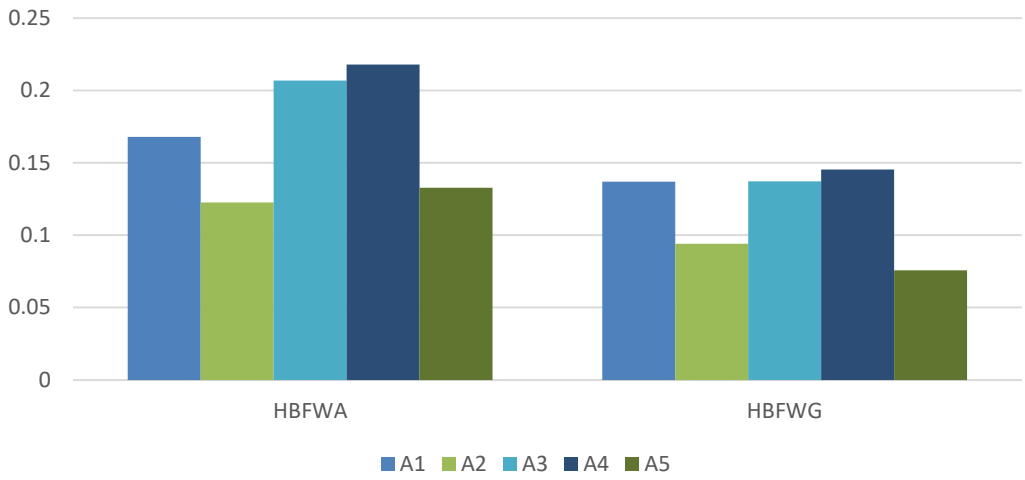

Fig. 4. Ranking of alternatives.

B. Result and Discussion

To evaluate the MLMs that are best suited for industrial robotics, the following Aos HBFWAO and HBFWGO have been employed, in this study. The proposed operators show that the Gradient Boosting Machines (GBM) model i.e. A_4 ranks higher than the other models, as shown by Table IV i.e. ranking of the ML model for industrial robotics based on these operators. By utilizing both AOs i.e. HBFWAO and HBFWGO, the results show that $\mathcal{A}_4$ is the most appropriate model, followed by $\mathcal{A}_3, \mathcal{A}_2$, and so on. The ultimate rankings in Table 5 indicate that $\mathcal{A}_4$ is the best-fit ML model based on both operators. The constancy of these operators' rating findings demonstrates their competence in decision-making, guaranteeing that the best model is chosen for industrial robotics jobs.

V. COMPARATIVE ANALYSIS

To check the validity and effectiveness of the proposed operator, this comparison study demonstrates the benefits and drawbacks of several fuzzy-based operators, from the simpler FS to the more sophisticated HBFAO. While HFS adds the capacity to model uncertainty but lacks flexibility, FS are limited in their ability to handle complicated attribute interactions. Although BFS introduces both positive and negative attribute dimensions, they are still insufficient for parametric flexibility, which hinders decision-making. Flexibility is further increased by operators like HBFWAO and HBFWGO, which consider the weighted relationships between criteria. We have compared the proposed AOs with the prior operators as shown in Table VI, which demonstrates how inadequate and ineffective the previous approaches are at handling connections between attribute values. To close this gap, we developed the HBFWAO and HBFWGO, which support optimal decision-making by thoroughly addressing these constraints.

TABLE VI. COMPARISON BETWEEN PRIOR APPROACHES AND THE PROPOSED APPROACH

Approaches	Connection Between Two Attributive Values	Relationships between Various Attributive Values	Reduced Adverse Effects	Parametric Method Increases Flexibility	Scalability	Robustness
FS [5]	✗	✗	✗	✗	✗	✗
HFS [13]	✓	✗	✗	✗	✗	✗
BFS [15]	✓	✓	✗	✓	✗	✗
HFAO [21]	✓	✓	✓	✗	✗	✗
BFAO [22]	✓	✓	✓	✓	✓	✗
HFGO [21]	✓	✓	✓	✗	✓	✗
BFGO [22]	✓	✓	✓	✓	✓	✗
HBFAWO (Proposed Operator)	✓	✓	✓	✓	✓	✓
HBFGWO (Proposed Operator)	✓	✓	✓	✓	✓	✓

So, the above Table VI demonstrate the proposed operators has the ability to highlights the relation between the various attributive values and reducing the adverse effects which make it flexible, efficient and versatile operator which assists the decision makers in making decisions. The proposed HBFWAO and HBFWGO operators are advanced and less laborious approaches to decision making under uncertainty, conflict, and incompleteness. Compared to earlier works, they afford a superior incorporation of uncertainty and flexibility with respect to complex with many criteria and objectives problems, especially those relating to industrial robotics, which have been the focus of this study.

VI. CONCLUSION

The MLMs are increasingly utilized in industrial applications to automate the complex activities, reduce human error, and enhance decision-making by analyzing large volumes of data in real-time. In this paper, a comprehensive novel approach for evaluating the best MLMs in industrial robots has been developed by utilizing the hesitant bipolar fuzzy and dual hesitant bipolar fuzzy AOs within the averaging and geometric framework. i.e. HBFWAO, HBFWGO, DHBFWAO, and DHBFGO. These operators, inspired by arithmetic and geometric operations, effectively address MCDM challenges and capturing the uncertainties associated with hesitancy and bipolarity which enabling a robust evaluation of positive and negative attributes. To demonstrate the effectiveness and robustness of proposed operator, an exemplary case study has been defined which is evaluated by utilizing the proposed decision-making algorithm. The proposed operators demonstrated their practical utility, providing precise and adaptable solutions for real-world applications in industrial robotics.

Moreover, a rigorous comparative analysis demonstrates the superiority of the proposed approach over existing methods and highlighting its robustness, accuracy, and flexibility. The parametric adaptability of the framework ensures its broad applicability across various decision-making scenarios, minimizing errors and optimizing the outcomes in complex industrial environments.

A. Limitations and Future Direction

To demonstrate the thorough evaluation and defines the balanced perspective, it is necessary to discuss the limitations of the proposed approach.

- The proposed approach offers complexity in handling a large data set, resulting in a high processing time and memory consumption.
- The proposed operators may be sensitive towards the various parameters and then improper selection may affect the accuracy and effectiveness.
- The complex nature of integrating the hesitant and bipolar environment can lead to complex situations in evaluating decision-making problems.
- Although the proposed operators show flexibility and robustness, however, it is not applicable in a highly dynamic framework and demands further modification.

So, to improve the precision and adaptability of decision-making, future research could concentrate on merging the proposed operators with sophisticated fuzzy logic systems [23], Intuitionistic fuzzy framework [24], and Pythagorean fuzzy set (PyFS) [25] framework, Neutrosophic framework [26] that may handle hesitation and more complex decision scenarios precisely. Furthermore, it can be extended by utilizing the AOs [27], [28], [29], [30] that can be useful for dealing with noisy or incomplete data. More resilient and adaptable decision-making models can be created by fusing these operators with sophisticated fuzzy techniques. Moreover, it could expand the applicability of these models beyond industrial robots to industries where uncertainty is crucial, such as healthcare, finance, and autonomous systems. Including different sectors, such as healthcare in diagnostic decision support systems, finance in risk assessment tools and autonomous systems for vehicle navigation or resource allocation, in the research

activities or case studies developed would serve to indicate the extensibility of the methods suggested. This wider perspective reveals not only the usefulness of the methods in practice across different sectors, but also the desire to appeal to a larger audience. Such examples would emphasize how these types of models can be adapted to different industries yet remain internally consistent and accurate in the face of uncertainty when making decisions.

***Abstract*—This paper aims to improve the accuracy and efficiency of SCADA software design and testing for oil and gas pipelines. It proposes a JavaWeb-based SCADA software solution optimized by the Bird Foraging Search (BFS) algorithm combined with an Echo State Network (ESN) for enhanced testing and analysis. A multi-tiered distributed SCADA software architecture based on the Java EE framework was designed to provide real-time data acquisition, monitoring, control, and data analysis. The BFS algorithm was used to optimize the hyperparameters of the ESN model to improve testing accuracy and convergence speed. The BFS-ESN model was compared with other optimization algorithms such as PSO and DE. Experimental results show that the BFS-ESN model achieved a testing accuracy of 97.33% and faster convergence within 700 iterations. It outperformed other algorithms in both accuracy and convergence speed. The JavaWeb-based SCADA software design for oil and gas pipelines is feasible, and the BFS-ESN model significantly enhances the accuracy and efficiency of SCADA software testing. This approach demonstrates the potential for application in SCADA systems, with future research needed to simplify the model and extend its applicability for large-scale deployment.**

***Keywords*—JAVAWeb; oil and gas pipelines; SCADA software; design analysis; bird foraging search algorithm**

I. INTRODUCTION

Supervisory Control and Data Acquisition (SCADA) is a kind of industrial control system for long-distance data acquisition and monitoring [1], which is widely used in long-distance oil and gas pipelines [2], and its ability to work properly directly affects the production and operation of oil and gas pipelines and even the national oil and gas industry [3]. In recent years, with the great development of pipeline construction, the normal operation of the pipeline has had a direct impact on the production and operation of oil and gas pipelines and even the national oil and gas industry [3]. In recent years, with the great development of pipeline construction, the pipeline scale is getting bigger and bigger, the demand for SCADA system software is getting higher and higher, the database management scale reaches millions of nodes, the supported devices are diversified, and the number of collection devices is required to reach hundreds or even thousands [4]. In order to improve the efficient, stable and safe operation of the system, combined with Java Web technology, the design of SCADA software, to build multi-level, distributed applications [5]. In the consideration of safe production, after the SCADA software for oil and gas pipelines passes the software test in the laboratory simulation environment, it is also necessary to select real scenarios at the operation site and use the SCADA software to carry out a controlled range of trial operation [6]. Therefore, the study of SCADA software analysis for oil and gas pipelines based on Java Web technology is of great significance for software design, which is not only conducive to the efficiency of software design, but also contributes to the efficient, stable and safe operation of SCADA systems [7].

The research on the design and analysis of SCADA software for oil and gas pipelines based on Java Web technology mainly includes the research on the demand analysis of SCADA system for oil and gas pipelines, Java Web development of SCADA software, and test analysis of SCADA software [8]. Oil and gas pipeline SCADA system requirements analysis is mainly to improve the performance of oil and gas pipeline SCADA system, study in [9] from the perspective of market research, analysed the existence of pipeline transmission characteristics, for this feature, designed a long-distance oil and gas pipeline SCADA system; study in [10] from the perspective of economic benefits, research on oil and gas pipeline SCADA project construction specific design ideas. SCADA software Java Web development is mainly to study the process of developing SCADA software based on Java Web technology, study in [11] used Java Web technology to develop SCADA software for oil and gas pipelines, and introduces the relevant functions and structure. SCADA software testing and analysis research is mainly the use of software testing process, according to the test indexes, analyse the effectiveness and functionality of SCADA software. The effectiveness and functionality of SCADA software is analysed according to the testing indexes. Currently, data-driven algorithms are used to test SCADA software, including neural networks [12], SVM [13], LSTM [14] and other methods. Although scholars at home and abroad have done a lot of rich research on the design and analysis of SCADA software for oil and gas pipelines based on Java Web technology, there are still some problems [15]: firstly, there are fewer research studies on the development of SCADA software for oil and gas pipelines based on Java Web technology; secondly, there are fewer methods for testing SCADA software for oil and gas pipelines; and lastly, the testing methods for SCADA software accuracy is not high enough.

In order to improve the accuracy of SCADA software testing and analysis methods for oil and gas pipelines based on Java Web technology, this paper provides relevant ideas for the design problems of SCADA software for oil and gas pipelines based on Java Web technology, focusing on the key problems of SCADA software design and testing for oil and gas pipelines, combining the Echo State Network [16] with the Bird Foraging Search Algorithm [17], and proposing a method based on the BFS-ESN network in Java Web framework of oil and gas pipeline SCADA software design testing method. The experimental results of relevant data analysis show that the SCADA software design method for oil and gas pipelines based on BFS-ESN network under the Java Web framework realises the SCADA software design and analysis problems of oil and gas pipelines, and improves the accuracy and efficiency of the SCADA software design test.

II. SCADA Software for Oil and Gas Pipelines

A. Java Web Technologies

Java Web is a web development framework based on Java technology [18] for building dynamic websites and enterprise applications. It includes a variety of technologies and server-side components, such as Servlet, JSP (JavaServer Pages), Spring, Hibernate, as well as web servers and application servers, such as Apache Tomcat, Jetty, GlassFish and WildFly. The Java Web technology system covers the full range of development needs from front-end presentation to back-end logic processing. Java Web technology system covers a full range of development needs from the front-end display to the back-end logic processing. Java Web schematic diagram shown in Fig. 1.

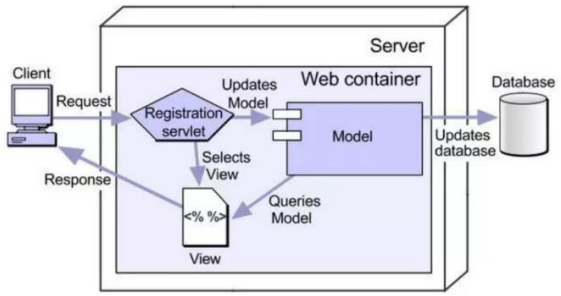

Fig. 1. Java web technology.

The technology system of Java Web includes front-end technologies (HTML, CSS, JavaScript) and back-end technologies (Servlet, JSP, MVC frameworks, database interaction technologies) [19]. Developers can use these technologies to create dynamic web pages, handle user requests, access databases, and implement business logic. The Java Web technology system and roles are shown in Fig. 2.

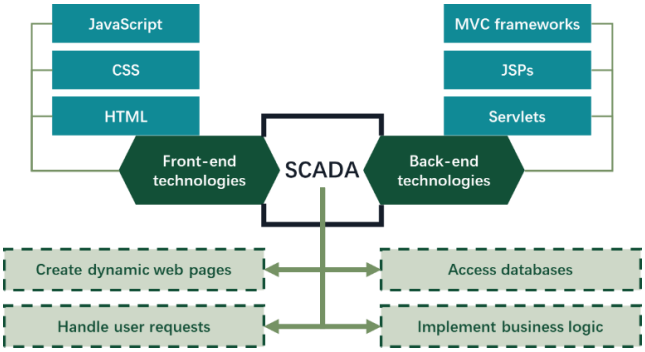

Fig. 2. Java Web technology system and role.

Java Web servers usually work based on a B/S (Browser/Server, browser and server) model (Fig. 3). The client sends an HTTP request to the server through the browser, and the server receives the request and processes it according to the type of request (static resource or dynamic resource). If it is a dynamic resource, the server forwards the request to the Web container (Tomcat), which loads the Servlet or JSP page, executes the corresponding business logic, and returns the generated dynamic content to the client browser.

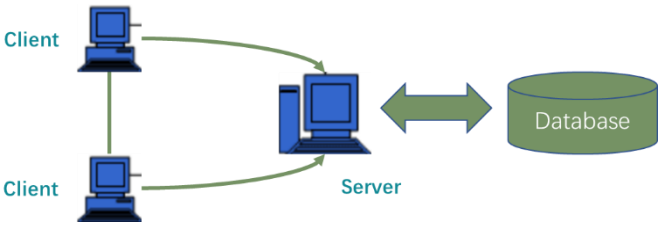

Fig. 3. Java web server fundamentals.

B. SCADA System for Oil and Gas Pipelines

Oil and gas pipeline SCADA (Supervisory Control And Data Acquisition) [20] systems are key industrial control systems used to monitor and control oil and gas transmission processes. Java Web-based SCADA software design typically involves the use of the Java EE (Jakarta EE) technology stack to build multi-tiered, distributed applications that provide real-time data acquisition, monitoring, control, and data analysis, as shown in Fig. 4.

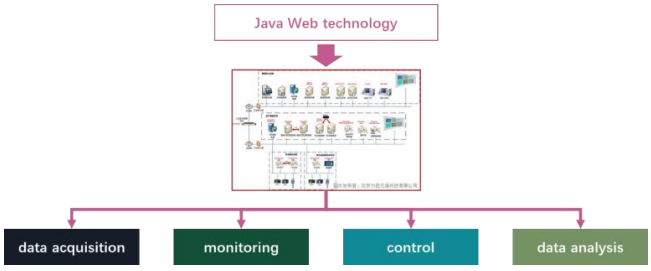

Fig. 4. Logical relationship between SCADA and Java Web.

In designing Java Web-based SCADA software for oil and gas pipelines, the multi-tier architecture provided by the J2EE platform can be used, including the client layer, Web layer, business logic layer, and enterprise information system layer [21]. Such an architecture helps to improve the modularity, maintainability, and scalability of the system.1) The client layer can be a Web-based interface for remote access; 2) the Web layer handles HTTP requests and responses and provides the user interface; 3) the business logic layer contains components that process data and execute control logic; and 4) the enterprise information system layer is responsible for integrating with external systems such as energy Management System (EMS). Fig. 5 shows Java Web-based SCADA software design architecture.

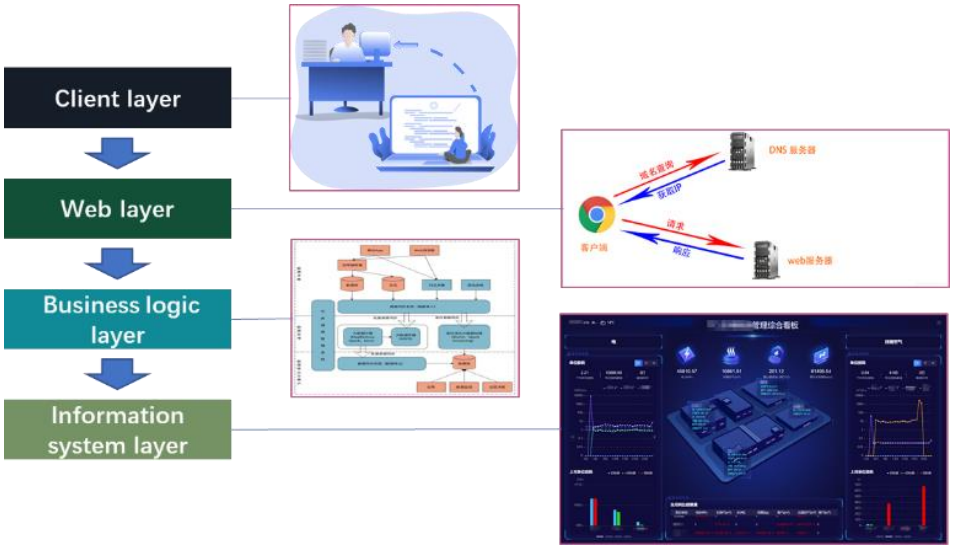

Fig. 5. Java Web-based SCADA software design architecture.

C. Design Thinking

According to the Java Web-based SCADA software design architecture for oil and gas pipelines, this paper uses various technologies and services provided by Java EE (Servlet, JavaServer Pages (JSP), Enterprise JavaBeans (EJB), Java Message Service (JMS), Java Transaction API (JTA)) to achieve high performance, reliability and security of the system; using a database management system (DBMS) to store historical data and real-time data; the use of Web services and RESTful APIs to achieve inter-system communication and data exchange, as shown in Fig. 6.

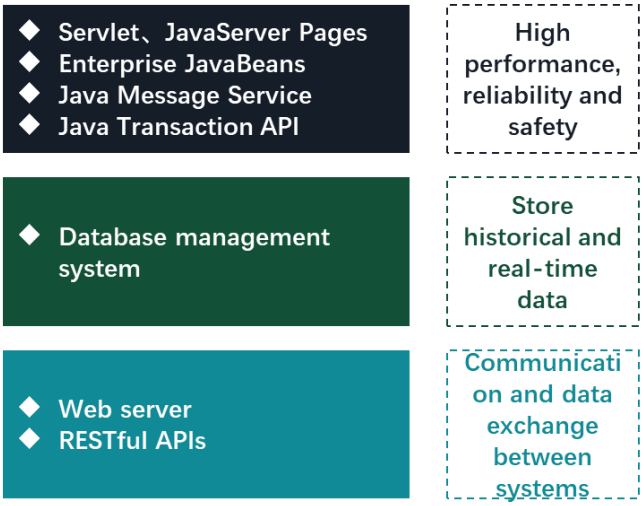

Fig. 6. Key technologies and tools.

With the help of these tools and technologies, security and reliability are fully considered to ensure that real-time data monitoring and control response can be provided, and interface interaction is designed to enable operators to easily monitor pipeline status and perform necessary control operations. The design flow of Java Web-based SCADA software is shown in Fig. 7.

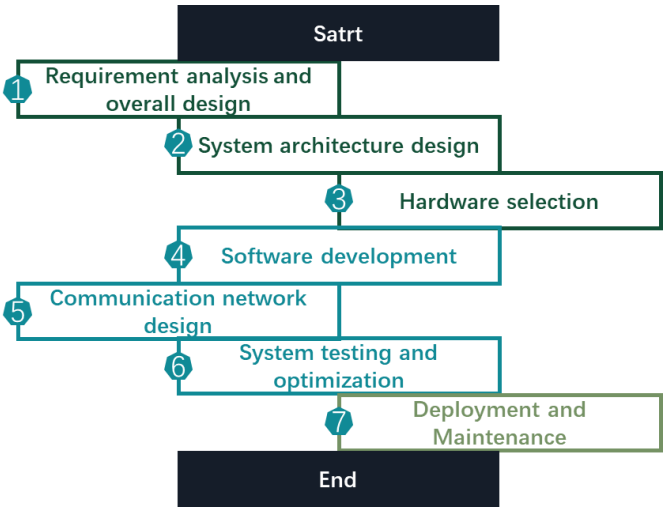

Fig. 7. Design flow.

III. Software Design Application and Test Analysis

A. Echo State Network

One type of recursive neural network is the echo state network (ESN) [22], which is typically used for time series

prediction [19] and builds the network hidden layer using the "reserve pool" technique. The input layer, storage layer, and output layer comprise the vast majority of ESN. Fig. 8 illustrates its precise configuration. Following the initial randomization, the connection weights between the input layer and the storage pool $\boldsymbol{W}_{in}^{r\times n}$ are not trained and won't be altered. Similarly, the state feedback weight $\boldsymbol{W}^{r\times r}$ is arbitrarily initialized and does not require training, while the reserve pool input is derived from the output of the previous state of the input layer and the reserve pool, respectively. A reserve pool for the output layer weights $\boldsymbol{W}_{out}^{m\times r}$ must be trained, typically using the Ridge regression (Ridge regression) method for connection weights. This method is expressed as follows:

$$\boldsymbol{W}_{out}=\boldsymbol{Y}_{long}\boldsymbol{H}^{T}\left(\boldsymbol{H}\boldsymbol{H}^{T}+\lambda_{r}\boldsymbol{I}\right)^{-1} \tag{1}$$

The storage pool state and the regularization factor are represented by $\boldsymbol{H}$ and λ_r, respectively. The condition $\boldsymbol{H}$ of the pool is depicted below:

$$\boldsymbol{H}\left(t\right)=\tanh\left(\boldsymbol{W}_{in}\boldsymbol{X}_{long}\left(t\right)+\boldsymbol{W}\boldsymbol{H}\left(t-1\right)\right) \tag{2}$$

where the hyperbolic tangent activation function is indicated by tanh.

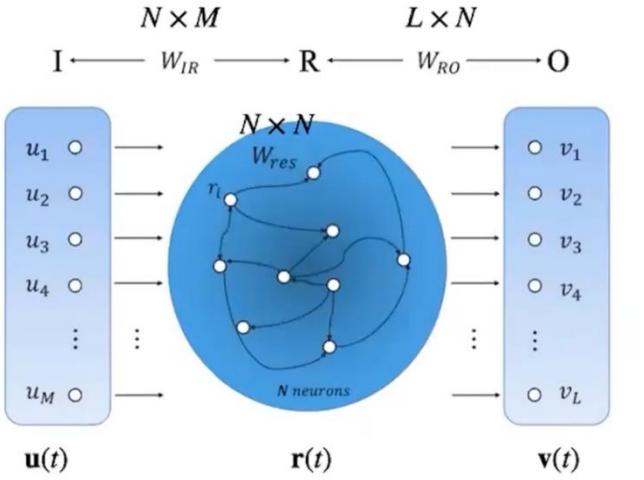

Fig. 8. Echo state neural network.

The Echo State Network (ESN) algorithm consists of two main phases: the initialization of weight parameters and the training process. During the initialization phase, the connection weights within the network are randomly generated. Specifically, the connection weights between neurons in the reservoir (or storage pool) are sparsely distributed, meaning that not all neurons are connected, which helps reduce computational complexity. In the training phase, only the weights connecting the reservoir to the output layer are adjusted, typically using methods like Ridge regression, while other weights remain fixed [23], where the ESN hyperparameters include the size of the storage pool N_r, the spectral radius SR, and the input scaling factor IS, storage pool sparsity SD.

A key characteristic of ESNs is the relatively large number of neurons present in the reservoir, which allows the network to capture complex dynamics. However, the performance of an ESN is highly dependent on its hyperparameters, making hyperparameter tuning a crucial step for optimal performance. The key hyperparameters include the size of the reservoir, which determines how much internal memory the network has; the spectral radius, which controls the stability and dynamic range of the network; the input scaling factor, which influences the sensitivity of the reservoir to input signals; and the sparsity of the reservoir, which affects the degree of connectivity between neurons. Proper adjustment of these hyperparameters is essential for improving the prediction accuracy of the ESN, especially in time series forecasting and other complex tasks.

B. Bird Foraging Search Algorithm

Drawing inspiration from the diverse behaviors exhibited by birds while foraging, this paper introduces a new swarm intelligence optimization algorithm known as the Birds Foraging Search (BFS) algorithm [17]. Each phase contributes uniquely to the optimization process.

In the flight search behavior phase, birds engage in exploratory movements, mimicking how birds scout for food sources over large areas. This phase primarily focuses on exploration, allowing the algorithm to cover a wide search space. The domain behavior phase, on the other hand, emphasizes exploitation, where birds refine their search within specific territories to locate better resources more precisely. The balance between these two phases—exploration and exploitation—is essential for optimizing the algorithm's performance. The cognitive behavior phase enhances the algorithm's search efficiency by allowing individual birds to learn from their past experiences. This phase simulates self-learning, enabling birds to adjust their strategies based on previously gathered information, which helps in avoiding redundant searches and accelerating convergence. The detailed search strategies for each phase are illustrated in Fig. 9.

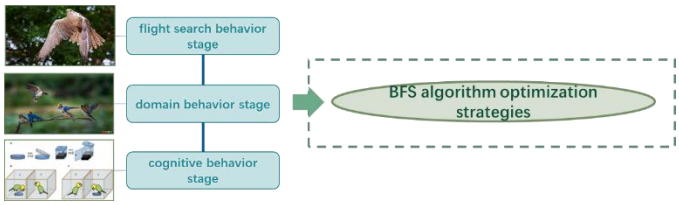

Fig. 9. Search strategy of the BFS algorithm.

The initial position of the bird in space is represented as follows:

$$X_i=UB-r_1\cdot(UB-LB) \tag{3}$$

where X_i denotes the position of the ith bird, UB and LB denote the upper and lower bounds of the search space, respectively, and r_1 is a random value.

1) Flight search behaviour stage: Birds of prey, like falcons, typically choose areas with high potential for finding prey and hover over these regions while searching for food. Through extensive research, scientists have observed that the flight patterns of these raptors closely resemble a logarithmic spiral. This spiral movement allows the birds to efficiently cover a specific area, increasing their chances of locating prey. The spiral pattern is mathematically defined, and its unique structure enables the predator to maintain focus on a targeted zone while gradually expanding or contracting their search radius, optimizing their hunting strategy (as shown in Fig. 10):

$$X_i^{iter+1} = D_{i-p} \cdot e^{\theta} \cdot \cos(2\pi\theta) + PA^{iter} \quad (4)$$

where $i \in [1, 2, 3, \ldots, N]$, and N is the population size. θ is a random number between -1 and 1. $D_{i-p} = \left| X_i^{iter} - PA^{iter} \right|$ denotes the distance from the i[th] bird to the potential region, X_i^{iter} denotes the position of the i[th] bird at iter iteration, and PA^{iter} denotes the position of the potential region at iter iteration.

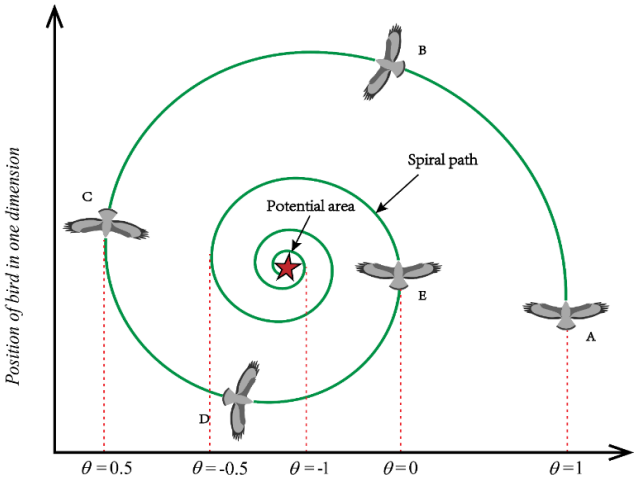

Fig. 10. Logarithmic spiral flight pattern.

2) Stages of domain behavior: In the Birds Foraging Search (BFS) algorithm, these two types of birds follow different movement behaviors. The territorial bird focuses on patrolling a small region around its current position, both to search for better food sources and to defend its territory from other competing birds. This localized exploration allows the territorial bird to refine its current solution while preventing others from entering its domain. Meanwhile, the invasive birds attempt to enter the territory in search of resources. The behavior of the territorial bird, balancing exploration and defense, can be mathematically modeled as follows:

$$X^{T,iter+1} = X^{T,iter} + r_d \cdot \lambda \quad (5)$$

Where, $X^{T,iter}$ is the position of the territorial bird at iterth iteration; r_d is a random value between -1 and 1, representing the search direction of the territorial bird; λ is a scale factor, which is generally set to $(X^{T,iter} - X^{S,iter})$, and $X^{S,iter}$ is the position of the suboptimal individual.

Once a territorial bird has claimed a region as its exclusive domain, all invading birds will begin moving toward that area in search of resources. At this stage, the territorial bird takes defensive action to protect its claimed space, using warning calls or chirping to deter the invaders. This defense mechanism can lead to two possible outcomes.

a) Scenario 1: In this case, the invasive bird's position is updated as it moves closer to the territory. The invasive bird's persistence reflects a focus on resource acquisition, and the algorithm models this movement as a rapid progression toward the territorial bird's domain, following a predefined mathematical update rule. This allows the invasive bird to keep adjusting its position despite the territorial bird's efforts to protect its resources.

$$X_j^{I,iter+1} = X_j^{I,iter} + r_2 \cdot (X^{T,iter} - IF \cdot X_j^{I,iter}) \quad (6)$$

Where, $X_j^{I,iter}$ is the position of the jth invasive bird at the iterth iteration, r_2 is a random number between 0 and 1; IF is the invasion factor, which determines how the position of the invasive bird changes, and the specific effects are shown in Fig. 11.

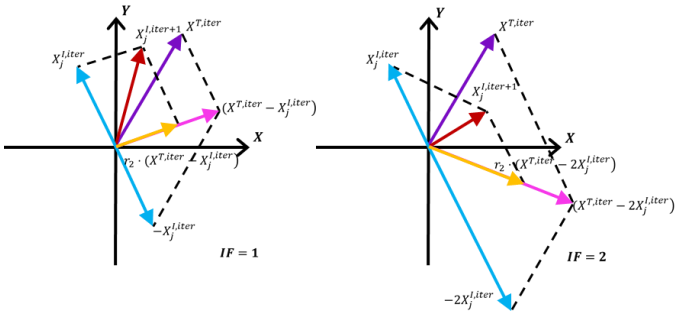

Fig. 11. Vector representation of invasive bird movements with different invasion factors.

b) Scenario 2: When the bird continues its search but fails to discover an improved solution, its current position remains unchanged from the previous one($X_i^{iter} = X_i^{iter-1}$). In this scenario, the bird's movement is modeled using a Gaussian distribution, allowing for random variations in its search path. This randomness helps the bird explore new areas more effectively.

$$X_{j,d}^{I,iter+1} = X_{j,d}^{I,iter} + r_3 \cdot (X_{k,d}^{I,iter} - X_{m,d}^{I,iter}) + r_4 \cdot (X_{l,d}^{I,iter} - X_{h,d}^{I,iter}) \quad (7)$$

The Scenarios 1 and 2 optimisation process is summarised as:

$$\begin{cases} X_j^{I,iter+1} = X_j^{I,iter} + r_2 \cdot (X^{T,iter} - IF \cdot X_j^{I,iter}) & if\ P^{iter} \le rand \\ X_{j,d}^{I,iter+1} = X_{j,d}^{I,iter} + r_3 \cdot (X_{k,d}^{I,iter} - X_{m,d}^{I,iter}) + r_4 \cdot (X_{l,d}^{I,iter} - X_{h,d}^{I,iter}) & otherwise \end{cases} \quad (8)$$

3) Cognitive behavioural stage: Cognitive behavior in birds is essentially a self-learning process that draws on accumulated experience. Birds use the information gathered from previous searches to refine their strategies, helping them avoid redundant or inefficient searching. This self-guided learning enhances their foraging efficiency, allowing them to focus on more promising areas. Cognitive behavior can be broken down into two distinct parts.

a) Scenario 1: In this case, the birds are continuously discovering better food sources, which means their current position differs from the previous one $X_i^{iter} \neq X_i^{iter-1}$. Here, the birds actively learn by leveraging the gradient information from their previous searches. By following this targeted search approach, they adjust their movements in a way that is guided by prior successes, which ultimately helps them refine their foraging strategy. This focused learning process not only allows them to zero in on better resources but also significantly speeds up the algorithm's convergence. The efficiency gained from this self-learning behavior means the birds are more likely to optimize their search pattern faster, avoiding unnecessary wandering and making the overall process more streamlined. The specific mathematical calculations for updating their positions during this phase are based on their learning from previous gradients.

$$X_i^{iter+1} = X_i^{iter} + r_5 \cdot (X_i^{iter} - X_i^{iter-1}) \quad (9)$$

Where X_i^{iter} and X_i^{iter-1} are the i-th bird at iter-th iteration and iter-1 iteration position respectively; r_5 is a random number between 0 and 1.

b) Scenario 2: The bird continues to search but fails to find a better result. That is, the current position is the same as the previous position ($X_i^{iter}=X_i^{iter-1}$). The process is implemented based on Gaussian distribution:

$$X_i^{iter+1}=Gaussian(X_{best}^{iter},\ \xi) \quad (10)$$

Where $Gaussian(X_{best}^{k},\ \xi)$ denotes a Gaussian distributed random number with mean X_{best}^{k} and standard deviation ξ ; X_{best}^{iter} is the population optimal solution for iter iteration number.

$$\xi = (\log(iter)/iter)\cdot abs(X_{best}^{iter} - r_6 \cdot X_i^{iter}) \quad (11)$$

where r_6 is a random value and $\log(iter)/iter$ denotes the size used to adjust the standard deviation.

To prevent such ineffective searches, BFS introduces a boundary control policy:

$$X_{i,d}^{iter} = UB - r_7 \cdot (UB - LB) \quad if \quad X_{i,d}^{iter} < LB \ or \ X_{i,d}^{iter} > UB \quad (12)$$

where $X_{i,d}^{iter}$ denotes the position of the dth dimension of the ith individual at the iter iteration number and r_7 denotes the random value.

According to the optimisation strategy of the BFS algorithm, the pseudo code is shown in Table I.

C. BFS-ESN Method

In order to improve the feasibility and accuracy of SCADA software design test for oil and gas pipelines based on Java Web technology, this paper uses to optimise the hyperparameters of ESN network using BFS algorithm to construct the SCADA software design test model, and the specific structure is shown in Fig. 12.

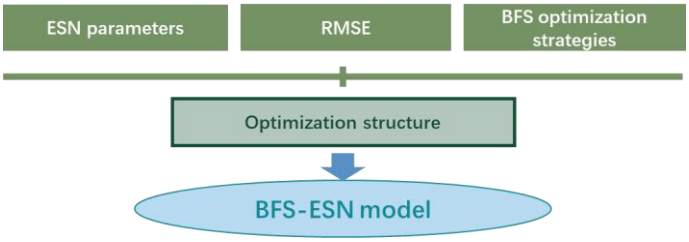

Fig. 12. BFS-ESN structure.

BFS-ESN uses ESN hyperparameters, i.e., storage pool size N_r , spectral radius SR , input scale factor IS , and storage pool sparsity SD as the optimisation variables, and the coding mode is real number coding mode, the specific coding structure is shown in Fig. 13.

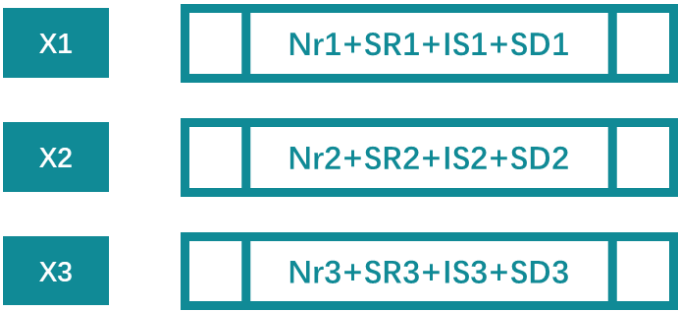

Fig. 13. BFS-ESN coding structure.

BFS-ESN uses RMSE as the optimisation fitness value and the on-the-fly search behavioural phase, domain behavioural phase, and cognitive behavioural phase of the BFS algorithm as the ESN optimisation strategy.

D. Test and Analysis Method for Designing SCADA Software

Taking the BFS-ESN model as the software testing model, in order to solve the oil and gas pipeline SCADA software design testing analysis, this paper proposes the oil and gas pipeline SCADA software design testing analysis method based on the BFS-ESN model, and the specific application flowchart is shown in Fig. 14. The application process of the BFS-ESN algorithm consists of the following processes: 1) According to the user's security and reliability of the system The application process of the BFS-ESN algorithm includes the following processes: 1) according to the user's demand for system safety and reliability, specify the actions and functions to be achieved by the control object; 2) design the topology of the SCADA system; 3) develop the front-end interface and the back-end logic of the SCADA software by using the JavaWeb technology; and 4) test the system by using the BFS-ESN model after the completion of the software development.

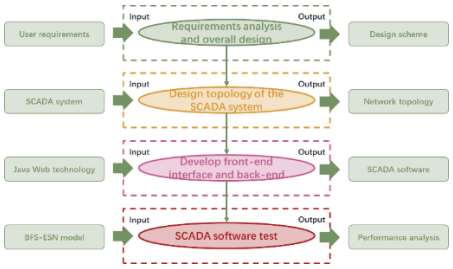

Fig. 14. Flow of BFS-ESN algorithm application.

IV. Results and Discussion

A. Experimental Set-up

In order to verify the effectiveness and feasibility of the method proposed in this paper, this paper adopts the oil and gas pipeline SCADA system software and related data as the analysis data, and selects PSO, DE, ABC, CS, GSA, FA as the comparison algorithms of hyperparameter optimisation of the ESN network, and the parameter settings of each algorithm are shown in Table II. The population sizes of PSO, DE, ABC, CS, GSA, FA algorithms are chosen as 100 and the maximum number of iterations is set to 1000.

TABLE II. Parameter Settings of the Optimisation Algorithm for the Comparison Model

Arithmetic	Parameterisation
PSO	w=0.6, c1=c2=2
DE	F=0.5, CR=0.9
ABC	limit=(N*D)/2, hired bees=scout bees=0.5N
CS	G0=100, α=20
GSA	β = 1.5, p = 0.25
FA	α = 0.2, β0 = 1 and γ = 1
BFS	Parameter-free optimisation algorithm

The experimental simulation system is Wins 10 and the programming language is Matlab2024a.

B. Analysis of Test Results

1) BFS optimisation performance analysis: In order to analyse the optimisation performance of BFS algorithms, in this section, the single peak benchmark functions (F01-F06) are used to analyse and compare the BFS, PSO, DE, ABC, CS, GSA and FA algorithms, and the basic information of the functions is shown in Table III.

The optimisation curves of the BFS, PSO, DE, ABC, CS, GSA and FA algorithms are given in Fig. 15. From Fig.15, it can be seen that in terms of convergence speed, BFS is significantly better than the remaining six algorithms; in terms of convergence accuracy, BFS is significantly better than the other optimisation algorithms.

TABLE III. Test Function Description

Test function	name (of a thing)	dimension (math.)	realm	optimum value
F01	Sphere	30	[-100,100]	0
F02	Schwefel2.22	30	[-10,10]	0
F03	Schwefel 1.2	30	[-100,100]	0
F04	Schwefel2.21	30	[-100,100]	0
F05	Rosenbrock	30	[-30,30]	0
F06	Step	30	[-100,100]	0

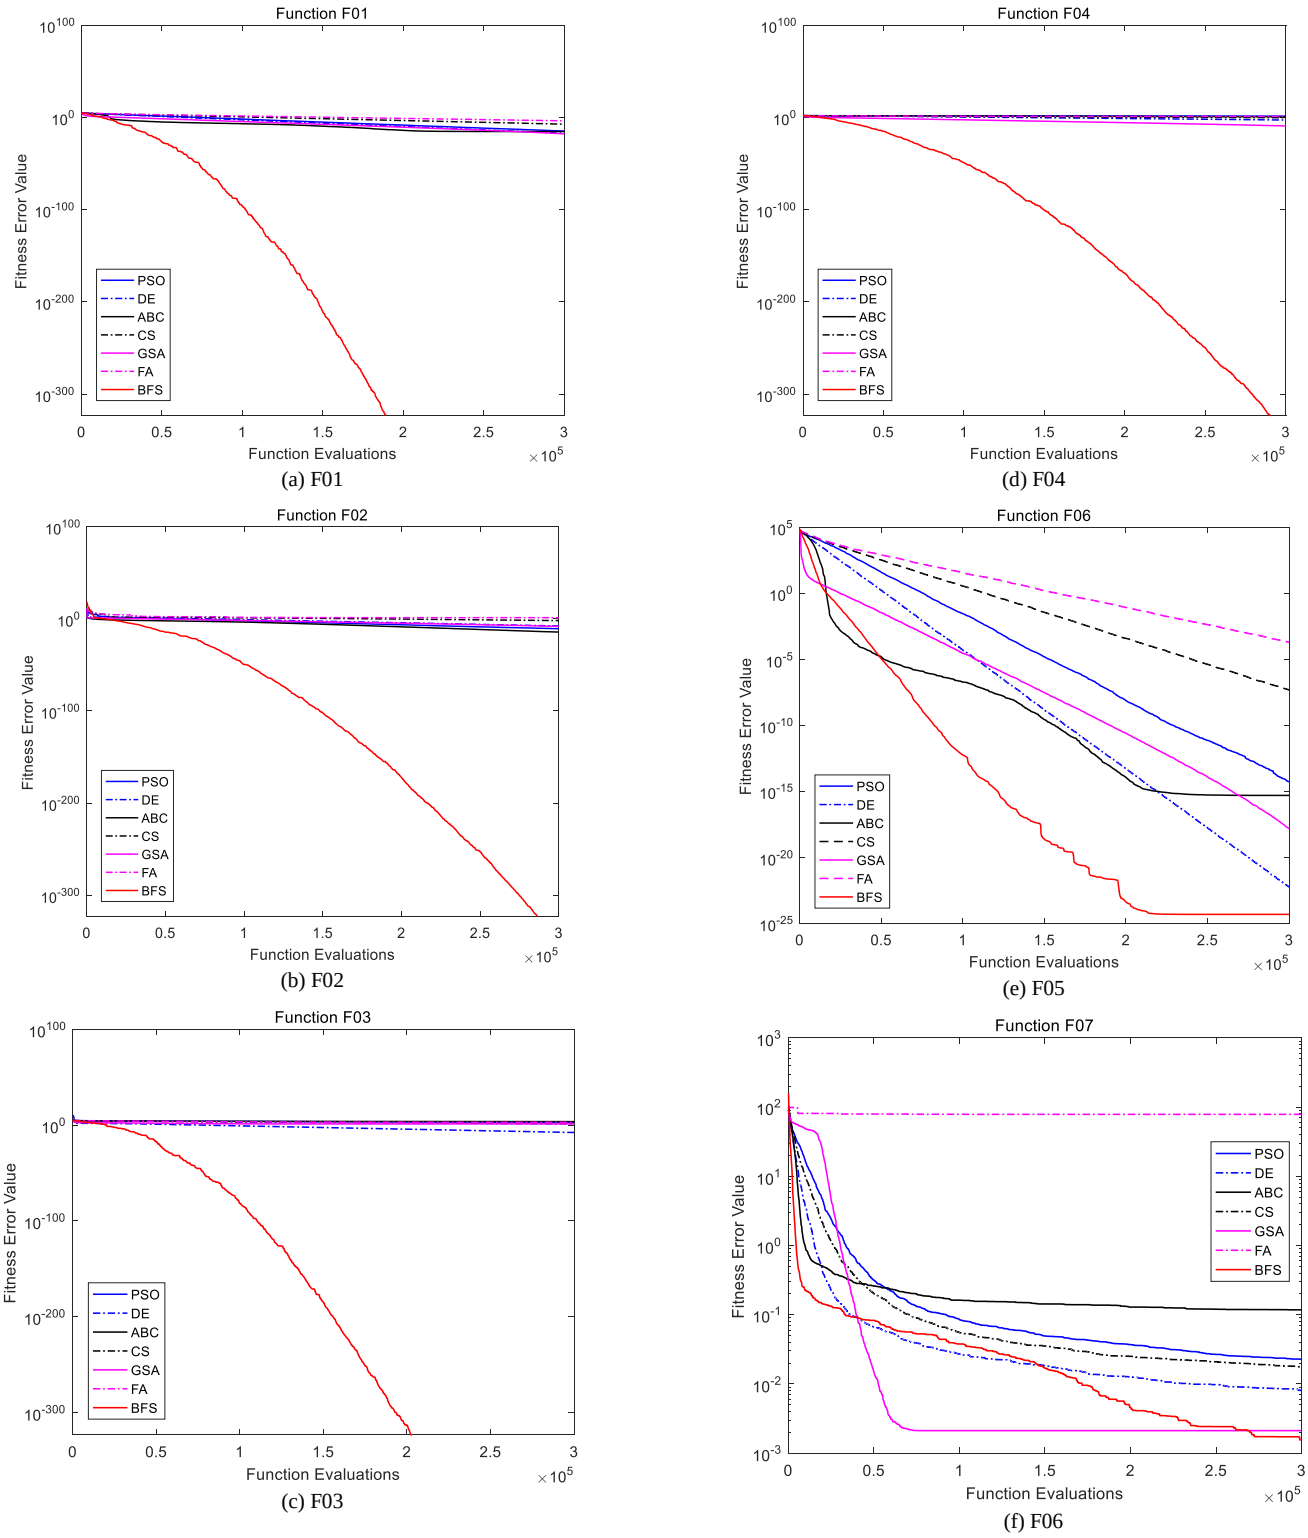

Fig. 15. Flow of BFS-ESN algorithm application.

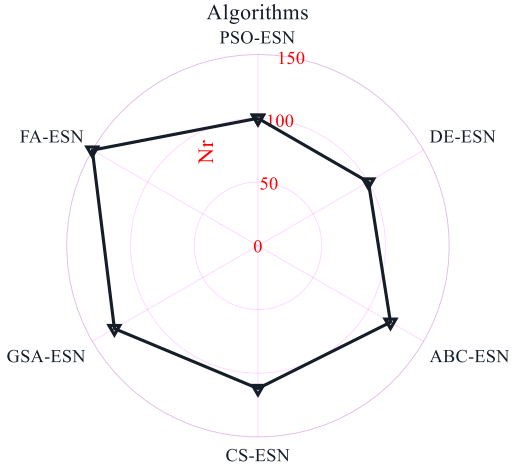
2) Java web design software effectiveness analysis: Using Java Web technology, this paper designs SCADA system software for oil and gas pipelines, and the specific effect diagram is shown in Fig. 16. As can be seen from Fig. 16 the oil and gas pipeline SCADA system software achieves the functions of real-time data acquisition, monitoring, control and data analysis.

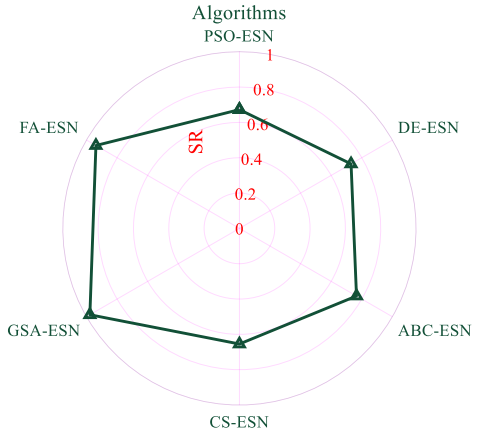
Fig. 16. Flow of BFS-ESN algorithm application.

3) SCADA software test and analysis: In order to verify the validity and feasibility of the SCADA software testing and analysis method based on the BFS-ESN model, this section uses PSO, DE, ABC, CS, GSA, FA algorithms to optimise the ESN model for comparative analysis with the BFS-ESN, and the results are shown in Fig. 16 and Fig. 17.

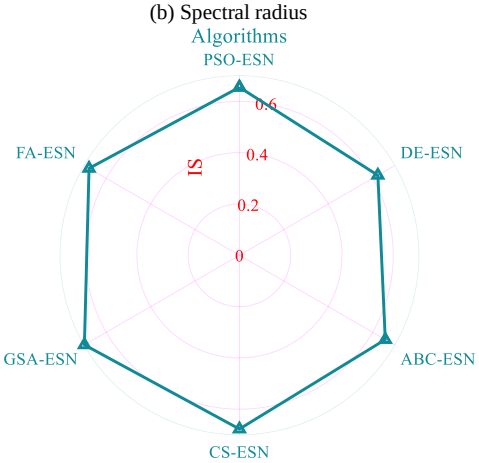
Fig. 17 gives the results of optimising the ESN hyperparameters for the comparison algorithms. As can be seen from Fig. 17, the results obtained by BFS for optimising the hyperparameters of the ESN model are as follows: storage pool size $N_r = 150$, spectral radius $SR = 0.9381$, input scale factor $IS = 0.6772$, storage pool sparsity $SD = 0.4951$.



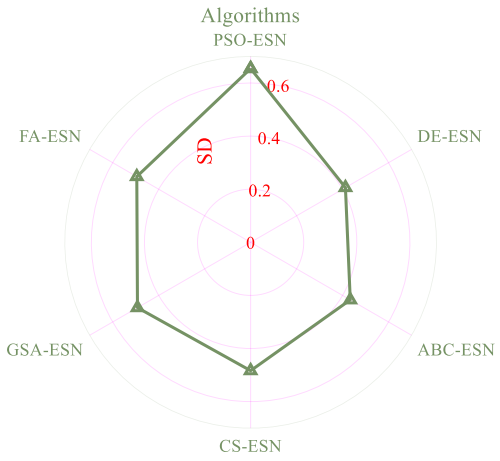
(a) Size of storage tanks



(b) Spectral radius



(c) Input scale factor



(d) Sparsity of storage tanks

Fig. 17. Contrasting algorithms to optimise ESN hyperparameters results.

The optimisation iteration curves of the compared algorithms are given in Fig. 18. From Fig. 18, it can be seen that the test accuracy of SCADA software design for oil and gas pipelines in Java Web framework based on BFS-ESN model is better than other algorithms, the optimisation iterations converge faster than other algorithms, and an accuracy of 97.33% is obtained at 700 iterations.

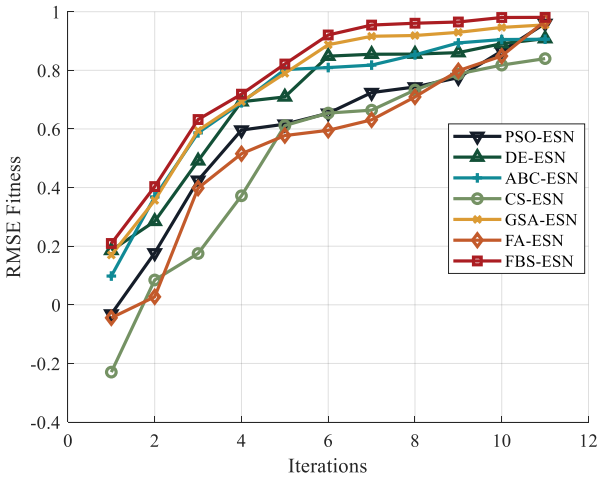


Fig. 18. Contrasting algorithm optimisation iteration curves.

V. Conclusion and Outlook

This paper presents the design and testing methods for oil and gas pipeline SCADA software based on JavaWeb technology, with the aim of improving accuracy, efficiency, and real-time data monitoring. The key innovation lies in the integration of the Bird Foraging Search (BFS) algorithm with the Echo State Network (ESN) to optimize the SCADA software design and testing process.

1) The paper outlines a multi-tiered software architecture using Java EE technologies to ensure the efficient operation of SCADA systems for oil and gas pipelines. The design includes real-time data acquisition, monitoring, control, and data analysis functionalities.

2), A novel combination of the Bird Foraging Search algorithm and Echo State Network is proposed to optimize the software testing process. This method enhances accuracy and convergence speed in SCADA system testing, outperforming other algorithms like PSO and DE.

3), Experimental results using actual SCADA data confirm the feasibility of the BFS-ESN model, showing significant improvements in testing accuracy, reaching 97.33% accuracy with faster convergence rates compared to traditional methods.

We also find some shortcomings: Firstly, the validation is based on specific SCADA data from oil and gas pipelines, which may limit the generalizability of the proposed method to other industrial applications. Secondly, while the model improves accuracy, its complexity might pose challenges in real-world implementation, particularly in terms of computational resource requirements. Finally, although the paper discusses system security briefly, the analysis of potential cybersecurity risks and scalability issues, particularly in larger pipeline networks, is not fully explored.

Future studies could extend the BFS-ESN approach to different SCADA systems in industries beyond oil and gas, to verify its broader applicability and performance. Reducing the computational complexity of the BFS-ESN model to make it more suitable for large-scale deployments in real-time environments. Exploring the integration of advanced security protocols and testing methods could strengthen the robustness of SCADA systems against potential cyber threats.

***Abstract*—Cyber resilience plays an important role in dealing with cybersecurity and business continuity uncertainty in the post-COVID-19 era. The fundamental problem of cyber resilience is the complexity of real-world problems. Therefore, it is necessary to reduce the complexity of real-world problems to be simple and easy to analyze through cyber resilience model. The first part is the representational model by utilizes world models. It utilizes the stochastic nature of latent data to generate log-likelihood values by data-generating process. The second part is the inference model. This concludes the observation of log-likelihoods using a self-supervised anomaly detection approach. This is related to optimizing decision boundary in anomaly detection, which is achieved by supervising two competing hypotheses based on bias-variance alignment and likelihood ratios. The optimization operates a dynamic threshold supervised by a supervisory signal from the underlying structure of log-likelihoods. The paper contributes by conducting research on the cyber resilience model from the perspective of statistical machine learning. It enhances the representational modeling of world models with the Gaussian mixture model for multimodal regression (GMMR). Additionally, it examines the issue of misleading log-likelihood for out-of-distribution inputs caused by the generalization error and optimizes decision boundary in minimizing the generalization error with a new metric named the harmonic likelihood ratio (HLR). Finally, it aims to boost the performance of anomaly detection using self-supervised learning.**

Keywords*—Cybersecurity; anomaly detection; cyber resilience model; statistical machine learning; data generating process; bias variance alignment; likelihood ratios; self-supervised learning

I. Introduction

In the post-COVID-19 era, cyber resilience plays an important role in dealing with cybersecurity and business continuity uncertainty. The problems and methodology for cyber resilience, especially in the scope of small and medium enterprises (SMEs), have been described systematically in the cyber resilience progression model [5], [6]. The model helps SMEs prioritize cyber resilience proposing the natural evolution of implementation. It designed to be more flexible based on available resources. It focuses on insights into operationalizing cyber resilience strategies by describing ten domains. One of the ten domains is detection processes and continuous monitoring has been chosen as the central domain [4]. In description, it is explained that there are two strategies for this domain: actively monitor the company's assets and define a detection process that specifies when to escalate anomaly into incidents [5], [6]. This description allows self-supervised anomaly detection technology that works fully automatically to detect and monitor processes.

The cyber resilience model that will be studied refers to technical architectures in [4]. The technical architecture was built on five layers. The five layers were services, data, generative models, data analysis, and resilience scale [4]. Each layer had different structures and functions but was part of a system. The technical architectures are necessarily simplified without changing the fundamental architecture so that the complexity of the problem is reduced and more focused on anomaly detection. The fundamental architecture that continues to go is Gaussian mixture models (GMMs), one of the first-generation generative models with high flexibility in handling data distribution, statistical modeling, and inference. GMMs are the fundamental architecture of cyber resilience with the underlying structure of a probabilistic model approach [4]. However, GMMs fail if applied directly as the basis of cyber resilience model. GMMs fail in high-dimensional data. GMMs can be used for density estimation but the perfect density model cannot guarantee anomaly detection [23]. Also, GMMs work in an unsupervised setting that often produces high false positive rates in a dynamic system [28]. The paper studies GMMs as a reliable generative model for anomaly detection.

The cyber resilience model designed by a two-part model: the representational model in layers 1 to 3, which play a role in data collection, and the inference model in layers 4 and 5, which play a role in data analysis. The complexity of real-world problems of cyber resilience encapsulated by data collection and analysis as the key of a data-driven approach. The paper studies critically the problems of the representational and inference model to set up the appropriate cyber resilience model, such as misleading log-likelihood, the bias-variance alignment, and two competing hypotheses.

As the core of the representational model, the world model [14] that lies in layer 2 takes the principal role in data-generating process to strengthen a data-driven approach. Hence, it needs to be enhanced to become part of the representational model that meet the requirements for data collection in a new setting. That is different from it utilized previously. For developing the data-generating process, the world model needs to avoid generating misleading log-likelihood [3]. Also, it needs to be integrated in a supervised setting [11], [12] to align the self-labeling problem of an unsupervised learning algorithm [1], [28].

The inference model in layers 4 and 5 focuses more on inferring the observed samples with data analysis directed by anomaly detection. The concept of anomaly detection explains that samples can be distinguished into normal and anomaly

samples [28], [35] with a two-class decision boundary [1], [8] determined by two competing hypotheses [33], [41]. The factual problem is aligning a two-class decision boundary with two competing hypotheses so that the model can perform anomaly detection properly, which will be studied in this paper.

II. Review of Existing Techniques

One fundamental study as the basis of cyber resilience model is anomaly detection [4]. Anomaly detection, in this case, is similar tasks to novelty detection (ND) [1], one-class classification (OCC) [29], and out-of-distribution (OOD) [8], [27], [33], [41]. An anomaly is an observation that deviates significantly from some concepts of normality [35]. This definition is also suitable for ND, OCC, and OOD [16], [35]. If the distribution of normal instances is P, an anomaly is a sample drawn from any distribution other than P. Furthermore, ND has a new region of P; OCC has a one-class decision boundary of P; OOD has fine-grained P during training [28], [35]. Thus, there is a shared concept between anomaly detection and ND, OCC, OOD.

The cyber resilience model represents a cyber resilience system as a technical framework to measure the resilience scale. The resilience scale denotes a scale of the service resilience against cyber threats. In the domain of cyber resilience, numerous services like Domain Name System (DNS), firewall, web services, resource planning, and supply chain are required to explore anomaly detection for monitoring the continuity of services. It is necessary for one specific service to bring about the model as suggested in [4] which points to DNS. This choice is reasonable because DNS used by most services and applications of the Internet, even critical infrastructures of the Internet. Also, DNS provides an authentic data distribution of anomalies by the system so that anomaly detection works in factuality. DNS is the hierarchical name system that uses the globally distributed database and stores the information about every Internet domain [39]. DNS information is stored on DNS servers and can be accessed anytime based on user queries. DNS is like a phone book. It contains addresses that make it easier for users to access the Internet in cyberspace. Each address has a unique identity and is different from one another. This identity is called an Internet Protocol (IP) address. DNS translates these numbers into names because IP addresses are complicated for users to remember. DNS is made simple to solve IP address resolution issues, however, it does not come with a security proficiency by nature [4]. Therefore, a DNS measurement method is needed to enable security proficiency by design.

DNS measurement methods are categorized into two types: passive and active DNS. Passive DNS [39] allows observation of DNS ecosystem limited to clients, resolver servers, authoritative servers and the networks between the three. Active DNS allows observing a global hierarchical DNS ecosystem. It involves very large DNS networks. It does not pay attention to the complete contents of the query and response from a particular client, so it has difficult to apply for data collection and analysis. The mechanism for DNS queries only supports one type of query. One query of the domain name and one response of an IP address. Other lookup keys must be converted to domain names before being used in DNS queries. Thus, passive DNS provides advantages over active DNS in reconstructing specific queries/responses useful for anomaly detection.

Passive DNS, as a local representative of the active DNS ecosystem, contributes to efficient traffic data collection. Many DNS traffic analysis uses passive DNS including anomaly detection. The earlier DNS anomaly detection is based on supervised model. The model produce high precision, low false positive rates, and efficient anomaly detection in specific patterns [28]. However, the model depend on training data. The ability to recognize anomaly patterns depends on the anomaly patterns that have been trained during training time [16], [28], [35]. The trained anomaly patterns are limited to the capacity of datasets. While DNS ecosystem is always evolving, threats to DNS security never stop, and DNS resilience needs to be monitored continuously. Therefore, supervised models are less suitable for DNS traffic anomaly detection in dynamic real world environments.

Since DNS traffic is dynamic, unsupervised model is inherently suitable for anomaly detection. Labeling normal and anomaly traffic are not necessary during training time. The model accepts all types of unlabeled traffic and classify it with certain rules into two classes that can distinguish normal or anomaly traffic. The model does not depend on training data [16], [28], [35]. The ability to recognize anomaly patterns does not depend on the trained anomaly patterns during training time. The model can recognize new anomaly patterns using a classifier algorithm. However, the model often produces high false positive rates and fails to recognize patterns from the genuine labeled data [28]. The model's ability to recognize normal and anomaly patterns is not as precise as the supervised model because there is no strong connection between the model and the genuine labeled data [28]. In this model, the genuine labeled data is not defined. Normal and anomaly labels are not explicitly defined.

A machine learning algorithm that makes use of the structure within data for self-labeling is self-supervised model [16], [32]. Self-supervised model has been designed as a hybrid approach of supervised and unsupervised models. The model produces pseudo-labels, but the model directs pseudo-labels to follow the underlying structure of the genuine labeled data. Anomaly detection can utilizes self-supervised model based on likelihood ratios [32], [33], [41]. Likelihood ratios can manage the relationship between supervised and unsupervised models. Likelihood ratios have signal to measure the performance of regression and classification functions in a supervised setting [19], [22], [25], [37]. Likelihood ratios also have signal to control self-labeling in an unsupervised setting [1], [2], [19], [21], [33], [41].

III. Methodology

Cyber resilience plays an important role in facing business continuity uncertainty. Outside of business matters, business continuity uncertainty can be affected by data uncertainty in data collection and analysis. Various sources, such as noisy data, incomplete data, sampling errors, measurement errors generalization errors, and anomalies, which will cause data uncertainty. It is necessary to manage data uncertainty to

improve the reliability of data collection and analysis. One of the approaches chosen to address the problem of data uncertainty is to study anomaly detection in more depth. It has several indicators that will be used to obtain reliable data collection and analysis. The indicators are bias, variance, and likelihood ratios.

This section explains the research methodology of cyber resilience model, consist of the representational model to realize reliable data collection using data-generating process and the inference model to realize reliable data analysis based on likelihood ratios. Process flow diagram of the methodology as seen in Fig, 1.

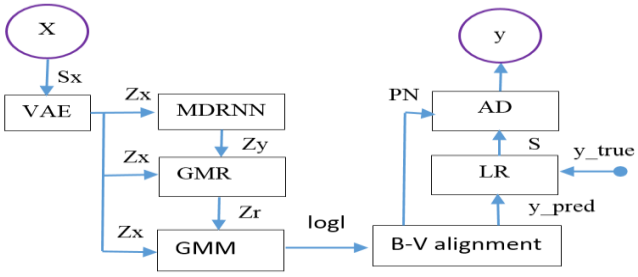

Fig. 1. Process flow diagram of the methodology.

A. Characteristics of Raw Datasets

The raw dataset is a collection of data from a network capture-based DNS logger. The raw dataset was taken from November 2018 to February 2020 on DNS servers (dnsanalyzer.info) amount 1,000 samples (Sx). The tool used to collect the raw dataset is GoPassiveDNS [26].

The raw dataset contains three feature vectors (X): TTL (x_1), latency (x_2), and throughput (x_3). The K-Means algorithm was used to collect data for classifying positive and negative classes from the raw dataset. The negative class have fine grain structure with two type subdistributions: the sample variance of subdistributions in one standard deviation (inliers) and the sample variance of subdistributions more than two standard deviations (outliers). Inliers of the negative class represent DNS normal. Inliers of the negative class have the lowest anomaly level in the resilience scale. The positive class have fine grain structure with three type subdistributions: the sample variance of subdistributions in one standard deviation (inliers), the sample variance of subdistributions more than two standard deviations (outliers), and anomaly. Anomaly refers to the response of RCODE more than 0 (zero) by GoPassiveDNS. RCODE more than 0 indicates DNS failure [26]. Otherwise, RCODE equal to 0 indicates DNS normal. The anomaly subdistribution have the highest anomaly level in the resilience scale.

The raw dataset exhibit different data characteristics named the generator of in-distribution, which is the source of normal datasets, and the generator of out-of-distribution, which is the source of anomaly datasets. The raw dataset needs to be further processed to generate reliable datasets.

TABLE I. CHARACTERISTICS OF RAW DATASETS

Datasets	In distribution		Out-of-distribution		
Classes	Negative		Positive		
Types	Inlier	Outlier	Inlier	Outlier	Anomaly
Variances	≤68%	>95%	≤68%	>95%	-
RCODE	0	0	0	0	>0
Subdistributions	1	2	3	4	5
Samples	500	25	75	200	200
Anomaly levels	1	2	3	4	5

Table I presents two sources of raw datasets: In-distribution (ID) and out-of-distribution (OOD). The ID dataset comes from the generator of in-distribution. The OOD dataset comes from the generator of out-of-distribution. Conceptually, the two generators should produce different two sources of datasets and naturally not overlap each other. However, in practice, the two generators cannot avoid producing two overlapping datasets.

Table I explains that the overlap occurs due to the two approaches taken in data collection. The first approach, data collection uses DNS sensors. The sensors are limited in representing data from the real world with only three feature vectors. The sensors are also limited in responding accurately to RCODE. Furthermore, the sensors can only classify DNS events by default based on the value of RCODE.

TABLE II. DNS RESPONSE CODE

RCODE	**Message**	**Description**
0	NOERROR	DNS query completed successfully
1	FORMERR	DNS query format error
2	SERVFAIL	Server failed to complete the DNS request
3	NXDOMAIN	Domain name does not exist
4	NOTIMP	Function not implemented
5	REFUSED	The server refused to answer for the query
6	YXDOMAIN	Name that should not exist, does exist
7	XRRSET	RRset that should not exist, does exist
8	NOTAUTH	Server not authoritative for the zone
9	NOTZONE	Name not in zone

Table II defines the DNS response code which have been implemented in GoPassiveDNS [26]. It describes RCODE values of the various types of DNS events that occur most

frequently. Refers to Table I that RCODE produces high false negative rates. Subdistribution 1, 2, 3, and 4 are classified as DNS normal even though some are DNS failure according to K-Means. In contrast, the second approach, data collection uses K-Means to classify two different datasets. Table I shows that K-Means produce high false positive rates. Subdistribution 3, 4, and 5 are classified as the positive class even though some are the negative class according to RCODE. The problem of the first approach is that normal and anomaly labeling in the raw dataset is based on RCODE even though many failure functions cannot be recognized by RCODE. The second approach uses the algorithm of machine learning. The K-Means is the simplest unsupervised learning algorithm for basic self-labeling. It can be utilized to classify the raw dataset into two classes on a specific rule.

It is a similarity between the two approaches. None of anomaly samples in subdistribution 5 that has been classified by the first approach are part of normal samples that has been classified by the second approach. In other words, anomaly samples from the first approach is the same as anomaly samples from the second approach. So, it is concluded that the classification of one sample as anomaly and another sample as not anomaly is true. However, there are anomaly samples from the second approach that are not anomaly samples from the first approach such as samples in subdistribution 3 and 4. Therefore, the first approach is not able to recognize new patterns of anomaly other than those already recognized by RCODE. This urges the use of machine learning algorithms to better recognize new patterns of anomalies. Meanwhile, the second approach is able to recognize new patterns of anomaly other than those already recognized by the first approach. However, not all of the new anomaly patterns of the second approach are true due to the limitations of K-Means based on a specific shape of the decision boundary and no training to do for anomaly samples.

B. Data Collection

The representational model are useful in improving the reliability of data collection. The reliability of data collection is improved by modeling the raw dataset into latent samples (Zx), a sequence of latent samples (Zy), and a density of latent samples (logl).

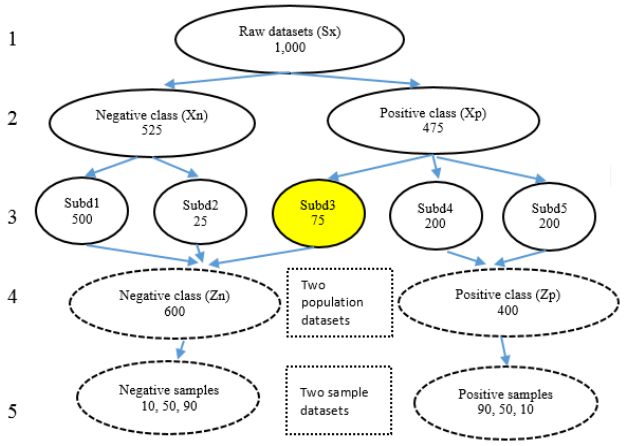

Fig. 2. Process flow diagram of data collection.

Fig. 2 describes process flow diagram of data collection which consists of five steps. The first step is initial data collection which produces raw datasets as 1,000 samples (Sx). The samples are a data distribution of 200 data points so raw datasets are 200,000 data points in size. The samples are designed as a data distribution to understand the underlying generator of datasets through latent variable models. The samples have parameters from a data distribution that show the principal component of datasets.

The second step classifies positive (Xp) and negative (Xn) classes from raw datasets using the K-Means algorithm. The positive class are samples that assert the presence of anomaly. The negative class are samples that assert the absence of anomaly. The K-Means algorithm succeeded in classifying raw datasets into 525 negative samples and 475 positive samples from selected samples.

In the third step, each class is divided into two subdistributions, namely inliers and outliers, so that in total there are four subdistributions plus one specific subdistribution produced by DNS sensors as the ground truth of anomaly samples. So the total becomes five subdistributions, each of 500, 25, 75, 200, and 200 selected samples respectively. Inliers and outliers are formed using an outlier detection technique [42].

The fourth step as the key of reliable data collection is processes that generate data specifically event, memory, and density processes. The three processes set up the data-generating process properly. A detailed explanation of each process is in the following subsection. Furthermore, one sample subdistribution differs from another. It estimated by the Expectation-Maximization (EM) algorithm [9].

TABLE III. EM AS A SAMPLE CLASSIFIER

	subd2	**subd3**	**subd4**
subd1	1.419	2.949	5.026
subd5	5.423	3.893	1.816
DI	4.004	0.944	3.210

abbreviations: subd = subdistribution, DI = difference index

Table III explains the process of classifying normal and anomaly samples using EM. Two polars are defined as the centroids of normal and anomaly classes. Subdistribution 1 with the lowest anomaly level selected as the polar of normal class. Subdistribution 5 with the highest anomaly level selected as the polar of anomaly class. The smaller difference between a subdistribution and two polars defines the label of subdistribution. As subdistribution 2 and 3 are closer to subdistribution 1 than 5, subdistribution 2 and 3 are classified as normal class. As well subdistribution 4 is closer to subdistribution 5 than 1, subdistribution 4 is classified as anomaly class. It can be seen that K-Means and EM are the same in classifying subdistribution 1, 2, 4, and 5 but different in classifying subdistribution 3. K-Means classify subdistribution 3 as anomaly class while EM classify subdistribution 3 as normal class. K-Means classify patterns with a specific shape for all subdistributions, while EM classifies patterns dynamically following the underlying

structure of each subdistribution. It seems EM is more flexible than K-Means. EM is not limited by shape but depends on unobserved latent variables performed properly by data-generating process.

The output of data-generating process is primary datasets (logl) that consist of 1,000 samples treated as a population of observation. The samples come from five subdistributions of raw datasets, each of 500, 25, 75, 200, and 200 respectively. In the last step, the observation sample is generated as a random variable of normal and anomaly samples. One hundred random variables configure the observed samples that are taken randomly from the population. Be appointed, the sample size is 10% of the population provided for any observation. The data-generating process will consider data collection more appropriate as required.

C. The Event Process

The event process is the first part of data-generating process. It encodes DNS events into a latent variable model. It reproduces the idea from the world model [14] that pattern recognition was performed indirectly through a latent variable model. The model in latent space provides more advantages than in data space. The pattern encoded as a principal component is more concise. The principal component has information sufficiency that can be further encoded in another process smoothly, so it is easier to analyze in the next part of data-generating process. VAEs take the task of encoding for a latent variable model.

Variational autoencoders (VAEs) are an artificial neural network architecture in which the latent space has good properties to enable generative processes [21] utilizing stochastic backpropagation [34]. It plays a role in transforming data distribution in data space (X) into data distribution in latent space (Zx) by the latent variable model. It recognizes the characteristic of data distribution through EM by estimating the joint distribution between X and Zx [9]. EM will maximize the similarity between the two. If the joint distribution Zx is a close approximation of X, then Zx will be indistinguishable from X. Analysis of compressed data distribution produces a principal component. This is called dimensionality reduction. Principal components in latent space are more ready to use to recognize the behavior of data distribution than feature vectors in data space. It summarize the pattern of data distribution without eliminating the principal information substance.

VAEs use two neural networks: encoder (generative model) and decoder (variational approximation) [21]. The encoder part transforms samples of discrete data distribution from DNS events into continuous latent variables by taking the characteristic of probability distribution. In this case, probability distribution as the core of a latent variable model that has two parameters: mean (μ) and standard deviation (Σ). The mean represents the expected value of DNS events, and the standard deviation represents the variability of DNS events. The type of probability distribution to generate the latent sample is Gaussian distribution. So, a latent variable model may be called a Gaussian model. The use of VAE encoder as a generator of latent samples refers to the vision model of world models [14].

One important component of neural networks that quantifies the difference between the predicted and actual outputs is the loss function. There are two loss functions for VAEs: Mean Square Error (MSE) and Kullback–Leibler Divergence (KLD). These two loss functions are standard for measuring how fit a model explains the data. The decoder part reconstructs latent samples into the predicted outputs (S'x). In the experiment, the decoder part is only needed at training to measure how fit a Gaussian model has been encodes DNS events by comparing the difference between the predicted and actual outputs (S'x-Sx). Flow diagram of VAEs as seen in Fig. 3.

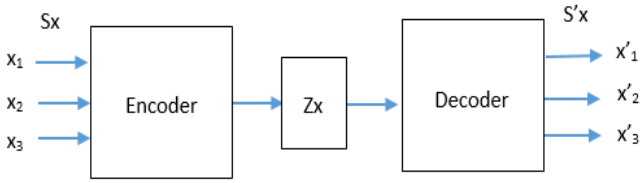

Fig. 3. Flow diagram of VAEs for the event process.

The performance of training can be evaluated from training and testing loss. Suppose the loss gets smaller for larger epochs, the loss shift convergence to a specific value, testing loss is smaller than training loss, that are indicating that VAE training has achieved appropriate performance tasks. Latent variables at training are set to $\mu + \Sigma \times \varepsilon$. The ε is random noise added to the latent variable so that the loss will always converge to a specific value [21], [34]. Some of the reasons testing loss is smaller than training loss are that at training: (1) the latent variable overloaded with random noise, whereas, at testing, it does not, (2) testing loss measured after training, and (3) training loss measured for all epochs while testing loss measured once after completing the training epoch. However, training and testing loss are limited to optimizing the loss function in estimating the difference between the actual (Sx) and predicted (S'x) DNS events and not optimizing model parameters. The model parameter is optimized by the architecture of encoder and decoder, hyperparameter tuning, and using more flexible prior distributions. This means that the model parameter of training is better than those of testing because it is used as a reference for testing. The performance of VAEs training as seen in Fig. 5(a).

VAEs are built with one input layer for three feature vectors, two hidden layers, each with sizes 64 and 16, and one output layer for training purpose only. One data distribution of the input layer come from two hundred data points. One latent sample is composed of two hundred latent vectors, in other words, the two hundred dimensions of Zx. Then, a μ vector of length two hundreds and a Σ vector of length also two hundreds, so the VAE parameters are four hundreds. In these configuration, two hundred latent vectors are a good sample size to reduce the log-likelihood of sampling errors. The observed samples need to be ensured to be independent (one discrete data of DNS events does not depend on other discrete data of DNS events in the same data distribution) and identically distributed (in one data distribution of DNS events, the probability distribution of data distribution is the same).

Consequently, a latent sample which generated by the model meets the criteria of independent and identically distributed (i.i.d) as a stochastic random sample, making it well-suited for addressing an observation sample of DNS events in latent space.

D. The Memory Process

The memory process is the second part of data-generating process that play a role in encoding a sequence of latent samples from the event process into a latent dynamics model. A latent sample which is the output of the event process does not have the sequence because it is an i.i.d sample. Meanwhile, one observation consists of many latent samples to form a sequence. The event process needs to be extended with another process called the memory process so that it can encode the sequence. Hence, the memory process is an extended event process.

Mixture density-recurrent neural networks (MDRNNs) are one specific neural network architecture that combines mixture density networks (MDNs) and recurrent neural networks (RNNs) to build a latent dynamics model. MDNs encode the output of a neural network parametrize a mixture of Gaussian distribution, which can model general conditional probability densities [2]. RNNs are an artificial neural network architecture of dynamic models that have been used to generate sequences [13], [15]. Dynamic models simplified representations of real-world problems by algorithms, such as dynamic models of signal processing, automatic speech recognition (ASR), and time-series forecasting. As a sequence generator, MDRNNs encode a sequence of latent samples Zx generated by a Gaussian model to latent samples Zy generated by a latent dynamics model. The use of MDRNNs as a sequence generator refers to the memory model of world models [14].

RNNs are used as the forefront of a sequence generator. RNNs have a recurrent layer (a cell) to remember its previous inputs by internal memory. A recurrent layer works with iterative sampling from the output, then feeding in the sample as input at the next step [13]. The problem with standard RNNs is that it is used only for basic sequential data tasks and cannot be used to store information about previous inputs for a very long time [13]. Hence, a type of RNNs called long short-term memory networks (LSTMs) [15] was designed to address the problem of standard RNNs. LSTMs can be used for advanced sequential data and artificial long-time lag tasks [15], such as tasks to predict a sequence of latent samples, and then store information in internal memory with memory cells and gating mechanisms for long-term. Memory cells store information from the previous step and use it to update the cell output for the current step. Gating mechanisms remove unimportant information, store new information, and encode information from the cell state to the output layer.

Practically, LSTMs need MDNs for modeling advanced sequential data. LSTMs and MDNs are compatible with each other. MDNs consist of two components: a feed-fordward neural network and a mixture model [2]. The output layer of LSTMs is the final layer of a feed-fordward neural network and a fully connected layer that connects all units in the layer directly to every unit in the previous layer, so it can be utilized as an interface between LSTMs and MDNs.

MDNs can smoothly encode the outputs of LSTMs to form the parameters of a mixture model, generally with Gaussian models for each mixture component [2], [10]. These parameters are mean (μ), standard deviation (Σ), and weight (π). The mean represents the expected value of DNS events, the standard deviation represents the variability of DNS events, and the weight represents mixing each Gaussian distribution of DNS events into a mixture distribution. These parameters involve shaping probability density functions (PDFs) for each mixture component and categorical distribution from the mixture weights [2], [10]. Additionally, there are two reasons why LSTMs require MDNs: different mixture components represent different stochastic events and different situations [10]. In other words, MDNs are able to model different stochastic events and situations for any DNS events in Gaussian models for each mixture component. Therefore, LSTMs and MDNs can seamlessly work together in MDRNNs. Flow diagram of MDRNNs as seen in Fig. 4.

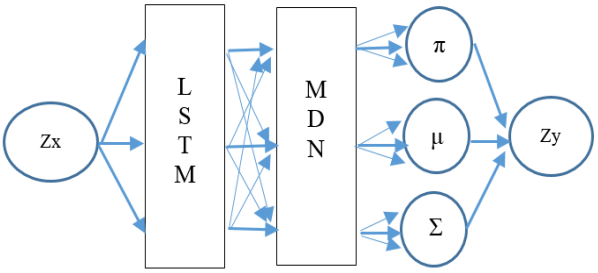

Fig. 4. Flow diagram of MDRNNs for the memory process.

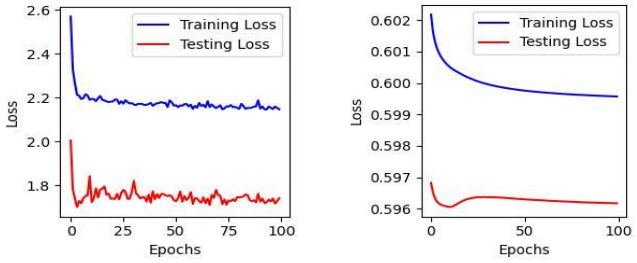
One observation consists of some latent samples. In a sequence, one latent sample is related to other latent samples. MDRNNs training recognize the underlying generator of a sequence by making relationships between one sample and another using a time-series regression approach. Some samples are treated as independent variables, while the dependent variable is taken from the independent variable itself which has been shifted in a sequence. In this case, the independent variable is Zx while Zy is constructed from shifted Zx with a sequence length of four.

LSTMs have been applied to realize this time-series regression. Because LSTMs can memorize previous input, then for each latent sample, MDNs would encode the output of LSTMs into a mixture component that was a combination of individual distributions in the form of a mixture distribution. To identify that MDRNNs training has been able to recognize the underlying generator of a sequence, it was evaluated using the logsumexp function. The logsumexp function is a smooth approximation to the maximum function in a logarithmic scale. This provides a numerically stable estimation of PDFs for each sequence and sample. The logsumexp is used to measuring the similarity between the sequence and sample by maximizing the log-likelihood.

MDRNNs are built with one input layer, a single hidden LSTM layer, the output layer of LSTMs as the input of MDNs, a sequence length is four at training time, and a

mixture distribution from three Gaussian distributions as a mixture model. Three Gaussian distributions were chosen because the input distribution is not complex, it only consists of three feature vectors. One data distribution of the input layer comes from two hundred latent vectors. A single hidden layer with sixteen units is enough to perform computations on the input which consists of two hundred latent vectors. MDNs aim to model a sequence of latent samples that can be drawn from one of several possible distributions with a certain probability. Several possible distributions come from three Gaussian distributions. Each parameter of three Gaussian distributions needs two hundred vectors, so MDNs parameterize 3×3×200 = 1,800 parameters. These parameters will generate two hundred latent vectors as the output of MDRNNs (Zy). MDRNNs training uses the data of VAEs training so that the performance of MDRNNs training follows of VAEs training such as shown in Fig. 5.



a. The performance of VAEs training b. The performance of MDRNNs training

Fig. 5. The performance of VAEs and MDRNNs training.

E. The Density Process

The density process is the last part of data-generating process that play a role in producing the density (logl) from a sequence of latent samples. The density process works to enhance the density of the memory process. The memory process is designed to encode a sequence of latent samples, not the density. It is not sufficient to produce reliable density because a standard MDN as part of the memory process is prone to mode collapse [25]. Mode collapse happens when a standard MDN fail to generate data samples from the underlying probability distribution of Zx. It will turn multimodal learning [38] into unimodal so that all of the generated samples are very similar [25]. To overcome the problem, a joint distribution was built on Zx and Zy, denoted p(Zx, Zy). In this case, Zx and Zy represent the input and target variables respectively. The relationship between the input and target variables has been initialized by LSTMs in the memory process through time-series regression. It is the conditional distribution, which is the probability that Zy happens given Zx has happened, denoted p(Zy|Zx). It is created to build a more proper regression that is the joint probability density functions (joint PDFs). All the statistical information of the input and target variables is stored in the joint PDFs [37]. Furthermore, learning the joint PDFs of the input and target variables is a form of supervised learning [12]. It is a statistical approach to transform from unsupervised learning of the event process, denoted p(Zx), into supervised learning of the density process, denoted p(Zx, Zy). The joint PDFs and the conditional distribution are the statistical basis for multimodal regression.

An important factor in the joint PDFs is to predict target variables from input variables. A type of supervised learning algorithm that has been used to predict target variables from input variables as part of the joint PDFs is Gaussian mixture regression (GMR) [11], [12], [20], [36], [37], [40]. GMR is a regression approach that models probability distributions of latent samples from the event process and the memory process into multimodal regression using Gaussian mixture models (GMMs). It can be used to predict distributions of variables Zy by computing the conditional distribution p(Zy|Zx). The first process in GMR is to learn the joint PDFs through EM, then compute the conditional distribution to predictions. Training is the same procedure as in GMMs [11].

GMMs and GMR can seamlessly work together called the Gaussian mixture model for multimodal regression (GMMR), which applies two functions in one: the prediction function and the score function. The prediction function to predict target variables from input variables, this is the role of GMR. The score function to estimate the new joint PDFs of the input and class label, this is the role of GMMs. The realization of GMMR is in two steps. Step 1 is to predict target variables Zr from input variables (Zx, Zy) or Zxy using the prediction function. This target variable Zr is also used to predict class labels. Step 2 is to produce log-likelihood (logl) from bivariate data (Zx, Zr) or Zxr using the score function. Therefore, GMMR specifically is designed to enhance the reliability of the log-likelihood estimation produced by world models [14]. Flow diagram of GMMR as seen in Fig. 6.

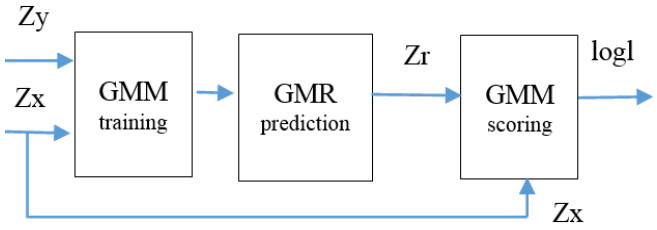


Fig. 6. Flow diagram of GMMR for the density process.

In step 1, GMMR has utilized the mixture of experts (MoE) [20] for developing the GMR prediction. MoE gives a simple approach to combine parametric and nonparametric regression methods by taking the analytic advantages of parametric and the flexibility of nonparametric [12], [19], [37]. The parametric method has been realized by a mixture of linear models [36] and the nonparametric method has been realized with divide-and-conquer principles [20]. In fact, the model log-likelihood function disregards the global data density [32], because the global maximum that indicates the global data density does not smoothly regress all local maxima. Then, MoE replaces a single global model with a weighted sum of local models (experts) [11], [12], [20], [40] to achieve the stability of multimodal regression as follows:

$$p(Zx, Zy) = \sum_{k=1}^{K} \pi_k N_k(Zx, Zy|\mu(Zxy_k), \Sigma(Zxy_k)) \quad (1)$$

$$p(Zy|Zx) = \sum_{k=1}^{K} \pi(Zy|Zx_k) N_k(Zy|\mu(Zy|Zx_k), \Sigma(Zy|Zx_k)) \quad (2)$$

Eq. (1) is the joint PDFs of GMMs via the EM algorithm [9]. $N_k(Zx, Zy|\mu(Zxy_k), \Sigma(Zxy_k))$ are Gaussian distributions with means $\mu(Zxy_k)$, covariances $\Sigma(Zxy_k)$, five Gaussian components (K=5). Weights $\pi_k \in [0, 1]$ are priors that sum up to one. EM is an iterative method for fitting GMMs to the negative class label of latent samples (Zx, Zy) or Zxy in an OCC setting. Eq. (2) is GMR model via the MoE to predict distributions of variables Zr by computing the conditional distribution p(Zy|Zx). The conditional distribution of each Gaussian distribution is $N(Zx,Zy|\mu(Zxy),\Sigma(Zxy))$ then the conditional distribution of a mixture of Gaussian distributions is $N_k(Zy \mid \mu(Zy \mid Zx_k), \Sigma(Zy \mid Zx_k))$ with means $\mu(Zy|Zx_k)$ and covariances $\Sigma(Zy|Zx_k)$. Weights $\pi(Zy|Zx_k) \in [0, 1]$ are priors that sum up to one.

In step 2, GMMR has utilized EM [9] for developing the score function. EM has a role for fitting GMMs to the negative class label of latent samples (Zx, Zr) or Zxr in an OCC setting again. The joint PDFs are used to store the statistical information of the input and target variables such in Eq. (3). The target variable is assumed class labels. In this case, class labels for the global model are missing, then EM is used to compute the parameters of each mixture component and estimate the maximum log-likelihood of GMMs as the score function such in (4).

$$p(Zx, Zr) = \sum_{k=1}^{K} \pi_k N_k(Zx, Zr|\mu(Zxr_k), \Sigma(Zxr_k)) \quad (3)$$

$$logl = \log p(Zx, Zr) \quad (4)$$

Fig. 7 demonstrates GMMR with five local models, which yield the predicted outcome Zr_pred in the output space y-axis when conditioning by Zx on the input space x-axis. GMMR has worked well to combine linear and non-linear models. The key model of GMMR is p(Zy|Zx) which produces p(Zx, Zy) from p(Zx) that can be well represented by a set of Gaussians [36] so that GMMR can be analyzed easily using a mixture of linear models. For this reason, the evaluation of GMMR is carried out on the linear regression model. It is linear in the parameters. The linearity of parameters is shown by a linear relationship between the predictor (Zx), observed outcome (Zy), predicted outcome (Zr) in performing local regression [19], [20], [36] at the query point on demand. The query point on demand using: (1) the nearby training observations [19], (2) a nested sequence of regions [20], and (3) a small set of close points [36], to build a mixture of linear models. From global regression into local regression referred to as a memory-based procedure [19] of experts and gates. It can predict the outcome according to the memory of experts, each expert specializes in one local regression, and the gate defines the regions where the memory of an individual expert are trustworthy.

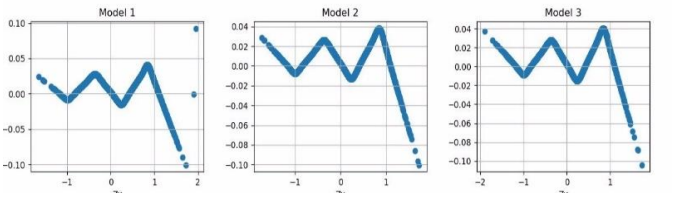

Fig. 7. GMMR with five local models.

The mechanism of GMMR with the local models has been explained specifically in hierarchical mixtures of experts (HME) [20]. The mechanism works on a set of experts and gates collaborating to solve a nonlinear function by dividing the input space into a nested sequence of regions [20], [40]. The experts learn the simple parameterized surfaces in these partitions of these regions, and the gate makes a soft split of the input space. The simple parameterized surface in both experts and gates can be learned using the EM algorithm [9].

The common metric to evaluate a regression model is root mean squared error (RMSE) and R-squared (R^2) [22]. RMSE is a function of the model residuals which is the difference between Zr_true and Zr_pred: in [0, ∞], the smaller the better. R^2 can be interpreted as the proportion of the variance in Zr_pred which is explained by the model: in [−∞, 1], the closer to 1 the better. R^2 is a measure of correlation, not accuracy [22]. The other metric is mean absolute error (MAE) which is the average of the absolut difference between Zr_true and Zr_pred: in [0, ∞], the smaller the better. The performance of GMMR for three selected models is shown in Table IV.

TABLE IV. MEASURING PERFORMANCE OF GMMR

Model	RMSE↓	R^2↑	MAE↓
1	0.0022	0.9752	0.0010
2	0.0010	0.9928	0.0009
3	0.0011	0.9926	0.0009

F. The Bias-Variance Alignment

The center point of cyber resilience model is in GMMs which build the fundamentals of representational and inference models. GMMs work on a probabilistic model to estimate maximum log-likelihood via the EM algorithm [9]. GMMs are a simple generative model that utilizes a mixture of Gaussian distributions to build a weighted sum of PDFs but GMMs have high flexibility in the predictive and inference modeling. The weakness is that GMMs fail in high-dimensional data [4]. To address the problem, the three methods take into account. The first method, dimensionality reduction to summarize important information from feature vectors into latent samples. The method uses VAEs for analyzing latent samples and MDRNNs for generating sequences of latent samples. The second method, multimodal regression to transform the non-linear function of latent samples into a mixture of linear models so that latent samples are easier to analyze just using linear regression but more stable in handling the density with local regression. The method uses MoE to combine parametric and nonparametric estimates of the model for a regression function. The third method, decision boundary optimization to conclude log-likelihood. The method uses the bias-variance alignment described in this subsection and likelihood ratios described in the next subsection.

The bias-variance tradeoff and alignment have similarities in decomposing the generalization error into bias and variance. The bias-variance tradeoff is often used to analyze

the generalization error in a regression setting [19], [22], while the bias-variance alignment is more suitable used to analyze the generalization error in a classification setting [7]. Quantitative measures of the generalization error in regression are derived from the mean squared error (MSE) which also can be calculated by squaring RMSE. The expected test MSE can be decomposed into bias and variance [19], [22] as follows:

$$E[MSE] = \sigma^2 + (\text{model bias})^2 + \text{model variance} \quad (5)$$

The first part (σ^2) is an irreducible error. It cannot be eliminated in predictive modeling. It shows intrinsic noise in the model due to unknown variables. The second part is the squared bias of the model. It shows the relationship between the predictor (Zx) and the outcome (Zr_true and Zr_pred) of the model. High bias means the model is unable to relate accurately between the predictor and the outcome, Zr_pred is very different from Zr_true that indicates underfitting. The third part is the model variance. It shows the sensitivity of predictive modeling to different datasets. High variance means the model learns more about the noise than the underlying patterns in datasets. More fitting in training data but poor in testing data indicates overfitting. The expected test MSE simultaneously achieves low bias and low variance.

Eq. (5) also works to multimodal regression via MoE. The variance model of multimodal regression can be expressed as the sum of two parts: the first part is related to the variance of the expert networks and the second part is related to the covariance of the expert networks [18]. This shows that a model that can be analyzed using a regression function means it can also be analyzed using bias-variance tradeoff, including GMMR.

TABLE V. TWO SAMPLES FOR CLASSIFICATION

Model	N(Zn)	N(Zp)	H
1	10	90	Hp
2	50	50	Hp
3	90	10	Hp
1	10	90	Hn
2	50	50	Hn
3	90	10	Hn

Table V describes two samples for classification. The samples size is one hundred for one observation. Positive samples denoted Zp and the size denoted N(Zp). Negative samples denoted Zn and the size denoted N(Zn). The hypothesis of classification models denoted H. There are two hypotheses: a positive hypothesis (Hp) and a negative hypothesis (Hn). A positive hypothesis is an observation that tests log-likelihood in an expected finding of the presence of an anomaly if the hypothesis is true. Quantitative measures of the presence of an anomaly are indicated by the positive likelihood ratio (PLR). Low log-likelihood is an instance from the presence of an anomaly. A negative hypothesis is an observation that tests log-likelihood in an expected finding of the absence of an anomaly if the hypothesis is true. Quantitative measures of the absence of an anomaly are indicated by the negative likelihood ratio (NLR). High log-likelihood is an instance from the absence of an anomaly.

The idea of using two samples for classification is motivated by the one-class classification method that suffered spurious detection [29] and perfect density models that could not guarantee anomaly detection [23]. One-class classification in the density process aims to learn a one-class decision boundary by GMMR that minimizes false positive rate (FPR) [35]. In this problem, the underlying patterns of negative samples is well-recognized by the model. However, because positive samples were not trained on the model, the model did not know the underlying patterns of positive samples. As a consequence, it suffers from spurious detection. The next problem, even though the data-generating process produces reliable log-likelihood, it does not mean that low log-likelihood is identical to the presence of an anomaly and vice versa. If the inference model of log-likelihood is not well-defined, high log-likelihood may be interpreted as the presence of an anomaly [8], [27]. The low and high log-likelihood of the representational model need to be proven quantitatively as the decision boundary that discriminates the two [33]. Therefore, anomaly detection using a single-sample distributional test is impossible [41]. The existency of positive and negative samples is a must for developing two competing hypotheses [33], [41]. The samples may be derived from ground truth or without. The model will learn from the samples and justified by two competing hypotheses. However, one-class classification is still required to define initial assumptions about the samples before modeling two competing hypotheses.

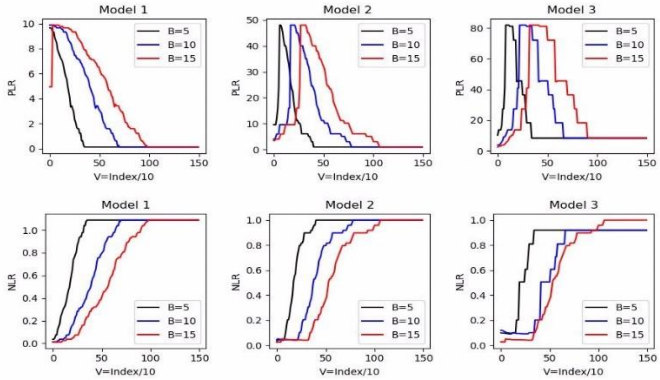

Fig. 8. The bias-variance alignment.

Fig. 8 describes the bias-variance alignment. The bias-variance alignment plays a role in decision boundary optimization to conclude log-likelihood. GMMR as part of data-generating process that produces log-likelihood is not free from the generalization error. The generalization error causes the estimated log-likelihood to shift from the true log-likelihood. This is called misleading and weak log-likelihood. However, the bias-variance tradeoff does not completely explain the phenomenon in a classification setting [7] as follows:

$$(\text{model bias})^2 \approx \text{model variance} \quad (6)$$

Eq. (6) about the phenomenon, which is different from bias-variance tradeoff in general that models of low capacity have high bias but low variance and vice versa. While in Eq. (6) shows the flexibility of bias-variance tradeoff. The model that has high bias does not tend to have low variance or vice versa. Eq. (6) suggests that the bias-variance alignment is specific to large neural networks. Meanwhile, for the small model as in Fig. 8 shows the same results that bias and variance are aligned at a sample level although squared bias does not approximately equal variance, as seen in a full and not-full concave curve of optimal likelihood ratios. It means that the effect of bias-variance tradeoff does not lost at all in a classification setting. Fig. 8 shows that decision boundary in a classification setting has optimized by bias-variance alignment. The relation between decision boundary and bias-variance alignment is as follows:

$$\text{aligned\_logl} = \text{logl-B}\times\mu(\text{Ze})\times\text{logl} \quad (7)$$

$$T = \mu(\text{aligned\_logl})\text{-V}\times\Sigma(\text{aligned\_logl}) \quad (8)$$

$$\text{y\_pred} = \begin{cases} 1, & \text{aligned\_logl} < T \\ 0, & \text{aligned\_logl} \geq T \end{cases} \quad (9)$$

In Eq. (7), aligned_logl has related to a bias factor (B) and the mean of the predictors at testing time μ(Ze). Meanwhile, a decision boundary threshold (T) has related to a variance factor (V), means μ(aligned_logl), and standard deviations Σ(aligned_logl). Eq. (7) shows that log-likelihood needs to be aligned so that it shifts closer to the true log-likelihood, then aligned_logl performs as a parameter in determining the variability of thresholds together with a variance factor.

In Eq. (9), the threshold T creates a decision boundary that classifies log-likelihood into two classes: low log-likelihood if aligned_logl < T and high log-likelihood if aligned_logl ≥ T. Low log-likelihood being labeled positive samples (predicted positive/PP) and high log-likelihood being labeled negative samples (predicted negative/PN). Eq. (9) applies if the bias-variance alignment has achieved the optimal likelihood ratio.

G. Likelihood Ratios

A likelihood (L) is the relative probability of the observed data given a hypothesis parameter value [3]. It refers to the probability or density of a sample under a distribution [41]. It is related to the observed data, statistical models, and statistical hypotheses. It indicates the hypothesis for the goodness of fit of a model to the observed data. With these roles, the data-generating process is designed to produce the likelihood datasets that construct hypothesis. A hypothesis is a prediction for the observed data that can be tested for truth. Hypothesis testing is an important step to ensure that a model being built fits the observed data. Together with the observed data, statistical models, and statistical hypotheses are actual components to be able to draw inferences. The likelihood ratio (LR) is the ratio of two likelihoods for parameter values for two different hypotheses H_1 over H_2 given the observed data x [3] that can be written as follows:

$$LR = L(H_1|x)/L(H_2|x) = P(x|H_1)/P(x|H_2) \quad (10)$$

The likelihood ratio LR represents and measures statistical evidence. The LR is not a probability but a relative measure of evidence for competing two hypotheses. The likelihood of a hypothesis H given the observed data x (L(H|x)) is proportional to the probability of the observed data x under a hypothesis H (P(x|H)). L(H|x) builds a likelihood model. As a consequence, the LR builds a model to represent statistical evidence. Then, the LR model performs as an evidence measure for the observed data. Two different evidences will be measured: evidence from ground truth datasets (y_true) as explained in the subsection III.B and evidence from the bias-variance alignment (y_pred).

In the LR, hypotheses can be easily derived from the model and vice versa. Eq. (7) represents the observed data in a model and (9) is the hypothesis of the model. Eq. (9) formulates the positive hypothesis H_1 (align_logl<T) and the negative hypothesis H_2 (align_logl≥T). In contrast, the hypotheses formulated in (9) together with ground truth datasets build a new model, as seen in Fig. 9(b). The LR model measures statistical evidence by support, denoted S. Statistical evidence for two hypotheses on the graded scale can be seen in Table VI.

TABLE VI. INTERPRETING SUPPORT [3]

LR (1/LR)	Support (log LR)	Interpretation H_1 over H_2
1 (1.00)	0	No evidence
2.7 (0.37)	1	Weak evidence
7.4 (0.14)	2	Moderate evidence
20 (0.05)	3	Strong evidence
55 (0.02)	4	Extremely strong evidence

Table VII shows likelihood intervals or support intervals and their corresponding frequentist confidence intervals (CI) for the standard Gaussian distribution. Similar to confidence intervals, likelihood intervals describe the accuracy and reliability of estimation obtained from the observed data. Likelihood intervals measure the level of confidence in the estimation that expected parameters fall within a certain range. Likelihood intervals are a need to interpret likelihood clearly that the likelihood evidence points are confidence within a certain range.

TABLE VII. LIKELIHOOD INTERVALS [3]

S	LR	1/LR	% CI
1.6	4.95	0.202	92.6
2	7.39	0.135	95.4
3	20.09	0.050	98.6
4	54.60	0.018	99.5
5	148.4	0.007	99.8
6	403.4	0.0025	99.95
7	1096.6	0.0009	99.98
8	2981.0	0.0003	99.99

The LR is about the relative strength of evidence for two competing hypotheses. In contrast, the frequentist approach use of type I and type II errors allows one to specify the probability of rejecting the null hypothesis when it is true, and of not rejecting it when it is false [3]. The LR was built to test two hypotheses: predicted label as an outcome and true label as a reference standard. The two hypotheses compete to measure the relative strength of evidence.

In this paper, a competition is performed by considering ground truth datasets as a reference standard to test the hypothesis in (9) as predicted label. It will produce the outcome of a test: (1) y_pred=1 for a positive label, (2) y_pred=0 for a negative label, and (3) the relative strength of evidence for the observed data. Therefore, the outcome of a test by the LR is not to reject or not reject the null hypothesis (H_0 or H_2). If the relative strength of evidence is not misleading and not weak, the hypothesis may be accepted.

The 2×2 contingency table describes a matrix format used to display a frequency distribution of two variables with the vertical columns denoting instances of reference standard, or true label and the horizontal rows denoting instances of outcome of a test, or predicted label [24]. The relative strength of evidence is measured using the 2×2 contingency table as seen in Fig. 9.

	align_logl<T	align_logl≥T
y_pred=1	TP	FP
y_pred=0	FN	TN

a. The 2×2 contingency table to evaluate the performance indicator of a model

	y_true=1	y_true=0
y_pred=1	TP	FP
y_pred=0	FN	TN

b. The 2×2 contingency table to assess the relative strength indicator of evidence

Fig. 9. The 2×2 contingency table for binary classification.

Table VIII defines a measure factor in the 2×2 contingency table and its derivative. The limitation in the evidential approach is that no observed values are zero [3]. The generalization error controlled by the bias-variance alignment is only a reducible error part not all error conditions [19], [22]. A measure factor of TPR, TNR, FPR, and FNR is an error-based measure. A measure factor, such as TPR or TNR, has a test's ability to detect correctly a condition when it is present and to rule it out correctly when it is absent. A measure factor, such as FPR or FNR, has a test's propensity to detect incorrectly a condition when it is absent and not to detect it correctly when it is present [24]. Therefore, a measure factor of TP, TN, FP, and FN is considered to be not zero.

PLR measures the change in pre-test to post-test odds and diagnostic gain. It also combines information about TPR and FPR [24]. If a sample from population tested positive, PLR represents the relative strength of evidence that a sample is an anomaly given a positive test result. However, the relative evidence of PLR also depends on the explicit prior in the Bayesian approach which is not discussed in this paper. To reduce uncertainty due to factors that influence it, PLR utilizes information from NLR.

Ideally the PLR value is 1/NLR [3], but in practice, the PLR value is sometimes greater than 1/NLR so that the relative strength of evidence for the observed data is less properly. It is necessary to combine PLR and NLR for a single test value as the performance indicator of a model and the relative strength indicator of evidence. Basically, PLR and NLR are the ratio of paired measures [24]. Hence the approach taken is based on the harmonic mean method [43] to combine PLR and NLR that gets a new measure factor, namely, the harmonic likelihood ratio (HLR):

$$HLR = 2\times PLR/(1+(PLR\times NLR)) \quad (11)$$

TABLE VIII. A MEASURE FACTOR IN THE 2×2 CONTINGENCY TABLE AND ITS DERIVATIVE

Term	Denoted	Formula	Description
True positive	TP	TP > 0	Correct predictions of anomaly
True negative	TN	TN > 0	Correct predictions of normal
False positive	FP	FP > 0	Incorrect predictions of anomaly
False negative	FN	FN > 0	Incorrect predictions of normal
True positive rate	TPR	TP/(TP+FN)	The rate of an anomaly sample tested positive
True negative rate	TNR	TN/(TN+FP)	The rate of a normal sample tested negative
False positive rate	FPR	1-TNR	The rate of a normal sample tested positive
False negative rate	FNR	1-TPR	The rate of an anomaly sample tested negative
Positive likelihood ratio	PLR	TPR/FPR	The ratio of an anomaly sample tested positive and a normal sample tested positive
Negative likelihood ratio	NLR	FNR/TNR	The ratio of an anomaly sample tested negative and a normal sample tested negative

The idea of a self-supervised binary classifier is to utilize the structure within data from the samples (logl) to build a supervisory signal for the classifier. A supervisory signal comes from the underlying structure of the samples realized in producing two samples using (7), (8), and (9). A supervisory signal first finds the bias B and variance V that give the maximum likelihood ratios of the two samples. For simplicity, the bias B is assumed to be 10 refers to the B value in the description of the bias-variance alignment in Fig. 8 and the variance V is tried to find iteratively within a certain range on the PLR or HLR value is the maximum, denoted _PLR_ and _HLR_. This maximum value indicates the relative strength of evidence for two samples that the classifier has worked to classify the two samples properly.

The performance evaluation of classifiers involves three models, two groups of observation, and five indicators. Classification is designed in two stages. The first stage is about training samples with a one-class classification method for fine-grained negative samples from subdistributions 1, 2, and 3. Three types of training samples were realized with a negative sample size of 10, 50, and 90, respectively. Training samples were taken from ground truth datasets randomly.

Training samples were the initial assumptions about the prior distribution implicitly (the implicit prior). The second stage is about testing samples with a binary classification method for fine-grained negative samples from subdistributions 1, 2, and 3 and positive samples from subdistributions 4, and 5. Ninety-nine types of testing samples were realized with a negative sample size from 1 to 99 and a positive sample size from 99 to 1, respectively. Testing samples were taken from ground truth datasets randomly. The second stage applies (7), (8), and (9).

Table IX shows that 4 out of 5 performance indicators of the group of observation _HLR_ are better than the group of observation _PLR_. This proves that HLR as a single test value of performance indicators has worked well to evaluate the performance of binary classifier even though the absence of the explicit prior. This correspond to the result of the area under the receiver operating characteristic (AUROC). While the area under the precision-recall curve (AUPRC) is almost the same.

TABLE IX. THE METRIC TO EVALUATE THE PERFORMANCE OF BINARY CLASSIFIERS

Model	Model 1		Model 2		Model 3	
Group	_PLR_	_HLR_	_PLR_	_HLR_	_PLR_	_HLR_
V	1.148	0.576	1.556	0.741	1.352	0.683
T	3.815	5.127	3.868	5.114	3.908	5.067
PLR↑	36.128	22.432	36.664	20.053	37.811	22.591

AUROC↑	0.894	0.941	0.895	0.938	0.897	0.938
AUPRC↑	0.922	0.935	0.927	0.931	0.926	0.939

IV. EXPERIMENTAL RESULTS

The study in this paper was conducted using an experimental method. The experiment was conducted in four stages. The first stage was an experiment with raw datasets that produce ground truth datasets: true or to be true positive (TP) samples and true or to be true negative (TN) samples using the K-Means and EM algorithms.

The second stage was an experiment with the LR as the performance indicator of a model (HLR). The experiment uses data-generating process to produce the logl. The bias-variance alignment enhances likelihood by shifting the logl closer to true likelihood thereby producing the LR model. An indication that the logl closer to true likelihood if the LR model is not misleading and not weak refers to Table VI. The LR model constructs two hypotheses: a positive hypothesis (H_1) and a negative hypothesis (H_2). A measure factor HLR facilitates the resolution of two hypotheses to obtain the variance V properly based on the underlying structure of the two samples. The variance V is proper if the HLR has reached its maximum within a certain range of variance. Together with the bias B, the variance V constructs a supervisory signal for the classifier by a threshold T. Referring to (9), the LR model produces predicted datasets: predicted positive (PP) samples and predicted negative (PN) samples. In the LR, two samples present two models and two hypotheses. Otherwise, two models and two hypotheses represent two samples.

The third stage was an experiment with the LR as the relative strength indicator of evidence (S). Evidence comes from ground truth and predicted datasets which construct two hypotheses: a primary hypothesis (H_1) and a null hypothesis (H_0). Once again, a measure factor HLR makes it easier to resolve two hypotheses to get the relative strength of evidence.

The fourth stage was an experiment to build up a self-supervised anomaly detection (AD) approach. The resilience scale (RS) and anomaly score (AS) can be written as follows:

$$RS = 2\times IPN\times S/(IPN+S) \quad (12)$$

$$AS = 4-RS \quad (13)$$

In (12), the support S is the natural logarithm of a measure factor HLR. It assumes the highest relative strength of evidence is 4 that refers to Table VI. Also, the highest index of PN is 4, because PN is in the range of 0 to 100, the index of PN (IPN) is PN/25. So that the IPN and S have the same ratio from 0 to 4, then both variables can be estimated smoothly using a harmonic mean method [43] to derive (12). Eq. (13) assumes the resilience scale and anomaly score are complements to the support S.

The experiments were realized using a Python programming language, a deep learning library Pytorch [30] to implement an artificial neural network, a Python module Scikit-learn [31] to implement a machine learning model, a Python library gmr [11] to implement a mixture of experts, a Python toolbox PyOD [42] for benchmarking anomaly detection methods, and a 2D graphics package Matplotlib [17] for the visualization of observational and experimental results.

TABLE X. THE LOG-LIKELIHOOD SCORE OF EACH SUBDISTRIBUTION

subd	1	2	3	4	5
Zx	-1.238	-1.199	-1.281	-1.372	-1.475
Zxy	-1.217	-1.193	-1.233	-1.278	-1.335
Zxr	5.078	5.104	5.057	4.985	4.921
Zxr, B=5	6.211	5.514	4.726	3.652	2.712
Zxr, B=10	7.344	5.925	4.395	2.318	0.502
Zxr, B=15	8.477	6.335	4.064	0.985	-1.707

Table X presents the log-likelihood score of each subdistribution for some latent variables and the bias factor that affects the log-likelihood score. The latent variable Zx is the latent samples generated by VAEs. The latent variable Zxy is the latent samples generated by VAEs and MDRNNs also known as world models [14]. The latent variable Zxr is the

latent samples generated by VAEs, MDRNNs, and GMMR also called the representational model.

Table X proves that the log-likelihood score of Zx and Zxy is too low, below zero. GMMR can increase the log-likelihood score significantly from Zxy to Zxr. However, the log-likelihood score generated by GMMR is not strong enough to be used as evidence. The log-likelihood scores of one subdistribution and the others are difficult to distinguish as normal and anomaly classes. It shows that the classification of the two samples is not clear. The reason is that the latent samples are generated by the model, while a model is not free from the generalization error.

In Table X, the bias factor B as one of a supervisory signal straightens the weak evidence by shifting the log-likelihood score closer to the true classification of the two samples. A higher B value has implications for a higher log-likelihood score of subdistributions 1, and 2 and a lower log-likelihood score of subdistributions 3, 4, and 5. This simple experiment explains that subdistributions 1, and 2 tend to be samples of normal class and subdistributions 3, 4, and 5 tend to be samples of anomaly class.

Fig. 10 gives three indicators of the cyber resilience model: the predicted negative PN, the support S, and the resilience scale RS. The predicted negative PN about two samples needed in a likelihood ratio model. One sample represents a reference standard used as an example (ground truth datasets). The other sample represents the observed data (predicted datasets). Ground truth and predicted datasets construct a likelihood ratio model. In the context of cyber resilience, the samples that need to be monitored are the predicted negative (PN) as part of the predicted datasets. PN is the total number of elements labeled as belonging to the negative class. PN is true negative (TN) + false negative (FN). True negative (TN) is as part of the ground truth datasets while false negative (FN) indicates incorrect predictions of the negative class. So, FN is the difference between PN and TN. The PN indicator proves the relationship between PN and the number of negative samples N(Zn), TN, FN.

The support S about the relative strength indicator of evidence. Two samples in a likelihood ratio model construct two competing hypotheses. A measure factor HLR makes it easier to resolve two competing hypotheses to get the support S. From the experiment, it is known that the support S is not affected by the number of negative samples linearly in the training and testing phases except for extreme numbers, such as less than 10 or more than 90 if the sample size is 100. As a consequence, the number of negative samples of 10 has met the requirement as training data.

The resilience scale RS about the resilience scale of the service. It is the indicator to measure the behavior of cyber resilience model. The cyber resilience model requires two data to realize (12): the predicted negative (PN) and the support (S). Because RS derives from the PN and S, which refers to Table VI, the resilience scale RS also has an interpretation that refers to Table VI.

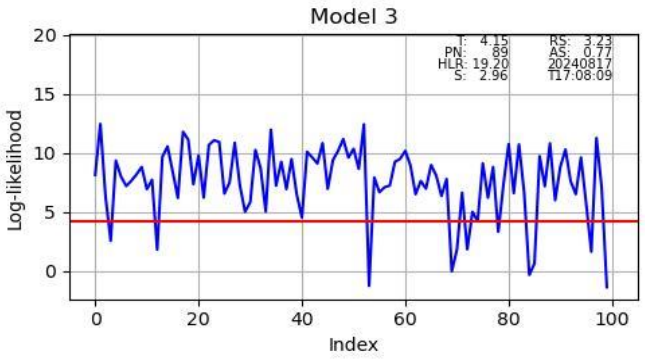

Fig. 10. The cyber resilience model.

Referring to this experimental results, it is known that the cyber resilience model is identical to a likelihood ratio model (LRM). A likelihood ratio model is effectively carried out based on anomaly detection. In anomaly detection, two samples are clearly defined. LRM summarizes complete information about the observed data, statistical models, and statistical hypotheses of DNS events. It identifies the individual and group behavior of each sample shown by the PN and S indicator.

The PN indicator can be used to estimate the status of the data. High PN shows that DNS events are normal and low PN shows otherwise. In addition, LRM provides information about the stability of the model in predicting the observed data. The stability of the model can be seen from the S indicator. A high S shows that the model has the ability to predict the data normally and a low S shows otherwise. Furthermore, the two indicators are used to test the hypothesis of DNS events. A high anomaly score or low resilience scale indicates a DNS anomaly. A low anomaly score or high resilience scale indicates a DNS normal. Table VI will help interpret both in a more understandable form. Therefore, the anomaly score AS is a complement to the resilience scale RS as has been formulated in (13).

Anomaly detection is designed using a specific binary classification task to build a reliable anomaly detection method in dealing with dynamic models. The binary classification task goes through two stages. The first stage is fitting data using regression to obtain the initial value of the relationship between the model and the genuine labeled data (the implicit prior) and the second stage classifies the log-likelihood by a decision boundary threshold to define high and low log-likelihoods. The complete differences between some anomaly detection methods (PyOD) and the tested method (LRM) in the experiment can be seen in Table XI.

TABLE XI. THE DIFFERENCE OF PYOD AND LRM IN THE EXPERIMENT

PyOD	LRM
Input from the log-likelihood score of latent samples (logl) about 100 samples	Input from latent samples (Zxr) about 2×200×100 latent samples
Fitting and predicting in classification	Fitting in regression Predicting in classification
Fitting is done on the negative samples	Fitting is done on the negative latent samples
Predictors are the negative and positive samples	Predictors for regression are the negative latent samples Predictors for classification are the negative and positive samples
Not using latent samples but directly using the log-likelihood score as the observed samples	For each latent sample, the maximum log-likelihood score is taken as the observed samples

Some anomaly detection methods that have been compared: Angle-Based Outlier Detection (ABOD), Isolation Forest (IForest), K-Nearest Neighbors (KNN), and One-Class Support Vector Machines (OCSVM). The methods represent four different anomaly detection methods that have been implemented in PyOD [42]. The results of the benchmarking show that LRM has high performance and stability as an anomaly detection method as seen in Table XII.

TABLE XII. BENCHMARKING THE FOUR METHODS AND LRM

Model	Indicator	ABOD	IForest	KNN	OCSVM	LRM
1	HLR↑	6.003	14.236	14.236	17.626	17.626

V. DISCUSSION AND FUTURE WORK

Two samples can be well-modeled with the LR model so that the interpretation of the observed data is more objective, depending only on the data itself. It is relevant to be used for anomaly detection. It is also relevant to be used for normal detection (resilience). Based on a self-supervised anomaly detection approach, self-labeling in a dynamic model can be realized with measurable supervision. Self-labeling directed by a supervisory signal consisting of a bias factor B, a variance factor V, and a threshold T. The evaluation of regression and classification models with results as follows: RMSE=0.0014, R^2=0.9869, MAE=0.0009 for fitting 3 regression models at training time and HLR=15.456, AUROC=0.939, AUPRC=0.935, S=2 (2.738) with the S-2 likelihood interval for 297 (3×99) classification models at testing time. It means that the LR model does not generally produce misleading and weak log-likelihood. In this LR, the relative strength of evidence is defined by a primary hypothesis that models self-labeling and a null hypothesis that models a standard reference of the samples. In the experiment, it has been proven that a primary hypothesis is accepted, S=2 with a 95% confidence level.

The difference index (DI) of likelihood in the EM as a sample classifier is the difference between a subdistribution classified as positive and negative samples. The larger DI, the larger the disjoint support between the distribution of positive and negative samples. In Table III, subdistribution 2 has a DI of 4.004, subdistribution 3 has a DI of 0.944, and subdistribution 4 has a DI of 3.210. It means the difference index of subdistribution 3 is small, then the disjoint support is also small. As a consequence, subdistribution 3 is less reliable as a standard reference of samples.

To address the problem of misleading and weak log-likelihood required aligning bias-variance and optimizing likelihood-ratios. In Table X, the bias factor B has been worked properly for subdistributions 1, 2, 4, and 5 but not for subdistribution 3. This is correlated with the analysis of Table III that the disjoint support of subdistribution 3 is small so subdistribution 3 produces anomaly interpretation: some parts tend to be negative samples and others tend to be positive samples.

Referring to the facts in Table III and X, it is necessary that a null hypothesis may need to be redesign. A null hypothesis represents ground truth datasets as examples of positive and negative samples that declare a reference standard of the observed samples in two competing hypotheses. The next study focused on enhancing the ground truth datasets, especially to address the problem of subdistribution 3 that produces a stronger relative strength indicator of evidence. Furthermore, predictive modeling only relies on examples of positive and negative samples from those trained to the model as the implicit prior.

VI. CONCLUSION

There is a relationship between the cyber resilience and likelihood ratio models. The likelihood ratio model (LRM) is useful in building the cyber resilience model. It meets the requirements needed to realize the representational and inference models in practice. The representational model has been realized with likelihood maximization inside data-generating process and the inference model has been realized with likelihood ratios inside two competing hypotheses. In the representational model, the Gaussian mixture model for multimodal regression (GMMR) enhances the ability of world models produces log-likelihood. The log-likelihood needs to be aligned by the bias-variance factor to be worthy of being used as evidence. In the inference model, evidence from ground truth datasets and evidence from the model build two competing hypotheses to handle anomaly detection tasks in self-supervised settings. Evidence from the model has been labeled through a self-labeling technique that supervised by three supervisory signals: a bias factor, a variance factor, and a threshold to optimize decision boundary in minimizing the generalization error of predictive modeling with the harmonic likelihood ratio (HLR).

ACKNOWLEDGMENT

This study was conducted in collaboration between Universitas Muhammadiyah Malang and Universiti Teknologi Malaysia. The authors fully acknowledge to Rector of Universitas Muhammadiyah Malang for the research grant (E.5.c/1693/UMM/XII/2020) that helps in funding the research works. Special thanks to all the reviewers for their valuable feedback.

***Abstract*—The stability and reliability of the electric grid strongly depend on the ability to schedule and forecast the energy output of all sources. Even though the share of photovoltaic installation in the energy mix is continuously increasing, they have one major drawback: their dependence on different environmental parameters, such as solar irradiance, ambient temperature, cloudiness, etc., which have a highly variable nature. Six machine learning algorithms are compared in this study, regarding their ability to forecast the power generation of a rural rooftop photovoltaic installation using different combinations of the input data. The features selected for investigation are solar radiation, ambient temperature, and wind speed, obtained from a meteorological station, as well as two additional time-based variables – the time of the day and the month of the year. During the validation and testing phases, four models performed better – artificial neural network (ANN), k-Nearest neighbor (kNN), Decision tree (DT), and Random Forest (RF), with ANN achieving the best results in all cases. The optimal combination of input data includes solar radiation, ambient temperature, wind speed, and hour of the day, though the difference with the other scenarios was small. The optimal ANN model achieved R^2, MAE, and RMSE of 0.995, 6.71 Wh, and 13.7 Wh, respectively. The results obtained in this study indicate that the yield of PV installations located in rural areas could be forecasted with high probability using a limited number of meteorological data.**

Keywords*—PV yield; forecasting; machine learning; deep learning; features; solar radiation; ambient temperature; wind speed; hour of the day

I. Introduction

Renewable energy technologies have greatly developed during the last decades, with photovoltaics holding the largest share. Many reasons exist for this, such as their low maintenance costs [1, 2], abundant availability of solar energy [3], the possibility for building integration [4], relatively easy installation, reliability [4], etc. However, one major drawback could be defined for PV installations: their strong dependence on weather conditions and especially on solar radiation, which has a highly variable nature. For this reason, the output of photovoltaic power in a stations changes wide range over time and is generally difficult to forecast. One of the options to deal with this problem is the application of energy storage systems, allowing energy charging during daylight hours and using it according to the requirements of the load profile [5, 6]. However, with the current development of energy storage technologies, this approach is still too expensive and its return on investment is too low without government incentives and subsidies [7]. Furthermore, the batteries' life expectancy is still relatively low, which requires additional investment during the PV park operation for battery replacement [8].

Reducing power uncertainties in the electric grid is a major task, which is required to ensure its energy balance. Therefore, forecasting the output of photovoltaic installations is crucial for maximizing the economic benefit and ensuring customers receive electric energy of acceptable quality and reliability [9]. The power production of PV installations depends on many environmental factors, such as solar irradiance, cloudiness, ambient temperature, wind speed [10, 11, 12], and even relative humidity and rainfall. [13, 14]. Moreover, when a photovoltaic installation is installed in an urban or suburban environment, additional factors affecting power production are introduced or enhanced, such as soiling [15, 16], shading [17, 18], panel degradation [19, 20], etc.

Different forecasting approaches exist mostly based on statistical methods (ARIMA, ARCH, GARCH) and machine learning methods, even though physical and hybrid approaches are also used [21, 22]. Machine learning has many applications in the renewable energy field, such as yield forecasting [23], condition monitoring [24], fault detection [25, 26], PV cell degradation [27], MPPT tracking [28], energy management [29], etc. When it comes to PV yield or power forecasting, different machine learning regression algorithms are used, such as Support Vector Machine (SVM), Linear regression (LR), Random Forest (RF), Regression tree (RT), etc. For example, in study [30] the global horizontal irradiance and atmospheric temperature were used, obtained from a meteorological station with a 5-minute timeframe. Several regression models were investigated, such as Gaussian process regression (GPR), LR, RT, and SVM. All models achieved similar performance, with R^2 varying between 92% and 96%, yet the RT achieved the highest score. Similarly, in the study [31] the 5 min horizontal global radiation and ambient temperature in Berlin were used as input data for a machine learning algorithm. It predicted the generated AC energy of a photovoltaic installation and achieved a coefficient of determination of 0.87.

A study for Jordan used nine features to predict the power of a PV installation: irradiation, air temperature, module temperature, as well as several time-based features – day of the week, month number, day type, week number, hour of the day

and year type [32]. RF achieved the highest performance, closely followed by Bagging-REFTree. In study [33], the possibility of forecasting PV energy output in numerous regions with limited plant-specific data was investigated. The authors enriched the features by adding 1-hour-lagged meteorological data and tested different machine-learning regression methods, such as Kernel Ridge and RF. The models achieved a normalized root mean square error (NRMSE) of 3% in the case of lagged power used as input, corresponding to a 1-h time horizon.

Three types of forecasting exist when it comes to photovoltaic output: short-term, medium-term, and long-term [34]. In study [35], a predictive model for PV power generation in Korea was presented, based on a recurrent neural network (RNN) and meteorological data. Four predictive features were selected: air temperature, relative humidity, solar radiation, and wind speed. Error rates of 13.8% and 13.2% were reported, respectively for the single- Long Short-Term Memory (LSTM) and multi-LSTM models. In another study, nine input parameters were used to train an artificial neural network that forecasts the output of a photovoltaic installation – global horizontal irradiance, global diffuse radiance, ambient temperature, precipitation, wind speed, air pressure, sunshine duration, relative humidity, and surface temperature [36]. The reported error rates vary between 72.64% and 0.74% for low and high insulation values, respectively. In study [37] the 24 h PV yield was forecasted using solar radiation and ambient temperature as input data. The authors proposed an artificial neural network (ANN) Multi-Layer Perceptron (MLP) model, which achieved an R^2 between 96% and 99% for sunny days and between 0.88% and 92% for cloudy days. Similarly, in [38] ultra-short PV power forecasting was investigated based on neural networks and four features – global horizontal irradiance, wind speed, ambient temperature, and relative humidity. The different models achieved an R^2 between 0.889 and 0.967 in the validation phase and between 0.910 and 0.971 in the testing phase.

Some studies have also compared the performance of the machine learning and deep learning approaches. In [39] the temperature of the PV surface, the solar irradiance, and the wind speed were used to predict the power output of a rooftop photovoltaic installation in Russia. A comparison between ANN and regression models showed the first had better performance with error rates between 0% and 30% for the different days. Similarly, in study [40] the power of a PV installation in Egypt was forecasted using three models – RF, Facebook Prophet, and LSTM. The features used are different components of the solar irradiance, wind speed at 10 m, temperature at 2 m, and sun height. The best-performing model was Prophet with R^2=0.93, which was confirmed by its mean square error (MSE) and MAE coefficients. In study [23] were used seven machine learning algorithms for short-term prediction of photovoltaic generation - extreme gradient boosting algorithm (XGB), support vector regressor (SVR), random forest (RF), classic MLP, and three LSTM-based models. Their achieved R^2 values varied from 0.90 to 0.91 for 15-minute-ahead forecasting, from 0.88 to 0.89 for 30-minute-ahead forecasting, and from 0.86 to 0.89 for 1-hour-ahead forecasting.

However, one of the key factors for forecasting the PV yield is the availability of reliable predictions for solar radiation. This task can also be implemented using either machine or deep learning. In study [41] different machine learning algorithms were evaluated in their ability to forecast solar radiation and ambient temperature, which are considered to have the highest impact on the PV output. Similarly, in study [42] predictions of the hourly solar radiation were made for time horizons h+1 and h+6 in Odeillo, France. They were based on ANN and RF models and the past solar radiations as input data. The RF algorithm achieved better results at forecasting the global horizontal irradiation with an NRMSE of 19.65% for the h+1 timeframe and 27.78% for the h+6 timeframe.

Other studies combined the forecasting of solar energy and PV power. In study [43], the MLP ANN method to forecast the PV power was used with a 10-minute discretization step. The authors investigated two scenarios – one with measured solar irradiance data and the other with predicted one. The precision of the models was estimated using different errors. The best-performing scenario achieved a 7% error for a scenario, which relies on three days of previous solar radiation data. Similarly, in study [44] two hybrid models were investigated for PV power forecasting. A statistical model for estimating solar radiation and a physical or statistical (ANN) model for estimating output power were trained. The ANN-based model achieved lower relative root mean square error, varying from 3.59% to 8.65% for 3 days ahead forecasting and from 5.25% to 11.85% for 6 days ahead forecasting.

The analysis of previous studies shows that a wide range of input data is used for forecasting photovoltaic power. Basic meteorological data, such as solar irradiance, ambient temperature, wind speed, relative humidity, rainfall, and cloudiness is used, as well as some parameters of the PV installations, such as module temperature and yield. Additional time-based features are often added, such as day of the week, month number, day type, week number, hour of the day, year type, etc. Previous authors have reported different accuracies of the existing models, which can be explained by the influence of local factors, such as shading, soiling, etc., and the chosen features. Furthermore, there isn't an obvious winner amongst the used approaches, such as machine learning and deep learning.

The agricultural sector has a great potential for creating additional value with the help of energy from photovoltaic installations. Such applications include powering of irrigation systems [45], animal farms [46,47], etc., and are commonly rooftop mounted. Rural areas are characterized with lack of high-rise buildings and other artificial objects, which could potentially influence the energy production of photovoltaics by creating shadings. Considering the above mentioned, it is important to investigate the possibilities for precise forecasting of the output PV power under such conditions.

This study aims to investigate the influence of different features on the performance of machine learning and deep learning models for forecasting the yield of PV installations located in rural areas.

II. Materials and Methods

A. Data Acquisition

This study relies on two data sources: a mid-scale PV park and a dedicated meteorological station. They are located in the village of Staro Selo, near the city of Tutrakan, Bulgaria, coordinates 43°59'11"N 26°32'49"E (Fig. 1).

Fig. 1. Geographic location of the experimental facility.

The photovoltaic park is installed on the roof of a building and its total power is 68.040 kWp. It is built of 378 monocrystalline modules SPV180M-24 by Sinski PV Co., Ltd. (Wuxi, Jiangsu, China). They are characterized by 180 Wp peak power, 14.1% efficiency, 45V open-circuit voltage, and 5.3 A short-circuit current under standard testing conditions. The orientation of the PV modules has an azimuth angle of 3° and an angle of inclination of 30°. The installation also contains 9 Sunny Mini Central 6000TL single-phase grid-connected inverters by SMA Solar Technology AG (Niestetal, Germany). Their key characteristics are 97.7% efficiency, 1 MPPT with four inputs, and an MPP voltage range of 333 V to 500 V. The inverters are connected to the internet via a Sunny WebBox and all data is stored on the SunnyPortal platform with a 1-hour time step.

The meteorological data is collected using a Sunny Sensor box by SMA Solar Technology AG (Niestetal, Germany), which includes:

- A solar radiation sensor with a measuring range 0÷1500 W/m^2 and an accuracy of 8%.
- A temperature sensor with a measuring range -30÷80 °C and an accuracy of 0.5°C.
- An anemometer with a measuring range of up to 40 m/s and an accuracy of 0.5%.

It is installed near the PV panels and similarly to the inverter, transmits data to the SunnyPortal platform via the Sunny WebBox with a 1-hour time step.

B. Methodology for Data Processing and Data Analysis

In this study, we have applied a data analysis methodology, which includes the following steps (Fig. 2): data preparation, feature preparation and engineering, model optimization, and features evaluation.

1) Step 1. Data preparation: In this step, the data is extracted from the cloud platform. The four datasets are exported in Microsoft Excel format and are merged into a single file with five columns – timestamp, energy yield, solar radiation, temperature, and wind speed. During the merging process, special attention should be paid to the correspondence of the timestamps of the records.

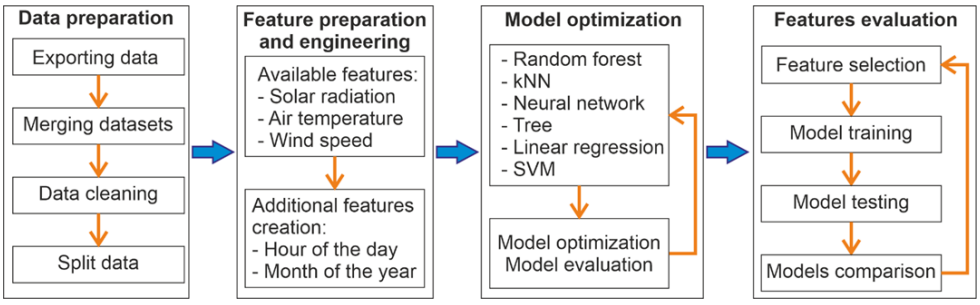

Fig. 2. Overview of the methodology used.

Next, the created dataset is analyzed for inconsistencies, such as:

- Empty or invalid values;
- The solar radiation is non-zero, while the PV yield is zero and vice-versa.

All records with such inconsistencies are removed from the dataset. Finally, the available data is divided into training/validation and testing datasets.

2) Step 2. Features preparation and engineering: In this step, the main features of the machine learning are selected. As previous authors have stated, the factors with the highest influence on the energy yield of photovoltaic installations are solar radiation, ambient temperature, and wind speed [22, 48]. Therefore, they are selected as the main features for model training. Secondary features, which are known to be correlated with solar radiation are the "month of the year" and the "hour of the day". They are extracted from the timestamp of the datasets using Microsoft Excel's "Month" and "Hour" functions. This way the "month of the year" feature takes values from 1 to 12 and the "hour of the day" feature takes values from 0 to 23.

3) Step 3. Model optimization: This step aims to obtain the optimal parameters of each of the selected machine-learning models, using all available features. In this study, we

have chosen the Orange Data Mining v3.36 tool, developed by the University of Ljubljana (Ljubljana, Slovenia) [49]. The reason for choosing it is the wide range of available components for training regression models, evaluation and comparison, modification of the input and output data, etc.

The goal is to train regression models, which can forecast the photovoltaic energy yield using the available features, i.e. the output of the models should be the predicted energy. Based on the results of previous studies, the following machine-learning algorithms are selected for evaluation:

- *Decision tree (DT)* – builds regression organized as a tree structure.
- *Random forest (RF)* – works by creating numerous DTs during the training phase. Each tree is constructed using a random subset of the dataset to measure a random subset of features in each partition. It can be used for both classification and regression tasks. Overfitting is a common problem that may worsen the model performance, which is commonly dealt with by adding enough trees in the forest.
- *K-nearest neighbor (kNN)* – a supervised machine learning algorithm that can be used for classification and regression tasks. It requires more time and memory and is commonly useful with smaller datasets.
- *Artificial neural network (ANN)* – a set of algorithms designed for recognizing patterns in data. They are modeled after the structure and function of the human brain and have shown acceptable results in all spheres of science.
- *Support vector machine (SVM)* – a selective classifier formally defined by dividing the hyperplane. The SVM algorithm intends to find a hyperplane in an N-dimensional space that classifies the data points.
- *Linear regression (LR)* – computes the linear relationship between the dependent variable and one or more independent features by fitting a linear equation to observed data.

The output of the abovementioned regression models is additionally modified (if required), to make sure no energy production is forecasted during the dark hours of the day:

$$E_{pred.m} = \begin{cases} E_{pred};\ Solar\ radiation \geq 0 \\ 0;\ Solar\ radiation < 1 \end{cases} \quad (1)$$

During this step, the parameters of each model are changed and their performance is assessed with the help of a 5-fold cross-validation. Several statistical metrics are used that allow to evaluate the difference between the original and the predicted values:

- Coefficient of determination (R^2) - it takes values between 0 and 1 and shows how well a model predicts the outcome:

$$R^2 = 1 - \frac{\sum_i^n (y_i - \widehat{y_i})^2}{\sum_i^n (y_i - \bar{y})^2}, \quad (2)$$

where, y_i and $\widehat{y_i}$ are the i^{th} samples of the actual and predicted variables and $\bar{y}$ is the mean of the actual values. It is known that when multiple regression models are evaluated, it is better to use the adjusted R^2 metric, which penalizes the additional features. However, this is true only when the number of records is relatively low. When the number of records is significantly higher than the number of features, R^2 and the adjusted R^2 have insignificant differences. That is why in this study the application of R^2 is considered appropriate.

- Mean square error (MSE) – measures the average squared difference between the actual and the predicted values with extra penalty to large errors:

$$MSE = \frac{1}{n}\sum_{i=1}^{n}(y_i - \widehat{y_i})^2 \quad (3)$$

- Root mean square error (RMSE) – measures the average magnitude of the errors in the prediction and is the square root of MSE:

$$RMSE = \sqrt{MSE} = \sqrt{\frac{1}{n}\sum_{i=1}^{n}(y_i - \widehat{y_i})^2}. \quad (4)$$

- Mean absolute error (MAE) – measures the average magnitude of the errors in the prediction and is useful when large errors should not be given extra penalty:

$$MAE = \frac{1}{n}\sum_{i=1}^{n}|y_i - \widehat{y_i}|. \quad (5)$$

- Non-zero mean absolute error (NZMAE) – measures the average magnitude of the errors in the prediction using only the non-zero records. This metric gives more accurate results, as excludes nighttime records, where no energy is generated and no error is expected.

This step is repeated numerous times with different parameters of each regression model until a peak R^2 value is achieved.

4) Step 4. Features evaluation: This step aims to evaluate the influence of the selected features on the performance of the trained models. The following variants are considered:

- Variant 1. Only solar radiation;
- Variant 2. Solar radiation and ambient temperature;
- Variant 3. Solar radiation, ambient temperature, and wind speed;
- Variant 4. Solar radiation, ambient temperature, wind speed, and hour of the day;
- Variant 5. Solar radiation, ambient temperature, wind speed, hour of the day, and month of the year.

For each of the abovementioned variants:

- The training dataset is modified to include only the corresponding features. This is implemented directly in the Orange Data Mining software, by selecting the necessary columns from the Files component.
- The six models are trained again with the selected features.

- The testing dataset is modified similarly to the training one.
- The trained models are applied to the testing dataset and the metrics from Step 3 are evaluated.

Next, the evaluated metrics are compared and the performance of each model with the different feature variants is obtained. The optimal variant and model are determined.

Other than the hourly generated energy, another important parameter of photovoltaic installations is the cumulative daily generated energy. Therefore, during this phase is also estimated the cumulative energy production for each of the testing days according to:

$$E_D = \sum_{i=0}^{23}(E_H), \quad (6)$$

where, E_H is the hourly energy production. The estimated daily energy productions can be compared to each other to identify problems where a model's predictions are dominantly above or below the actual values.

III. Results and Discussion

The datasets were prepared using data obtained in the period from 4 January 2020 to 20 December 2022. Previous studies have recommended the datasets for accurate PV forecasting to be at least 1 full year [38], therefore the used data conforms to this recommendation. Following the proposed methodology, four datasets were exported with 1 h timestep: specific yield in kWh/kWp, solar radiation in W/m^2, ambient temperature in °C, and wind speed in m/s. Thereafter, they were merged, and all records with missing, incomplete, or inconsistent data were removed. The data was split into training and testing datasets as follows:

- The training data includes 13781 records from 4 January 2020 to 31 July 2021;
- The testing data includes 3394 records from 1 August 2021 to 20 December 2021.

Next, the two additional features ("month of the year" and "hour of the day") were added to the datasets. A sample from the prepared training dataset is shown in Fig. 3. The first column (Timestamp) is not used as a feature but is kept as metadata for easier analysis. The last column contains the target variable (the specific energy yield, produced by the PV installation for 1 h), which should be forecasted.

Timestamp	Month of the year	Hour of the day	Solar rad, W/m2	Tavg, °C	Wind speed m/s	specific_yield, Wh/kWp
05.01.2020 06:00	1	6	1.86	4.8	2.89	0
05.01.2020 07:00	1	7	1.97	4.28	4.15	0
05.01.2020 08:00	1	8	1.83	3.72	5.37	0
05.01.2020 09:00	1	9	2.2	3.09	3.76	0
05.01.2020 10:00	1	10	14.8	2.63	0.56	8
05.01.2020 11:00	1	11	25.81	2.06	0.23	17
05.01.2020 12:00	1	12	93.64	2.78	0	79
05.01.2020 13:00	1	13	120.53	3.11	0.2	105
05.01.2020 14:00	1	14	183.53	4.31	1.27	158

Fig. 3. A sample from the prepared training data.

Next, the training and testing procedure were implemented in Orange Data Mining, as shown in Fig. 4. According to step 3 of the methodology, the optimal parameters of the six machine learning algorithms were obtained experimentally using all available features so that their R2 values were as close to 1 as possible. Their optimal parameters are summarized in Table I.

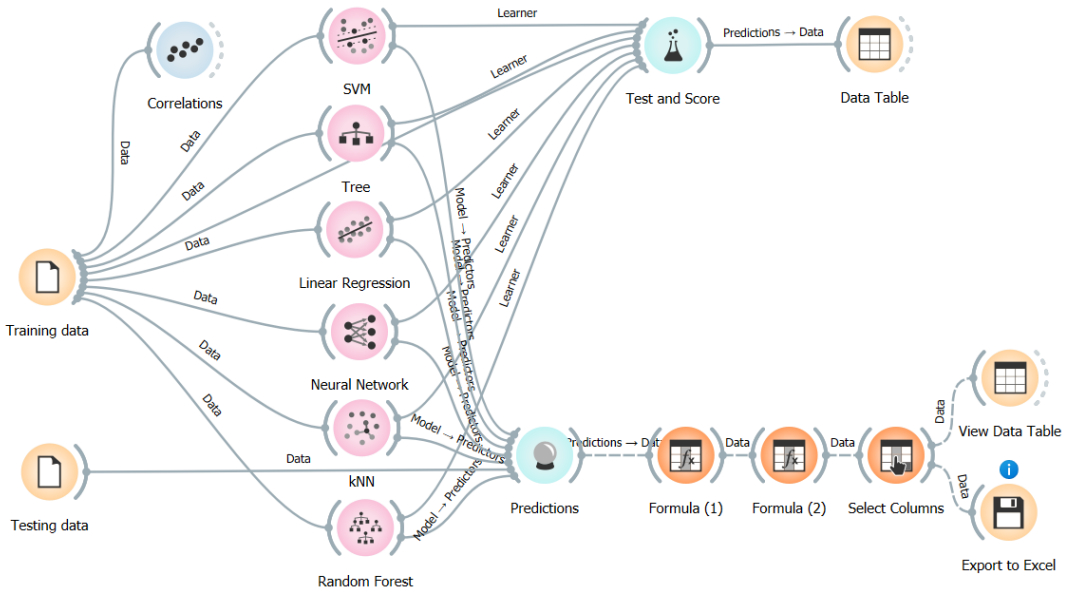

Fig. 4. Implementation of the training and testing methodology in orange data mining.

TABLE I. PARAMETERS OF THE OPTIMAL MODELS

Model	Parameters
Random forest	Number of trees: 6 Number of attributes considered at each split: not checked Replicable training: checked Balance class distribution: not checked Limit depth of individual trees: not checked Do not split subsets smaller than: not checked
K nearest neighbor	Number of neighbors: 5 Metric: Euclidean Weight: Uniform
Artificial neural network	Neurons in hidden layers: 20 Activation: ReLu Solver: L-BFGS-B Regularization, α=0: Maximal number of iterations: 300 Replicable training: checked
Linear regression	Fit intercept: checked Regularization: No regularization
Decision tree	Induce binary tree: not checked Min number of instances in leaves: 12 Do not split subsets smaller than: not checked Limit the maximal tree depth to: not checked Stop when majority reaches: 95%
Support vector machine	SVM type: SVM Cost (C): 1.40 Regression loss epsilon (ε): 0.10 Kernel: Linear Numerical tolerance: 0.0010 Iteration limit: 20 000

The model is validated using 5-fold cross-validation, which means that 20% of the records are randomly chosen for validation and the remaining 80% are used for training. The results from the models' training and validation are summarized in Table II, ordered decreasingly by their R^2 value. The best-performing algorithm is the ANN, RMSE, and MAE, with R^2 respectively 0.995, 18.3, and 7.5.

TABLE II. COMPARISON OF THE MODELS' VALIDATION PERFORMANCE

Model	MSE	RMSE	MAE	R^2
ANN	336	18.3	7.50	0.995
RF	383	19.6	6.94	0.994
kNN	390	19.8	7.31	0.994
DT	411	20.3	7.74	0.994
LR	952	30.9	18.7	0.985
SVM	1041	32.3	15.5	0.984

The order of the next three models is disputable for the following reasons:

- The RF has the second-best R^2 equal to 0.994; however, its MAE (6.94) is the lowest. In other words, if we choose the optimal model based on its MAE then the RF model performs slightly better than the trained ANN.
- The kNN model has the same R^2 as RF, and its MAE (7.31) is also lower than ANN's.
- The DT has the same R^2 as RF and kNN, and almost the same MAE (7.74).

In general ANN, RF, kNN, and DT perform almost equally well in our study. The other two models (LR and SVM) perform slightly worse, though their R^2 values are still impressive – 0.985 and 0.984, respectively. However, their MAE metrics are more than twice as bad (18.7 and 15.5, respectively), which means their forecasts contain more errors. This is also indicated by their RMSE metrics (30.9 and 32.3, respectively), which penalize large errors.

Next, according to the developed methodology, the performance of the models was evaluated for the different feature variants. For each one the corresponding features were selected from the training and testing datasets and the models were retrained and reevaluated with the testing dataset. The results from Variants 1, 2, 3, 4, and 5 are summarized in Table III, Table IV, Table V, Table VI, and Table VII, respectively.

TABLE III. RESULTS FROM THE TESTING OF VARIANT 1 (ONLY SOLAR RADIATION)

Model	MSE	RMSE	MAE	NZMAE	R^2
ANN	567	23.8	10.2	21.2	0.990
DT	638	25.3	10.8	22.6	0.989
kNN	691	26.3	11.3	23.7	0.988
RF	838	29.0	12.6	26.6	0.986
LR	985	31.1	13.8	28.8	0.983
SVM	1021	32.0	13.8	28.9	0.983

TABLE IV. RESULTS FROM THE TESTING OF VARIANT 2 (SOLAR RADIATION AND AMBIENT TEMPERATURE)

Model	MSE	RMSE	MAE	NZMAE	R^2
ANN	323	18.0	6.41	13.4	0.994
kNN	352	18.8	6.72	14.3	0.994
DT	347	18.6	6.83	14.3	0.994
RF	406	20.1	7.15	15.2	0.993
LR	930	30.0	13.5	28.3	0.984
SVM	1022	32.0	13.9	28.9	0.983

TABLE V. RESULTS FROM THE TESTING OF VARIANT 3 (SOLAR RADIATION, AMBIENT TEMPERATURE, AND WINDSPEED)

Model	MSE	RMSE	MAE	NZMAE	R^2
ANN	314	17.7	6.12	12.8	0.995
kNN	358	18.9	6.61	14.1	0.994
DT	355	18.8	6.90	14.5	0.994
RF	383	19.6	6.84	14.5	0.993
LR	930	29.9	13.60	28.4	0.984
SVM	1025	32.0	13.86	28.9	0.983

TABLE VI. RESULTS FROM THE TESTING OF VARIANT 4 (SOLAR RADIATION, AMBIENT TEMPERATURE, WINDSPEED, AND HOUR OF THE DAY)

Model	MSE	RMSE	MAE	MZMAE	R^2
ANN	299	17.3	5.71	11.9	0.995
kNN	357	18.9	6.65	14.2	0.994
DT	358	18.9	6.93	14.6	0.994
RF	372	19.3	6.56	14.1	0.993
LR	930	30.5	13.6	28.4	0.984
SVM	1022	32.0	13.9	28.9	0.983

TABLE VII. RESULTS FROM THE TESTING OF VARIANT 5 (SOLAR RADIATION, AMBIENT TEMPERATURE, WINDSPEED, HOUR OF THE DAY, AND MONTH OF THE YEAR)

Model	MSE	RMSE	MAE	NZMAE	R^2
ANN	335	18.3	6.44	13.4	0.994
kNN	367	19.2	6.65	13.7	0.994
DT	373	19.3	6.93	14.0	0.994
RF	436	20.9	6.56	14.1	0.993
LR	936	30.6	16.2	28.4	0.984
SVM	1023	32.0	14.0	28.9	0.983

If we take a look at the obtained coefficients of determination, several things can be noticed:

- The ANN models have the best performance in all five variants of the input features with R2 ranging between 0.990 and 0.995;
- The RF, kNN and DT models return very close results in all cases with R2 between 0.986 and 0.994;
- The SVM and the LR models have the worst performance in all cases, although it is not significantly worse. They are practically the same in all five variants; i.e., if these algorithms are selected, solar radiation can be used as the only feature.

All models in all variants achieved excellent coefficients of determination, ranging between 0.983 and 0.995. At first glance, the last statement means that there is not any significant difference between the six algorithms. That is why a closer look should be taken at the other metrics. For Variant 1 (Table III) the ANN model achieved an MAE of 10.2 Wh/kWh/h, which means that for the investigated testing period (3394 hours or approximately five months) the expected cumulative error is 34.6 kWh/kWp. However, if only the non-zero records are accounted for, as no error is expected during the dark hours of the day, the NZMAE metric is 21.2 Wh/kWh/h, i.e. approximately twice as high as MAE. For the worst-performing model (SVM) the MAE and NZMAE are 13.8 Wh/kWp/h and 28.0 Wh/kWhp/h, respectively, corresponding to a cumulative error of 46.837 kWh/kWp.

For Variant 2, ANN's MAE and NZMAE reach 6.41 Wh/kWp/h and 13.4 Wh/kWp/h, respectively (i.e., a cumulative error of 21.8 kWh/kWp), and for Variant 3 – 6.12 Wh/kWp/h and 12.8 Wh/kWp/h, respectively (a cumulative error of 20.8 kWh/kWp). The best performance was achieved for Variant 4, where ANN's MAE and NZMAE reached 5.71 Wh/kWp/h and 11.9 Wh/kWp/h (a cumulative error of 19.4 kWh/kWp), while for Variant 5 the score was slightly worse.

If the RMSE metric is analyzed, which adds a penalty to higher errors, once again the optimal value is achieved by the ANN model with Variant 4 – 17.3 Wh/kWp/h and the lowest by the SVM model, which is 32.0 Wh/kWp/h for all five variants.

For a better understanding of the precision of the trained models, the worst-case (Variant 1) and best-case (Variant 4) models are further compared. In Fig. 5 statistics about the total daily absolute error of the models for Variant 1 is presented. The minimal daily errors for the different models vary between 0.6 (SVM) and 4.0 (kNN) Wh/kWp/Day. The maximum daily errors vary between 523 (ANN) and 711 (LR) Wh/kWp/Day. The average daily error is the lowest for DT (169.973 Wh/kWp/Day and the highest for SVM (218.508 Wh/kWp/Day). The cumulative daily error for the investigated period is the lowest for DT (24136 Wh/kWh) and the highest for SVM (31028.2 Wh/kWh).

Similarly, in Fig. 6 the total daily absolute errors for Variant 4 (best-case) are presented. It is interesting to notice that the maximal daily errors are higher in this situation and vary between 596 (kNN) and 767 (RF) Wh/kWp/Day. Nevertheless, the cumulative errors for the investigated period are significantly lower for all algorithms except SVM and LR. The lowest cumulative error was achieved by ANN (10813 Wh/kWp) and the highest again by SVM (31045.4 Wh/kWp). Similarly, the lowest average daily error was achieved by ANN (76.82 Wh/kWp/Day) and the highest again by SVM (218.63 Wh/kWp/Day).

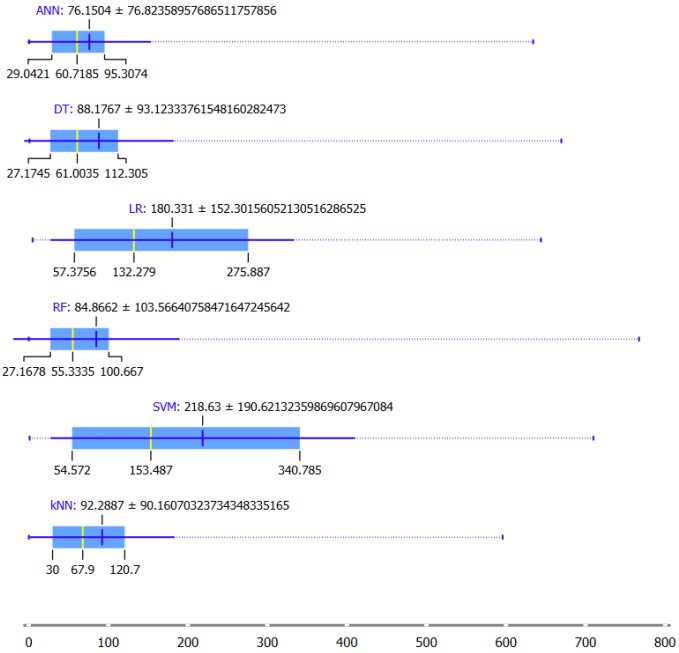

Fig. 5. Cumulative absolute daily errors of the 6 models for Variant 4 of the selected features: dark blue vertical line – mean value; thin blue – standard deviation; yellow line – the median; blue highlighted area – the values between the first and the third quartile.

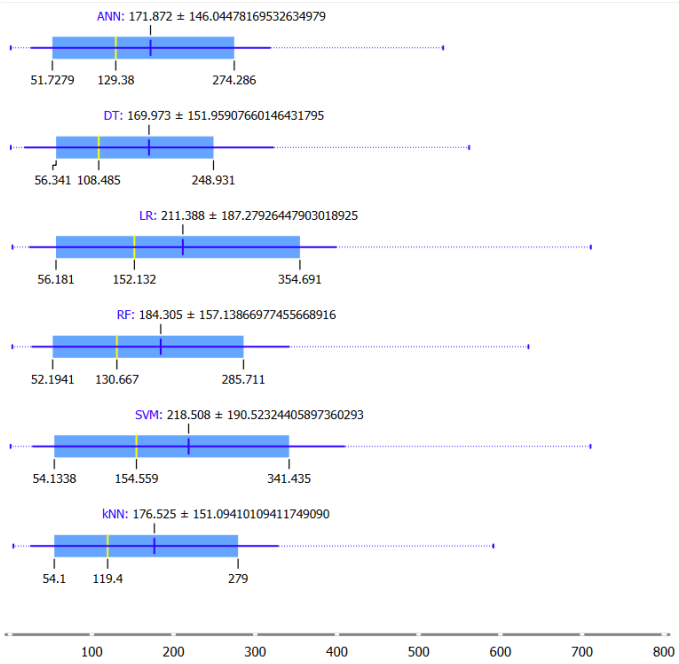

Fig. 6. Cumulative absolute daily errors of the 6 models for Variant 1 of the selected features: dark blue vertical line – mean value; thin blue – standard deviation; yellow line – the median; blue highlighted area – the values between the first and the third quartile.

Furthermore, the following examples of the actual and predicted hourly PV yields with high errors are demonstrated:

- Example 1: Hourly data forecasts of one of the days with the worst cumulative absolute error of the ANN model in Variant 1 (4 August 2022) and the corresponding predictions in Variant 4 (Fig. 7).
- Example 2: Hourly data forecasts of one of the days with the worst cumulative absolute error of the ANN model in Variant 4 (27 November 2022) and the corresponding predictions in Variant 1 (Fig. 8).

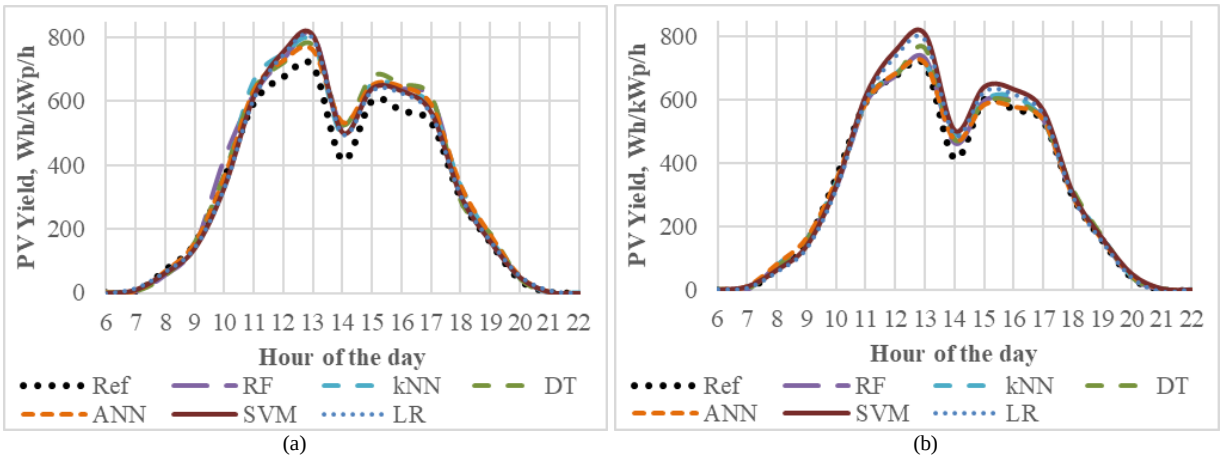

Fig. 7. Sample data from 4 August 2022 for Variant 1 (a) and Variant 4 (b) of the used features.

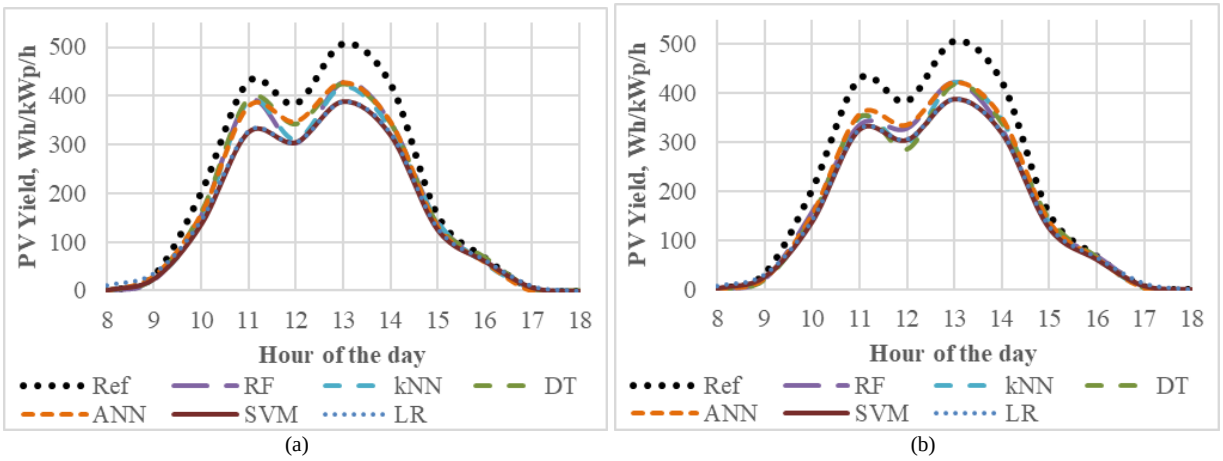

Fig. 8. Sample data from 27 November 2022 for Variant 1 (a) and Variant 4 (b) of the used features.

Both examples show that the higher errors occur mostly on days with varying cloudiness. This behavior is expected, because of the increased errors when estimating the average hourly solar radiation introduced by the period of discretization. Nevertheless, in both situations, the obtained forecasts by the ANN model are slightly better in Variant 4, compared to Variant 1, in which only solar radiation is used as a feature. Other examples are presented in Fig. 9(a) and Fig. 9(b), where the actual and forecasted values from 25 September to 27 September 2022 are shown, representing the models from Variants 1 and Variant 4, respectively. In this case, no significant deviations are observed from the actual values and this refers to both variants of the features used. The maximum absolute difference of the ANN model from the observed values does not surpass 50 Wh/kWp/h for Variant 1 and 36 Wh/kWp/h for Variant 4.

Finally, predicted vs. actual scattered graphs were prepared for all six models with Variant 4 of the selected features, which should provide a clear understanding of their performance. They are presented in Fig. 10, where the models are ordered in the decreasing order of their coefficient of determination.

The following observations could be made:

- One anomaly with all 6 models could be noticed, most likely caused by a maintenance procedure or some technical fault with the PV installation.
- The best performance of the ANN models is also confirmed by the lowest scattering of the predicted vs. actual points [(Fig. 10(a)].
- The kNN [(Fig. 10(b)] and DT [(Fig. 10(c)] models perform almost as well as ANN; however, several points are separated slightly from the main group, which explains their lower score.
- Two of the points of the RF model [(Fig. 10(d)] are significantly separated from the main group. However, if these records are excluded from the testing dataset, the RF model could be a contender for the top spot.
- The performance of the LR [(Fig. 10(e)] and SVM [(Fig. 10(f)] models is significantly worse, and it can be noticed that their predicted vs. actual graph can be better approximated with a polynomial, rather than a straight line.

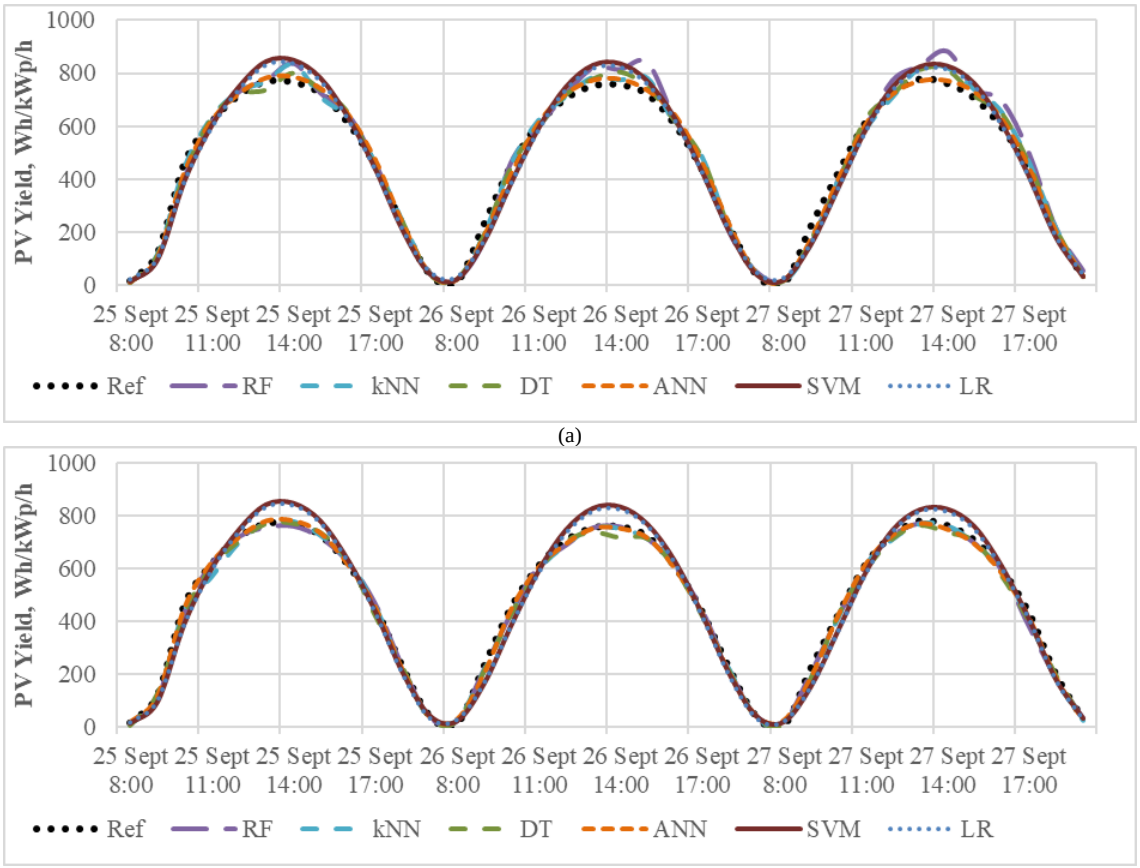

Fig. 9. Sample data from the daylight hours of 25-27 September 2022 for variant 1 (a) and variant 4 (b).

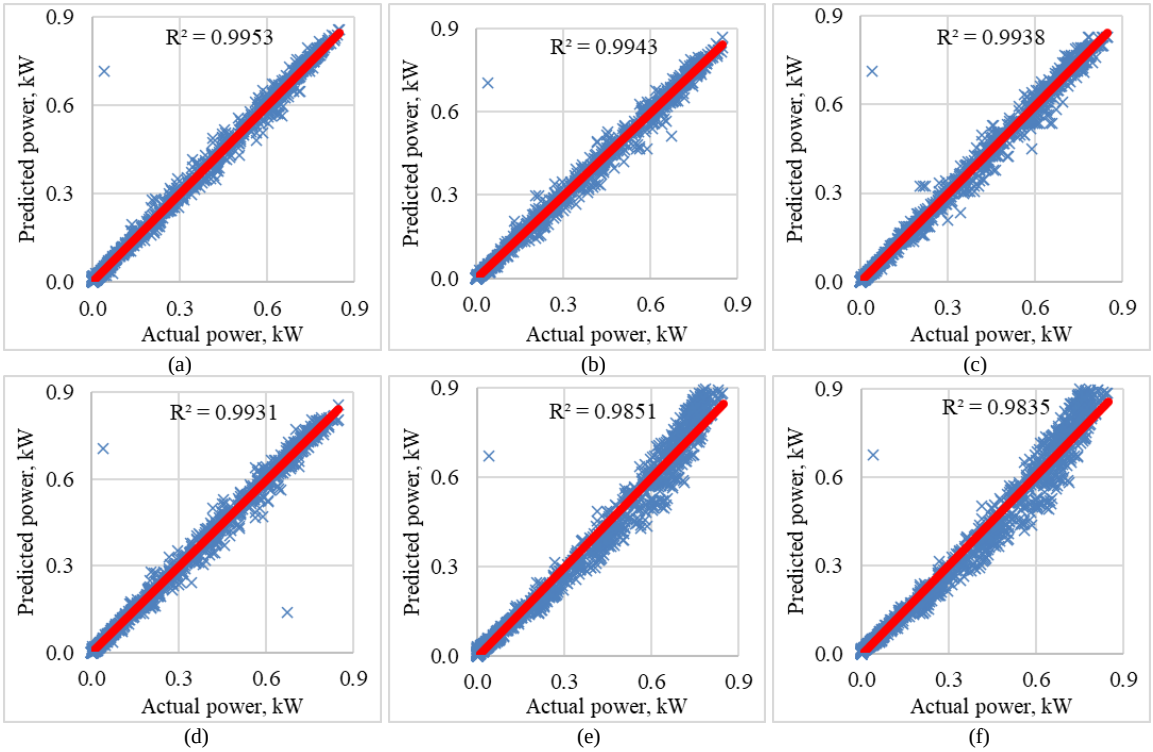

Fig. 10. Comparison between actual and predicted specific yields for the six models with variant 4 of the features: a) ANN; b) kNN; c) DT; d) RF; e) LR; f) SVM.

The performance of the trained models could be compared with that achieved in previous studies. In [32] different machine learning algorithms for forecasting the power of a PV installation were evaluated using eight features. The best-performing model was RF, which achieved an R^2 of 0.95 and an MAE of 68.7 W. Similarly, in study [30] different machine-learning models using ambient temperature and solar irradiance as features were compared. The Fine tree model achieved the highest R^2 and RMSE, 0.959 and 5.83 W, respectively.

If compared with studies relying on deep learning, our results are also ranked very well. In study [35] several meteorological parameters, the day, and time were used as features to predict the PV yield. The multiple LSTM neural network achieved an RMSE of 37.1 Wh and an error rate of 13.2%; however, no MAE and R^2 were reported. Similarly, in [40] solar irradiance, windspeed, ambient temperature, and the Sun height were used as input data to predict the PV power. The optimal model was Facebook Prophet, which achieved an R^2 of 0.93, an MAE of 8.77 W, and an RMSE of 3.28 W.

A significantly different approach was used in study [23], where the previous PV yield was used as input data for ANN models to predict the 1-hour-ahead yield. The optimal model achieved R^2, MAE, and RMSE of 0.89, 13.4 Wh, and 27.5 Wh, respectively. A similar approach in [43], where the 3 days ahead solar radiation was used, led to an MAE of 0.00 kW and a RMSE of 35.4 kW with a MLP ANN; though no info was provided about the coefficient of determination.

In study [50] was used a hybrid machine learning model, combining variational mode decomposition (VMD), whale optimization algorithm (WOA), and long short-term memory neural network (LSTM) to forecast power. The study relied on the ambient temperature, relative humidity, global and diffuse horizontal radiation to achieve an R^2 of 0.997.

The above-mentioned is summarized in Table VIII and allows us to conclude that our results position themselves very well. Out of the papers that provided a coefficient of determination, we achieved the second-best results with an R^2 of more than 99%, and were outperformed only by the hybrid model, proposed in study [50]. Similarly, the MAE we achieved is the lowest, compared to the previous studies; however, in terms of RMSE, our optimal models are ranked 3rd. The last information indicates that the models trained in this study returned several wrongly forecasted values, which differ significantly from the actual ones.

TABLE VIII. COMPARISON OF THE ACHIEVED RESULTS WITH THOSE OF PREVIOUS STUDIES

Article	Regression model	Features	Target	R^2	MAE	RMSE
Alhmoud et al [32]	RF	Irradiation, air temperature, module temperature, day of the week, month number, day type, week number, hour of the day, and year type	PV power in W	0.95	68.7 W	N/A

IV. CONCLUSIONS

The performance of different machine learning algorithms (ANN, kNN, DT, RF, LR, and SVM) for forecasting the yield of a rural photovoltaic installation was evaluated in this study. An almost complete hourly dataset from 2020 and 2021 was used and divided into training/validation and testing datasets. Five combinations of the input features (solar radiation, ambient temperature, wind speed, hour of the day, and month of the year) were evaluated.

During the 5-fold cross-validation step the ANN achieved the highest R^2 (0.995), closely followed by RF, kNN, and DT (0.994). LR and SVM returned a lower coefficient of determination (0.985 and 9.984, respectively), though it is not significantly lower. During the testing stage, the worst results were achieved with solar radiation as the only feature, and the best results with solar radiation, ambient temperature, wind speed, and hour of the day. In all cases, the ANN model had the highest performance in terms of R^2, MAE, RMSE, and NZMAE, though once again it was very closely followed by kNN, DT, and RF.

The obtained results allow us to conclude that when a PV installation is located in a rural or ruruban area, which is characterized by a lack of significant shadings influencing its operation:

- the optimal combination of features for forecasting the output power is solar radiation, ambient temperature, wind speed, and hour of the day;
- the optimal models are ANN, kNN, DT, and RF;
- in case of limited availability of meteorological data, it is acceptable (in terms of forecasting errors) to use solar

radiation and ambient temperature or only solar radiation data as features.

The results obtained in this study could be useful to energy experts and farm owners, who are trying to maximize their profit and added value. However, it should not be forgotten that with such an approach the models also need reliable input data, such as solar radiation, ambient temperature, and wind speed. Therefore, it is also important to investigate the influence of the forecasted feature errors on the precision of the trained models, i.e. if a certain error is added to the meteorological data, what absolute and relative difference will it create. Moreover, in the present paper, we accepted that the PV installation produces only active power, which is not always the case. The presence of reactive consumers in the industry might be a significant problem when PV installations produce only active power and require a thorough investigation. The abovementioned problems were not addressed in this study and are an object for future research.

Edge Computing in Water Management: A KPCA-DeepESN and HOA-Optimized Framework for Urban Resource Allocation

Hanchao Liao[1*], Miyuan Shan[2]
School of Civil Engineering, Changsha, Changsha 410022, Hunan, China[1]
Business School of Hunan University, Changsha 410002, Hunan, China[1, 2]

***Abstract*—This paper presents a novel approach to optimizing urban water resource allocation by integrating Kernel Principal Component Analysis (KPCA) with a Deep Echo State Network (DeepESN), further optimized using the Hiking Optimization Algorithm (HOA). The proposed model addresses the issue of achieving an optimal balance between water supply and demand in urban environments, utilizing advanced machine learning techniques to enhance prediction accuracy and allocation efficiency. KPCA is employed to reduce the dimensionality of key water resource indicators, capturing nonlinear relationships in the dataset. DeepESN, a deep recurrent neural network model, is then applied to predict water consumption trends. HOA, a meta-heuristic algorithm inspired by hiker behavior, is used to fine-tune the DeepESN network parameters, ensuring faster convergence and higher accuracy. The experimental setup includes water resource data from January 2010 to December 2023, divided into training, testing, and validation sets. The model's performance is compared with other approaches, such as PCA-DeepESN and standalone DeepESN. Results show that the KPCA-HOA-DeepESN model achieves the lowest prediction error and fastest convergence, making it a superior solution for urban water management. Optimized network parameters include a reservoir size of 140, a spectral radius of 0.3, an input scaling factor of 0.22, and a reservoir sparsity degree of 0.72. This study demonstrates the applicability of distributed computing techniques in water resource management by utilizing cloud-based data processing and real-time predictions. The proposed approach not only improves resource allocation but also showcases the potential for edge computing to enhance the responsiveness of water management systems.**

Keywords*—KPCA Method; water supply and demand equilibrium; allocation of resources in urban water environment; optimization strategy for hiking; DeepESN

I. INTRODUCTION

Water, being an essential natural resource for the existence of humans, is intricately linked to both social stability and economic progress [1]. The fast expansion of civilization and population increase have resulted in an uneven distribution of water resources and pollution produced by human activities. This has led to a crisis in water resources, which is a pressing problem for every country and industry. In recent years, professionals and academics in the area have paid attention to the evaluation of water resources usage efficiency, recognizing its importance in the best allocation of water resources [2]. Studying objective and accurate approaches for optimizing the allocation of urban water resources may assist the water resources management department in enhancing the efficiency of water resource utilization and improving the precision of water usage solution control [3]. The analysis of water resources encompasses the evaluation of water resource utilization efficiency, the examination of water resource policies and regulations, the creation and implementation of water resource management strategies, the study of variables that influence water resources, and the evaluation of water resource utilization efficiency [4]. The efficient distribution of water resources is a crucial aspect of water resources analysis. The use of water resources is assessed by identifying key areas for review and employing data analysis methods to construct mathematical models that optimize resource distribution.

Presently, the water resource optimal allocation techniques encompass the fuzzy comprehensive assessment method, Tobit regression analysis method, machine learning algorithms, neural networks, deep learning networks, and other approaches [5]. Aghu and Reddy [6] employ an enhanced fuzzy set and fuzzy comprehensive evaluation method to assess and analyze the carrying capacity of water resources. The principal component analysis technique is combined with the particle swarm optimization algorithm, using an improved projection tracing model method, to evaluate the hierarchical water resources carrying capacity [7]. The inefficient use of urban water resources is simulated and analyzed using the least squares method and the Tobit regression model [8]. Lv et al. [9] examine the problem of water resource sustainability through a multi-level fuzzy comprehensive evaluation model and provides relevant water use measures. In literature [10], the random forest algorithm is utilized to predict and analyze water balance and forecast data. Lastly, Mangal et al. [11] introduces a deep echo state network based on a multi-layer self-coder and applies it to the evaluation of urban water resources. While there have been significant achievements in researching the best way to allocate urban water resources both domestically and internationally, there are still certain limitations and flaws in the methodologies used for water resource analysis. Firstly, the analysis method relies on subjective evaluation, which can easily compromise the objectivity of the results. Additionally, relying solely on evaluation or allocation methods can impact the accuracy of the results. Moreover, the optimization model used for water resources allocation in the local area fails to adequately reflect equilibrium and does not contribute to enhancing the overall utilization rate of water resources [12].

This study utilizes the hiking optimization algorithm and deep echo state network to address the issue of optimal allocation of urban water resources, with the aim of analyzing the current research situation. The structure of this paper is:

- Examine the problem by considering water resources analysis and water resources optimization.
- Design the appropriate index parameters and optimize the parameters of the deep echo state network using the hiking optimization algorithm.
- Develop a method for optimizing and allocating urban water resources based on the HOA-DeepESN model.
- Suggested approach is utilized in the examination of data about the allocation of urban water resources.
- Contrasted with alternative models in order to confirm its superiority and correctness.

II. Water Allocation Challenges

A. Examination of Water Resources

Water resources analysis is the application of systems analysis techniques to comprehensively examine the design, planning, management, and challenges related to water resources. Its aim is to develop a scientifically sound and rational program. The analysis of urban water resources typically involves the selection of indicators, processing without dimensions, finding a solution for weighting, calculating a comprehensive score, and analyzing the efficiency of the city's water benchmarking by considering spatial and temporal differences. Additionally, a seven-step analysis is conducted to assess the potential for water conservation, as depicted in Fig. 1.

Regarding indicator selection, this paper opts for four urban water resources analysis indicators: 10,000 RMB GDP water consumption A, 10,000 RMB industrial output value water consumption B, per capita comprehensive water consumption C, and per capita living water consumption D [13], as depicted in Fig. 2.

Furthermore, this study uses Z-score methodology to standardize the analysis indicators for urban water resources. It utilizes principal component analysis to determine the weights of the indicators and develops complete assessment indicators using the weighted average approach.

B. Efficient Distribution of Water Resources

1) Guidelines for efficient distribution of water resources: To achieve the best allocation of water resources, it is recommended to utilize the comprehensive score obtained from analyzing urban water resources as an explanatory variable. Additionally, select the influencing factors of each field at each level as explanatory variables and employ the regression algorithm to construct the water resources allocation model. The water resource optimization allocation process involves many key processes, including indicator selection, correlation analysis, building of an allocation model, and optimization of the allocation model [14]. These steps are illustrated in Fig. 3.

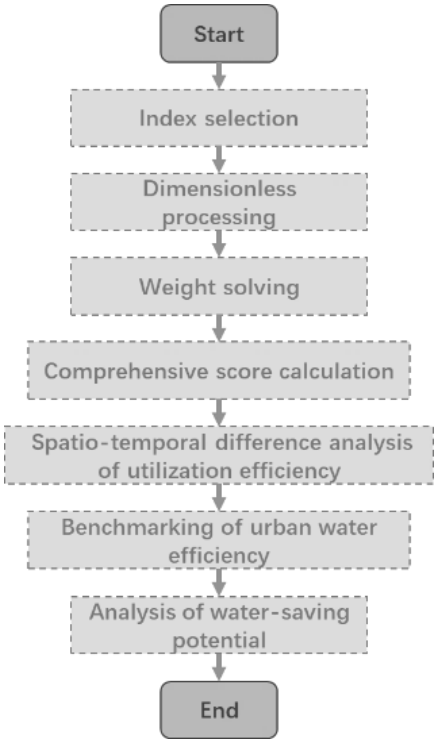

Fig. 1. Sequential process of assessing urban water resources.

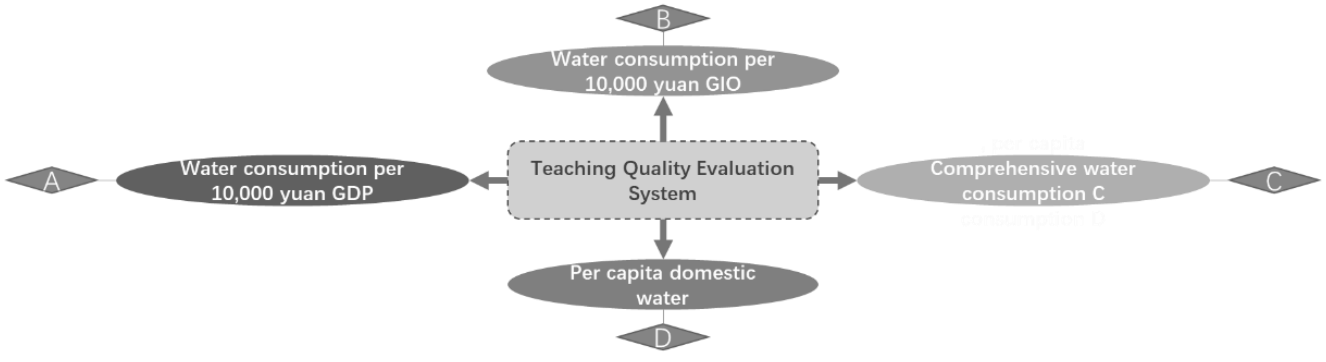

Fig. 2. Indicators used to analyze urban water resources.

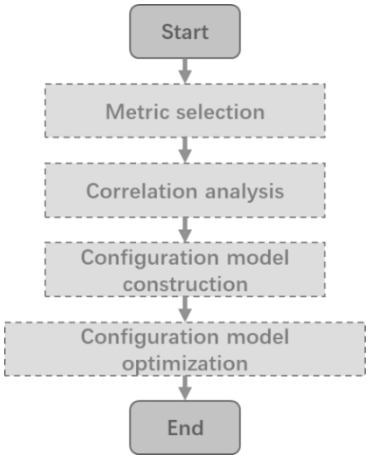

Fig. 3. Steps for optimal allocation of urban water resources.

2) Choosing appropriate indicators for efficient distribution of water resources: Several variables influence the efficiency of water resource consumption, such as natural factors, economic considerations, scientific and technological factors, and the organization of industrial water use. Hence, this article chooses water resource optimization indicators based on four viewpoints: natural factors, economic aspects, scientific and technical considerations, and industrial water usage structure [14]. 1) Natural factors indicators consist of total annual water supply (S1), per capita water possession (S2), and per capita regional gross domestic product (S3). 2) Economic factors indicators include the proportion of the first industry (J1), the proportion of the second industry (J2), and the proportion of the third industry (J3). 3) Scientific and technological factors indicators include the investment cost of wastewater treatment (K1). 4) Industrial investment cost of wastewater management (K1) is also an indicator of scientific and technological factors. 5) Indicators of industrial water use structure include agricultural water use (C1), industrial water use (C2), domestic water use (C3), and ecological water use (C4). Fig. 4 shows selection of indicators for optimal allocation of urban water resources.

3) Optimal allocation modeling of water resources: Water resource optimization and allocation model construction is the use of machine learning algorithms or mathematical agent model analysis training to construct a nonlinear mapping relationship between the water resource optimization and allocation indicators and the comprehensive score of water resource utilization efficiency. In this paper, we propose to use the deep learning algorithm to construct the water resources optimization model, and at the same time, we adopt a meta-heuristic optimization algorithm inspired by the hiker's travel experience to optimize the parameters of the deep learning algorithm to optimize the prediction accuracy of the water resources optimization model, which is shown in Fig. 5.

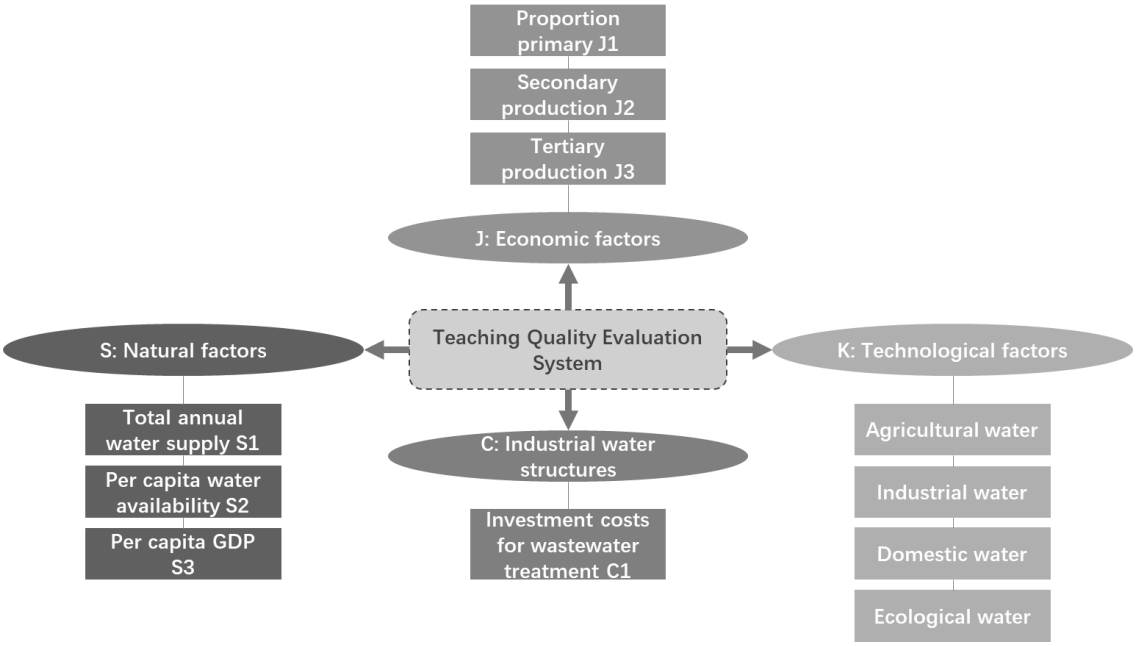

Fig. 4. Selection of indicators for optimal allocation of urban water resources.

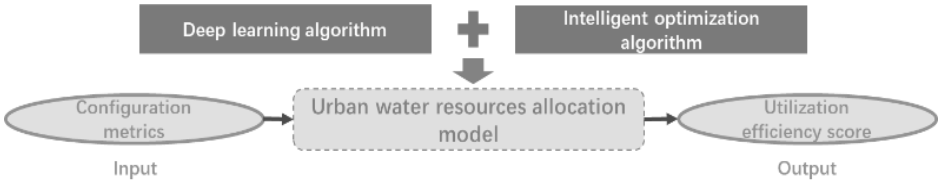

Fig. 5. Model construction of optimal allocation of urban water resources.

III. Risk Assessment Problems

A. Kernel Principal Component Analysis (KPCA)

Kernel Principal Component Analysis (KPCA) [15] is an enhanced version of Principal Component Analysis (PCA) [16] that addresses nonlinear data structures by transforming the data into a feature space with a higher dimensionality. KPCA, unlike classic PCA, does not directly calculate the covariance matrix and eigenvectors in the original data space. Instead, it employs a kernel function to transform the data into a new feature space and then calculates the principal components in this transformed space. Some frequently employed kernel functions include the linear kernel, Gaussian kernel (also known as radial basis function), polynomial kernel, and others. KPCA effectively captures the non-linear characteristics of the data and is particularly useful for datasets that cannot be accurately represented using linear approaches in their original form. Fig. 6 provides a schematic representation of the precise structure.

The fundamental procedures of KPCA are as follows: 1) Choose a suitable kernel function, such as the radial basis function; 2) Calculate the kernel matrix; 3) Center the kernel matrix; 4) Perform eigenvalue decomposition; 5) Normalize the eigenvectors; 6) Select the principal components; 7) Compute the nonlinear principal components; 8) Reconstruct the data.

KPCA is mostly employed in pattern recognition, image processing, bioinformatics, and fault detection, as seen in Fig. 7. It aids researchers in identifying intricate patterns in data, decreasing data dimensionality, and enhancing the efficiency and precision of future analysis.

B. HOA-DeepESN Network

1) Algorithm for optimizing hiking: The Hiking Optimization method (HOA) [17] is a meta-heuristic optimization method that draws inspiration from the act of hiking. Hikers consciously or unconsciously consider the incline of the land when they try to reach the top of mountains, hills, or rocks. This activity is a well-liked recreational pursuit that acknowledges the resemblance between the search landscape of an optimization problem and the rugged terrain that hikers navigate, as depicted in Figure. The number 9. The mathematical model of HOA is based on the Tobler hiking function, which considers the height of the terrain and the distance walked to calculate the walking pace of the hiker (agent). During the optimization phase, the Tobler hiking function (THF) is employed to ascertain the precise whereabouts of the hiker.

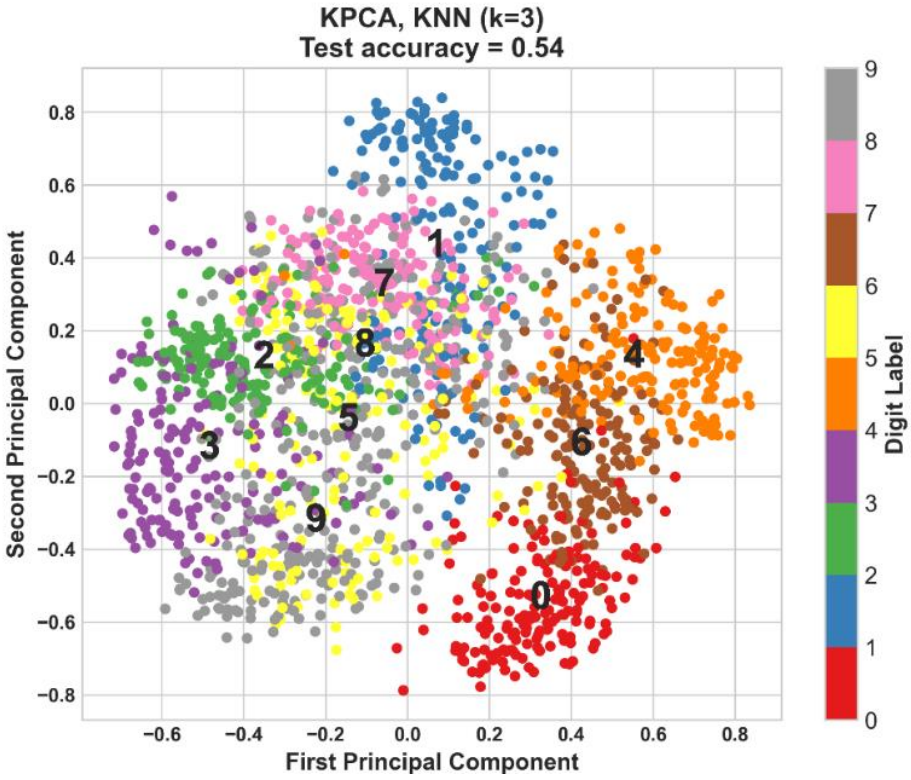

Fig. 6. KPCA structure.

Fig. 7. Types of machine learning algorithms.

a) Principles of Homeowners Association (HOA): The mathematical basis of HOA is derived from the renowned Tobler Hiking Function, initially introduced by Waldo Tobler, a Swiss-American geographer and cartographer. The Tobler Hiking Function is an exponential function that calculates the velocity of a hiker, considering the incline or slope of the terrain or path. The precise mathematical model of the THF is as follows:

$$W_{i,t} = 6e^{-3.5\left|S_{i,t}+0.05\right|} \tag{1}$$

Where, $W_{i,t}$ denotes the speed of hiker i in km/h; and $S_{i,t}$ denotes the slope of the terrain, which is calculated as follows:

$$S_{i,t} = \frac{dh}{dx} = \tan\theta_{i,t} \tag{2}$$

Where, dh is the hiker elevation gradient, dx is the difference in hiker distance, and θ denotes the angle of terrain inclination, typically at [0, 50°].

HOA algorithms hikers as a group for the benefit of social thinking and individual hikers for the benefit of their personal cognitive abilities. The updated or actual speed of a hiker is a function of the initial speed determined by the THF, the position of the leading hiker, the actual position of the hiker, and the sweep factor. Thus, the current speed of hiker i is calculated as follows:

$$W_{i,t} = W_{i,t-1} + \gamma_{i,t} \cdot \left(\beta_{best} - \alpha_{i,t}\beta_{i,t}\right) \tag{3}$$

where $\gamma_{i,t}$ is a uniformly distributed random number; β_{best} is the position of the lead hiker; $\alpha_{i,t}$ is the scan factor SF for hiker i, which lies between 1 and 3; SF ensures that hikers do not stray too far from the lead hiker so that they can see the direction of the lead hiker and receive signals from the lead hiker.

The location update for hiker i is calculated as follows:

$$\beta_{i,t+1} = \beta_{i,t} + W_{i,t} \tag{4}$$

In addition, the HOA algorithm initializes the hiker population as follows:

$$\beta_{i,t+1} = \phi_j^1 + \delta_j\left(\phi_j^2 - \phi_j^1\right) \tag{5}$$

where δ_j is a uniform distribution and ϕ_j^1 and ϕ_j^2 denote the upper and lower bounds of the jth dimension of the optimization problem.

The exploratory and exploitative tendencies of the HOA algorithm are influenced by the SF parameter. When the SF range increases, the HOA algorithm tends to the developmental stage; when SF decreases, the HOA algorithm enters the exploratory stage.

b) Sequential progression of the HOA algorithm: Table I displays the pseudo-code for the hiking optimization method.

TABLE I. HIKING PSEUDO-CODE

	Algorithm 1: Hiking Optimization Algorithm
1	Nout upper and lower limits, Max_iter, Np, d;
2	Intislize hikers' position randomly;
3	Calculate fitnss and output best fitness;
4	For t = 1:Max_iter
5	Determine best fitness of hikers;
6	Determine trail/terrain angle of elevation;
7	Compute the slope;
8	Determine the actual velocity of hiker;
9	Update hiker's position;
10	Bound position using upper and lower limits;
11	Update best hiker position;
12	End
13	Output best solution.

2) DeepESN network: The Deep Echo State Network (DeepESN) [18] is a customized deep recurrent neural network designed for the processing of temporal data. The model is an expansion of the Echo State Network (ESN) [19]. DeepESN is an advanced technique used to create recurrent neural networks that are trained efficiently. It involves combining multiple recurrent layers to create a network that can represent temporal information at different time scales. This makes DeepESN more effective at processing data that changes over time. The precise configuration is illustrated in Fig. 8.

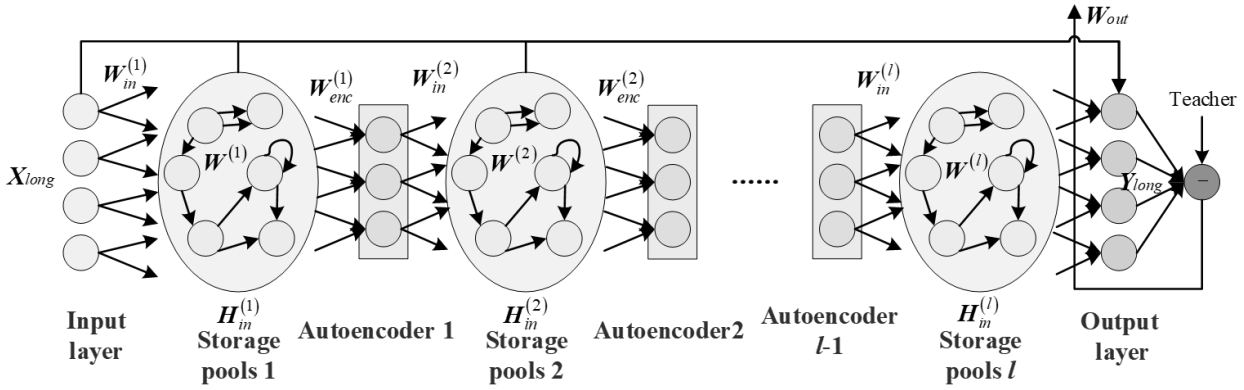

Fig. 8. DeepESN structure.

DeepESN is a variant of Echo State Networks (ESNs) that enhances the depth of the reservoir by employing a self-encoder mapping. In the DeepESN network architecture, the preceding reservoir echo state is compressed to lower dimensions using an Autoencoder (AE). This compressed state is then fed into the subsequent reservoir pool, and the process continues until reaching the last layer. In the final layer, all the echo states are organized and the ultimate result is outputted to the network. The mathematical model is precisely defined as follows:

$$\boldsymbol{H}_{in}^{(l)}(t)=\boldsymbol{W}_{in}^{(l)}\boldsymbol{X}_{in}^{(l)}(t)+\boldsymbol{W}^{(l)}\boldsymbol{H}^{(l)}(t-1) \tag{6}$$

$$\boldsymbol{X}_{in}^{(l)}(t)=\begin{cases}\boldsymbol{X}_{long}(t), l=1\\ f_{enc}\left(\boldsymbol{W}_{enc}^{(l-1)}\boldsymbol{H}^{(l-1)}(t)\right), l>1\end{cases} \tag{7}$$

$$\boldsymbol{H}^{(l)}(t)=\left(1-SD^{(l)}\right)\boldsymbol{H}^{(l)}(t-1)+SD^{(l)}\tanh\left(\boldsymbol{H}_{in}^{(l)}(t)\right) \tag{8}$$

$$\boldsymbol{Y}_{long}(t)=g\left(\boldsymbol{W}_{out}\boldsymbol{H}(t)\right) \tag{9}$$

Where, $\boldsymbol{H}_{in}^{(l)}(t)$ denotes the weighted input data of storage pool in layer *l* at moment *t*, $\boldsymbol{W}_{in}^{(l)}$ denotes the connection weight from input to storage pool in layer *l*, $\boldsymbol{X}_{in}^{(l)}(t)$ denotes the input in layer *l* at moment *t*, $\boldsymbol{W}^{(l)}$ denotes the state feedback weight of storage pool in layer l, $\boldsymbol{H}^{(l)}(t-1)$ denotes the state of storage pool in layer *l* at moment t-1, $\boldsymbol{W}_{enc}^{(l-1)}$ denotes the projection weight of the self-encoder in layer l-1 at moment t, $f_{enc}(\cdot)$ denotes the activation function of the self-encoder, $\boldsymbol{X}_{long}(t)$ denotes the input variable at moment t, $\boldsymbol{H}^{(l)}(t)$ denotes the state value of storage pool in layer l at moment t, and denotes the degree of sparsity of storage pool in layer l at moment t. represents the state value of storage pool in layer *l at* time t, and $SD^{(l)}$ is the sparsity degree of storage pool in layer *l*. The state value of storage pool in layer l at time t is the state value of storage pool in layer l. $\boldsymbol{H}(t)$ The vector formed for the states of all storage pools is denoted as $\left[\boldsymbol{H}^{(1)}(t),\boldsymbol{H}^{(2)}(t),\cdots,\boldsymbol{H}^{(l)}(t)\right]$; $g(\cdot)$ denotes the activation function of the output layer. The DeepESN neural network training process is generally solved by regularized ridge regression.

The core strength of DeepESN is its deep structure, which allows the network to learn features on different time scales. Its cascading structure not only helps to achieve multi-timescale representations, but also improves unsupervised reservoir adaptation and network design. Application scenarios for DeepESN [20-25] include environmentally-assisted living, medical diagnosis, speech and music processing, weather forecasting, energy prediction, transportation forecasting, and financial market forecasting (Fig. 9).

3) DeepESN network model based on hiking optimization algorithm: In order to increase the design effect of the optimal urban water resources allocation scheme, this paper takes the parameters of DeepESN network (storage pool size N_r , spectral radius SR , input scale factor IS , storage pool sparsity SD) as the optimization decision variables, HOA algorithm hiker optimization strategy as the optimization method, and MAPE error value as the fitness function, and the specific process steps are shown in Table II.

C. Application of KPCA and HOA-DeepESN

This study utilizes the KPCA (Kernel Principal Component Analysis) and HOA-DeepESN (Higher Order Autoregressive-Deep Echo State Network) algorithms to identify the main factors affecting urban water resources allocation. The aim is to enhance the effectiveness and precision of water resources optimization and allocation. The specific procedure is illustrated in Fig. 10. The urban water resources optimization allocation method consists of five main components: water resources analysis, extraction of water resources allocation index, principal component analysis of allocation index, preprocessing of allocation index data, and construction of optimal allocation model. These components are based on the KPCA and HOA-DeepESN method.

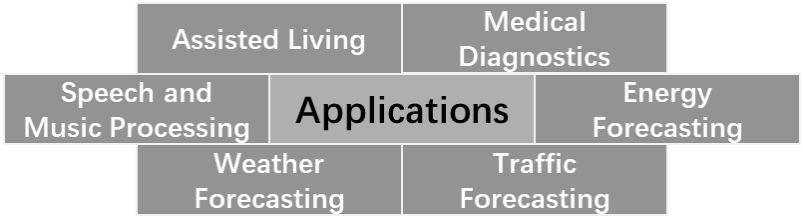

Fig. 9. DeepESN application.

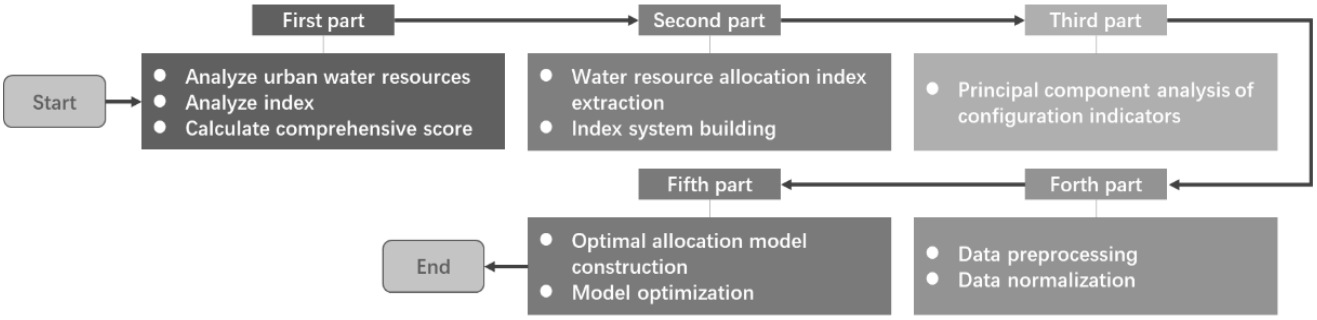

Fig. 10. KPCA with HOA-DeepESN algorithm application.

IV. Case Study

The operating system on which the instance analysis program operates is Windows 10, and the software utilized for the analysis technique is Matlab 2019b. The experiment will utilize the urban water environment resource-related index data from January 2010 to December 2023. The data will be divided into training, test, and validation sets in a ratio of 7:2:1. To analyze the impact of the principal components of the KPCA technique, we will compare the performance of DeepESN, PCA-DeepESN, and KPCA-DeepESN. The specific configurations for these models are described in Table III.

TABLE III. Parameter Settings of the Comparison Algorithm

No.	Algorithms	Descriptions
1	DeepESN	SD=0.7, Nr=100, SR=0.2, IS=0.25, 3layers of AE with 50 nods per layer of AE
2	PCA-DeepESN	PCA technique, 3 layers of AE with 50 nodes in each layer.
3	KPCA-DeepESN	Kernel Principal Component Analysis (KPCA) technique, Radial Basis Function (RBF) was selected, three layers of AE with 50 nodes per layer
4	KPCA-HOA-DeepESN	Kernel Principal Component Analysis (KPCA) technique, Radial Basis Function(RBF) selection, Three layers of AE with 50 nodes per layer, HOA algorithm to optimise DeepESN parameters

This paper aims to validate the effectiveness of the HOA algorithm in enhancing the efficiency of urban water environment resource allocation using the DeepESN network. To achieve this, the SCA, BBO, KMA, and QIO algorithms are employed to optimize the DeepESN network and the HOA algorithm. A comparative analysis of the specific algorithm parameter settings can be found in Table IV. The dimensions of the storage pool, the spectral radius, the input scale factor, and the range of sparsity parameters for the storage pool are displayed in Table V.

TABLE IV. Parameter Settings of Intelligent Optimization Algorithm for Optimizing DeepESN Network

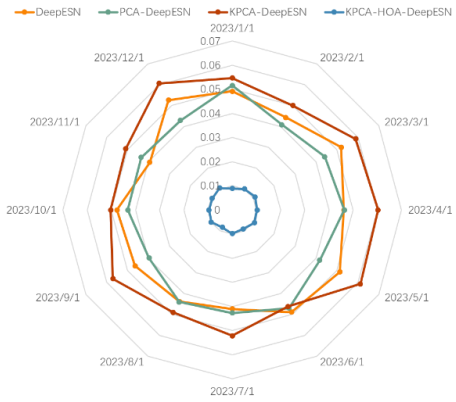
No	Algorithms	Parameter Settings
1	SCA-DeepESN	A reduce linearly 2 to 0
2	BBO-DeepESN	Probability of modifying a habitat is 1
3	KMA-DeepESN	Mlipir rate=0.5, Female mutation rate=0.5, Female mutation radius=0.5
4	QIO-DeepESN	No
5	HOA-DeepESN	Angle of inclination is [0,50], SF=[1,3]

TABLE V. Decision Range Settings for Parameters to be Optimized in the DeepESN Network

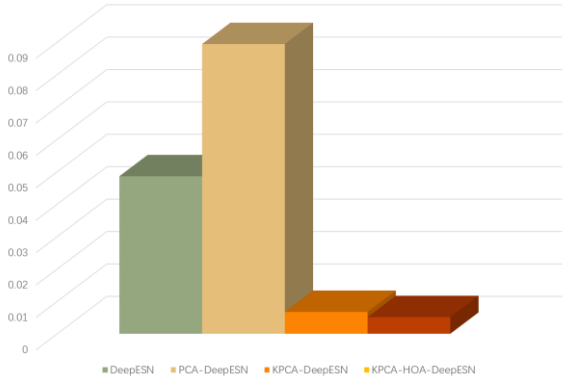
No	Variables	Range Settings
1	Nr	[50,300]
2	SR	[0.4,0.9]
3	IS	[0.1,0.8]
4	SD	[0.1,0.5]

A. Evaluation of the Impact of using the KPCA Approach

This article examines the efficiency of resource allocation in the urban water environment for four models: DeepESN, PCA-DeepESN, KPCA-DeepESN, and KPCA-HOA-DeepESN. The particular connections between these models are illustrated in Fig.11.



(a) Comparison of forecast errors.



(b) Comparison of projected time consumption.

Fig. 11. Comparison of urban water resources prediction error and time-consuming results of different algorithms.

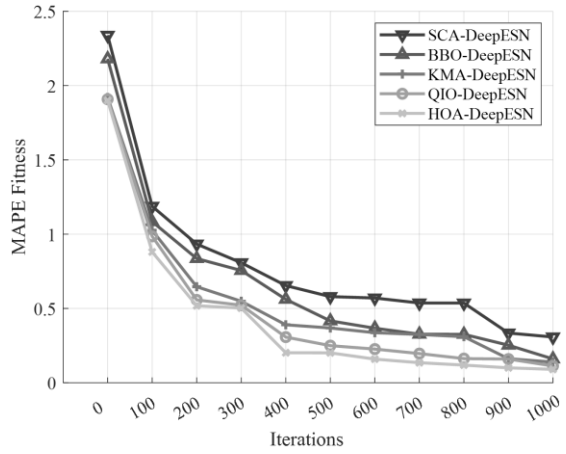
Fig. 11 presents the prediction error and time consumed for urban water allocation for the four algorithms. From Fig. 11, it can be seen that KPCA-HOA-DeepESN has the lowest prediction error among the 12-month prediction errors of the test set; KPCA-DeepESN is compared with PCA-DeepESN, which indicates that the principal component analysis method of KPCA is more effective; and the prediction time consumed by KPCA-HOA- DeepESN is the lowest.

B. Analysis of the Effectiveness of the Water Resources Optimization Model

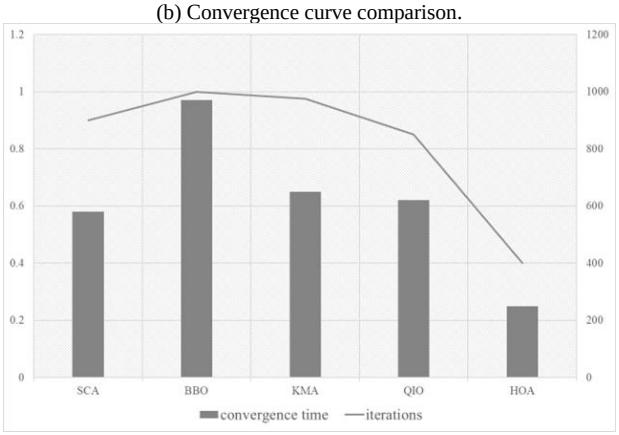
The water resources optimization configuration data is used as input to optimize the DeepESN network parameters using SCA, BBO, KMA, QIO, and HOA algorithms. The optimization results, convergence curves, and speeds are obtained and shown in Fig. 12(a)-(c). According to the Fig. 12, it is evident that the HOA algorithm enhances the optimization of DeepESN network parameters by achieving quicker convergence speed and greater convergence accuracy. The resulting optimized parameters are Nr=140, SR=0.3, IS=0.22, and SD=0.72.

No.	Parameters	SCA-DeepESN	BBO-DeepESN	KMA-DeepESN	QIO-DeepESN	HOA-DeepESN
1	Nr	103	120	145	120	140
2	SR	0.19	0.27	0.33	0.3	0.3
3	IS	0.21	0.26	0.29	0.24	0.22
4	SD	0.79	0.7	0.65	0.7	0.72

(a) Comparison of Optimal DeepESN Network Parameters.



(b) Convergence curve comparison.



(c) Convergence time vs. number of iterations.

Fig. 12. Comparison of optimization results of different algorithms.

V. Conclusion and Future Work

The HOA-DeepESN method, which integrates KPCA and deep learning techniques, effectively addresses the urban water balance resource allocation problem and enhances the efficiency of the allocation model. This paper begins by examining the optimal allocation problem, taking into account the equilibrium between the supply and demand of water resources. We then use the optimal allocation model to establish a method for urban water resources allocation based on the HOA-DeepESN network. The objective function is defined as the minimum of MAPE, and the optimization decision vector consists of the DeepESN network structure parameters. The proposed method is simulated and analyzed using urban water environment resource data from January 2010 to December 2023. The following conclusions are drawn: (1) The use of the KPCA technique improves the model training, testing, and prediction time. (2) Optimizing the parameters of the DeepESN network using the HOA algorithm enhances the prediction accuracy of the optimal allocation model. (3) The optimal values for the storage pool size, spectral radius, input scale factor, and storage pool sparsity are 140, 0.3, 0.22, and 0.72, respectively.

The study also has several limitations: The model is tested on urban water resource data from a specific period and location. Its performance may vary across different regions or under different environmental conditions. The choice of water resource indicators, though based on widely accepted criteria, may not capture all relevant factors, especially in more complex ecosystems.

Based on the above analysis, we look forward to future research directions, which can be started from the following three aspects: 1), Future studies could apply the KPCA-HOA-DeepESN approach to other geographic locations or sectors to validate its generalizability. 2), Integrating real-time data streams, such as satellite observations or sensor data, could further enhance the precision of the model in dynamic environments. 3), exploring other meta-heuristic optimization algorithms or combining HOA with other methods, like genetic algorithms or particle swarm optimization, could lead to even more robust models for resource allocation.

Road Surface Crack Detection Based on Improved YOLOv9 Image Processing

Quanwu Li*, Shaopeng Duan
School of Information Engineering and Artificial Intelligence, Zhengzhou Vocational University of Information and Technology, Zhengzhou 450008, China

***Abstract*—Road surface crack detection is a critical task in road maintenance and safety management. Cracks in road surfaces are often the early indicators of larger structural issues, and if not detected and repaired in time, they can lead to more severe deterioration and increased maintenance costs. Effective and timely crack detection is essential to prolong road lifespan and ensure the safety of road users. This paper introduces CrackNet, an advanced crack detection model built upon the YOLOv9 architecture, which integrates a fusion attention module and task space disentanglement to enhance the accuracy and efficiency of road surface crack detection. Traditional methods often struggle with the complex and irregular nature of road cracks, as well as the challenge of distinguishing cracks from their backgrounds. CrackNet overcomes these challenges by leveraging an attention mechanism that highlights relevant features in both the channel and spatial dimensions while separating the tasks of classification and regression. This approach significantly reduces false negatives and improves localization accuracy. The effectiveness of CrackNet is validated through comparative analysis with other segmentation models, including Unet, SOLO v2, Mask R-CNN, and Deeplab v3+. CrackNet consistently outperforms these models in terms of F1 and Jaccard coefficients. This study highlights the critical role of accurate crack detection in minimizing maintenance costs and enhancing road safety.**

***Keywords*—Road crack; YOLOv9; deep learning; surveillance**

I. Introduction

Road surface damage refers to the occurrence of deterioration, cracks, and potholes in the road surface layer, which are major factors affecting road performance. Therefore, timely and accurate detection of road surface damage is a crucial aspect of road maintenance. Cracks are the initial manifestation of various types of road surface diseases, making the detection and repair of road cracks particularly important [1-3]. Not only do road surface cracks affect the appearance and comfort of driving, but if they are not repaired promptly, they can widen and worsen, leading to structural damage and reducing the overall performance and lifespan of the road. Thus, early detection and timely repair of cracked roads not only reduce the economic cost of road repairs but also ensure the safety of vehicles and drivers on the road. Moreover, with the increasing number of traffic accidents, road safety has become a global challenge. Therefore, the detection and repair of road surface cracks should be prioritized to ensure road safety and longevity [4-6].

Historically, road surface detection and maintenance primarily relied on manual inspection, which was not only time-consuming and labor-intensive but also low in accuracy and fraught with risks. Scholars around the world have utilized the latest scientific and technological advancements to conduct extensive and in-depth studies to accurately and effectively extract crack information from images. In 2014, Wang et al. [7] proposed a crack extraction method based on the valley boundary, employing a series of image processing algorithms to achieve crack detection results. In 2015, Liang et al. [8] introduced a road crack connection algorithm based on Prim's minimum spanning tree, which involves filling cracks to create a structured crack map.

However, these traditional methods of crack detection have obvious disadvantages. Each method is designed for specific databases or scenarios, and the crack detectors fail if there are changes in the dataset or scenario. This highlights a significant gap between conventional methods and current demands in real-world applications, where crack patterns, lighting conditions, and environmental variations pose challenges for traditional models. In particular, many existing models struggle with detecting fine or irregular cracks under diverse conditions, which leads to false positives or missed detections. This gap emphasizes the need for more robust, adaptable models that can address these challenges and ensure accurate detection in real-world settings.

In recent years, deep learning methods have been increasingly applied to road crack detection and segmentation, integrating deep learning techniques with road crack detection technologies, significantly enhancing the efficiency and accuracy of road crack detection. Lee et al. [9] researched a CNN-based road-surface crack detection model that responds to changes in brightness. They discovered that a preprocessing model, which adjusts the image brightness before inputting it into the crack detection model, enhances the consistency of road-surface crack detection, maintaining stable performance under varying brightness conditions.

Hammouch et al. [10] and colleagues studied an automated methodology for crack detection and classification in Moroccan flexible pavements using Convolutional Neural Networks (CNN). They found that good crack detection and classification are achieved on the dataset using both the CNN and a pre-trained Visual Geometry Group 19 (VGG-19) model. However, the accurate identification of road cracks remains a challenging issue due to their high similarity to the background, small size, and irregular shape in real-world scenarios. Enhancing the precision and timeliness of image-based crack extraction has become a focal point of current research. Originally utilized in

*Corresponding Author

the medical field for cell segmentation, YOLO networks handle complex noise interference better than road surface cracks and can extract both high and low-level features from objects. Despite their simplicity and high accuracy in cell segmentation, these networks have limitations in shallow feature extraction layers and the introduction of irrelevant features through the fusion of different feature levels. Consequently, this paper proposes an improved YOLO method for crack detection. During the feature extraction phase, a Fusion Attention Module (FAM) is embedded, which applies non-uniform weighting across channel and spatial dimensions to highlight useful information. Additionally, a Task-Aware Spatial Disentanglement Head (TSDHead) decouples classification and regression tasks, effectively addressing issues of crack misdetection and inaccurate localization, thus ensuring real-time detection while enhancing the accuracy of road crack detection.

At the end of this introduction, the structure of the paper is outlined as follows: Section II provides a detailed explanation of the improved YOLOv9 architecture and the modifications made to enhance crack detection accuracy. Section III describes the experimental setup, including the dataset used and the evaluation metrics employed to assess the model's performance. Section IV presents the results and a comparative analysis with other segmentation models, highlighting the strengths of CrackNet. Finally, Section V concludes the paper with a discussion on the potential applications of the model in real-world road maintenance systems and suggestions for future research directions. This structure is designed to guide readers through the study and provide a clear understanding of the proposed methodology and its practical implications.

II. Improved YOLOv9 Model

In this study, we conducted a comparative analysis of several segmentation models (including Unet, SOLO v2, Mask R-CNN, and Deeplab v3+) in the context of road crack detection tasks. The strengths and weaknesses of each model are summarized as follows:

Unet: The U-shaped architecture of Unet allows it to perform well on smaller datasets and enables end-to-end training, making it suitable for crack detection tasks. However, due to its reliance on a symmetrical encoder-decoder structure, Unet may suffer from over-segmentation or under-segmentation when detecting complex crack patterns, particularly in cases where crack boundaries are unclear.

SOLO v2: As an instance segmentation model, SOLO v2 transforms the segmentation task into a pixel classification problem, eliminating the need for proposal generation. As a result, it can deliver good segmentation results in crack detection, especially in complex background scenarios. However, SOLO v2 still struggles with accurately detecting fine and low-contrast cracks.

Mask R-CNN: Mask R-CNN uses a Region Proposal Network (RPN) to precisely localize crack regions and generate instance masks. This makes it highly accurate for detecting wide cracks. However, it comes with a high computational cost and tends to over-segment or miss finer cracks during detection.

Deeplab v3+: Combining atrous convolution with an encoder-decoder structure, Deeplab v3+ is well-suited for extracting features at large scales and handling crack images with complex backgrounds. However, its ability to recover fine details is limited, resulting in less effective performance when detecting small cracks compared to other models.

In contrast, CrackNet introduces a Fusion Attention Module and Task Space Disentanglement mechanism, which effectively enhances crack feature extraction, reduces false detections, and improves the localization of cracks. This is especially true when handling fine and irregular cracks. Therefore, CrackNet consistently outperforms the aforementioned models in terms of F1 and Jaccard coefficients, demonstrating superior overall performance [11-13].

A. YOLOv9 Model

The YOLO network has undergone multiple iterations to overcome the limitations of previous versions and enhance performance, achieving a good balance between speed and accuracy. The latest version, YOLOv9-Seg, comprises three components: Backbone, Neck, and Head, as illustrated in Fig. 1. The Backbone extracts features from the input image, while the Neck further processes these features and integrates information across different levels. Finally, the Head layer and subsequent post-processing steps generate the classification, location, and pixel segmentation results of detected objects.

The Backbone of YOLOv9-Seg is composed of three key modules: Conv, ADown, and RepNCSPELAN4. The Conv module, a standard component in convolutional neural networks (CNNs), utilizes convolution, batch normalization, and activation functions to extract features from the input image. The ADown module applies pooling operations to downsample the feature matrix. The RepNCSPELAN4 module plays a critical role in the YOLOv9-Seg network by segmenting and merging the feature matrix through layer aggregation, thereby reducing redundant computations and enhancing feature extraction efficiency.

The Neck component consists of a feature pyramid structure that integrates a Feature Pyramid Network (FPN) and a Path Aggregation Network (PAN). Lower-level convolutional features, despite having less semantic information and more noise, offer higher resolution and more detailed location data. On the other hand, higher-level features provide richer semantic information but compromise resolution and detail. FPN combines high-level and low-level features through a top-down upsampling approach, creating feature maps that are rich in semantic information. PAN further enhances the location accuracy across levels by propagating location information from the bottom to the top, strengthening the overall feature pyramid based on FPN.

SPPELAN combines the advantages of Spatial Pyramid Pooling Fast (SPPF) and Efficient Local Aggregation Network (ELAN). SPPF captures spatial information across multiple scales, improving the model's robustness, while ELAN is a lightweight network structure that enhances feature extraction through local aggregation and global integration. The combination of SPPF and ELAN further boosts feature extraction capabilities.

The head network includes three segment detectors, each operating on feature matrices at different scales to locate and

segment target objects, improving detection performance through multi-scale integration. In our implementation, we utilized pre-trained weights on a large dataset for transfer learning. Furthermore, we incorporated Programmable Gradient Information (PGI) and Generalized Efficient Layer Aggregation Network (GELAN) architectures to optimize both the model's performance and efficiency, as shown in Fig. 1.

B. Fusion Attention Module

Drawing from the design concepts of FcaNet (Frequency Channel Attention Networks) and CBAM (Convolutional Block Attention Module), this paper introduces the Fusion Attention Module (FAM). This module comprises a multispectral channel attention module and a spatial attention module, as illustrated in Fig. 2. The multispectral channel attention module, based on the multispectral frequency information of feature maps, adaptively models the importance of each channel, highlighting significant channel features. The spatial attention module focuses on areas within the feature map rich in detail, addressing the loss of some spatial information in the multispectral channel attention module [14, 15]. By chaining these two modules, the design retains both critical channel features and detailed features around the cracks.

1) Multispectral channel attention module: As shown in Fig. 2, the multispectral channel attention module utilizes the Discrete Cosine Transform (DCT) to extract multispectral frequency features from the feature maps. These features are used to model the importance of each channel, and subsequently, different weights are assigned to these channels to implement an attention mechanism along the channel dimensions. This paper employs 2D-DCT technology to transform the feature extraction process for different channels into a feature compression process using multispectral frequency components. Specifically, 2D-DCT maps time-domain signals from the spatial domain to the frequency domain, transforming energy dispersion in the time domain into relatively concentrated energy forms in the frequency domain.

The specific data processing flow of the multispectral channel attention module is as follows:

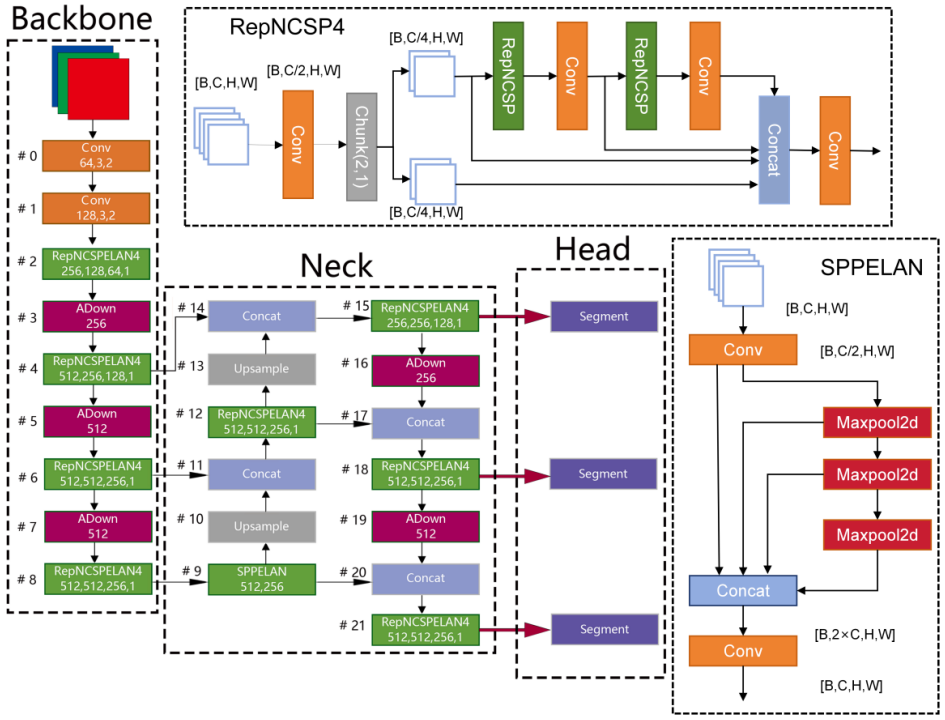

Fig. 1. Architecture of YOLOv9.

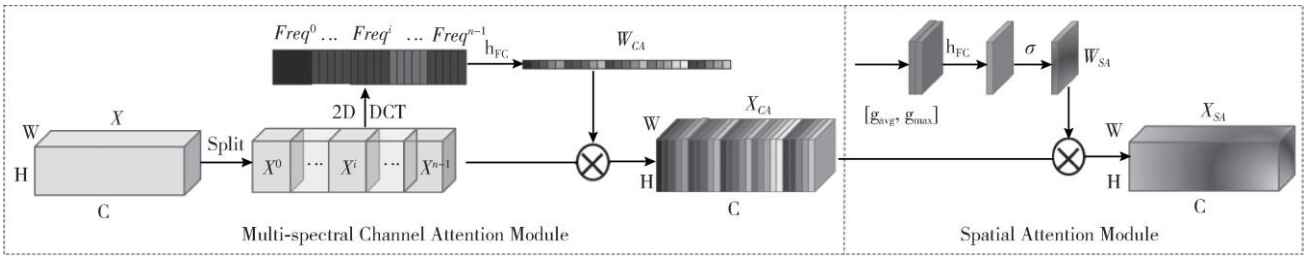

Fig. 2. Structure of the fusion attention module.

Step 1: As shown in Fig. 2, the input feature map $X \in R^{C\times H\times W}$ is split along the channel dimension into n feature map blocks $X^i \in R^{\frac{C}{n}\times H\times W}$.

Step 2: For each feature map block Xi, utilize the two-dimensional Discrete Cosine Transform (2D-DCT) to extract the corresponding multispectral frequency information, obtaining the feature vector $\mathrm{Freq}^i \in R^{\frac{\mathrm{C}}{\mathrm{n}}\times 16}$ as described by Eq. (1) and Eq. (2). Here, H and W represent the height and width of the feature map, respectively, and u, v are the two-dimensional indices for the feature map block Xi.

$$\mathrm{Freq}^i = 2DDCT^{\mathrm{u,v}}\left(X^i\right) = \sum_{h=0}^{\mathrm{H}-1}\sum_{w=0}^{\mathrm{W}-1} X^i_{:,h,w} B^{\mathrm{u,v}}_{h,w} \tag{1}$$

$$\mathrm{B}^{u,v}_{h,w} = \cos\left(\frac{h}{\mathrm{H}}\left(\mathrm{u}+\frac{1}{2}\right)\right)\cos\left(\frac{w}{\mathrm{W}}\left(\mathrm{v}+\frac{1}{2}\right)\right) \tag{2}$$

Step 3: Concatenate the feature vector Freqi along the channel dimension to form the multispectral frequency information Freq∈R C×16. As indicated in Eq. (3), after a fully connected and Sigmoid operation, the channel weight matrix WCA∈R 1×1×C is obtained. This matrix is then multiplied by the input feature map to produce the channel-attention-weighted feature map XCA.

$$W_{CA} = \sigma\left(h_{\mathrm{RC}}(\mathrm{Freq})\right) \tag{3}$$

Eq. (3) where σ represents the Sigmoid function and hRC denotes the fully connected operation.

2) Spatial attention module: As depicted on the right side of Fig. 2, the spatial attention module focuses on the cracks and their surrounding areas within the image based on the input feature map. Specifically, according to Eq. (4), the feature map XCA undergoes both max pooling and average pooling. Subsequently, these pooled features are concatenated along the channel dimension, and a fully connected operation is used to generate the spatial weight matrix WSA ∈ RH×W×1. This matrix is then multiplied by the feature map XCA to produce the output feature map XSA.

$$W_{SA} = \sigma\left(h_{\mathrm{FC}}\left(\left[\mathrm{g}_{\mathrm{avg}}\left(X_{CA}\right), \mathrm{g}_{\mathrm{max}}\left(X_{CA}\right)\right]\right)\right) \tag{4}$$

Eq. (4) where hFC represents the fully connected operation, gavg and gmax denote average pooling and max pooling, respectively, and σ is the Sigmoid function.

C. Task Space

In deep learning, classification tasks focus on capturing the overall information of the target, while regression tasks are more dependent on the edges and finer details of the object. Drawing inspiration from TSD and RetinaNet, this paper introduces a Task-Space Disentanglement Head (TSDHead), which separates the classification and regression tasks during the multi-dimensional prediction phase. This decoupling allows the model to optimize each task independently, without the need to balance between them. The classification branch optimizes weights by following the steepest descent of the classification loss gradient, while the regression branch optimizes in a similar manner for its own specific task.

As shown in Fig. 3, the TSDHead processes the fused feature map to perform classification and regression predictions, and then inputs the results into the Non-Maximum Suppression (NMS) module for further processing. Specifically, the TSDHead comprises both a classification and a regression branch. The classification branch, used for predicting object categories, includes four structurally identical depthwise separable convolutional layers and one category prediction layer. Each depthwise separable convolution layer consists of a depthwise convolution layer (kernel size of 3×3 and the same number of channels as the input feature map) and a pointwise convolution layer (kernel size of 1×1, with 256 channels). The category prediction layer uses a kernel size of 3×3 and a channel count of K×A, where K represents the number of categories (set to 5 in this paper, including four types of cracks and background) and A represents the number of preset anchor boxes per spatial position on the feature map, set to 3. The structure of the regression branch mirrors the classification branch, except that the K in the prediction layer of the regression branch is 4, indicating the offsets for the center position and dimensions of the bounding boxes. After processing through the TSDHead, the feature map yields the crack categories and bounding box coordinates, which are refined by the NMS module to produce the final prediction results.

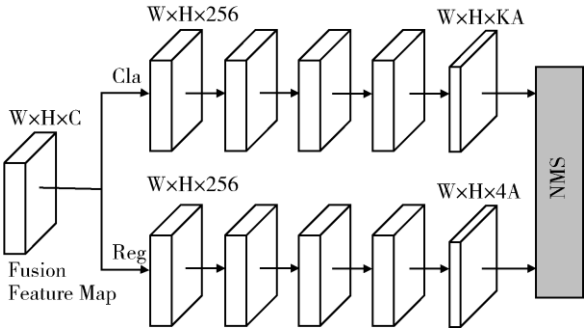

Fig. 3. Structure of the task-space disentanglement head.

1) K-means clustering of crack anchor box sizes: To address the diversity of road crack shapes and extreme aspect ratios, this paper employs the K-means clustering algorithm to cluster the sizes of bounding boxes in a constructed road crack dataset. Following the design philosophy of YOLOv5, the paper clusters large, medium, and small target sizes at three down sampling scales (8x, 16x, and 32x). Each down sampling scale is preset with three anchor boxes, with the clustering results presented in Table I.

TABLE I. CLUSTERING SIZES OF ANCHOR BOXES

	Scale_D32	**Scale_D16**	**Scale_D8**
Anchor_1	23,11	57,40	335,25
Anchor_2	76,8	212,13	115,89
Anchor_3	24,46	46,78	216,86

III. Experiments and Analysis

A Model Training and Testing Trials

1) Experimental data: The research dataset was constructed in two parts. The first part originated from the Crack500 dataset [11], where Yang and colleagues [11] used smart digital devices to capture 500 images of road surface cracks at Temple University with a resolution of 2000×1500, 24-bit RGB, creating the Crack500 dataset for crack detection. To enrich the experimental data, a photographic collection platform was established using smart digital devices to capture an additional 300 images of road surface cracks at a resolution of 1920×1080, 24-bit RGB, forming the second part. The digital devices used were equipped with three cameras, capable of capturing images up to 48 million pixels.

For ease of model training, a total of 800 images from both parts were cropped and filtered to produce 1600 images with a resolution of 320×320, 24-bit RGB. Of these, 1350 images were used as the training and validation set, which was randomly divided in a 9:1 ratio, and 250 images served as the test set. The test set was used solely for testing and did not participate in network training. Each collection was divided into two categories: fine narrow cracks and clearly visible wide cracks. Table I presents the number of each type of crack, and Fig. 4 provides examples of the crack images. The crack images were annotated using the LabelMe tool and further formatted into the VOC dataset structure.

TABLE II. Experimental Data

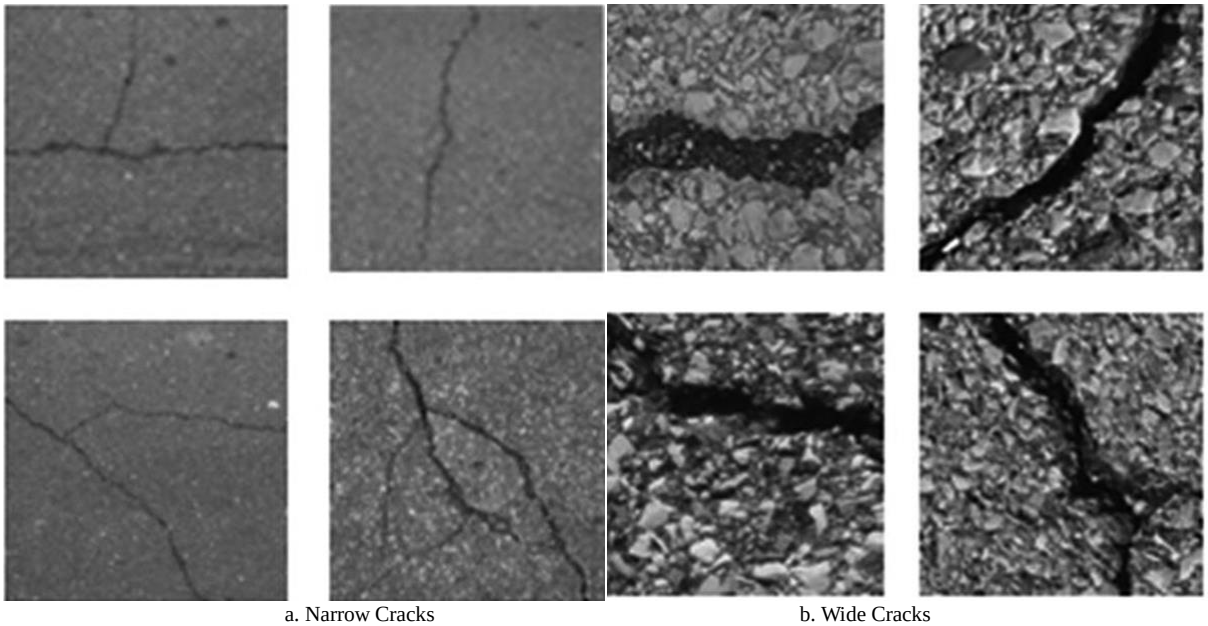
Training	Number of Images	Validation Set	Number of Images
Narrow Cracks	498	Narrow Cracks	91
Wide Cracks	852	Wide Cracks	159

2) Comparison of segmentation network models: This study compares the Improved YOLOv9 with Unet, SOLO v2 [12], Mask R-CNN (Mask Recycle Convolutional Neural Network), and Deeplab v3+ (Deep Convolutional Neural Networks v3 Plus) [13]. SOLO v2 and Mask R-CNN are instance segmentation algorithms, whereas Improved YOLOv9, Unet, and Deeplab v3+ are semantic segmentation models.

a) Unet: This network architecture features a clear U-shaped structure with symmetrical encoding on the left and decoding structures on the right, enhancing the extraction of feature map information. The Unet structure has low dependency on the number of images and can complete end-to-end training with only a small set of images, making it suitable for medical image segmentation.

b) Mask R-CNN: This network builds on the Faster Recycle Convolutional Neural Network (Faster R-CNN), adding a mask branch that runs in parallel with the classification and bounding box regression branches to predict segmentation masks. It employs a top-down, detection-based method that detects regions of each instance first and then segments the instance masks within these areas. Detection-based methods are generally highly accurate and rely on precise bounding box detection, which requires substantial computational resources [14].

c) SOLO v2: Unlike Mask R-CNN, this network transforms the segmentation task into a pixel classification problem, eliminating the need for proposal generation. The network has two branches: a category prediction branch that predicts the semantic category of the target, and a mask branch that predicts the instance mask of the target [15].



a. Narrow Cracks b. Wide Cracks

Fig. 4. Crack image of pavement.

d) Deeplab v3+: This network represents the latest generation of Deeplab models, using Deeplab v3 as the encoding structure and incorporating a decoder to address the loss of fine detail information caused by direct up-sampling of feature maps in Deeplab v3, thereby achieving advanced semantic segmentation performance.

3) Testing trial setup: After training, the models load the optimally saved weights from the training process to predict the test set, which consists of 250 images with a resolution of 320×320, 24-bit RGB. The test hardware platform includes an AMD Ryden 5 3600 CPU and NVIDIA GeForce GTX 2060 GPU, running on Windows 10 with Python version 3.6. Except for Mask R-CNN, which is tested using TensorFlow version 1.13, the other models are tested using PyTorch version 1.4. The test results are RGB three-channel images, which are then binarized and compared with the true images of the test set to compute evaluation metrics.

4) Evaluation metrics: To assess the segmentation performance of Improved YOLOv9 and the comparison models, this study employs the Jaccard coefficient and F1 score as evaluation metrics. Precision and recall are crucial parameters for binary classification problems and are important indicators of model segmentation performance. Calculations for precision and recall are provided in Eq. (5) and Eq. (6).

$$P = \frac{n_{\mathrm{TP}}}{n_{\mathrm{TP}} + n_{\mathrm{FP}}} \tag{5}$$

$$R = \frac{n_{\mathrm{TP}}}{n_{\mathrm{TP}} + n_{\mathrm{FN}}} \tag{6}$$

For a single image, segmenting the crack regions essentially means performing binary classification for each pixel, where nTP (true positives) represents pixels correctly identified as cracks, nFP (false positives) represents non-crack pixels predicted as cracks, nFN (false negatives) represents crack pixels predicted as non-cracks, and nTN (true negatives) represents non-crack pixels correctly identified as non-cracks.

A higher precision indicates a larger number of correctly identified crack pixels among those predicted as cracks by the model. Relying solely on either precision or recall to evaluate model performance is not advisable. For example, if all pixels in a test image are predicted as cracks, the recall would be 1, but the precision might be low.

Therefore, the harmonic mean of precision and recall, known as the F1 score, is used to measure model performance. The F1 score reflects the similarity between the predicted crack pixel set and the true crack pixel set. The F1 score ranges from 0 to 1, with higher values indicating better crack segmentation effectiveness. The calculation is shown in Eq. (7).

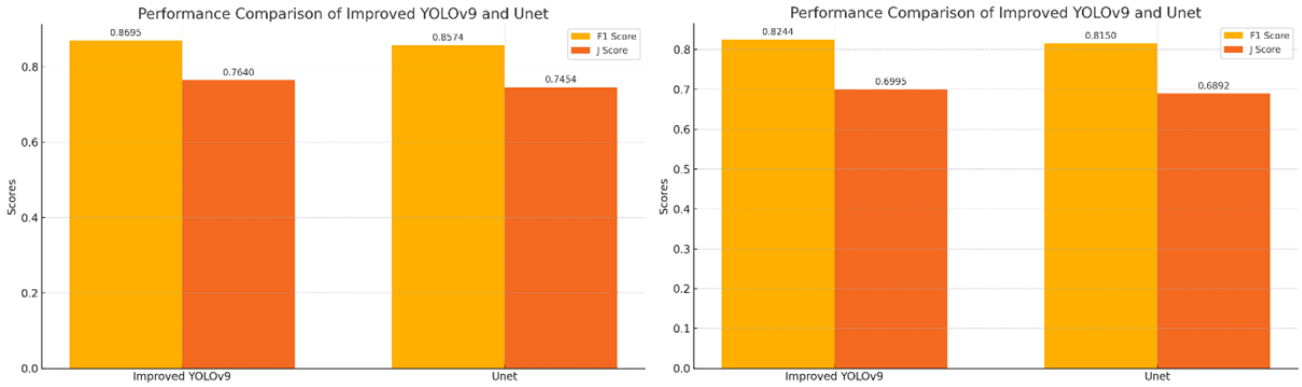
$$F_1 = \frac{2PR}{P + R} \tag{7}$$

The Jaccard coefficient measures the similarity between the predicted crack region and the actual crack region. It is calculated as the percentage of the intersection of the predicted and actual regions relative to the union of these regions. The value of the Jaccard coefficient ranges from 0 to 1, with higher values indicating a greater overlap between the predicted and actual areas, meaning that the predicted crack regions more closely match the actual regions. The calculation of the Jaccard coefficient is shown in Eq. (8).

$$J = \frac{n_{TP}}{n_{TP} + n_{FP} + n_{FN}} \tag{8}$$

B Experimental Results

1) Comparison of evaluation metrics between improved YOLOv9 and Unet models: This study first analyzes the enhancements made in Improved YOLOv9. The road surface crack test dataset includes two types of images: (1) fine narrow cracks with low contrast and narrow width, and (2) clear images of wider cracks. The F1 and Jaccard coefficients for Improved YOLOv9 and Unet under these two categories are shown in Fig. 5. As seen from Fig. 5, the metrics for Improved YOLOv9 are higher than those for Unet in both types of cracks, indicating that Improved YOLOv9 performs better in segmenting both narrow and wide cracks. Specifically, the F1 and Jaccard coefficients for narrow cracks are 4% to 6% lower than those for wide cracks, suggesting that crack width impacts the segmentation performance of the models.



a. Wide cracks b. Narrow cracks

Fig. 5. F1 and Jaccard coefficients of YOLOv9 and Unet.

Fig. 6 and Fig. 7 show the real and predicted segmentation results for narrow and wide cracks using Improved YOLOv9 and Unet models. The first column is the original image, the second column is the ground truth, and the third and fourth columns are the predictions from Unet and Improved YOLOv9, respectively, with white areas representing the crack regions.

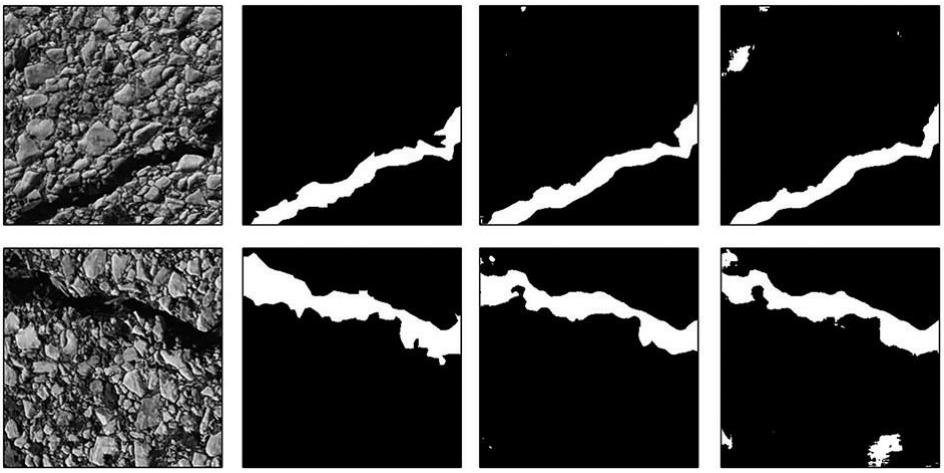


Fig. 6. Long and narrow crack segmentation result.

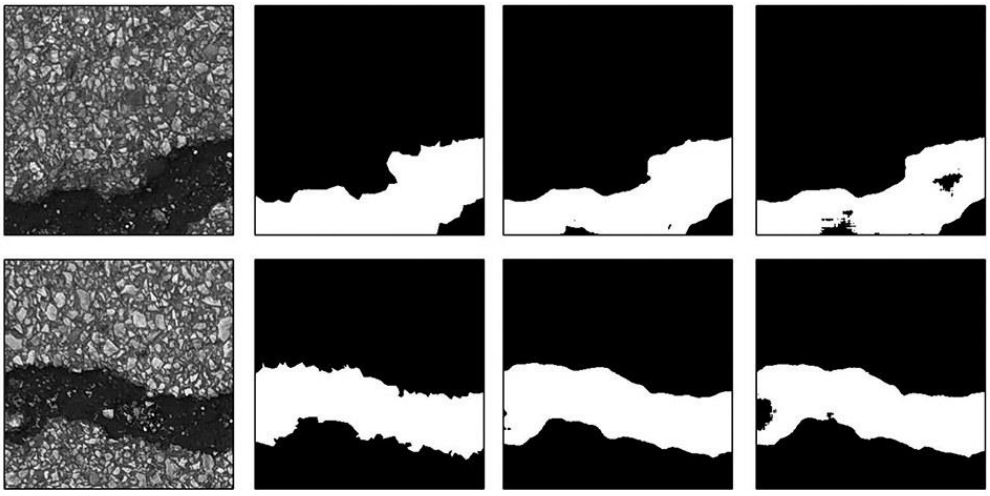

Fig. 7. Non-narrow crack segmentation result.

From the Figures, it is evident that Unet suffers from issues of over-segmentation and under-segmentation, particularly severe over-segmentation for narrow cracks (as shown in column 3 of Fig. 7) and under-segmentation for wide cracks (column 3 of Fig. 8). Compared to Unet, the Improved YOLOv9 proposed in this paper demonstrates better segmentation performance, with enhancements in feature extraction and the application of crack attention units contributing to more accurate crack image segmentation.

2) Real-time analysis of improved YOLOv9 and comparative models: This section of the study focuses on analyzing both the real-time performance and computational costs of the Improved YOLOv9 model compared to other segmentation models (Unet, SOLO v2, Mask R-CNN, and Deeplab v3+). The key metrics evaluated include single-frame image inference times, model complexity, and the balance between speed and accuracy.

As illustrated in Fig. 8, the inference time comparison shows that Improved YOLOv9 has a slightly longer inference time per frame (0.089 seconds) compared to Unet (0.084 seconds), but it offers significantly higher segmentation accuracy. This indicates that Improved YOLOv9 strikes an effective balance between speed and precision, which is essential for tasks requiring both real-time performance and high reliability, such as crack detection in road surfaces.

Other comparative models, such as SOLO v2 and Mask R-CNN, have considerably longer inference times (0.130 and 0.162 seconds per frame, respectively), making them less suitable for real-time applications where quick response is crucial. These models, while offering strong segmentation capabilities, suffer from higher computational costs and slower processing times, which could be a disadvantage in large-scale, real-time crack detection tasks.

Deeplab v3+ performs more closely to Improved YOLOv9, with an inference time of 0.093 seconds per frame. While this

model is competitive in terms of speed, it does not match the segmentation accuracy of Improved YOLOv9, especially in detecting fine and irregular cracks. Thus, for applications requiring both high accuracy and efficient real-time performance, Improved YOLOv9 proves to be the more optimal choice.

In terms of model complexity, the architectural advancements in Improved YOLOv9, such as the Fusion Attention Module and Task Space Disentanglement, contribute to its slight increase in computational cost compared to Unet. However, these enhancements also lead to more accurate feature extraction and better localization, particularly in complex road conditions. As a result, the minimal trade-off in processing time is justified by the superior detection performance in real-world applications.

This analysis highlights the strengths and weaknesses of each model regarding both real-time performance and computational efficiency. While Improved YOLOv9 may have a slightly higher computational cost compared to Unet, its improved accuracy and relatively low inference time make it the best choice for practical road maintenance operations where detection quality and speed are both critical. In contrast, models such as SOLO v2 and Mask R-CNN, despite their strong segmentation capabilities, exhibit slower processing times, making them less suitable for real-time deployments in large-scale applications.

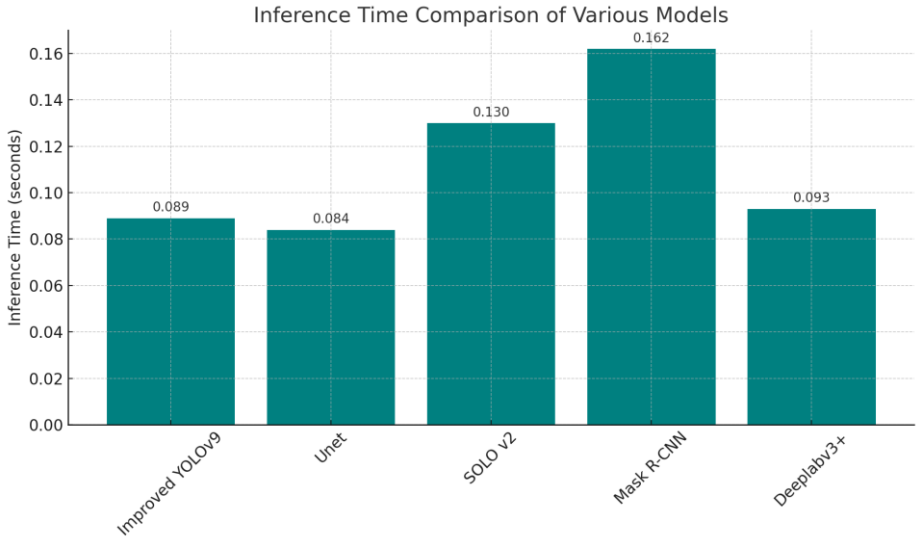

Fig. 8. Inference time of different models.

3) F1 and Jaccard indices of improved YOLOv9 and comparative models: In order to evaluate the segmentation performance of the Improved YOLOv9 model in detail, this research compares its results against those of Unet, SOLO v2, Mask R-CNN, and Deeplab v3+ on a test set consisting of 250 images. These images include two distinct types of cracks, providing a diverse basis for assessment. The average F1 and Jaccard coefficients obtained from the testing are graphically represented in Fig. 9.

The analysis of the results demonstrates that Mask R-CNN and Deeplab v3+ score significantly lower on both F1 and Jaccard indices compared to Improved YOLOv9 and Unet. This lower performance highlights the challenges these models face in accurately segmenting fine and narrow cracks, as well as broad and distinct cracks, under the testing conditions. Specifically, the metrics for Improved YOLOv9 are slightly higher than those for Unet, marking it as the superior model among the four evaluated. With F1 and Jaccard coefficients of 0.8403 and 0.7221, respectively, Improved YOLOv9 demonstrates the highest performance in terms of set evaluation metrics, indicating its enhanced capability in image segmentation and crack detection accuracy across diverse road surfaces.

These findings underscore the effectiveness of Improved YOLOv9 in handling varying crack types and conditions, potentially leading to more reliable and robust road maintenance and safety protocols. The integration of advanced feature extraction and attention mechanisms within Improved YOLOv9 likely contributes to its elevated performance, suggesting avenues for future enhancements in similar segmentation models.

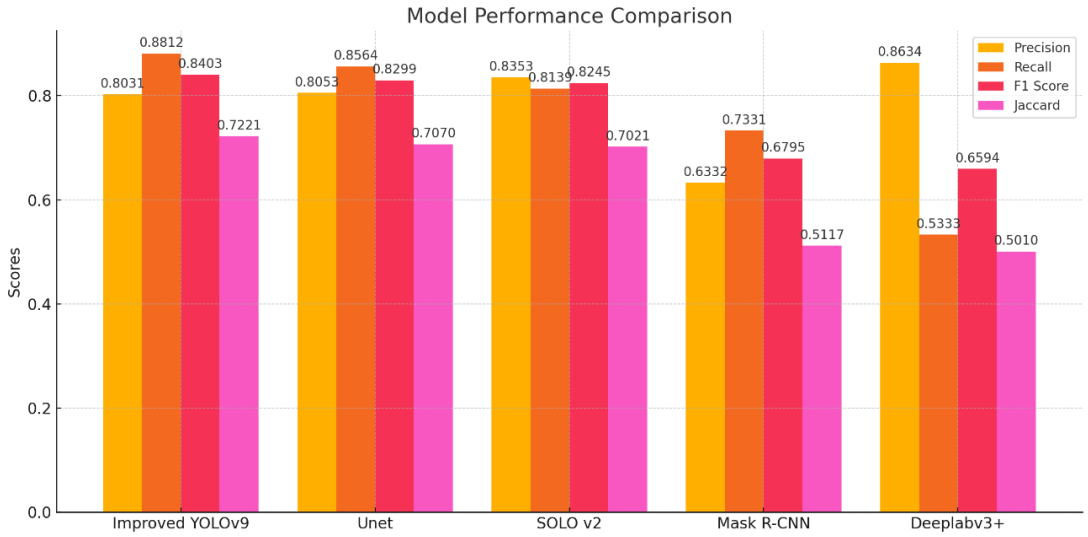

Fig. 9. F1 and Jaccard coefficients of different models.

4) Segmentation results on test data of improved YOLOv9 and comparative models: This study further analyzes the segmentation capabilities of the four models using the road surface crack test set. Three images of wide cracks with significant differences between the crack and the background were randomly selected from the test set for comparative analysis of predictions from the four models, as shown in Fig. 10. The segmentation results and evaluation metrics are consistent, with the Deeplab v3+ model performing poorly in actual segmentation, exhibiting issues such as excessive segmentation area and discontinuity. This indicates that Deeplab v3+ struggles with accurate crack image segmentation under conditions of limited image quantity. SOLO v2 and Mask R-CNN perform better than Deeplab v3+ but still show noticeable issues with crack misdetection. Improved YOLOv9 and Unet perform well in crack detection, with Improved YOLOv9 showing more precise crack segmentation, fewer misdetections, and better continuity.

To further investigate the performance of each model in segmenting fine narrow cracks with low contrast and narrow width, several such cracks were selected for comparison. Fig. 11 displays the segmentation results under conditions of narrow crack width and low contrast, where Mask R-CNN shows imprecise edge detection and misdetection issues (from left to right: original image, ground truth, Improved YOLOv9, Unet, SPLOv2, Mask R-CNN, Deeplabv3+). Deeplab v3+ not only has misdetection issues but also incorrectly identifies non-crack areas as cracks, particularly in cases of narrow longitudinal cracks, where misdetection is especially evident. Unet generally performs better than Mask R-CNN and Deeplabv3+ but also shows some misdetection. Improved YOLOv9, under conditions of narrow and low-contrast cracks, still clearly segments crack edges without misdetection or false detection, achieving the best segmentation results.

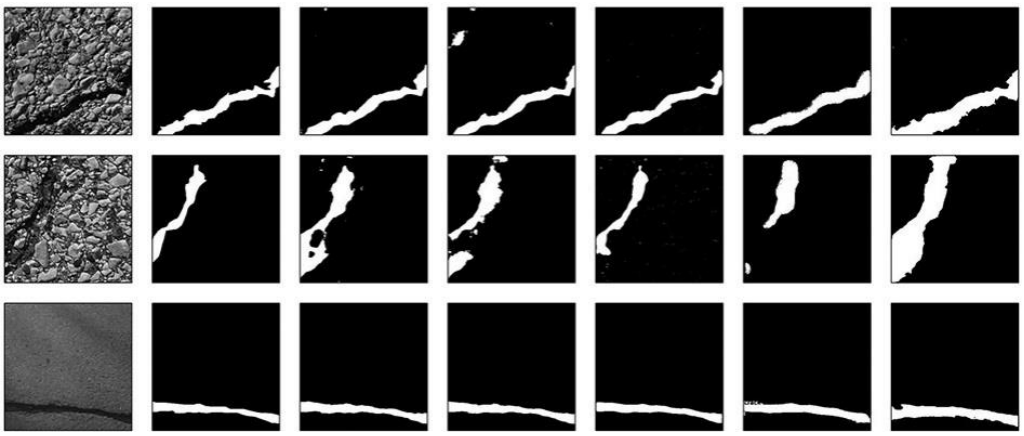

Fig. 10. Test results of pavement cracks under multiple models.

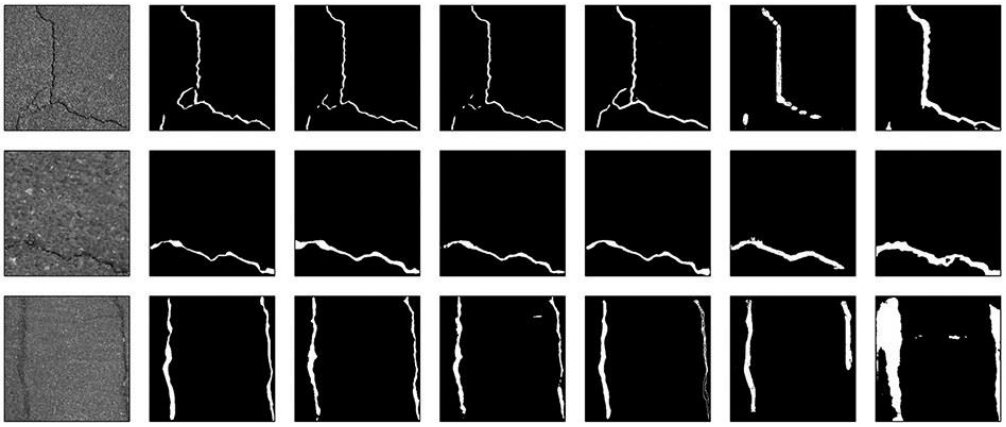

Fig. 11. Segmentation results of multiple models in the case of narrow crack width and low contrast.

IV. Discussion

To ensure the applicability of CrackNet in real-world road maintenance systems, deployment optimizations such as model pruning and quantization can be considered in the future.

Model Pruning: By removing less important connections or neurons, pruning can significantly reduce the model size and inference time without sacrificing much accuracy. This is particularly useful for deployment on mobile or edge devices with limited computational resources. Pruning can make CrackNet more efficient and suitable for resource-constrained platforms (such as drones or vehicle-mounted systems), enabling real-time crack detection in large-scale road inspections.

Quantization: Another potential optimization is model quantization, which converts high-precision weights (e.g., 32-bit floats) into lower precision (e.g., 8-bit integers). Quantization helps reduce the model size and speeds up inference, allowing faster computations while maintaining acceptable accuracy. This will make CrackNet more suitable for deployment in embedded systems and mobile devices, where memory and energy efficiency are critical.

V. Conclusion

Addressing the issues of imprecise edge segmentation and slow detection speed in traditional crack detection algorithms, this paper proposes a road crack detection method based on improved YOLOv9. By suppressing useless features extracted during high-low order feature fusion and enhancing the model's ability to extract crack features, the method achieves segmentation of both narrow and wide crack images.

F1 score and Jaccard coefficient are selected as evaluation metrics. A comparison between improved YOLOv9 and the basic Unet model in segmenting narrow and wide cracks demonstrates the superiority of the proposed method over the basic Unet algorithm, both quantitatively and qualitatively.

The real-time performance of the model is evaluated based on the inference time of a single-frame image. While the improved YOLOv9 outperforms Unet in segmentation performance, its inference speed is 0.089 seconds per frame, only 0.005 seconds slower than Unet, striking a balance between real-time performance and segmentation accuracy.

Further comparisons are made with three other classic segmentation networks. The results show that the evaluation metrics of the improved YOLOv9, with an F1 score of 0.8403 and a Jaccard coefficient of 0.7221, surpass those of classic segmentation models such as SOLO v2, Mask R-CNN, and Deeplabv3+. Compared to other models, the improved YOLOv9 achieves the highest evaluation metrics and the best segmentation performance, effectively extracting road cracks.

While the proposed model's segmentation performance on subtle narrow cracks is inferior to that on clear wide cracks, it does not account for the interference caused by different lighting conditions at different times. Future research will focus on adjusting the network structure to improve the segmentation performance on subtle narrow cracks and preprocessing images using image enhancement algorithms to eliminate the influence of lighting conditions, enabling high-precision crack detection under various lighting conditions. The proposed CrackNet model has significant potential for real-world applications in road maintenance systems. Its ability to accurately detect cracks in road surfaces, including fine and irregular cracks, positions it as a valuable tool for improving the efficiency and precision of road maintenance operations. By incorporating the CrackNet model into automated inspection systems, road maintenance departments can significantly reduce the time and labor costs associated with manual inspections, while ensuring more timely repairs, which are critical for preventing further road deterioration. Moreover, the model's real-time detection capability allows for continuous monitoring of road conditions, enhancing the safety of drivers and reducing the risks of accidents caused by undetected surface damage.

DBN-GRU Fusion and Decomposition-Optimisation-Reconstruction Algorithm in Advertising Traffic Prediction

Ronghua Zhang
College of Media and Design, Xi'an Peihua University, Xi'an 710125, Shaanxi, China

***Abstract*—As the premise and foundation of advertisement traffic selling and distribution, effective IPTV advertisement traffic prediction not only reduces the operation cost, but also improves the intelligent level of new media advertisement traffic management. In order to further improve the accuracy of new media advertisement traffic prediction, this paper proposes a new media advertisement traffic prediction method based on the hybrid prediction framework of decomposition-optimisation-integration, which is a hybrid model of gated recurrent unit neural network and deep confidence network improved by capsule swarm optimisation algorithm. Firstly, according to the principle of system construction, paper analyses the influencing factors and construct a complete new media advertisement traffic prediction index system; secondly, paper improves the optimisation process of the parameters of the deep confidence network and the gated recurrent unit network by using the quilt group optimisation algorithm, and put forward a new media advertisement traffic prediction method based on the decomposition-optimisation-integration framework; Finally, the proposed method is analysed using new media advertisement traffic data. The results show that the proposed method improves the accuracy of the prediction model and solves the problem of large prediction error in new media advertisement traffic prediction methods.**

Keywords*—New media advertising traffic prediction; kernel principal component analysis; variational modal decomposition; quilt group algorithm; deep learning; decomposition-optimisation-reconstruction algorithm

I. INTRODUCTION

With the development of Internet technology, network-based IPTV (Internet Protocol Television) [1] enters people's vision and life, ware using the programme resources provided by the broadcasting network, and adopting the broadband communication network with higher data transmission rate, wider coverage, and better operation condition as the basic network facilities [2].The introduction of IPTV makes people enjoy the personalised, interactive and customisable audiovisual services [3]. IPTV service adopts the model of cooperation between broadcasters and telecommunication, the user data is not peer-to-peer sharing, and the user behaviour data cannot be accurately managed, which leads to the increase in the cost of bidding and targeting advertisement, the decrease in the efficiency, and the lack of obvious effect [4]. Effective IPTV advertisement traffic prediction, as the premise and foundation of advertisement traffic selling and distribution, not only reduces the operation cost, but also improves the intelligent level of new media advertisement traffic management [5]. Currently, new media advertising traffic prediction using time series prediction model [6], from the time series smoothness, linearity or not, the prediction method is divided into Autoregressive integrated moving average model (ARIMA) [7], BP neural network model [8], support vector machine [9], fuzzy theory [10], Elman recurrent neural network [11] and other methods. The study in [12] used ARIMA model to construct the energy demand forecasting problem in Turkey, and analysed the mapping relationship between energy influencing factors and energy demand; study in [13] analysed the multivariate data structure characteristics, combined with neural networks, and carried out the forecasting analysis of power energy consumption; literature [14] constructed the risk function based on the empirical error and the canonical term, and used SVM algorithm to construct the stock price index for the prediction; study in [15] combines K-means clustering algorithm and fuzzy neural network to construct the market sales trend prediction model; study in [16] uses Elman neural network and SVM algorithm to construct the cat catch quantity prediction model. In response to the analysis of the above literature, the existing new media advertising traffic prediction method indicator system selection lacks objectivity and the prediction accuracy is not high [17-19]. The factors affecting advertisement traffic prediction include not only statistical variables, but also time series data. In order to improve the accuracy of advertising traffic prediction, this paper adopts different prediction models for different variables. The single prediction model and simple combination prediction model can no longer adapt to the significant volatility and nonlinearity of advertising traffic data, and the prediction accuracy requirements are increasing, the hybrid prediction model based on Decomposition-optimization-ensemble (DOE) [20] is applied to the new media advertising traffic prediction problem. The study in [21] combines EMD, LSTM and SVR to solve the prediction problem; study in [22] uses complementary integration of empirical modal decomposition, singular spectrum analysis, and ELM to construct a time series prediction model. Deep learning, as a prediction method based on intelligent algorithms, has been widely used in all kinds of prediction problems, and the prediction effect is relatively excellent. With the advertisement traffic fluctuation showing randomness and non-stationarity, the advertisement traffic prediction faces the influence of complex and variable factors, and a single deep learning model can no longer meet the requirements of advertisement traffic prediction.

In order to further improve the new media advertisement traffic prediction accuracy, this paper adopts the hybrid

prediction framework of decomposition-optimisation-integration.

- Analyse the influencing factors of the new media advertisement traffic prediction model and construct the input vector of new media advertisement traffic prediction;
- Decompose the original new media advertisement traffic data using the variational modal decomposition algorithm to obtain more detailed information features of the new media advertisement traffic sequence;
- Improve the GRU and DBN network by combining with the quilt swarm algorithm, and at the same time, put forward a new media advertisement traffic prediction method based on the quilt optimization algorithm improving the DBN-GRU hybrid model for new media advertisement traffic prediction;
- The new media advertisement traffic data verifies that this paper's method has higher prediction accuracy.

II. Analysis of the Problem of Predicting Advertising Traffic in New Media

In order to construct an objective, scientific and reasonable system of influencing factors for new media advertising traffic prediction, this section analyses the influencing factors and constructs a completely new media advertising traffic prediction index system according to the principle of system construction.

Scientific, objective and comprehensive new media advertising traffic prediction influencing factors system construction index selection should be in line with the following principles [23]: 1) independent and comprehensive; 2) operable; 3) temporal; 4) comparable. Influence factors can be compared not only in the time dimension, but also vertically over a number of cycles. The principles of impact factor selection are shown in Fig. 1.

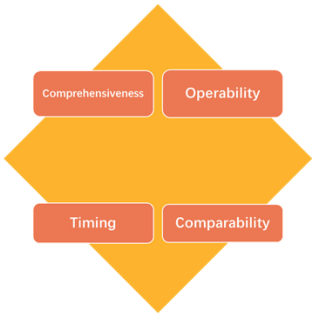

Fig. 1. Schematic diagram of the principle analysis.

According to the principled analysis of the selection of influencing variables for new media advertisement traffic prediction, the factors affecting the prediction should include the following dependent variables [24]: 1) daily click peak X1; 2) daily click peak X2; 3) platform code X3, the value of X3 is 1 means that the platform code is Inmobi, 2 means Zplay, 3 means Baidu, and 4 means Iflytek; 4) bidding reserve price X4; 5) Full insertion screen advert X5, the value of X5 is 0 for No and 1 for Yes; 6) Ad placement location information X6; 7) Ad provider X7; 8) Peak click time X8, Table I.

TABLE I. Influencing Variables of New Media Advertisement Flow

No.	Descriptions	Variables
1	The highest peak of daily clicks	X1
2	The lowest peak of daily clicks	X2
3	The platform code	X3
4	The reserve price of the auction	X4
5	Full interstitial ads	X5
6	The location information of the ad	X6
7	The value of the advertising provider	X7
8	The peak time of the click	X8

The new media advertisement traffic prediction impact variable system takes the key elements such as daily click peak X1, daily click minimum peak X2, platform code X3, bidding reserve price X4, full insertion screen advertisement X5, advertisement placement location information X6, advertisement provider X7, click peak time X8 as indicators, which fully embodies the whole elements of new media advertisement traffic prediction, and builds a scientific, objective, comprehensive and reasonable new media advertising traffic prediction impact vector system.

III. Related Technologies

A. KPCA

In order to extract the indicators with high contribution of the influence variables of new media advertisement traffic prediction, this paper adopts the Kernel Principal Component Analysis (KPCA) [25] method for feature extraction and dimensionality reduction of the influence variables. The principle of KPCA is shown in Fig. 2.

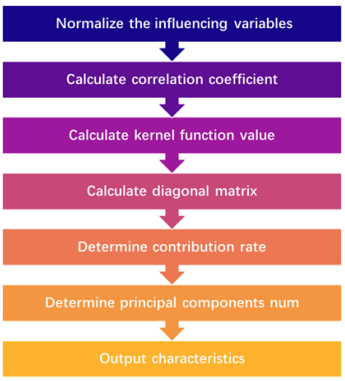

Fig. 2. The principle of kernel principal component analysis.

B. VMD

In order to better find the regularity of the time series of new media advertising traffic, this paper adopts the variational modal decomposition method to preprocess the predicted time series.

The main process of Variational mode decomposition (VMD) [26] is as follows:

1) Decompose $f(t)$ into k modal components with centre frequency and finite bandwidth, so that each mode satisfies the relevant conditions;

2) Obtain the optimal solution by obtaining the extreme points, update each modal component u_k with centre frequency ω_k;

3) Update λ with the value; 4) Judge whether the iteration stop condition is satisfied. satisfy the iteration stop condition. Repeat steps 2)-4) until the following iteration conditions are satisfied:

$$\frac{\sum_k \left\| \hat{u}_k^{n+1} - \hat{u}_k^n \right\|_2^2}{\left\| \hat{u}_k^n \right\|_2^2} < \varepsilon \tag{1}$$

In Eq. (1), $\varepsilon > 0$ is the determination accuracy.

C. Encapsulated Swarm Algorithm

Tunicate Swarm Algorithm (TSA) [27] is an intelligent swarm algorithm proposed to simulate the foraging behaviour of marine tunicate swarms, whose foraging process includes jet propulsion and swarm behaviour. The jet propulsion behaviour avoids conflicts between searching individuals and moves towards the optimal individual by means of the individual's own gravity, seawater current dynamics, and the interaction force between groups. The group determines the location of its companions through neural sensing of the current changes around itself and the light source of its companions, and gathers towards the food location to achieve group foraging (see Fig. 3).

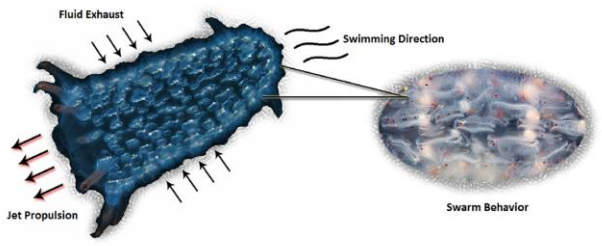

Fig. 3. Foraging behaviour of the periphyton

1) Jet propulsion: The quilt of the quilt swarm algorithm needs to avoid conflicts between individuals during jet propulsion. To avoid conflicts, new individuals are represented as follows:

$$A = \frac{G}{M} \tag{2}$$

In Eq. (2), G denotes the individual pendant force of the vesicle and M denotes the interaction force between the vesicle individuals, the calculation formula is as follows:

$$M = P_{\min} + c \cdot \left(P_{\max} - P_{\min} \right) \tag{3}$$

In Eq. (3), $P_{\max}, P_{\min}$ refers to the maximum and minimum values of the initial interaction velocity of individuals, respectively, which are usually set to $P_{\max} = 4, P_{\min} = 1$, and c is a random number.

After avoiding conflicts, the individual completes the search direction calculation using the distance between the optimal position and the current individual:

$$PD_i^t = \left| x_{best}^t - rand \cdot x_i^t \right| \tag{4}$$

In Eq. (4), x_{best}^t denotes the optimal individual, x_i^t denotes the current individual position, and $rand$ denotes a uniformly distributed random number.

Combining the distance between the optimal position and the current individual as well as the conflict avoidance strategy, the optimal individual drive-in formula for each vesicle individual term is as follows Eq. (5):

$$x_i^t = \begin{cases} x_{best}^t + A \cdot PD_i^t & rand \geq 0.5 \\ x_{best}^t - A \cdot PD_i^t & rand < 0.5 \end{cases} \tag{5}$$

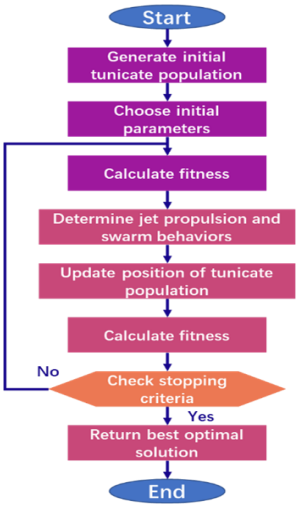

Fig. 4. Flowchart of TSA algorithm.

2) Group behaviour: The model for calculating the group behaviour of the quilt group is as follows:

$$x_i^{t+1} = \frac{x_i^t + x_i^{t-1}}{2 + c} \tag{6}$$

In Eq. (6), x_i^{t-1} denotes the updated position of the previous generation of vesicles relative to the most available individual, and c denotes a random value between 0 and 1.

3) TSA algorithm process and steps: According to the principle of TSA algorithm, the flowchart is shown in Fig. 4. During each iteration of the TSA algorithm, the location information of the encapsulated group is continuously evaluated and selected by the evaluation and selection strategy to obtain the final optimal solution.

This paper analyses the iterative optimization process of the TSA algorithm (see Fig. 5). From Fig. 5, the number of iterations increases and the population gradually converges to a centralised position.

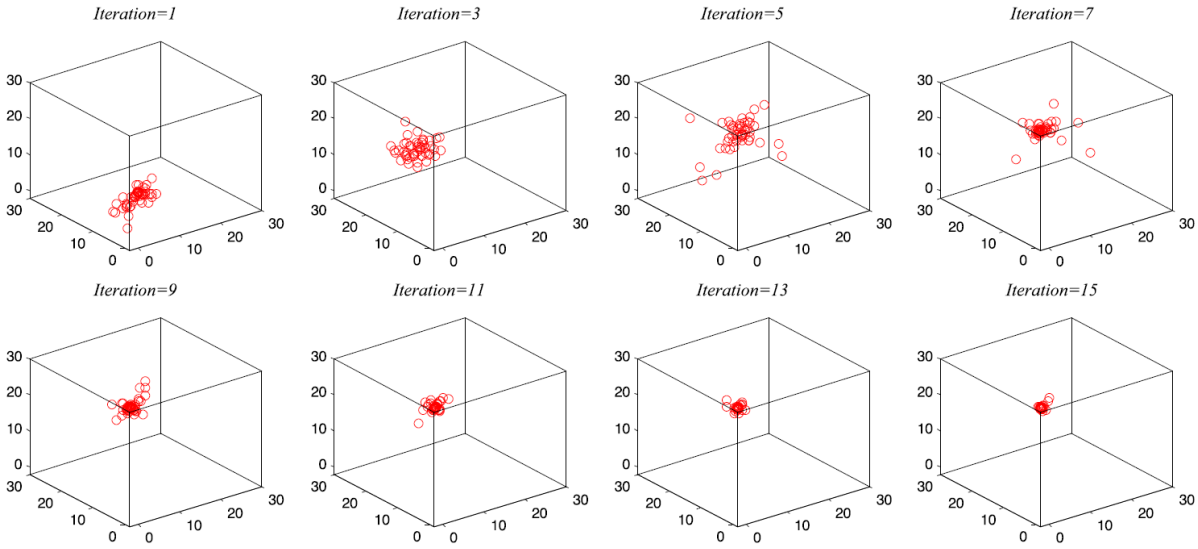

Fig. 5. Iterative optimisation process of the TSA algorithm.

D. Deep Confidence Networks

In order to analyse the mapping relationship between the influence variables of new media advertisement traffic prediction and the predicted value of traffic, this paper adopts deep confidence network as the prediction model construction algorithm, which solves the problem of constructing the model of influence variables and predicted value of traffic.

Deep Belief Networks (DBN) [28] consists of multiple layers of Restricted Boltzmann Machines (RBM), and the specific structure is shown in Fig. 6. The input layers v and h^1 constitute the first layer of Restricted Boltzmann Machines, and the input data is mapped through the activation function h_1, which is input to the second layer of Restricted Boltzmann Machines, and passes to reach the output layer in turn.

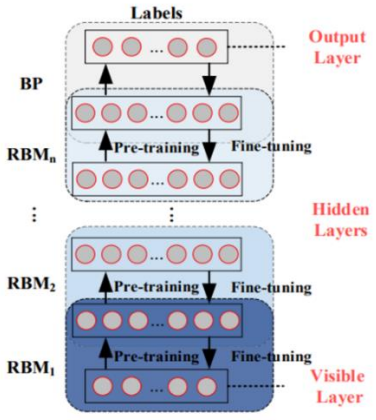

Fig. 6. Structure of deep confidence network.

1) Assuming that $\theta=(\omega,a,b)$ is a DBN network parameter, the energy function of RBM is expressed as:

$$E(v,h|\theta)=-\sum_{i=1}^{n}a_i v_i-\sum_{j=1}^{m}b_j h_j-\sum_{i=1}^{n}\sum_{j=1}^{m}v_i\omega_{ij}h_j \tag{7}$$

In Eq. (7) (v,h) is the state value, ω is the connection weight, and a and b are the biases.

2) Solve for θ^* by solving for the maximum value of the log-likelihood function:

$$\theta^*=\arg_\theta\max L(\theta)=\arg_\theta\max\sum_{k=1}^{K}\ln p\left(v^k|\theta\right) \tag{8}$$

In Eq. (8) *K* is the number of training samples.

3) Calculate the joint probability distribution function, Eq. (8) and Eq. (9):

$$p(v,h|\theta)=\frac{e^{-E(v,h|\theta)}}{Z(\theta)} \tag{9}$$

$$Z(\theta)=\sum_{v}\sum_{h}e^{-E(v,h|\theta)} \tag{10}$$

4) Calculate the activation probability of hidden layer nodes to determine the visible layer state, Eq. (11):

$$p\left(h_j=1|v,\theta\right)=sigmoid\left(b_j+\sum_{i=1}^{n}v_i\omega_{ij}\right) \tag{11}$$

5) Calculate the activation probability of the visual layer node as Eq. (12)

$$p\left(v_i=1|h,\theta\right)=sigmoid\left(a_i+\sum_{i=1}^{n}h_j\omega_{ij}\right) \tag{12}$$

(6) Update the RBM parameter θ, Eq. (13) to Eq. (15):

$$\Delta\omega_{ij}=\frac{\partial\log p(v)}{\partial\omega_{ij}}=\varepsilon\left(\left\langle v_i h_j\right\rangle_{data}-\left\langle v_i h_j\right\rangle_{predict}\right) \tag{13}$$

$$\Delta a_i = \frac{\partial \log p(v)}{\partial a_i} = \varepsilon\left(\langle v_i \rangle_{data} - \langle v_i \rangle_{predict}\right) \tag{14}$$

$$\Delta b_j = \frac{\partial \log p(v)}{\partial b_j} = \varepsilon\left(\langle h_j \rangle_{data} - \langle h_j \rangle_{predict}\right) \tag{15}$$

where ε denotes the learning rate, $\langle \square \rangle_{data}$ is the expectation of training after input data, and $\langle \square \rangle_{predict}$ is the expectation of the model itself.

E. Neural Network of Gated Recurrent Units

Compared with LSTM and RNN, GRU has a simple structure with fewer parameters and uses update gates and reset gates to control the network [29], and the structure is shown schematically in Fig. 7.

$$r_t = \sigma(W_{hr} h_{t-1} + W_{xr} x_t + b_r) \tag{16}$$

$$\tilde{h}_t = \tanh(W_{\tilde{r}h}(r_t * h_{t-1}) + W_{\tilde{x}h} x_t + b_{\tilde{h}}) \tag{17}$$

In Eq. (16) and Eq. (17), r_t is the reset gate which determines the amount of historical memory of h_{t-1}. $\tilde{h}_t$ is the latest information of the node at the current moment. h_{t-1}, h_t is the hidden layer information of the cell state at the moment of $t-1$ and t respectively, $W_{\tilde{r}h}$, $W_{\tilde{x}h}$, W_{xr}, W_{hr} are the weights, b_r, $b_{\tilde{h}}$ are the biases.

$$z_t = \sigma(W_{hz} h_{t-1} + W_{xz} x_t + b_z) \tag{18}$$

$$h_t = (1 - z_t) * h_{t-1} + z_t * \tilde{h}_t \tag{19}$$

In Eq. (18) and Eq. (19), W_{hz}, W_{xz} are weights and b_z is bias. z_t is the forgetting gate.

$$y_t = \sigma(W_{yt} h_t) \tag{20}$$

In Eq. (20), W_{yt} denotes the weights between the current hidden layer output h_t and the final output layer.

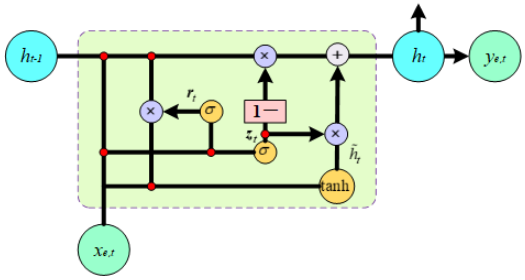

Fig. 7. GRU network.

F. Evaluation Indicators

This paper uses three evaluation indexes testing models such as Mean Absolute Error (MAE), Root Mean Square Five Error (RMSE), and Mean Absolute Percentage Error (MAPE), which are calculated by the following formulas:

$$RMSE = \sqrt{\left(\sum_{i=1}^{M}(\hat{y}_i - y_i)^2\right)/M} \tag{21}$$

$$MAE = \frac{1}{M}\sum_{i=1}^{M}|\hat{y}_i - y_i| \tag{22}$$

$$MAPE = \frac{1}{M}\sum_{i=1}^{M}\left|\frac{\hat{y}_i - y_i}{y_i}\right| \tag{23}$$

In Eq. (21) – Eq. (23), $\hat{y}_i$ denotes the predicted value based on the proposed algorithm, y_i denotes the true value and M is the number of test samples.

IV. A Methodological Process of New Media Advertisement Traffic Prediction Based on TSA-DBN-GRU Algorithm Under Decomposition-Optimisation-Reconfiguration Framework

A. DBN-GRU Prediction Model Based on TSA Algorithm

The combined DBN-GRU prediction model based on the TSA algorithm uses the TSA algorithm to optimise the DBN and GRU bias and weight values, and adopts the RMSE as the fitness function. The specific steps are as follows:

- Step 1: The Z-Score method was used to pre-process the raw data and divide the data set;
- Step 2: The TSA algorithm encodes the initial parameters of the DBN-GRU and calculates the value of the fitness function;
- Step 3: Using jet advancement and group behaviour, the DBN-GRU bias and weight value information is updated with the global optimal bias and weight values;
- Step 4: If the number of iterations satisfies the maximum number of iterations, output the bias and weight values and perform step (5), otherwise continue with step (3);
- Step 5: Decoding to obtain DBN-GRU bias and weight value training parameters;
- Step 6: Training to construct the TSA-DBN-GRU prediction model and analysing the prediction model using the test set.

B. Steps of the New Media Advertisement Traffic Prediction Process based on the Decomposition-Optimisation-Reconfiguration Framework

Combining VMD and KPCA, the TSA-DBN-GRU prediction method proposed in this paper is applied to the new media advertisement traffic prediction problem, and the flow chart is shown in Fig. 8, with the main steps:

- Step 1: Decompose the original new media advertisement flow time series by using Variable Modal Decomposition (VMD) to obtain $n+1$ components $\{VMF_1,\cdots,VMF_i,\cdots,VMF_k,Res_{vmd}\}$; use KPCA to perform principal component analysis and dimensionality reduction on the influencing variables of new media advertisement flow to obtain the transformed set of main influencing variables of new media advertisement flow;
- Step 2: For the eigenmode component VMF, GRU constructs the prediction model; for the main influencing variable of new media advertisement flow, DBN constructs the prediction model. In order to improve the accuracy of the prediction model, the TSA algorithm is used to optimise the bias and weight values of DBN-GRU, and select the optimal parameter values of bias and weight values;
- Step 3: Input each component and the influence factor data after dimensionality reduction into the component prediction model, and the output is superimposed and reconstructed to obtain the final prediction results.
- Step 4: Analyse the predictive model performance results.

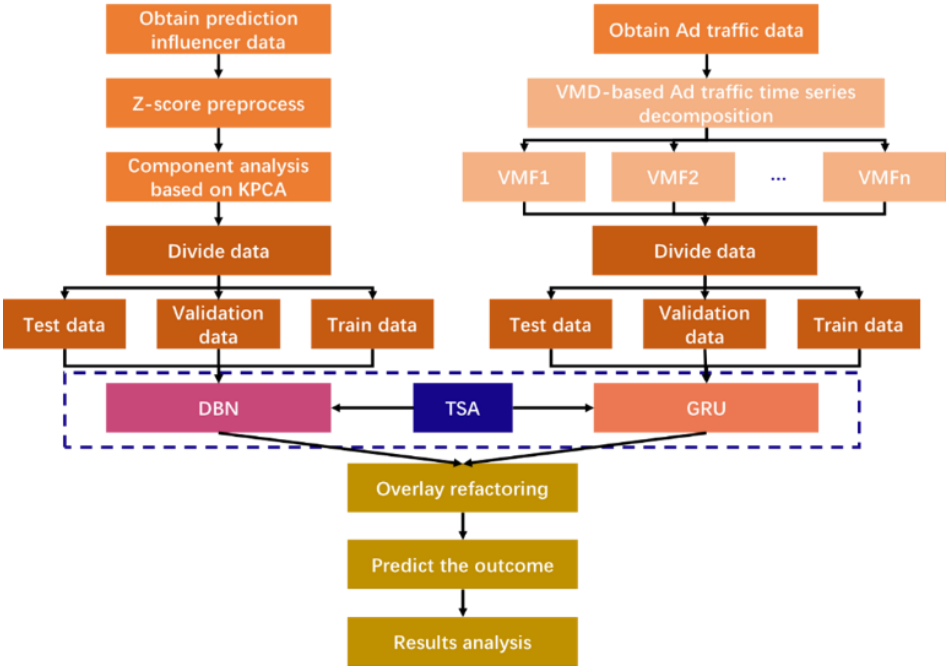

Fig. 8. New media advertisement traffic prediction.

V. Experiments and Analysis of Results

A. Algorithm Setup

The parameters of the new media advertising traffic prediction comparison algorithm are set in Table II.

B. Data Description

The data used in this paper comes from real data from a new media company's IPTV business. The data describes the number of viewing clicks of viewers 24 hours a day for almost three months. 70% of the data is selected as training set, 10% validation set and 20% as test set.

TABLE II. Parameter Settings of New Media Advertising Traffic Prediction Methods

Serial number	Arithmetic	Parameterisation
1	DBN-GRU	The number of DBN hidden nodes is 100, the number of GRU hidden nodes is 50, the activation function is the Relu function, and Adam's optimisation adjusts the weights
2	TSA-DBN-GRU	The number of DBN hidden nodes is 100, the number of GRU hidden nodes is 50, the activation function is Relu function and the number of TSA populations is 100
3	vmd-tsa-dbn-gru	The number of DBN hidden nodes is 100, the number of GRU hidden nodes is 50, the activation function is Relu function, the number of TSA populations is 100, and the VMD parameter settings refer to literature [30].
4	kpca-tsa-dbn-gru	The number of DBN hidden nodes is 100, the number of GRU hidden nodes is 50, the activation function is the Relu function, the number of TSA populations is 100, and the KPCA uses the Gaussian kernel function as the kernel function
5	vmd-kpca-tsa-dbn-gru	The number of DBN hidden layer nodes, the number of GRU hidden layer nodes, and the GRU network activation function is the Relu function

C. Correlation Analysis

In order to analyse the redundancy of the feature vectors of the new media advertising traffic prediction impact, this section uses Person correlation analysis method to analyse the feature vectors and advertising traffic. In Fig. 9, the new media advertising traffic is correlated with other variables, and all of them show positive correlation.

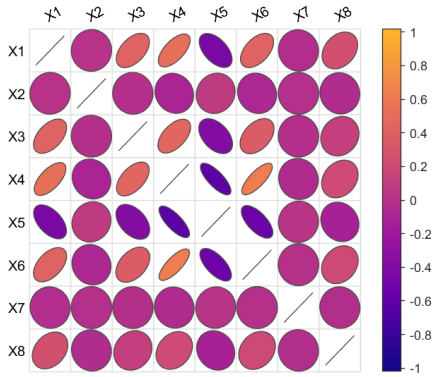

Fig. 9. Correlation analysis of factors influencing new media advertisement traffic prediction.

D. Parametric Analysis

In order to determine the optimal parameters, this paper analyses the results of choosing the parameters with higher prediction accuracy and less time-consuming by analysing different DBN hidden layer node number, GRU hidden layer node number, and population number conditions as shown in Fig. 10, 11, and 12. From Fig. 10, with the increase of the number of DBN hidden layer nodes, the prediction accuracy of the VMD-KPCA-TSA-DBN-GRU model increases, the time consumed increases, and the prediction accuracy tends to be stable when the number of DBN hidden layer nodes is 50; from Fig. 11, with the increase of the number of GRU hidden layer nodes, the prediction error of the VMD-KPCA-TSA-DBN-GRU model decreases, and the time consumed increases, and the prediction accuracy tends to be stable when the number of GRU hidden layer nodes is 60; from Fig. 12, the model prediction error decreases and the time-consuming time increases with the increase of the population. In summary, the VMD-KPCA-TSA-DBN-GRU model has a DBN hidden layer node number of 50, a GRU hidden layer node number of 60 and a population size of 80.

E. Performance Analysis

1) Flow breakdown analysis: The result of decomposing the original new media advertisement traffic sequence using VMD decomposition algorithm is shown in Fig. 13. From Fig. 13, the detailed features of the new media advertisement traffic sequence data are better decomposed by using the VMD decomposition algorithm for decomposition.

2) Performance comparison: In order to verify the effectiveness and superiority of the new media advertising traffic prediction method based on the VMD-KPCA-TSA-DBN-GRU algorithm, VMD-KPCA-TSA-DBN-GRU is compared with four other models, and the prediction results of each model are shown in Fig. 14 and 15. The prediction results of different algorithms with relative error results are given in Fig. 14 and 15, respectively. The new media advertising traffic prediction based on the VMD-KPCA-TSA-DBN-GRU algorithm has the smallest error and the highest prediction accuracy, and the rest of the algorithms ranked as KPCA-TSA-DBN-GRU, VMD-TSA-DBN-GRU, TSA-DBN-GRU, and DBN-GRU, respectively.

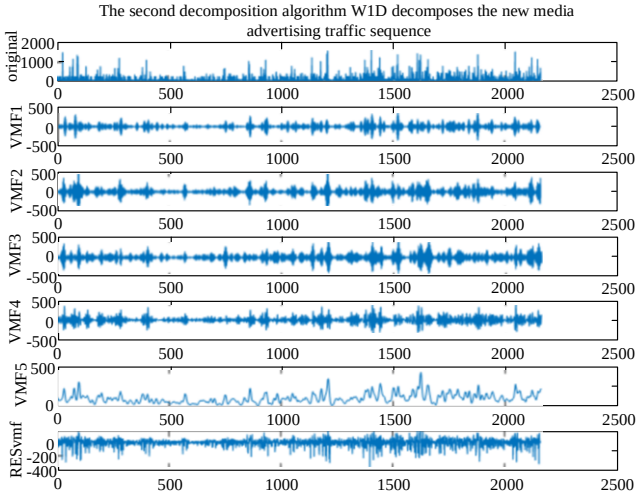

Fig. 13. Decomposition analysis of new media advertising traffic sequence.

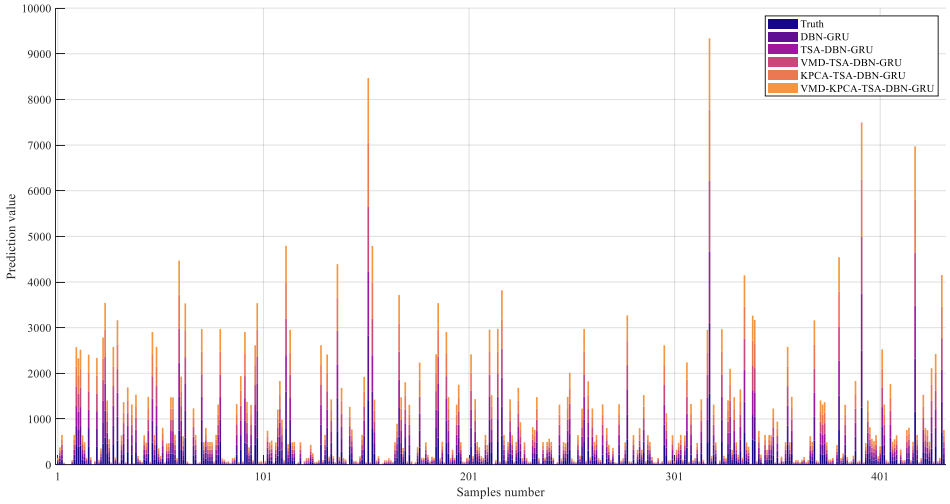

Fig. 14. Prediction results of different algorithms.

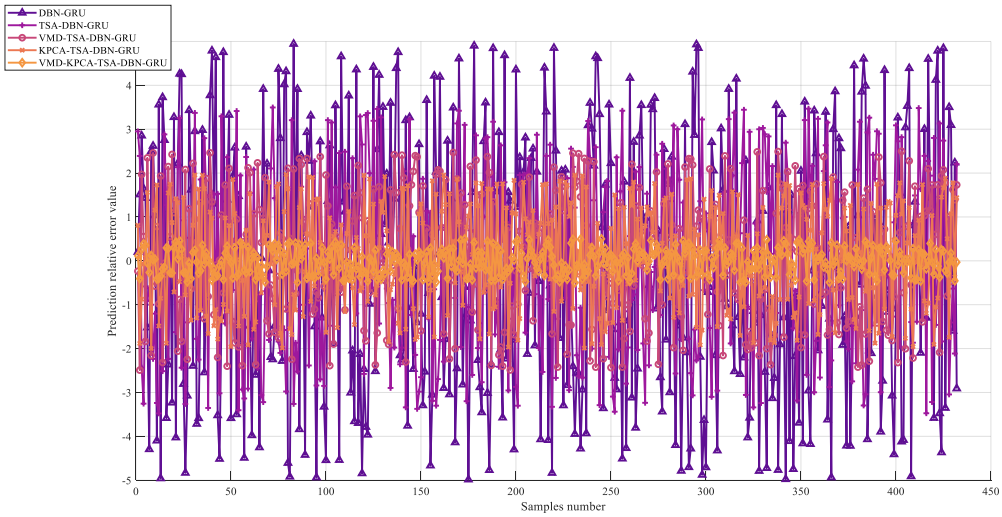

Fig. 15. Relative error results of different algorithms for prediction.

VI. Conclusion

In order to further improve the accuracy of new media advertisement traffic prediction, this paper proposes a new media advertisement traffic prediction method based on the optimisation of improved DBN-GRU network by the saccade swarm algorithm using the hybrid prediction framework of decomposition-optimisation-integration. The method analyses the new media advertisement traffic prediction problem, constructs a system of influence feature vectors, and adopts the nuclear principal component analysis method to analyse the principal components of the influence feature vectors; decomposes the original new media advertisement traffic time series using the variational modal decomposition method; and constructs a new media advertisement traffic prediction method by using the optimization of DBN-GRU network with the use of the quilt swarm algorithm. The specific conclusions are as follows:

- Kernel Principal Component Analysis (KPCA)-based methods were used to analyse the principal components of the eigenvectors of advertising traffic influence, and by comparing the prediction models that did not use KPCA, it was verified that KPCA analysis could improve the efficiency of the prediction models;
- The time series of new media advertisement flow is decomposed based on the VMD decomposition method, and by comparing the prediction model without the decomposition algorithm, it is verified that the VMD decomposition algorithm is able to improve the accuracy of the prediction model;
- The prediction accuracy of VMD-KPCA-TSA-DBN-GRU network prediction model is better than other models;
- The robustness of the prediction model proposed in this paper does not perform well, and further improving the VMD-KPCA-TSA-DBN-GRU prediction stability is the next research focus.

Applying Data-Driven APO Algorithms for Formative Assessment in English Language Teaching

Guojun Zhou*
Nanyang Medical College, Nanyang 473004, Henan, China

***Abstract*—This study proposes an innovative approach for improving the accuracy and efficiency of formative assessment in English language teaching. The method integrates the Artificial Protozoa Optimization (APO) algorithm with the Kernel Extreme Learning Machine (KELM) to overcome limitations such as local optima in traditional models. The study utilizes data from five university-level English courses, consisting of 327 samples divided into a training set (70%), validation set (15%), and test set (15%). The APO-KELM model is constructed by optimizing the KELM parameters using the APO algorithm. Comparative analysis is conducted against other models, including ELM, KELM, WOA-KELM, PPE-KELM, and AOA-KELM, in terms of accuracy (RMSE), MAPE (Mean Absolute Percentage Error), and convergence speed. The result shows that the APO-KELM model demonstrates superior performance with a Root Mean Square Error (RMSE) of 0.6204, compared to KELM (0.7210), WOA-KELM (0.6934), PPE-KELM (0.6762), and AOA-KELM (0.6451). In terms of MAPE, APO-KELM achieves 0.48, outperforming KELM (0.55), WOA-KELM (0.52), PPE-KELM (0.51), and AOA-KELM (0.49). Additionally, the APO-KELM model converged within 300 iterations, showing faster convergence compared to other models. The integration of the APO algorithm with the KELM significantly enhances the accuracy and efficiency of formative assessment in English language teaching. The APO-KELM model is more accurate and faster than traditional models, making it a valuable tool for improving assessment systems. Future research should focus on refining the APO algorithm for broader applications in educational assessments.**

I. INTRODUCTION

The implementation of education evaluation reform in China is increasingly gaining support from scholars and frontline teachers. This reform aims to achieve a comprehensive integration and effective connection between teaching evaluation and disciplinary parenting. It also seeks to establish a teaching evaluation index system that promotes students' physical and mental well-being, as well as their all-round development [1]. The development of a rigorous and efficient teaching evaluation index system is essential for conducting high-quality teaching evaluations. Additionally, the establishment of a comprehensive and systematic English teaching evaluation model not only facilitates the improvement of teaching evaluation practices and enhances disciplinary education outcomes, but also aligns with the contemporary goal of fostering moral values and educating individuals in the new era [2]. The use of big data technology to extract crucial information for the development of assessment methodologies has emerged as a future trend in teaching evaluation, owing to the growing volume of data generated by students and instructors throughout the teaching and learning process [3].

Currently, the study on formative assessment of English teaching using big data technology focuses mostly on two areas: the development of a teaching evaluation system and the creation of a teaching evaluation model. The objective of studying the English teaching evaluation system is to create an index system by analyzing the English teaching process, identifying the elements that influence the quality of teaching, and using appropriate algorithms to determine the final evaluation indexes [4]. Huang [5] develops teaching evaluation criteria based on the principles of effectiveness, differentiation, acceptability, and practicality. Assia and Samira [6] identify primary criteria from five aspects, including teachers, students, teaching content, teaching resources, and teaching media, to establish an English teaching evaluation system. Khodamoradi et al [7] divide the evaluation criteria for cultural teaching in senior high school English classrooms and constructs dimensions for the framework of the evaluation system. Chen and Yi [8] construct an evaluation system for secondary school English classrooms by examining and analyzing teaching plans, teaching methods, teaching attitudes, and classroom performance. The study on English teaching evaluation model mostly uses data-driven algorithms to develop the mapping link between English teaching evaluation indicators and evaluation scores [9]. The primary approaches used for teaching assessment include comprehensive fuzzy analysis [10], random forest [11], decision tree [12], extreme learning machine [13], neural network [14], and other similar techniques. The literature presents various approaches for evaluating English teaching. One study [10] suggests using an integrated fuzzy logic method, while another [11] utilizes random forest to establish the relationship between evaluation values and factors. Additionally, a high school English evaluation model is proposed [13], which is based on the extreme learning machine and tested using different datasets. Lastly, Shehu and Henay [14] propose a college English teaching evaluation model using a neural network. As the amount of data and the complexity of evaluation indexes increase, traditional machine learning algorithms may get stuck in local optima and fail to find the optimal evaluation model. To address this issue, intelligent optimization algorithms are employed to enhance the training process and improve the accuracy of the evaluation model. Furthermore, the English evaluation process lacks depth, resulting in an incomplete evaluation system and reduced efficiency. To overcome this

*Corresponding Author.

limitation, a more comprehensive evaluation system is utilized to enhance the accuracy of the evaluation model [15].

This paper addresses the limitations of the current English teaching evaluation method, which uses the Extreme Learning Machine algorithm [13]. These limitations include getting stuck in local optimal solutions, low evaluation accuracy, and time-consuming evaluations. To overcome these challenges, the paper proposes a formative assessment method for English teaching based on the APO-KELM model, which combines the Intelligent Optimization Algorithm with the Nuclear Extreme Learning Machine [16]. The primary contributions of this paper include: (1) analyzing the issue of formative assessment in English teaching using big data, and identifying comprehensive, scientific, effective, and quantifiable evaluation criteria for English teaching; (2) integrating the Artificial Protozoan Optimizer algorithm and the Kernel-Limit Learning Machine to develop a formative assessment approach based on an efficient data-driven algorithm for English teaching; (3) validating the effectiveness and robustness of the proposed method by utilizing formative data from English teaching in various colleges and universities.

II. Analysis of Formative Assessment Issues

A. Research Ideas on Formative Assessment in English Teaching

This work utilizes the research approach of problem identification, problem analysis, solution proposal, solution implementation, and solution validation [17] to investigate the issue of formative assessment in English education. The particular research concept is shown in Fig. 1.

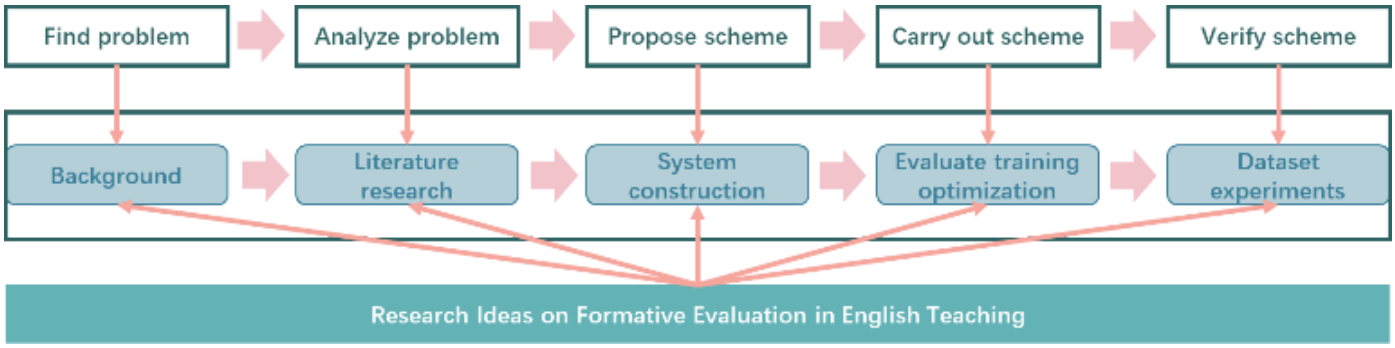

Fig. 1. Schematic diagram of the research idea.

The research ideas of this paper, as shown in Fig. 1, are as follows: 1) Identify the problem of formative assessment in English teaching by examining the background of formative assessment in English teaching; 2) Analyze the formative process of English teaching and identify the formative assessment indicators through literature research; 3) Develop the formative assessment indicator system for English teaching using data preprocessing and correlation analysis, while also proposing 4) Constructing a formative assessment model for English teaching by combining various machine learning algorithms and optimizing training for formative assessment of English teaching; 5) Validate the effectiveness and reliability of the proposed evaluation method using different datasets and data extraction methods.

Based on the analysis provided above, this paper conducts research on the problem of formative assessment in English teaching. The research includes the discovery and analysis of the problem, the establishment of an index system for formative assessment, the construction of a formative assessment model for English teaching, and the validation of the model's application. The specific key technologies are illustrated in Fig. 2.

B. Analysis of the Problem

The teaching evaluation issue revolves on the teaching evaluation index system, which involves examining and extracting the value of teaching evaluation indices. Machine learning techniques are then used to establish the mapping relationship between the index value and the evaluation value [18]. The issue of formative assessment in English teaching involves determining the teaching process by examining relevant literature, conducting analysis, and integrating the English curriculum, student development requirements, and English teaching evaluation practices. This process leads to the extraction of a formative assessment index system for English teaching. Furthermore, a data-driven algorithm is employed to construct a formative assessment model for English teaching. The specific problem analysis is illustrated in Fig. 3.

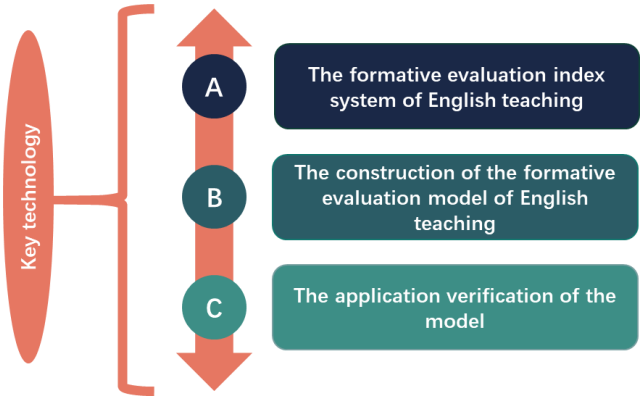

Fig. 2. Key technology content.

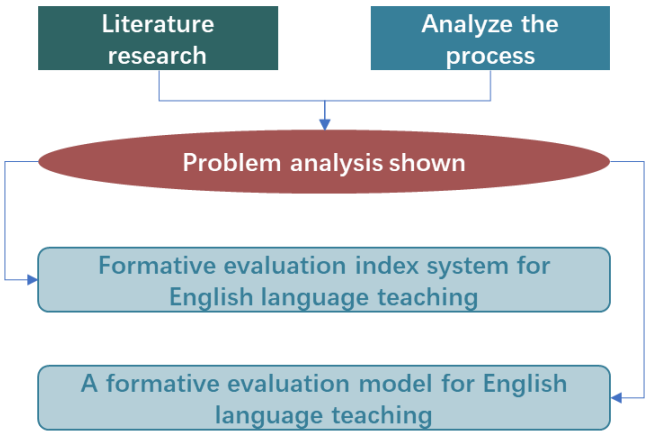

Fig. 3. Schematic diagram of the problem analysis.

C. Evaluation System Construction

The formative assessment problems in English teaching were analyzed to develop students' comprehensive language application ability. The focus was on the leading role of students' teaching evaluation and the diversity of evaluation methods and system construction. The teaching objectives, contents, methods, and effects were set as the first-level indicators, following the principles of human nature, scientific approach, developmental approach, systematic approach, and operability. The formative indicator system of English teaching was obtained through the use of the Delphi method questionnaire survey, deletion, and adjustment [19], as shown in Table I.

D. Analysis of Evaluation Models

The essence of the formative assessment problem of English teaching is a complex regression prediction problem, with the index value in the formative index system of English teaching as the input and the evaluation score as the output, the specific evaluation model is constructed as follows:

$$Y_{score} = F_{eval}\left(X_{index}\right) \quad (1)$$

Where Y_{score} is the evaluation score; F_{eval} is the evaluation model; X_{index} is the index value. In this paper, a data-driven algorithm is used to construct the formative assessment model of English teaching, as shown in Fig. 4.

TABLE I. EVALUATION INDICATOR SYSTEM

No.	Data set	Goal
1	A Teaching and Learning Objectives	A1 Developing students' language skills
		A2 Expanding Students' Cultural Awareness
		A3 Developing the quality of students' thinking
		A4 Improving Student Learning
2	B Teaching content	B1 English Language Knowledge
		B2 English Language Skills
		B3 Knowledge of English Culture
		B4 English Learning Strategies
3	C Teaching methods	C1 Inquiry-based teaching
		C2 Contextualised Teaching
		C3 Thematised Teaching
4	D Teaching Effectiveness	D1 Teaching effectiveness of teachers

III. APO-KELM ALGORITHM

In order to solve the problem of formative assessment in English language teaching, this section uses the artificial protozoan optimiser algorithm to improve the kernel-limit learning machine for the construction of formative assessment model in English language teaching.

A. APO Algorithm

1) Principle of APO algorithm: Swarm intelligence optimization system Artificial Protozoa Optimizer (APO) [20] is inspired by natural phenomena. The method introduces a new Artificial Protozoa Optimizer (APO) that is inspired by protozoa. APO imitates the foraging, quiescent, and reproductive behaviors of protozoa in order to replicate their survival strategies. From a practical perspective, the method is employed to resolve five common engineering design challenges in continuous environments with constraints. Moreover, the method is employed to perform multilevel picture segmentation in a discrete space while adhering to specific constraints.

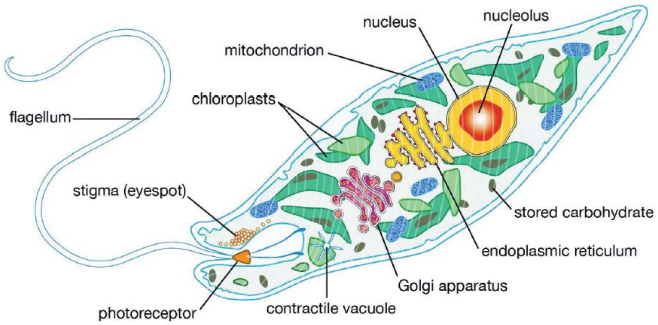

Fig. 5. Representation of protozoan behaviour.

Microorganisms have a unique advantage, as evidenced by research on a variety of biological processes. As microorganisms, bacteria, algae, and protozoa execute functions that are comparable to those of organelles in higher plants and animals. Specialized structures known as "organelles" execute these functions. Metabolism, reproduction, genetic continuity, adaptability to environmental stimuli, and variability are fundamental life features of microorganisms. Because of their simple and low-complexity structure, microbial beings are often more successful than larger organisms. Researching the principles of behavioral processes such as reproduction, dormancy, and foraging, the APO algorithm is employed. Fig. 5 shows representation of protozoan behavior.

a) Foraging

i) Self-supporting model: By generating carbohydrates via their chloroplasts, protozoa may provide nourishment. The protozoan will migrate away from its current location and towards a specific spot if it is subjected to extreme light intensity. When the light intensity around the protozoan is low, the protozoan relocates to a different position (Fig. 7). The autotrophic model may be described by the following particular model:

$$X_i^{new} = X_i + f \cdot \left(X_j - X_i + \frac{1}{np} \cdot \sum_{k=1}^{np} \omega_a \cdot \left(X_{k-} - X_{k+} \right) \right) \square\ M_f \tag{2}$$

$$X_i = \left[x_i^1, x_i^2, \cdots, x_i^{\dim} \right]$$
$$X_i = sort\left(X_i \right) \tag{3}$$

$$f = rand \cdot \left(1 + \cos\left(\frac{iter}{iter_{\max}} \cdot \pi \right) \right) \tag{4}$$

$$np_{\max} = \left\lfloor \frac{ps-1}{2} \right\rfloor \tag{5}$$

$$\omega_a = e^{-\left| \frac{f(X_{k-})}{f(X_{k+}) + eps} \right|} \tag{6}$$

$$M_f\left[di \right] = \begin{cases} 1 & randperm\left(\dim, \left\lceil \dim \cdot \frac{i}{ps} \right\rceil \right) \\ 0 & otherwise \end{cases} \tag{7}$$

where X_i^{new} denotes the updated protozoan position; X_i denotes the current protozoan position; X_{k-} denotes the randomly selected neighbourhood-1 protozoan; X_{k+} denotes the randomly selected neighbourhood+1 protozoan; f denotes the foraging factor; np denotes the individual of the neighbourhood pairs; $x_i^{\dim}$ denotes the dimensional position of the ith protozoan; $iter$ denotes the number of iterations; $iter_{\max}$ denotes the maximum number of iterations; ps denotes the population size; $f(\cdot)$ denotes the formula for calculating the fitness value; eps denotes the minimal value, which is generally taken as 2.2204e16; denotes the dimension index; denotes the fitness value; and denotes the mapping vector. The general value is 2.2204e-16; M_f is the mapping vector; di is the dimension index (see Fig. 6).

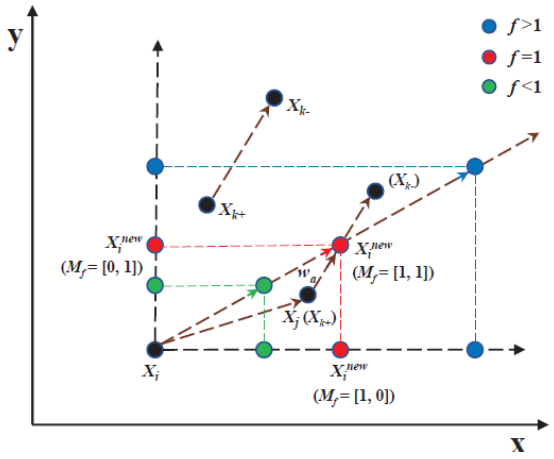

Fig. 6. Self-supporting model.

ii) Heterotrophic model: Protozoa are able to acquire nourishment by absorbing organic substances from their environment while under darkness. If X is a nearby location with abundant food, protozoa will travel towards it. The precise model of the heterotrophic model is as follows:

$$X_i^{new} = X_i + f \cdot \left(X_{near} - X_i + \frac{1}{np} \cdot \sum_{k=1}^{np} \omega_h \cdot \left(X_{i-k} - X_{i+k} \right) \right) \square\ M_f \tag{8}$$

$$X_{near} = \left(1 \pm Rand \cdot \left(1 - \frac{iter}{iter_{\max}} \right) \right) \square\ X_i \tag{9}$$

$$\omega_h = e^{-\left| \frac{f(X_{i-k})}{f(X_{i+k}) + eps} \right|} \tag{10}$$

$$Rand = [rand_1, rand_2, \cdots, rand_{\dim}] \quad (11)$$

where X_{near} denotes the neighbourhood position; X_{i-k} and X_{i+k} are the i-kth and i+kth neighbourhood positions, respectively; ω_h is the weight of the heterotrophic pattern; and $Rand$ is a random vector.

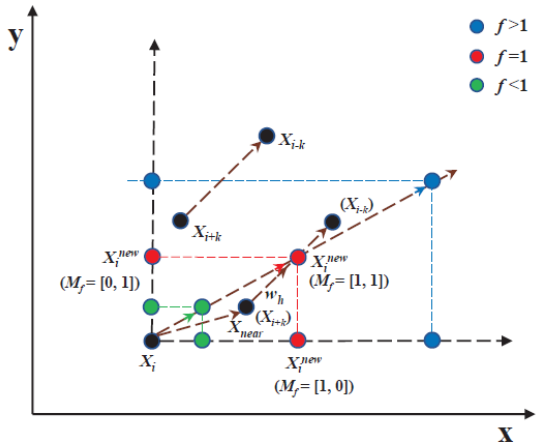

Fig. 7. Self-supporting model.

b) Dormancy: Every element of a single solution vector is multiplied by a random value selected from a Gaussian distribution to create a new offspring. The Gaussian random variable influences the number of interruptions introduced to the parent vector, aiding the algorithm in eliminating local optima. The offspring produced by the Gaussian variation at generation *m* is defined for every parent solution vector:

$$X_i^{new} = X_{\min} + Rand \square \left(X_{\max} - X_{\min}\right) \quad (12)$$

$$\begin{aligned} X_{\min} &= [lb_1, lb_2, \cdots, lb_{\dim}] \\ X_{\max} &= [ub_1, ub_2, \cdots, ub_{\dim}] \end{aligned} \quad (13)$$

where $X_{\min}$ and $X_{\max}$ denote the lower and upper bound vectors, respectively, and lb and ub denote the lower and upper bound variables, respectively (Fig. 8).

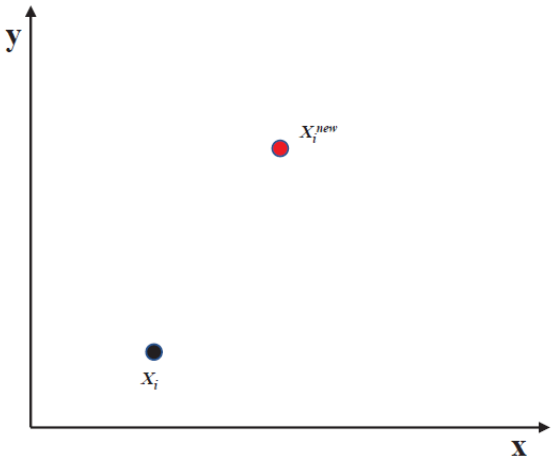

Fig. 8. Diagram of hibernation.

c) Reproduction: Protozoa are capable of asexual reproduction when they reach the appropriate age and are in good condition. In theory, this process of reproduction results in the protozoan dividing into two identical progeny. This behavior is simulated by creating a duplicate protozoan and analyzing a perturbation. The mathematical representation of reproduction is as follows:

$$X_i^{new} = X_i \pm rand \cdot \left(X_{\min} + Rand \square \left(X_{\max} - X_{\min}\right)\right) \square M_r \quad (14)$$

$$M_r[di] = \begin{cases} 1 & randperm\left(\dim, \lceil \dim \cdot rand \rceil\right) \\ 0 & otherwise \end{cases} \quad (15)$$

where $\pm$ denotes interference forward or backward, and M_r denotes reproduction mapping relationships (see Fig. 9).

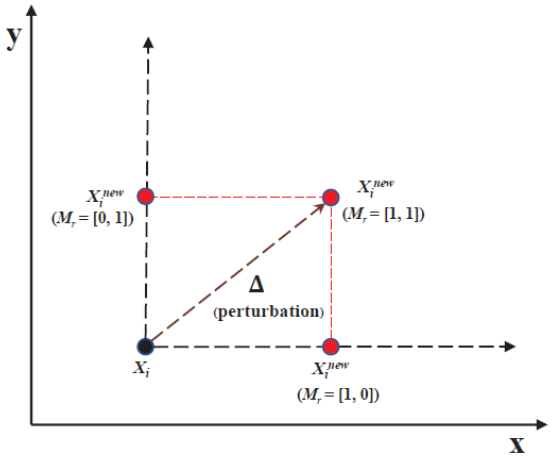

Fig. 9. Diagram of reproduction.

d) Other parameter settings: The other parameters of the APO algorithm are set as follows:

$$pf = pf_{\max} \cdot rand \quad (16)$$

$$p_{ah} = \frac{1}{2} \cdot \left(1 + \cos\left(\frac{iter}{iter_{\max}} \cdot \pi \right) \right) \quad (17)$$

$$p_{dr} = \frac{1}{2} \cdot \left(1 + \cos\left(\left(1 - \frac{i}{ps} \right) \cdot \pi \right) \right) \quad (18)$$

Where pf denotes the dormancy ratio parameter, $pf_{\max}$ is the maximum ratio parameter, p_{ah} is the conversion probability between autotrophic and heterotrophic modes, and p_{dr} is the conversion probability between dormancy and reproduction. The conversion probability is mainly used to balance the conversion of exploration and exploitation operators, as shown in Fig. 10.

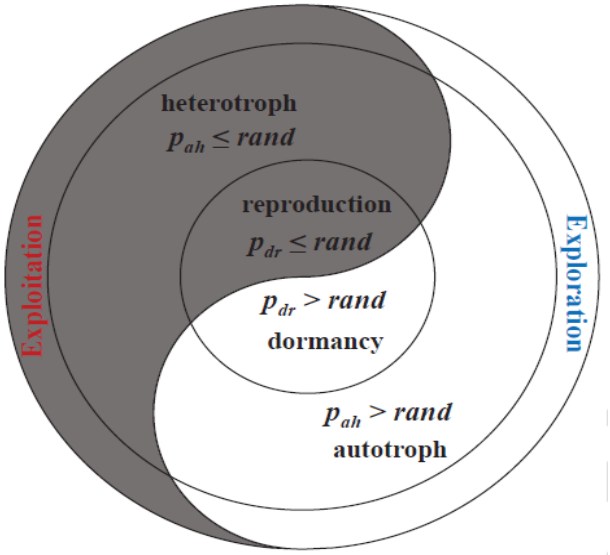

Fig. 10. Schematic diagram of the behavioural transition between development and exploration.

2) APO algorithm pseudo-code: According to the optimisation strategy of APO algorithm, the pseudo-code of APO algorithm is shown in Table II.

TABLE II. APO ALGORITHM PSEUDO-CODE

Algorithm 1: Artificial Protozoa Optimisation Algorithm (APO)
Initialise the parameters ps, dim, np, pfmax and MaxFEs;
Protozoan populations were randomly generated and fitness values were calculated;
While FEs<MaxFEs
Sort(Xi), calculating the scaling parameter, calculating the conversion probability
For i=1:ps do
If i in Drindex do
Individual positions are updated using either the dormant behaviour operator or the reproduction behaviour operator;
Else
Individual positions were updated using either the autotrophic behaviour operator or the heterotrophic behaviour operator;
End if
Calculate fitness values and compare updated populations;
End for
Output optimal protozoan individuals;
FEs = FEs + ps;
End while

3) Performance analysis of APO algorithm optimisation: In order to verify the convergence of the APO algorithm, this paper chooses F1-F8 test functions (see Table III) [21] to analyse the performance of APO, and the specific results are shown in Fig. 11.

TABLE III. TEST FUNCTION SETTINGS

serial number	name (of a thing)	n	realm
1	F1	30	[-100,100]
2	F2	30	[-10,10]
3	F3	30	[-100,100]
4	F4	30	[-100,100]
5	F5	30	[-30,30]
6	F6	30	[-100,100]
7	F7	30	[-1.28,1.28]
8	F8	30	[-500,500]

As can be seen from Fig. 11, the APO algorithm can converge to a certain accuracy and achieve a better optimal solution in the F1 to F8 function tests.

B. The KELM Model

Kernel Based Extreme Learning Machine (KELM) [22] is an extreme learning machine algorithm based on kernel functions, which achieves high-dimensional mapping of data through kernel functions, thus improving the performance of the model.KELM has better stability and generalisation capabilities when dealing with classification and regression problems compared to traditional Support Vector Machines (SVMs) and Extreme Learning Machines (ELMs) [23], which usually have better stability and generalisation capabilities. A key advantage of KELM is that it can directly handle multi-class classification problems and usually does not require complex weight adjustments as in traditional neural networks (see Fig. 12).

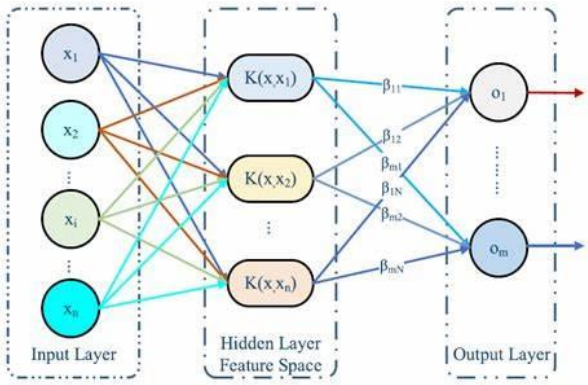

Fig. 12. KELM structure.

The KELM model is calculated as follows:

$$F(X)=\left[K(X,X_1);\cdots;K(X,X_n)\right]\left(\frac{I}{C}+\Omega_{ELM}\right)^{-1}L \tag{19}$$

Where, $(X_1, X_2, \cdots, X_n)$ is the given training sample, n is the number of samples, K is the kernel function, Ω_{ELM} is the kernel matrix and $F(X)$ is the learning objective function.

The steps of KELM are shown in Fig. 13 and described below:

- Determine the number of neurons in the hidden layer, randomly set the connection weights between the input layer and the hidden layer w and the bias of the hidden layer neurons b ;

- Choose an infinitely differentiable function as the activation function of the neurons in the hidden layer, and then calculate the hidden layer output matrix H ;
- Calculate the output layer weights.

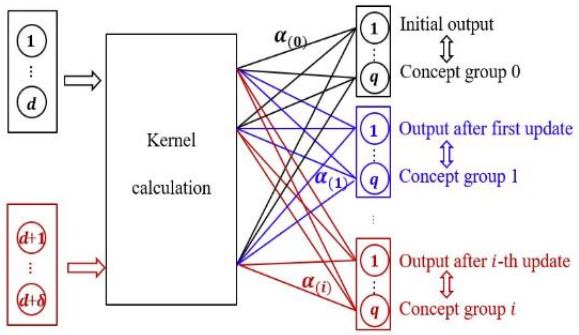

Fig. 13. KELM learning training steps.

The KELM model is mainly applied in the fields of data regression prediction, fault early warning, online data prediction, feature selection and parameter tuning, dealing with nonlinear and non-smooth data, and time series analysis [24], and the application schematic is shown in Fig. 14.

Fig. 14. KELM application.

C. APO-KELM Structural Steps

This paper utilizes the APO algorithm to optimize the parameters of the Kernel Extreme Learning Machine (KELM) model for constructing the formative assessment model of English language teaching. The objective is to enhance the evaluation accuracy and generalization of KELM. The specific optimization schematic can be seen in Fig.15. The APO method divides the decision variables into two parts [25] (Fig. 15): the first part consists of the weights and bias, and the second portion consists of the parameters of the activation function. The APO algorithm uses the RMSE function as the fitness function. Fig.16 displays the structure of the APO-KELM model, while Table IV presents the pseudo code.

Behavioural stage transition probabilities were calculated and populations were updated using autotrophic, heterotrophic, dormant or reproducing behavioural operators;
Calculate the fitness value;
Updating Optimal KELM Network Parameters Individual;
End while
Output optimal KELM network parameters;
Construction of the APO-KELM evaluation model.

IV. MODEL APPLICATION

In this paper, the APO-KELM model is applied to the problem of formative assessment of English teaching, which mainly solves the problem of constructing the formative assessment model of English teaching, i.e., the APO-KELM model is used to learn to optimise the mapping relationship between the values of the formative assessment indexes and the evaluation scores of English teaching, so as to obtain the formative assessment model of English teaching based on the APO-KELM algorithm, and the method of its application is shown in Fig. 17, and the specific steps are shown in Table V.

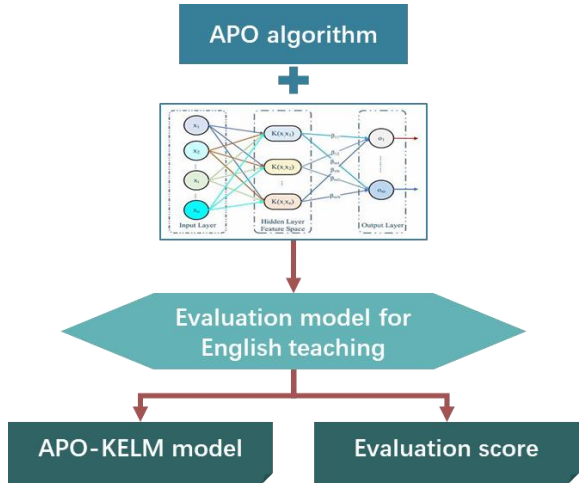

Fig. 17. APO-KELM applied in the formative assessment model of English language teaching.

TABLE V. APO-KELM ALGORITHM PSEUDO-CODE

Algorithm 3: Formative assessment Model Construction for English Language Teaching Based on APO-KELM Algorithm
Analysing evaluation problems in English language teaching and designing evaluation programmes;
Describe the process of English teaching, extract the evaluation indexes and construct the evaluation index system;
Data preprocessing and correlation analysis to construct a learning training set for formative assessment model of English language teaching;
Initialise the APO-KELM model;
The KELM model parameters were optimised iteratively using the APO algorithm optimisation strategy;
Obtain optimal KELM model parameters;
The APO-KELM model was retrained using the training set to obtain a formative assessment model for English language teaching;
Data validation analysis of the model.

V. VALIDATION ANALYSIS

A. Experimental Setup

1) Data setting: The research in this paper investigated five university English classes for questionnaires and obtained relevant data, which were divided into training set, validation set, and test set (as shown in Fig. 18), in which the ratio was 7:1.5:1.5, and the total number of sample sets was 327 groups, and only then did the questionnaire data were analysed with the SPSS 22.0 statistical software to obtain the final standardised data.

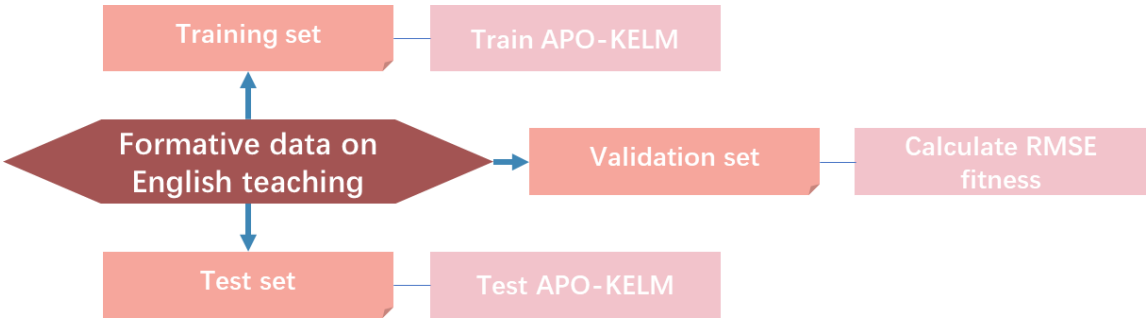

Fig. 18. Purpose of data set segmentation.

2) Algorithm parameter setting: In order to verify the superiority of comparing APO-KELM algorithms, ELM, KELM, WOA-KELM [26], PPE-KELM [27], and AOA-KELM [28] are used in this paper, and the specific parameter settings of each algorithm are shown in Table VI.

TABLE VI. COMPARISON ALGORITHM PARAMETER SETTINGS

No.	Arithmetic	Parameter settings	ELM/KELM Parameter Setting
1	ELM	No	The number of hidden layer nodes is 80
2	KELM	No	Hidden_node=80, kernel function is radial basis function
3	WOA-KELM	a=[2,0]	Refer to section 5.2 Analysis
4	PPE-KELM	a=1.1, c=0.2	Same settings as WOA-KELM
5	AOA-KELM	a=5, μ=0.5	Same settings as AOA-KELM
6	APO-KELM	np=1, pfmax=0.1	Refer to section 5.2 Analysis

3) Environmental settings: The simulation experiments in this paper are mainly executed on a laptop computer configured with Windows 11 operating system having 16GB RAM with Intel(R) Core(TM) i7-8750H CPU @2.20GHz 2.21GHz.The execution of each algorithm is analysed using Matlab2021a.

B. Analysis of Results

1) Parametric analysis: The CEC2022 standard function is used to analyze the size change of the APO algorithm's foraging factor in order to examine the influence of the foraging behavior factor with the number of iterations. The precise findings are shown in Fig. 19. The foraging factor diminishes as the number of iterations increases, causing the APO algorithm to choose exploration over exploitation.

This work examines the English evaluation accuracy under the APO algorithm population of 40, 50, 60, 70, 80, 90, 100, 110, 120, and 130 in order to investigate the effect of APO algorithm population on the evaluation performance of APO-KELM model. The precise findings are shown in Fig. 20.

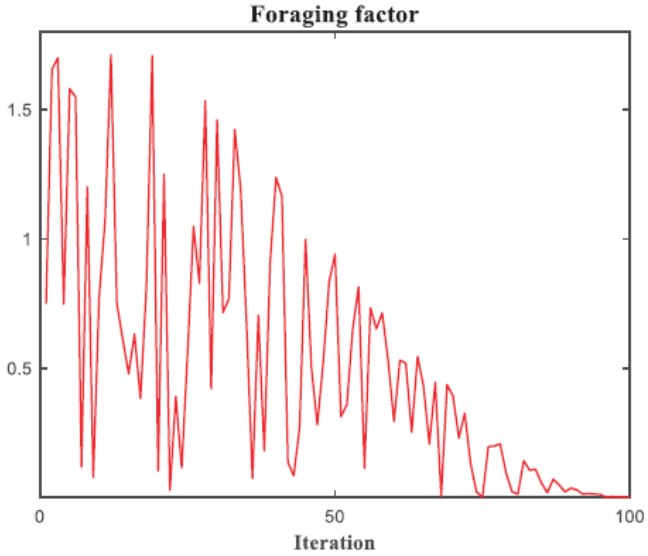

Fig. 19. Results of APO algorithm foraging factor change with increasing number of iterations.

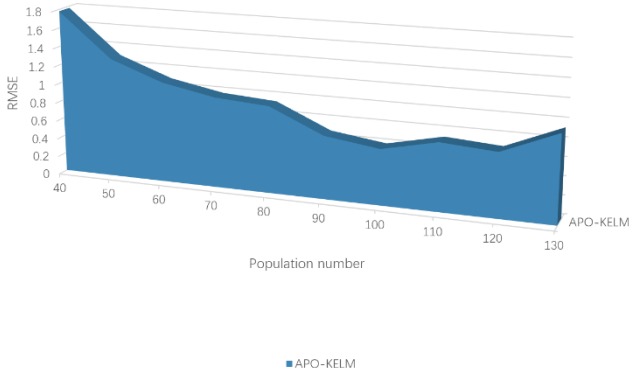

Fig. 20. Results of the effect of the number of populations of the APO algorithm on the performance of the APO-KELM model.

In order to explore the impact of the number of hidden layer nodes of KELM algorithm on the evaluation performance of APO-KELM model, this paper analyses the evaluation accuracy of English under the number of hidden layer nodes of KELM algorithm of 50, 60, 70, 80, 90, 100, 110, 120, 130, 140, and 150, and the specific results are shown in Fig. 21.

2) Comparative algorithm analysis: This study utilizes ELM, KELM, WOA-KELM, PPE-KELM, AOA-KELM, and APO-KELM to develop the formative assessment model for English instruction. The performance results of these algorithms are compared and shown in Fig. 22 and Fig. 23.

Fig. 22 displays the convergence outcomes of WOA-KELM, PPE-KELM, AOA-KELM, and APO-KELM in ELT formative data. Fig. 22 shows that as the number of iterations increases, the WOA-KELM, PPE-KELM, AOA-KELM, and APO-KELM models converge with a decrease in fitness value. In terms of convergence accuracy, the KELM model based on the APO algorithm has the lowest convergence fitness value. In terms of convergence speed, APO-KELM converges the fastest, starting to converge within the first 300 iterations.

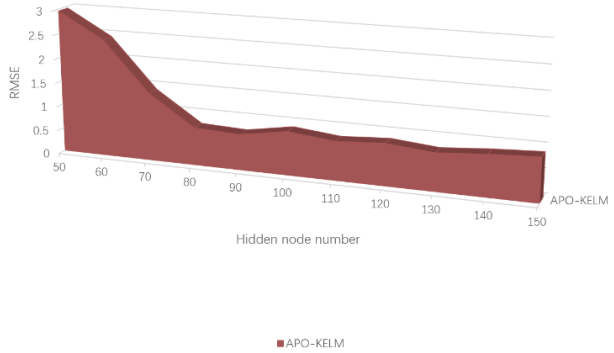

Fig. 21. Results of the effect of the number of KELM hidden layer nodes on the performance of the APO-KELM model.

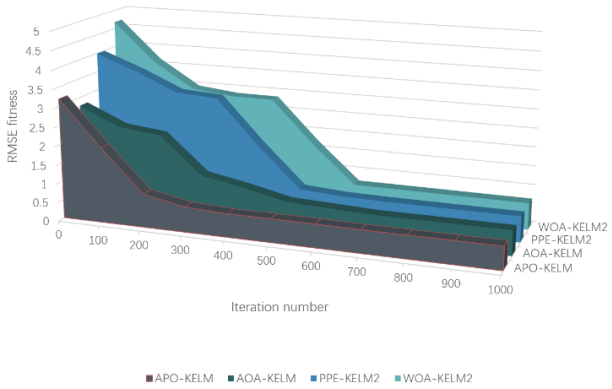

Fig. 22. Optimisation iteration process of KELM model with different optimisation algorithms.

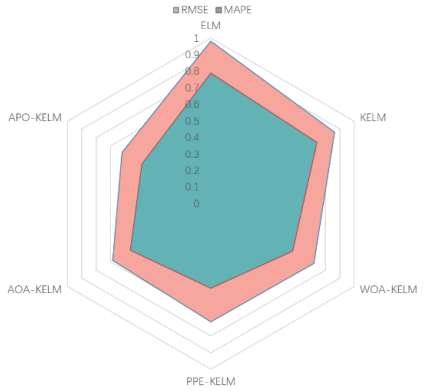
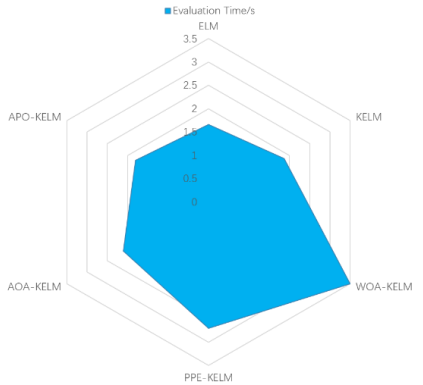
Fig. 23 displays the performance comparison findings of ELM, KELM, WOA-KELM, PPE-KELM, AOA-KELM, and APO-KELM algorithms. The comparison is based on the performance of formative assessment models used in English language teaching and learning. The performance metrics considered are RMSE, MAPE, and elapsed time. Fig. 23 clearly demonstrates that the APO-KELM model outperforms the other models in terms of RMSE, with a value of 0.6204. Additionally, in terms of MAPE, the APO-KELM model is superior to the other models, with a value of 0.48. The ELM model outperforms other algorithms, including the KELM, APO-KELM, APOA-KELM, PPE-KELM, and WOA-KELM models, in terms of time efficiency.



(a) RMSE and MAPE.



(b) Time consuming.

Fig. 23. RMSE, MAPE, and elapsed time results for the comparison algorithm model.

VI. CONCLUSION

This research use the APO algorithm and Nuclear Limit Learning Machine to analyze and simulate trials related to the issue of formative assessment in English instruction. Firstly, it examines the issue of formative assessment of English teaching in the context of big data technology. It identifies evaluation criteria and establishes an index system for formative assessment of English teaching. Secondly, to address the challenge of constructing a formative assessment model for English teaching, it enhances the KELM using the APO algorithm. It introduces the method of formative assessment of English teaching based on the APO-KELM model. Lastly, it applies the APO-KELM model to multiple sets of data for formative assessment of English teaching. The simulation studies demonstrate that the screening approach suggested in this research has superior stability, merit-seeking ability, and convergence accuracy.

Future study should focus on enhancing the precision and speed of convergence of the APO algorithm, as well as expanding its application to a wider range of teaching assessment challenges.

***Abstract*—Diabetic retinopathy (DR) ranks among the foremost contributors to blindness worldwide, particularly affecting the adult demographic. Detecting DR at an early stage is crucial for preventing vision loss; however, conventional approaches like fundus examinations are often lengthy and reliant on specialized expertise. Recent developments in machine learning, especially the application of deep learning models, provide a highly effective option for classifying diabetic retinopathy through retinal fundus images. This investigation examines the efficacy of geometric data augmentation methods alongside MobileNetV2 for the classification of diabetic retinopathy. Utilizing augmentation techniques like image resizing, zooming, shearing, and flipping enhances the model's ability to generalize. MobileNetV2 is selected for its impressive inference speed and computational efficiency. This analysis evaluates the effectiveness of MobileNetV2 in relation to InceptionV3, emphasizing metrics such as accuracy, precision, sensitivity, and specificity. The findings show that MobileNetV2 attains exceptional performance, achieving an accuracy of 97%. These findings highlight the promise of employing efficient models and augmentation strategies in clinical settings for the early identification of DR. The findings highlight the critical need to incorporate advanced machine learning methods to enhance healthcare results and avert blindness caused by diabetic retinopathy.**

***Keywords*—Diabetic retinopathy; data augmentation; InceptionV3; MobileNetV2; transfer learning**

I. INTRODUCTION

Diabetic retinopathy is a significant complication linked to diabetes mellitus, contributing significantly to the global incidence of blindness. The International Diabetes Federation (IDF) indicated that in 2019, around 463 million individuals globally were diagnosed with diabetes mellitus (DM), with projections suggesting a significant increase to about 700 million by 2045. Diabetic retinopathy (DR) remains a prevalent complication linked to diabetes, posing a significant health issue as it stands as a primary cause of preventable blindness, especially within the adult working-age demographic worldwide [1]. The condition is characterized by impairment of the retinal blood vessels, leading to potential leakage, bleeding, and the development of scar tissue. These alterations may ultimately result in diminished visual acuity or potentially irreversible blindness [2], [3]. It is essential to achieve a more profound understanding of the fundamental mechanisms of diabetic retinopathy and to create more effective approaches for its early detection to avert more severe outcomes.

Identifying diabetic retinopathy at an early stage is essential to prevent additional harm to the eyes. The application of early interventions, including the management of blood glucose levels and the arrangement of routine eye examinations, has been shown to decrease the likelihood of blindness [4]. This research suggests that through prompt identification and effective management, individuals with diabetes can preserve their ocular health and hinder the advancement of the condition. Nonetheless, a considerable obstacle remains, as numerous patients do not recognize the existence of diabetic retinopathy until symptoms become evident [5]. This research highlights the necessity for creating more effective approaches for the classification and detection of the disease.

Technological developments in retinal imaging and deep learning have pioneered new avenues for boosting the precision of diabetic retinopathy diagnoses. Conventional diagnostic techniques for identifying diabetic retinopathy, such as eye examinations by an ophthalmologist, are regularly laborious and rely on a physician's experience and acumen. Machine learning algorithms and imaging processing methods can heighten the effectiveness and exactitude of the categorization process. Convolutional neural networks (CNNs) are inspired by the structure and function of brain neurons with image input [6], [7]. The use of CNN has evidenced proficiency in detecting diverse medical conditions from medical visuals [8], [9],[10].

Numerous previous studies have attempted to classify diabetic retinopathy using Convolutional Neural Networks (CNN). State-of-the-art CNN architectures, such as VGG, ResNet, and Inception, have been applied for feature extraction, significantly improving the sorting process [11]. Additionally, investigations combining CNNs with preprocessing strategies like Contrast Limited Adaptive Histogram Equalization (CLAHE) have indicated enhanced model productivity and accuracy [12]. Furthermore, examination by [13] has proposed hybrid approaches that integrate machine learning and deep learning methods, for example, merging Support Vector Machines (SVM) and Random Forests with CNNs to further optimize categorization

performance. Moreover, transfer learning has been employed to utilize pre-trained models, minimizing the need for large data sets and reducing computational demands [14].

The use of augmentation techniques in image classification has been shown to impact model accuracy [15] significantly. In the realm of diabetic retinopathy classification, augmentation plays a crucial role in enhancing the model's ability to identify significant patterns and features that might be overlooked in the original dataset. In the realm of image data classification, geometric augmentation serves as an essential method for improving both the quality and quantity of training data utilized in machine learning models. Geometric augmentation includes various transformations such as rotation, cropping, and rescaling, which can enhance the learning process by presenting the model with the natural variations found in the data. Augmenting the training data allows us to reduce overfitting and improve the model's generalization, which in turn enhances classification accuracy [16],[17],[18].

Moreover, utilizing transfer learning model architectures like MobileNetV2 and InceptionV3, designed for enhanced efficiency and accuracy in image recognition, can significantly improve the classification ability for diabetic retinopathy [19], [20], [21], [22]. MobileNetV2 provides benefits regarding efficiency and inference speed [23], [24], [25], [26]. In a clinical setting, where the speed of diagnosis is essential, more efficient models can offer considerable benefits. MobileNetV2 demonstrates enhanced inference speed while maintaining a high level of accuracy, positioning it as a compelling choice for practical applications. In scenarios with constrained computing resources, MobileNetV2 emerges as a more viable option.

The comparative analysis and performance evaluation of MobileNetV2 and InceptionV3 in diabetic retinopathy classification reveals that each model has its unique strengths and weaknesses. Choosing the best model necessitates careful consideration of the unique needs of the clinical application, such as accuracy, efficiency, interpretability, and generalizability. Additional investigation is essential to explore the integration of the two models or to create a new model that harnesses the advantages of both.

It is crucial to highlight the importance of early detection and precise classification in diabetic retinopathy. Utilizing the most recent technological innovations in image processing and machine learning presents a significant opportunity to improve diagnosis and treatment results for individuals with diabetes. This study seeks to significantly enhance the prevention of blindness caused by diabetic retinopathy by refining classification accuracy through the application of geometric augmentation techniques and transfer learning models.

II. METHODOLOGY

The study was carried out in multiple phases, starting with the collection of datasets from Dr Sardjito and the APTOS 2019 dataset. The datasets were subsequently partitioned into three separate subsets: training sets, testing sets, and validation sets. The next step in the process involves enhancing the training data and training the model using the MobileNetV2 and InceptionV3 architectures. The last phase consists of assessing the model through a confusion matrix to derive the metrics for accuracy, precision, sensitivity, and specificity. Fig. 1 illustrates the research flow.

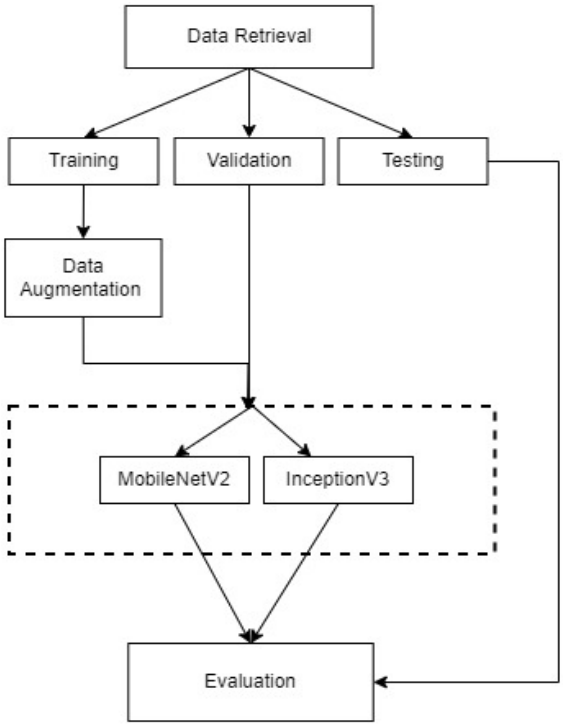

Fig. 1. Research flow.

A. Data Retrieval

The acquisition of data was crucial in this study, especially regarding the classification of diabetic retinopathy. The data for the retinal fundus images was sourced from two main origins. The data were collected from Dr Sardjito Hospital in Yogyakarta and the APTOS 2019 dataset. Dr. Sardjito Hospital stands out as a leading medical institution in Indonesia, featuring an extensive collection of retinal fundus images that covers a wide range of diabetic retinopathy severity. The data holds considerable importance as it accurately represents the condition of patients treated at the hospital, thus improving the relevance and precision of the developed classification model. Fig. 2 presents the exemplar of the retinal fundus image dataset.

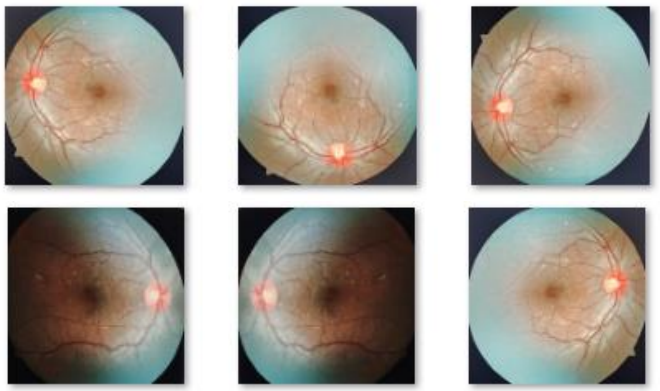

Fig. 2. Retina images dataset.

Additionally, the APTOS 2019 dataset, which is publicly available, was utilized in this study. This study employs a dataset consisting of 3,677 retinal fundus images, categorized into two groups: diabetic retinopathy positive (1,872 images) and average (1,805 images). The use of this dataset allows for model training with a larger volume of diverse data, which is essential for improving model generalization. For additional information concerning the datasets employed in this study, please consult Table I.

TABLE I. DATASET

No	Class	Data
1	Diabetic Retinopathy	1.872
2	Normal	1.805
	Total	**3.677**

Following the collection process, the data is divided into three separate sets: training data, validation data, and testing data. The dataset is segmented into three parts: 80% is allocated for training the model, 10% is designated for validation, and the final 10% is reserved for testing the model's accuracy. The proportional division plays a vital role in guaranteeing that the model learns from the available data while also being able to generalize to previously unseen data. This fact aligns with essential principles of machine learning that highlight the importance of validating models.

B. Data Augmentation

Subsequently, the geometric augmentation technique serves as a method to enhance both the quantity and diversity of training data through the modification of existing images. This study utilized various augmentation techniques, such as resizing images to a resolution of 224x224 pixels, adjusting the zoom by a factor of 0.2, applying shear transformations within a range of 0.2, and implementing both horizontal and vertical flip transformations. The application of these techniques is expected to enable the model to learn from a broader array of images, thus improving its ability to generalize in classification tasks.

Images were resized to (224x224) to maintain uniform resolution, an essential factor in training deep learning models. This size was chosen due to its status as a standard dimension commonly utilized in various neural network architectures, such as MobileNetV2 and InceptionV3. Maintaining a consistent size allows for more efficient and effective data processing by the model.

The utilization of a zoom range and shear range facilitates diversity in the viewing angle and perspective of the image. The model can learn to recognize important features of retinal fundus images at various scales through zooming. At the same time, the shear range allows for adaptation to distortions that may occur during image capture. This technique holds considerable importance due to the variability in the angles at which retinal fundus images are captured and the differing lighting conditions present during their acquisition. The implementation of horizontal and vertical flips serves as an essential technique in enhancing data through augmentation. The absence of a fixed orientation in retinal fundus images allows for the use of flip techniques, which helps the model learn from inverted images and improves its ability to recognize essential patterns. This study is especially relevant in the context of classifying diabetic retinopathy, as changes in image orientation can influence the precision of detection outcomes.

The choice of these geometric augmentation techniques is informed by the results of earlier studies that have shown that data augmentation can significantly improve model accuracy in image classification tasks [27], [28], [29]. Data augmentation plays a crucial role in reducing overfitting and improving model performance when working with limited data sets [30], [31]. The application of these techniques is expected to yield a model that demonstrates improved performance in classifying diabetic retinopathy.

C. Training Model

The model development process in this study involved training two well-known neural network architectures, specifically MobileNetV2 and InceptionV3. The selection of these two models is based on their proven effectiveness across various image recognition and classification tasks, along with their computational efficiency. MobileNetV2 is tailored for devices with constrained computational capabilities, whereas InceptionV3 provides enhanced depth and complexity, enabling a more thorough examination of the relevant features.

The model underwent training with the dataset that had been previously collected and prepared. The training parameters comprised a dropout rate of 0.2 to mitigate overfitting, a sigmoid activation function for binary classification, and the Adamax optimizer, known for its efficacy in tackling optimization challenges. The learning rate was established at 0.0001, a frequently utilized value to promote stable convergence throughout the training process. The training procedure was planned for 30 epochs, incorporating early stopping to halt the training if there was no enhancement in accuracy over five successive epochs.

Throughout the training process, evaluations of the model were conducted at consistent intervals to assess its performance. The evaluation described was carried out utilizing a validation data set that was separate from the training data set. This approach allows for the determination of whether the model is showing indications of overfitting. In this situation, the model becomes excessively dependent on the training data and needs to generalize to new data. Should this situation arise, adjustments might be made regarding the training parameters or the augmentation method utilized.

After training the model, the next step involves fine-tuning the chosen architecture. Fine-tuning involves adjusting a pre-trained model by utilizing a more specialized dataset. In this context, the MobileNetV2 and InceptionV3 models, previously trained on a substantial dataset, will be fine-tuned to the dataset of retinal fundus images that have been gathered. This process aims to improve the accuracy of models used for classifying diabetic retinopathy. By implementing a structured approach in model development, it is expected that both architectures will produce the best results in diabetic retinopathy classification. This study aims to enhance classification accuracy while

providing an in-depth understanding of the effectiveness of various techniques and architectures in the detection of diabetic retinopathy.

D. Evaluation

The evaluation of the model is a vital step in determining the effectiveness of the created classification system. This study utilized several evaluation metrics, such as accuracy, precision, specificity, and sensitivity. The chosen metrics offer unique insights into the model's effectiveness in classifying retinal fundus images according to the severity of diabetic retinopathy.

Accuracy serves as a crucial metric that reflects the ratio of correct predictions to the overall predictions generated by the model. This metric holds significant value, offering a comprehensive insight into the model's ability to identify images accurately. Nevertheless, depending solely on accuracy needs to be improved, especially in scenarios involving unbalanced datasets, where the quantity of images across different categories can differ significantly. As a result, further metrics, including precision and sensitivity, are also computed.

Precision measures the ratio of accurate positive predictions to all optimistic predictions, while sensitivity evaluates how effectively the model detects actual positive cases. In contrast, specificity measures the ability of the model to identify adverse conditions. The application of a combination of these metrics enables a more thorough understanding of the model's performance in diabetic retinopathy classification.

The testing process was carried out utilizing the previously segregated test data set. Following this, the outcomes of these tests undergo analysis aimed at pinpointing the model's strengths and weaknesses in classification. For example, when the model shows high accuracy yet low sensitivity, it may indicate that the model is more skilled at recognizing images without retinopathy than those that display signs of the condition.

The examination of these findings is essential for advancing model development. If the model shows less than ideal-performance, adjustments can be made to the architecture, training parameters, or augmentation techniques used. As a result, the evaluation of models serves not just as a final step but as a crucial part of the ongoing model development process.

III. Results and Discussion

Diabetic retinopathy is a significant contributor to global blindness, highlighting the critical need for precise classification to facilitate early intervention and effective disease management. This study presents a comparative analysis of two deep learning models, MobileNetV2 and InceptionV3, aimed at evaluating their performance in classifying retinal fundus images to detect diabetic retinopathy. The findings indicate that both models show acceptable performance, yet significant differences are apparent in the evaluation metrics.

MobileNetV2 exhibited higher accuracy than InceptionV3, achieving an accuracy rate of 97%. This result suggests that the model demonstrates enhanced capability in identifying relevant features within retinal fundus images. The accuracy of the MobileNetV2 model is particularly impressive, achieving 97%. This result suggests that the model is highly effective in reducing false positives. On the other hand, InceptionV3 demonstrates an accuracy of 94% and a precision of 97%. Although these values are noteworthy, they indicate that MobileNetV2 surpasses InceptionV3 in terms of overall accuracy. Fig. 3 presents the graph depicting the training accuracy of MobileNetV2.

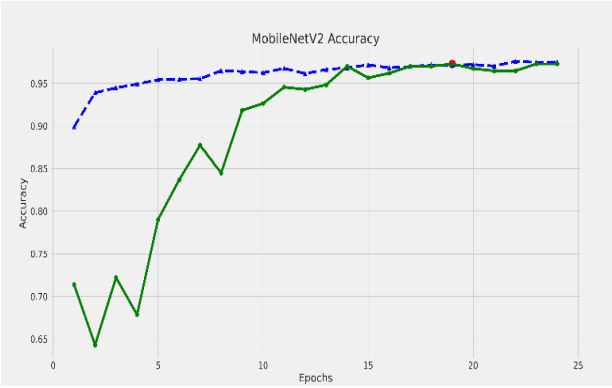

Fig. 3. MobileNetV2 training accuracy.

The model's sensitivity, characterized by its capacity to identify positive cases, produced some fascinating outcomes. MobileNetV2 showed a sensitivity of 96%, whereas InceptionV3 displayed a sensitivity of just 91%. This result suggests that MobileNetV2 demonstrates greater efficacy in recognizing patients with diabetic retinopathy, which holds considerable importance in a clinical environment where timely identification can avert more severe disease advancement.

The measure of specificity, reflecting the model's ability to identify negative cases correctly, showed similar results for both models, achieving a value of 97%. This result indicates that, even with differences in sensitivity and accuracy, both models demonstrate a similar ability to recognize individuals without diabetic retinopathy. The results indicate that InceptionV3 continues to be a dependable choice for clinical applications.

This study revealed that while InceptionV3 showed similar precision to MobileNetV2, the differences in sensitivity and accuracy suggested that MobileNetV2 performed better in detecting diabetic retinopathy. This results from the enhanced capability of MobileNetV2 to utilize augmentation data used during training, which improves the model's ability to generalize across variations in retinal fundus images.

Furthermore, both models underwent assessment using a varied dataset that included images of patients displaying different stages of diabetic retinopathy. The findings indicated that MobileNetV2 showed enhanced efficacy in detecting the early stages of the disease, which are frequently difficult to identify. This finding highlights the crucial influence that choosing the suitable model can exert on the precision of diagnosis and the management of patients after that. Fig. 4 illustrates the confusion matrix for the evaluation of MobileNetV2.

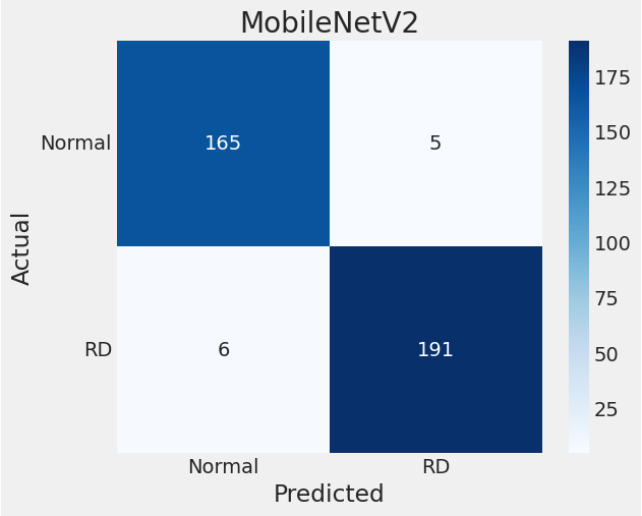

Fig. 4. Confusion matrix.

This study employs various methodologies that significantly diverge from those used in earlier investigations, enabling a more thorough analysis. A previous investigation by [32] utilized CNN to classify diabetic retinopathy, resulting in an accuracy of 75% and a sensitivity of 95%. A separate investigation conducted by [33] utilized ResNet50 to classify the APTOS 2019 dataset, achieving an accuracy of 91%. The findings from this study are thoroughly compared with those of several prior studies in Table II. The comparisons provide valuable insights into the progress and contributions of this study in relation to the current body of literature.

TABLE II. COMPARISON WITH OTHER STUDIES

No	Researchers	Method	Accuracy
1	Pratt	CNN	75%
2	Devi	ResNet50	91%
3	**Our Study**	**MobileNetV2**	**97%**

This study utilizes a range of methods that markedly diverge from those used in earlier investigations, facilitating a more thorough and detailed analysis. A comprehensive comparison of the findings from this study with those of several prior studies is outlined in Table I, emphasizing the differences in methodology, data processing techniques, and model performance across various experiments. The comparisons yield essential insights into the progress and contributions of this study in relation to the current body of literature.

IV. CONCLUSION

This study's findings demonstrate that MobileNetV2 and InceptionV3 serve as two effective models for classifying diabetic retinopathy through retinal fundus images. While both models showed commendable performance, MobileNetV2 revealed enhanced accuracy and sensitivity, positioning it as a more appropriate option for clinical applications. The implications of these findings are substantial for managing and preventing blindness caused by diabetic retinopathy, laying a groundwork for additional exploration in this area.

Future investigations should explore the potential advantages of integrating the MobileNetV2 and InceptionV3 models within an ensemble framework. This method enables the advantages of each model to be utilized, thus improving the overall accuracy and sensitivity. Moreover, it is essential to broaden the datasets employed for training and evaluating the models. Employing more extensive and varied datasets can improve model generalization and decrease the likelihood of overfitting. Additionally, gathering data from diverse geographical areas could improve our understanding of the differences in the clinical manifestations of diabetic retinopathy.

ACKNOWLEDGMENT

This study received full funding from the Ministry of Education, Culture, Research, and Technology, reference number 196.19/A.3-III/LRI/VI/2024. I would like to express my gratitude for the support which was instrumental in funding this work and facilitating the task at hand. This research would not have been possible without this generous funding.

Doctoral Program in Engineering Science, Universitas Sriwijaya, Palembang, Indonesia[1]
Faculty of Computer Science, Universitas Sriwijaya, Palembang, Indonesia[2, 3, 4]
Faculty of Computer Science and Engineering, Universitas Multi Data Palembang, Palembang, Indonesia[1]

Abstract*—This research aims to develop a new method in Structural Equation Modelling (SEM) analysis using the Apriori algorithm to accelerate the achievement of Goodness of Fit models, focusing on traditional retail purchasing decision models in Indonesia, especially in Palembang. SEM will be used to model causal relationships between variables that influence purchasing decisions in traditional retail. However, the Goodness of Fit model testing process takes a long time due to the complexity of the model. Therefore, this research uses the Apriori algorithm to filter variables that have a significant relationship in traditional retail purchasing decision models to reduce model complexity and speed up Goodness of Fit calculations. There are two stages in the research. First, the Apriori algorithm identifies frequent item sets that frequently appear among variables influencing traditional retail consumer purchasing decisions, such as product, price, and location. This pattern becomes the basis for SEM modeling, focusing on selected variables and, in the second stage, measuring the Goodness of Fit of the SEM model, namely GFI, RMSEA, AGFI, NFI, and CFI, to evaluate the suitability of the model which explains the factors that support traditional retail purchasing decisions in Palembang. The practical implications of this research are significant, as it provides a more efficient and effective method for modeling and understanding consumer behavior in the context of traditional retail. Based on other studies, if this research uses a conventional SEM approach, it does not meet the cut-off value of Goodness of Fit. Meanwhile, the results of the proposed method, namely combining Apriori into SEM, called APR-SEM, obtained a significant Goodness of Fit evaluation. The model coefficient of determination value from APR-SEM is R^2 0.71, higher than the conventional model, R^2 0.52. This method effectively simplifies the SEM model by identifying the most relevant relationships, thereby providing a clearer understanding of the critical factors influencing purchasing decisions in traditional retail in Palembang City.

Keywords*—APR-SEM; method; goodness of fit; traditional retail

I. Introduction

The existence of retail in Indonesia is relatively fast. According to 2021, Global Retail Development Index (GRDI) data, Indonesia managed to rank fourth, up one place from 2019 [1]. Meanwhile, Indonesia's retail sales growth was reported to increase by 3% in September 2021 [2]. The Indonesia Retail Summit 2023, which carries the theme ASEAN Retail: Epicentrum of Growth, shows the enthusiasm and commitment to Indonesia's role in strengthening the ASEAN and even the global retail industry. Currently, the Indonesian retail industry is the largest in ASEAN; Indonesia is in the number one position for retail in ASEAN [3].

In Indonesia, there are two forms of retail business run by the community, namely traditional retail and modern retail [4]. In contrast to traditional retail, modern retail is a shop with a self-service system that sells various types of goods at retail in minimarkets, malls (supermarkets and hypermarkets), department stores, or wholesale shops in the form of wholesalers [5].

With modern management, service, quantity, quality, and prices, modern retail has a higher competitiveness than traditional retail. Many traditional retailers then lack visitors, and their turnover decreases until they finally close due to their inability to compete with the many modern retailers nearby [6][7]. However, quite a few traditional retailers can survive amidst the invasion of many modern minimarkets popping up around these traditional retailers. These retailers continue to survive, sell, and serve buyers and are still busy with buyers. Interestingly, traditional retail in Indonesia also dominates the retail sales business in Indonesia [8]. Retail sales activities in Indonesia are still dominated by traditional retail. This can be seen from the number of outlets and the sales value which is much higher than modern retail outlets. According to data compiled by Euromonitor [8], there are 3.57 million traditional retail outlets in Indonesia.

With the current conditions, where the Indonesian retail industry is the largest in ASEAN, and traditional retail dominates the retail sales business in Indonesia, the large number of studies that discuss the existence of retail, including traditional retail types, are the basis for this research. Traditional retail businesses aim to increase competitiveness to survive with unique products, services, and facilities according to traditional retail characteristics and, of course, to make a profit. Increasing competitiveness in traditional retail businesses must be distinct from the owner's ability to manage the business. Traditional retail ownership, which is more personal, requires managers to survive by relying on brilliant ideas to advance their business. The use of ideas or concepts known as tacit knowledge is part of knowledge management [9]. Some research models are based on converting tacit knowledge into individual knowledge [10]. The purchasing decision model in traditional retail has 3 variables, namely product, price, and place which influence purchasing decisions [11].

In various disciplines such as marketing, management, and information technology, analysis of relationships between

variables is critical to understanding the dynamics that influence research results. Structural Equation Modelling (SEM) is a powerful method for analyzing complex relationships between latent variables and their indicators. Meanwhile, the Apriori algorithm, which originates from the field of data mining, is well known for analyzing association patterns between items in large data sets. Although SEM is very effective for modelling structural relationships between variables, this method is not designed to handle the analysis of high-frequency association patterns in large data sets. SEM can be obtained through the partial least squares structural equation modelling technique [12]. On the other hand, the Apriori algorithm can identify significant association rules in the data but cannot explicitly model the hypothesized causal relationships as SEM does. Apriori can generate association rules on data sets, for example, transactional basket data, to produce variations in sets of items (baskets) that adequately represent consumer purchasing patterns [13].

Therefore, combining these two methods offers a more comprehensive approach to analyzing complex data. This research aims to produce a model related to purchasing decisions in traditional retail using SEM analysis. SEM analysis tests the model's suitability by examining various Goodness of Fit criteria. However, the model Goodness of Fit testing process often takes a long time due to the complexity of the model. Therefore, combining the Structural Equation Modelling(SEM) method with the Apriori algorithm will make it easy to analyze complex relationships between variables and identify significant association patterns in the data. This approach can provide more profound and comprehensive insight into the relationships between variables so that Goodness of Fit criteria are quickly achieved.

This paper consists of several parts. In Section II, this paper reviewing several concepts related to research involving Structural Equation Modeling techniques and the Apriori Algorithm; besides looking at the retail conditions in Indonesia. Section III, this paper provides a general overview of research methodology, including respondent demographics and research model. Section IV of this paper explains the proposed research method regarding the stages. Section V, this paper provides results and discussion, and finally, Section VI concludes this paper.

II. Literature Review

The existence of traditional retail has a significant influence on economic development in Indonesia with the number of traditional retailers surpassing modern retail. Based on type, traditional grocery stores are the most numerous retailers in Indonesia. The number was recorded at 3.57 million units. A total of 38,323 retailers are in the form of department stores. Then, there are 1,411 supermarket-type retailers. Then, forecourt retail and hypermarkets were 358 units and 285 units, respectively, as in Table I.

The dominant type of retail in Indonesia is the traditional grocery store, which is both wholesale and retail. The types of products sold in traditional grocery stores are shown in Table II below.

TABLE I. Types of Retail and Number in Indonesia in 2022 [14]

Retail Type	Total (unit)
Traditional Grocery	3,935,238
Department Store	41,453
Supermarket	1,544
Food/Beverage Specialist	5,455
Hypermarket	298

TABLE II. Types of Products in Traditional Grocery Stores

Types of Products	Source
Necessities, snacks, drinks, toiletries and washing supplies, household supplies, medicines, kitchen spices, instant food, LPG gas, and stationery supplies.	[15]
Household equipment and necessities.	[16]
A variety of daily household needs	[17]

State-of-the-art research [18][19][20][21][22][23] which formulates business strategies for retail businesses, especially small-scale retail, in the form of developing business strategy models using data mining, artificial neural networks, and structural equation modelling, no one has combined the tools between data mining and structural equation modelling. However, research in study [24] and [25] has used a combination of SEM and data mining methods with model validation between 54%-89%. The research model [26] is the Apriori + hybrid structural equation model (SEM) using a data-based Apriori algorithm that explores large-scale hidden relationships between variables. Meanwhile, the SEM model captures user behaviour and decision-making procedures, providing interpretable results. Additionally, association rules in Apriori facilitate the specification of complex SEM models, thereby substantially reducing modelling calibration. The Goodness of Fit results show that the SEM + Apriori hybrid model performs better than the conventional model, namely with an R^2 value of 0.82, which is greater than the conventional model, 0.69.

From the previous research above, this is the first time anyone has specifically proposed a combination of Apriori and SEM analysis in formulating research models. Although research [26] has used a hybrid SEM + Apriori model, it is limited to the automotive industry. So, this research proposes SEM analysis using the Apriori algorithm to model purchasing decisions in traditional retail. The following are several theories related to the proposed method in this research, namely Association Rule, Apriori Algorithm, and Structural Equation Modelling.

A. Association Rule

Association rule mining is a data mining technique that finds similar rules in an event [27]. An example of an association rule that is often encountered is the process of purchasing merchandise at a shopping centre. From historical data it is known that the purchase of bread mainly follows the purchase of milk, so shop owners can increase their profits by arranging the location of milk and bread close together and providing discounts that attract buyers. Commonly used association methods are FP-Growth, Coefficient of Correlation, Chi-Square, Apriori, and others.

B. Apriori Algorithm

The Apriori algorithm, a classic in data mining, is a powerful tool for uncovering association rules. Its main purpose is to delve deep into the complex network of associationrelationships between variables [26], thereby showcasing the depth of the topic.

- Support is the probability that items A and B appear simultaneously, representing the importance of the corresponding association rule in the dataset.

$$support(A \rightarrow B) = P(A \cup B)$$

- Confidence is the proportion of the number of times that A and B appear simultaneously over the number of times that A appears. This represents the credibility of the association rule.

$$confidence(A \rightarrow B) = \frac{support(A \rightarrow B)}{support(A)}$$

Key metrics in the Apriori algorithm are based on:

- Support: Percentage of transactions containing itemsets or rules. The higher the support, the more frequently the item or rule occurs.
- Confidence: The probability that the consequent occurs when the antecedent exists. A value close to 1 indicates the strength of the rule.
- Lift: It's the key that unlocks the door to understanding association. The ratio between actual support and expected support if the antecedent and consequent were independent. Values greater than 1 indicate a positive association, enriching our knowledge about the data.
- Conviction: Measuring the strength of a rule by considering the frequency of antecedents that are not followed by consequents. The infinity (inf) value indicates the rule is firm.

The steps in the Apriori Algorithm are:

1) Determine minimum support and confidence
2) Find items that appear frequently (frequent itemsets)
3) Remove items that don't appear frequently
4) Create association rules
5) Evaluate association rules

C. Structural Equation Modelling

Structural Equation Modelling (SEM) is a technique for observing the interdependence between various variables. It is a confirmatory method to check the suitability of data and conceptual models. This is especially true when drawing conclusions where variables cannot be measured. SEM is also called a combination of factor analysis and multiple regression. If completed on a software platform, it can be completed using IBM SPSS AMOS, LISREL, and R [28]. The stages in the SEM method are [18]:

1) Development of a theoretical model
2) Development of path diagrams
3) Convert the path diagram into an equation
4) Select input matrix and model estimation
5) Possible identification problems
6) Evaluate goodness of fit criteria

The minimum number of samples in SEM recommended is 100-150 data [29]. Five or fewer constructs exist, each with more than three items (observed variables) and high item communality (0.6 or higher). Table III shows the goodness of fit in step 6 for the model.

TABLE III. MODEL-OF-FIT INDICES

Model-of-fit indices	Full name/key concerns	Cut off value
RMSEA	Root Mean Square Error of Approximation	Value between 0.08 and 0.10 (mediocre fit), <0.08 (good fit)
GFI	Goodness of fit statistics Exhibits bias towards samples	Value >0.90 or >0.95 (use 0.95 if factor loading and number of sample are low)
AGFI	Adjusted goodness of fit statistics Needs to be accompanied by other indices	Value of >0.80
NFI	Normed fit index Sensitive to sample size	Value of >0.90
CFI	Comparative fit index Revised version of NFI Less affected by sample size	Value of ≥0.90

III. RESEARCH METHODOLOGY

Questionnaire data collection used Google Forms [29] to reach all areas of the city of Palembang as research objects. Table IV shows the demographics of a total of 213 respondents.

TABLE IV. RESPONDENT DEMOGRAPHICS

Sample Characteristic		Percent (%)
Gender	Male	57.75
	Female	42.25
Age	Lower than 20 years	39.91
	20-29	49.30
	30-39	5.16
	40-49	4.69
	50-59	0.94
Occupation	Not yet working	0.94
	BUMN	0.47
	Teacher/Lecturer	1.41
	Housewife	48.83
	Student	43.19
	PNS/TNI/Polri	1.41
	Private	3.76
Area	Alang-alang Lebar	8.45
	Bukit Kecil	0.94
	Gandus	1.41
	Ilir Barat I	8.92

	lir Barat II	8.45
	Ilir Timur I	7.98
	Ilir Timur II	14.55
	Ilir Timur III	6.57
	Jakabaring	2.82
	Kalidoni	10.80
	Kemuning	0.47
	Kertapati	0.94
	Plaju	1.41
	Sako	8.45
	Seberang Ulu I	1.41
	Seberang Ulu II	0.94
	Sematang Borang	7.51
	Sukarami	7.98

The object of this research is traditional retail consumers in Palembang City. Fig. 1 shows the methodology adopted for this study. First, the research focuses on reviewing journal literature related to traditional retail existence models, producing a research conceptual model, and compiling a questionnaire based on this conceptual model.

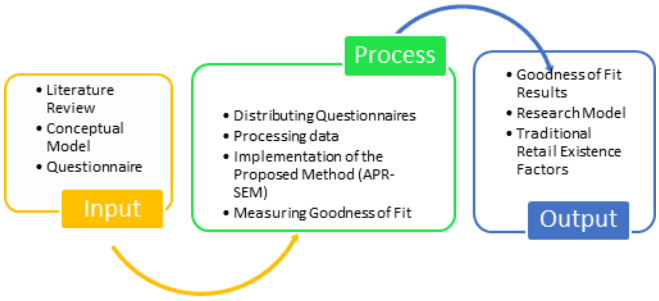

Fig. 1. Research methodology.

The conceptual model of purchasing decisions in traditional retail consists of four variables: exogenous variables: product, price, and place, and endogenous variables: purchasing decisions, as in Fig. 2.

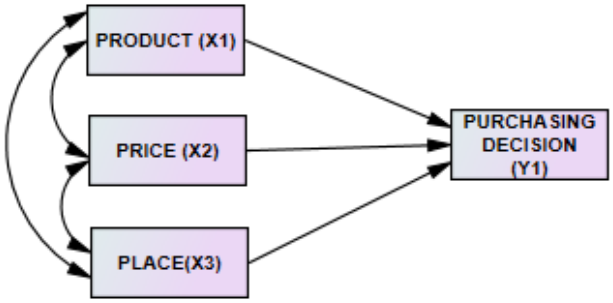

Fig. 2. Purchasing decision models in traditional retail.

Table V shows the indicators for each variable in this research.

TABLE V. INDICATORS OF EACH VARIABLE

Variable	Indicator	Code
Product (X1)	product availability	X11
	product variety	X12
	quality product	X13
	product packaging	X14
Price (X2)	price according to product quality	X21
	cheap price	X22
	discounts	X23
	bargaining price	X24
Place (X3)	comfortable and safe	X31
	clean	X32
	location	X33
	parking area	X34
Purchasing Decision (Y1)	self-interest	Y11
	make ends meet	Y12
	location near home	Y13
	time is not long	Y14
	social level	Y15

The questionnaires used Google Form media, and the data in this research used AMOS for SEM analysis and Jupyter Lab Python for the Apriori algorithm. The next step is to test the model's goodness of fit. One of the main challenges in SEM is a model's Goodness of Fit testing process, which evaluates how well a proposed model fits empirical data. These models, due to their complexity involving many variables and complex causal relationships, often take a long time to test, especially when they are highly complex.

IV. PROPOSED METHOD

This research proposes an APR-SEM method by integrating the Apriori algorithm in SEM analysis to overcome the challenges of this research model, which involves many variables, complex causal relationships, and testing processes. The Apriori algorithm is used in association analysis to find significant relationship patterns between variables. In the context of SEM, this algorithm can filter and identify variables with a significant relationship so that only relevant variables are included in the final model. So, Fig. 3 is a proposed method combining the Apriori algorithm into the SEM analysis technique with the following process.

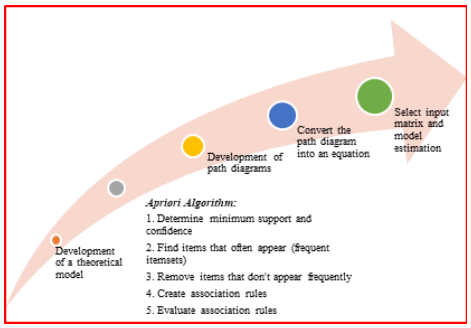

Fig. 3. Proposed method APR-SEM.

APR-SEM is an approach that combines the power of the Apriori algorithm to filter significant variables before use in an SEM model. This aims to:

1) Reduce the complexity of the SEM model by filtering out irrelevant variables.

2) Speed up achieving Goodness of Fit in the SEM model by looking for the strongest associations between variables.

Overall, this new method shows how the Apriori algorithm can be used upfront to filter out significant variables before inserting them into the SEM model, thereby speeding up and simplifying the SEM evaluation process.

V. Result and Discussion

A. Result

The stages in the SEM method are the development of a theoretical model. This stage builds a research model using an in-depth literature study related to research related to purchasing decisions in traditional retail. This stage produces consumer behaviour with the determining factors for purchasing decisions in traditional retail: price, product, and place variables. The next stage is the development of path diagrams. Before entering this stage, the Apriori algorithm will look for the strongest associations between the indicators in the research model. In this case, using Jupyter Lab Python, get the most robust association rule from the research variables. The results of the best rule association for each research variable are as in Table VI.

TABLE VI. Association Best Rule

Variable	Association Best Rule	Key Matric			
		Support	Confidence	Lift	Conviction
X1	X12→X11	98.4%	1.000	1.016	Inf.
	X11→X12	98.4%	1.000	1.016	Inf.
X2	X21→X22	59.8%	0.987	1.062	5.457
	X22→X21	59.8%	0.987	1.062	5.457
X3	X32→X31	98.4%	0.992	1.008	1.984
	X31→X32	98.4%	0.992	1.008	1.984
Y1	Y11→Y12	98.4%	1.000	1.008	Inf.
	Y12→Y11	98.4%	1.000	1.008	Inf.
	Y11→Y14	81.1%	0.824	1.016	1.073
	Y14→Y11	81.1%	0.824	1.016	1.073

The Apriori results will be compared between the conventional SEM results without Apriori and the proposed APR-SEM method for variable X1, as in Fig. 4.

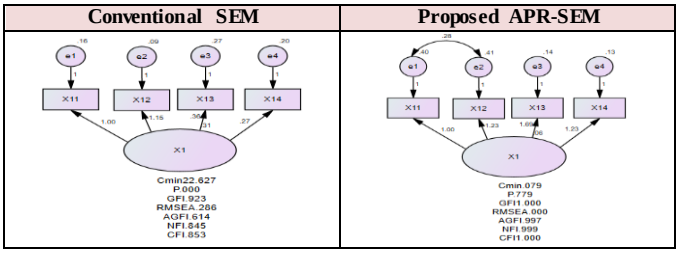

Fig. 4. The comparison of X1 results.

The goodness of fit results for variable X1, as in Table VII.

TABLE VII. Goodness of Fit Variable X1

Index	Cut off value	Conventional SEM	Proposed APR-SEM
GFI	> 0,90	0.923	1.000
RMSEA	< 0,08	0.286	0.000
AGFI	> 0,80	0.614	0.997
NFI	> 0,90	0.845	0.999
CFI	> 0,90	0.853	1.000

From the goodness of fit results of the product variable (X1), the goodness of fit results using the proposed Apriori-SEM method obtained results that all met the cut-off value.

The Apriori results will be compared between the conventional SEM results without Apriori and the proposed APR-SEM method for variable X2, as in Fig. 5.

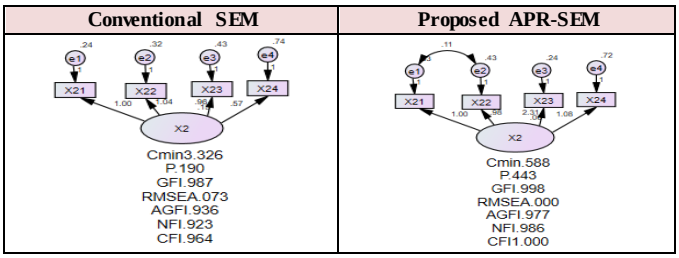

Fig. 5. The comparison of X2 results.

From the Apriori results, the best association rule is between variables X21 and X22, so there is a relationship between them in the path diagram. The goodness of fit results for variable X2, as in Table VIII.

TABLE VIII. Goodness of Fit Variable X2

Index	Cut off value	Conventional SEM	Proposed APR-SEM
GFI	> 0,90	0.987	0.998
RMSEA	< 0,08	0.073	0.000
AGFI	> 0,80	0.936	0.977
NFI	> 0,90	0.923	0.986
CFI	> 0,90	0.964	1.000

The goodness of fit results of the product variable (X2) using the proposed APR-SEM method obtained results that all met the cut-off value, the same as conventional SEM. But in this case, the P value in Fig. 5 is higher in the proposed APR-SEM model, namely 0.443, which shows that the model is better.

The Apriori results will be compared between the conventional SEM results without Apriori and the proposed APR-SEM method for variable X3, as in Fig. 6.

From the Apriori results, the best association rule is between variables X31 and X32, so there is a relationship between them in the path diagram. The goodness of fit results for variable X3, as in Table IX.

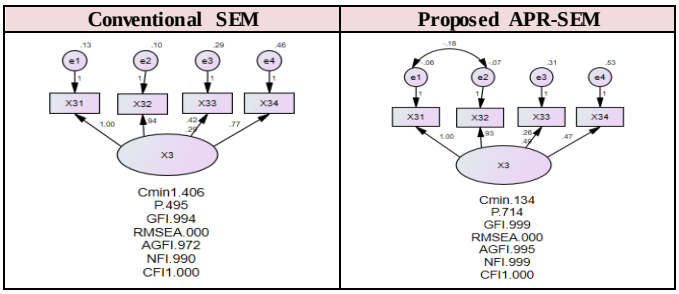

Fig. 6. The comparison of X3 results.

TABLE IX. GOODNESS OF FIT VARIABLE X3

Index	Cut off value	Conventional SEM	Proposed APR-SEM
GFI	> 0,90	0.994	0.999
RMSEA	< 0,08	0.000	0.000
AGFI	> 0,80	0.972	0.995
NFI	> 0,90	0.990	0.999
CFI	> 0,90	1.000	1.000

The goodness of fit results of the product variable (X3) using the proposed APR-SEM method obtained results that all met the cut-off value, the same as conventional SEM. But in this case, the P value in Fig. 6 is higher in the proposed APR-SEM model, namely 0.714, which shows that the model is better.

The Apriori results will be compared between the conventional SEM results without Apriori and the proposed APR-SEM method for variable Y1, as in Fig. 7. From the Apriori results, the best association rule is between variables Y11 and Y12 and also Y11 and Y14, so there is a relationship between them in the path diagram. The goodness of fit results for variable Y1, as in Table X.

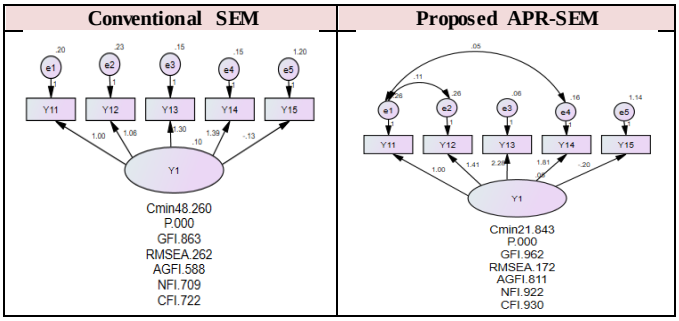

Fig. 7. The comparison of Y1 results.

TABLE X. GOODNESS OF FIT VARIABLE Y1

Index	Cut off value	Conventional SEM	Proposed APR-SEM
GFI	> 0,90	0.863	0.962
RMSEA	< 0,08	0.262	0.172
AGFI	> 0,80	0.588	0.811
NFI	> 0,90	0.709	0.922
CFI	> 0,90	0.722	0.930

The goodness of fit results of the purchasing decision variable (Y1) using the proposed Apriori-SEM method obtained results that all met the cut-off value except RMSEA, but this can be considered because the other indices have met. This is different from conventional SEM, which does not meet all requirements. This shows that the model is better.

Before describing the path diagram of the entire research model, it is necessary to convert it into equation form. The research model has latent variables (X1, X2, X3, and Y1) which are connected to several measurement variables such as X11, X12, X13, and X14 for X1 variable. X21, X22, X23, and X24 for X2 variable. X31, X32, X33, and X34 for X3 variable. Y11, Y12, Y13, Y14, and Y15 for Y1 variable. Convert the path diagram to an equation, namely:

1) Measurement model: X1 is determined by the indicators X11, X12, X13, and X14

$$X11 = \lambda_{11}X1 + e_1 \quad (1)$$

$$X12 = \lambda_{12}X1 + e_2 \quad (2)$$

$$X13 = \lambda_{13}X1 + e_3 \quad (3)$$

$$X14 = \lambda_{14}X1 + e_4 \quad (4)$$

X2 is determined by the indicators X21, X22, X23, and X24

$$X21 = \lambda_{21}X1 + e_5 \quad (5)$$

$$X22 = \lambda_{22}X1 + e_6 \quad (6)$$

$$X23 = \lambda_{23}X1 + e_7 \quad (7)$$

$$X24 = \lambda_{24}X1 + e_8 \quad (8)$$

X3 is determined by the indicators X31, X32, X33, and X34

$$X31 = \lambda_{31}X1 + e_9 \quad (9)$$

$$X32 = \lambda_{32}X1 + e_{10} \quad (10)$$

$$X33 = \lambda_{33}X1 + e_{11} \quad (11)$$

$$X34 = \lambda_{34}X1 + e_{12} \quad (12)$$

Y1 is determined by the indicators Y11, Y12, Y13, Y14, and Y15

$$Y11 = \lambda_{y11}Y1 + e_{13} \quad (13)$$

$$Y12 = \lambda_{y12}Y1 + e_{14} \quad (14)$$

$$Y13 = \lambda_{y13}Y1 + e_{15} \quad (15)$$

$$Y14 = \lambda_{y14}Y1 + e_{16} \quad (16)$$

$$Y15 = \lambda_{y15}Y1 + e_{17} \quad (17)$$

2) Structural model: Structural models explain the relationships between latent variables in the system. Y1 is influenced by X1, X2, and X3.

$$Y1 = \beta_{11}X1 + \beta_{12}X2 + \beta_{13}X3 + \xi_1 \quad (18)$$

3) Covariance between latent variables: The covariance between latent variables X1, X2, and X3 is written as the equation:

$$Cov(X1, X2) = \phi_{12} \quad (19)$$

$$Cov(X1, X3) = \phi_{13} \quad (20)$$

$$Cov(X1, X2) = \phi_{12} \quad (21)$$

So, the path diagram of the traditional retail purchasing decision research model is as in Fig. 8.

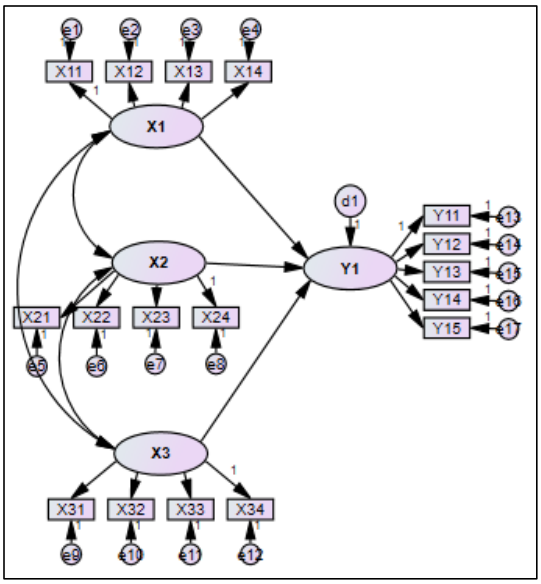

Fig. 8. Path diagram.

The next step is to choose the input matrix by selecting the Covariance Matrix or Correlation Matrix as the input data. After selecting the input matrix, determine the estimation method used. Maximum Likelihood (ML) is the default estimation method when using AMOS. After selecting the input matrix and estimation method, the next step is to run the analysis to obtain parameter estimates and model fit. The estimated calculation results from the research model using conventional SEM are shown in Fig. 9.

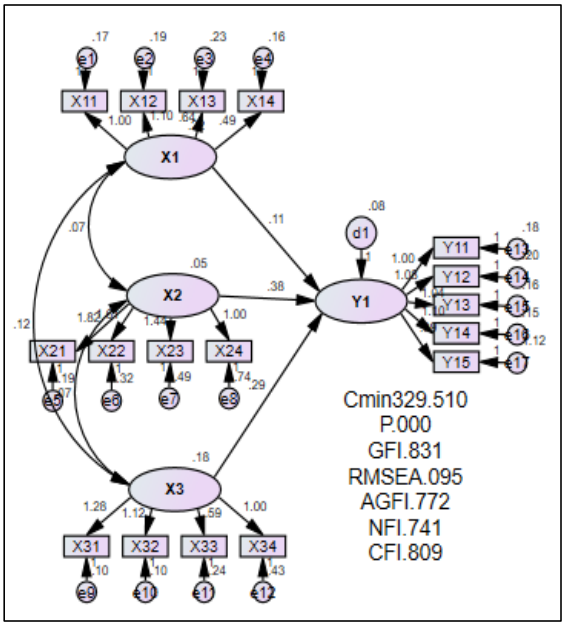

Fig. 9. The SEM conventional results.

From the Apriori results and modification of the path diagram model using AMOS, the calculated estimate results are in Fig. 10.

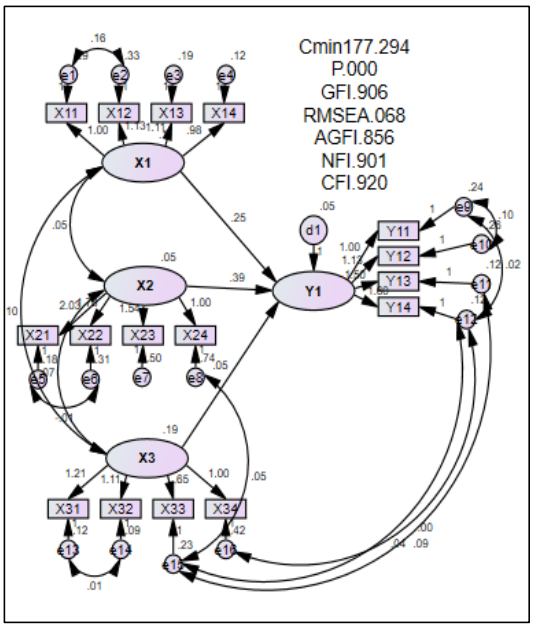

Fig. 10. The APR-SEM results.

From the Apriori results and the modification of the path diagram model using AMOS, the calculated estimate results meet the goodness of fit rules in conventional SEM and APR-SEM, as in Table XI.

TABLE XI. GOODNESS OF FIT FULL MODEL

Index	Cut off value	Conventional SEM	Proposed APR-SEM
GFI	> 0,90	0.831	0.906
RMSEA	< 0,08	0.095	0.068
AGFI	> 0,80	0.772	0.856
NFI	> 0,90	0.741	0.901
CFI	> 0,90	0.809	0.920

These results indicate that none of the measures of suitability when using conventional SEM are suitable. By adding the Apriori algorithm to find patterns or association rules between indicator variables and modifying the path diagram model using AMOS, the path diagram results for each variable X1, X2, X3, and Y1 obtained results that all met the cut-off value.

B. Discussion

From the results of research on the Goodness of Fit model using the APR-SEM method, it is stated that the purchasing decision model by traditional retail customers depends on three factors: product, price, and place. The model coefficient of determination value from APR-SEM is R^2 0.71, higher than the conventional model, R^2 0.52. Variable Y15, namely social level, has a value of 0 for the level of contribution to the model, so it is removed from the latent variable of the AMOS model. This is by the research results [30] and [31], which state that purchasing decisions at traditional retail are not based on a social level but

on consumer age, usually older, who is more likely to shop at traditional retailers.

This research also shows hidden relationships obtainedfrom association rules using the Apriori algorithm, namely the relationship between product availability and diversity, guaranteed product quality at low prices, and a comfortable, safe, clean place. Apart from that, there are four newcorrelations from the modification of the model from AMOS using Modification Indices. Namely, there is a relationship between the main tendencies of buyers in traditional retail because the retail location is close to home, and they can haggle over prices and not wait long for service. Besides that, there is a correlation between parking space availability for buyers who can be served quickly in traditional retail, such as shopping straight from their vehicle.

So, a clear agenda for future Structural Equation Modeling analysis to achieve the Goodness of Fit model (APR-SEM method) is to follow the following steps:

1) Development of a theoretical model
2) Evaluation of best association rules with the Apriori Algorithm
3) Development of path diagram
4) Convert the path diagram into an equation
5) Estimates goodness of fit model

VI. Conclusion

Combining the Apriori algorithm with the SEM method produces a more comprehensive analytical approach to understanding the relationships between variables and association patterns in the data. This can be seen from the purchasing decision model in traditional retail, which does not meet goodness of fit and becomes fit after adding the best association rules to the research model path diagram. The combination of SEM and Apriori allows the discovery of new insights that might have yet to be revealed if these two methods were used separately. For example, associations discovered by Apriori can lead to more in-depth modeling of structural relationships in SEM. This purchasing decision model in traditional retail will provide an analytical framework that helps in understanding the factors that influence the sustainability and competitiveness of traditional retail amidst market competition with modern retail and technological developments. This model will guide traditional retail owners in formulating appropriate strategies to increase their competitiveness, such as adaptingto consumer preferences, integrating technology, or improving service quality. However, combining these two methods, namely SEM and Apriori analysis, avoids including all associative patterns in SEM. Choose the most important relationships with strong theoretical or logical support. We cannot directly obtain goodness of fit in the model, but we must still modify the indices (MI) if necessary. However, be careful not to make modifications that violate the theory. Checkresidual correlations and eliminate non-significant relationships.

Optimizing Energy Efficient Cloud Architectures for Edge Computing: A Comprehensive Review

TA Gamage*, Indika Perera
Department of Computer Science and Engineering, University of Moratuwa, Sri Lanka

***Abstract*—Now-a-days, edge computing and cloud computing are considered for collaborating together to produce computing solutions that are more effective, scalable and adaptable. The proliferation of cloud infrastructures has drastically increased energy consumption leading to the need for more research in optimizing energy efficiency for sustainable and efficient systems with reduced operational costs. In addition, the edge computing paradigm has gained wide attention during the last few decades due to the rise of the Internet of Things (IoT) devices, the emergence of applications that require low latency, and the widespread demand for environmentally friendly computing. Moreover, lowering cloud-edge systems' energy footprints is essential for fostering sustainability in light of growing concerns about environmental effects. This research presents a comprehensive review of strategies aimed at optimizing energy efficiency in cloud architectures designed for edge computing environments. Various strategies, including workload optimization, resource allocation, virtualization technologies, and adaptive scaling methods, have been identified as techniques that are widely utilized by contemporary research in reducing energy consumption while maintaining high performance. Furthermore, the paper investigates how advancements in machine learning and AI can be leveraged to dynamically manage resource distribution and energy-efficient enhancements in cloud-edge systems. In addition, challenges to the approaches for energy optimization have been discussed in detail to further provide insights for future research. The conducted comprehensive review provides valuable insights for future research in the edge computing paradigm, particularly emphasizing the critical importance of enhancing energy efficiency in these systems.**

Keywords*—*Cloud computing; edge computing; energy efficiency; sustainability

I. Introduction

Cloud computing is a concept for providing computer resources such as servers, storage, databases, networking, software, and analytics over the internet. Users can obtain physical infrastructure and data centers on-demand from cloud service providers, negating the need to own and manage them and providing more flexibility, scalability, and cost-efficiency. Without the upfront expenses and hassles of maintaining traditional IT systems, cloud computing allows businesses and individuals to scale their IT needs as needed, covering everything from data storage to sophisticated application development [1] [2] [3].

The adaptability of cloud technology is one of its most intriguing features. Businesses can simply reallocate their computer resources to meet changing demands, allowing for ongoing scaling in response to changing business requirements. Global accessibility is yet another fundamental benefit of cloud computing. Moreover, cloud services reduce geographical barriers, enabling real-time collaboration across several regions and supporting the delivery of services to a global clientele with less idle time [2].

Edge computing is a distributed computing paradigm that moves data storage and computation closer to the point of demand, which is generally at the network's edge, close to the data generating source. Edge computing reduces latency, bandwidth utilization, and reaction times by processing data locally on IoT sensors, gateways, or edge servers rather than depending on a centralized cloud [4], [5]. This method is more efficient for time-sensitive applications where rapid decisions are essential, like real-time analytics, industrial automation, and driverless cars. Edge computing improves performance, security, and dependability in a variety of applications with the use of decentralized computing [6], [7].

Cloud computing has revolutionized the way businesses and organizations operate, offering scalable, on-demand computing resources. Nevertheless, the growth of cloud infrastructures has increased their energy consumption that has been a major concern. Therefore, the demand for energy-efficient cloud architectures has become a critical area of research due to environmental concerns, operational costs, and the need for sustainability. In addition, the proliferation of edge computing where data is processed closer to the data source to reduce latency and bandwidth usage adds another dimension to cloud energy optimization [8], [9].

The rapid growth of energy consumption by edge cloud computing infrastructures has been a significant focus of contemporary research considering the operational costs and environmental concerns aiming at the sustainability of cloud computing architectures. Among the approaches for a sustainable edge computing paradigm, dynamic resource allocation, AI driven energy optimization, energy-aware scheduling and load balancing, green data centres, virtualizations and containerizations are acquiring significant focus by the researchers [10], [11], [12], [13].

Nevertheless, the exponential growth of cloud computing infrastructures has resulted in inflated demand for further research on optimizing energy efficient cloud architectures in order to move towards a sustainable edge computing paradigm. In addition, maintaining performance and scalability while reducing energy consumption has also been a controversial topic that is further researched [14] [15]. Therefore, further research that enhance the green cloud architectures for edge

The open-access publication fee of this paper is supported by the SRC publication fee scheme of the University of Moratuwa

computing are required for the improved sustainability of the cloud computing paradigm.

The rest of the paper is laid out as follows. Section II discusses approaches that have been widely concerned to achieve sustainability in the edge computing paradigm focusing on energy efficiency while Section III broadly explores recent related work that makes use of different strategies for energy efficiency in the edge computing paradigm. Section IV provides a discussion of the conducted review work along with challenges and further insights into the energy-efficient approaches in the edge computing domain. Finally, Section V concludes the research findings along with future directions for the conducted research work.

II. Strategies for Energy Optimization

The following strategies were identified as the main approaches that are widely focused in research that aim at energy optimizations in edge computing. Nevertheless, the techniques that are utilized for edge computing and even in the cloud computing paradigm in contemporary research are a combination of the below-discussed approaches.

A. Energy Aware Scheduling and Load balancing

Energy-aware scheduling and Load Balancing in edge computing aims to optimize resource allocation while reducing energy consumption. In the context of an edge environment, resources are distributed across a number of small, geographically separated devices, requiring efficient scheduling algorithms to manage tasks without overloading nodes or consuming excessive amounts of energy [16], [17]. Energy-aware scheduling approaches prioritize tasks based on their energy demands and resource requirements, ensuring that high-priority tasks are executed on energy-efficient nodes while low-priority tasks are deferred across less critical resources. By optimizing task scheduling, systems can minimize energy wastage, extend device lifespans, and ensure seamless service delivery [18] [19].

Load balancing complements energy-aware scheduling by distributing computational workloads evenly across available nodes to prevent resource overuse and reduce energy consumption. In edge computing, load balancing techniques must consider not only the computational capacity of each node but also its current energy state. Dynamic load balancing ensures that tasks are allocated to nodes with sufficient energy reserves, minimizing the risk of node failure due to energy depletion. These approaches improve the efficiency and sustainability of edge computing setups, enabling them to support more applications and services without overwhelming the energy resources of distributed nodes [20] [21].

B. AI-Driven Energy Optimization

AI-driven energy optimization approaches that are utilized in Edge computing incorporate artificial intelligence strategies to improve the energy efficiency of edge networks and devices, which are frequently decentralized and resource-constrained. AI algorithms, in particular deep learning and machine learning, are able to track and forecast edge device energy consumption and task trends [22]. AI systems are able to make decisions about how best to assign jobs to nodes, modify power settings, and dynamically manage resource utilization based on needs by evaluating real-time data. With this real-time optimization, energy conservation is guaranteed without compromising the necessary performance and service levels.

AI can also provide intelligent load balancing and scheduling, which will optimize the energy consumption of edge computing systems. AI models, for instance, can anticipate high load periods and move workloads to nodes that use less energy or have unused resources. AI algorithms can also allow edge devices to transition into low-power modes while they are inactive or when processing demands drop, which will cut down unnecessary energy consumption. AI-driven energy optimization may dramatically increase the lifespan of edge devices, slash operating costs, and lessen the environmental effect of edge computing infrastructures by continually learning from and reacting to the system [23] [24].

C. Virtualization and Containerization

Virtualization and Containerization in edge computing play a significant role in improving resource usage, flexibility, and scalability of edge networks. Several Virtual Machines (VMs) can operate on a single physical server owing to virtualization, which makes it possible to abstract hardware resources. This makes it possible to consolidate edge resources and execute various applications or services in separate environments, making the best use of the hardware that is available. Virtualization assists in the management of various workloads and offers the flexibility to dynamically scale resources in response to variations in demand in edge computing [25], [26]. In addition, it makes it possible to handle software upgrades and system maintenance effectively without interfering with ongoing services that in turn increase system reliability.

Nevertheless, containerization, which bundles apps and their dependencies into containers, is a less complex substitute for virtualization. Since containers share the host operating system kernel, containers are more efficient than VMs in terms of startup times and overhead. Moreover, containerization facilitates the quick deployment and scalability of applications among dispersed nodes in edge computing. Due to its great degree of mobility, moving apps between various edge devices or contexts is much simpler. This is especially critical in edge environments, which are dynamic and heterogeneous and have a wide range of device capabilities [27], [28], [29]. Therefore, it can be stated that containerization is a perfect solution for the changing needs of edge computing since it allows for quicker application development cycles, better system responsiveness, and more effective resource management.

D. Network Optimization

Network optimizations in edge computing primarily aims to reduce latency, enhance bandwidth efficiency, and improve overall performance by bringing data processing and storage closer to end devices, such as IoT sensors or mobile users. By decentralizing computing power, edge computing reduces the amount of data that needs to be sent to central cloud data centers, minimizing delays in data transmission [30], [31]. Techniques like adaptive routing allow the network to choose the optimal path for data, considering real-time conditions such as congestion, which improves response times [32].

Moreover, Dynamic Voltage and Frequency Scaling (DVFS) is another approach in network optimization for energy efficiency that reduces energy consumption when full performance is not needed by adjusting the power consumption of networking devices depending on real-time demands [33], [34]. Network Function Virtualization (NFV) is also widely researched as an efficient approach for network optimization for energy efficiency in edge computing as it enables the operation of several network services on a single physical server, which eliminates the need for specialized hardware [35]. Adaptive transmission power control [36], [37] and the application of energy-efficient communication protocols [38], such as the enhanced energy efficiency features of 5G [39] are other approaches that wireless networks can reduce overall power consumption. Therefore, these approaches can significantly lower the energy footprint of networks without sacrificing the performance by following the network optimization techniques discussed above.

E. Green Data Centers

Edge data centers are typically smaller and distributed, which makes traditional data center energy efficiency techniques less applicable. By utilizing sustainable methods like the usage of renewable energy sources, cutting-edge cooling systems, and energy-efficient hardware, green data center features aim to reduce their environmental impact for sustainable and green data centers [40], [41]. The transition towards greener operations decreases carbon footprints and operational expenses, making these data centers a crucial element of sustainable IT infrastructure.

In contemporary research, other than the shift towards renewable energy sources in data centers that assists in reducing dependency on the grid, automation techniques, low power consuming electric equipment, and devices with extended thermal limits have also been incorporated in order to improve sustainability and to move towards green data centers [42]. In addition, thermal energy harvesting, kinetic energy and hybrid systems have also been noted in data centers to improve the resilience, and contribute to more sustainable and energy efficient infrastructures.

III. RECENT WORK

The authors in study [43] have conducted a comprehensive analysis of energy consumption across various cloud-related architectures, including cloud, fog, and edge computing. It introduces a taxonomy that categorizes these architectures based on their characteristics, such as the number and role of data centers and their connectivity. The authors propose a generic energy model that accurately estimates and compares the energy consumption of these infrastructures, taking into account factors like cooling systems and network devices. The findings of this research work indicate that fully distributed architectures can consume significantly less energy between 14% and 25% compared to centralized and partly distributed architectures, highlighting the importance of energy efficiency in the design and deployment of modern computing solutions. In summary, the study aims to provide a foundational framework for future research in energy consumption analysis within the evolving landscape of cloud computing technologies. However, while the proposed model effectively highlights architectural differences and provides insights into energy efficiency, it may benefit from more consideration of real-world variables, such as the uneven distribution of end users and the impact of varying application workloads on energy consumption. In addition, the reliance on existing simulators, which have their limitations, could affect the accuracy of the results.

Another group of researchers in study [13] have presented a novel framework that employs Deep Reinforcement Learning (DRL) to optimize workflow scheduling in edge-cloud computing environments, specifically targeting the challenges introduced by the proliferation of IoT devices. Traditional cloud architectures often struggle with the demands of IoT applications due to issues like high latency and limited bandwidth. This study aims to address these challenges by balancing the conflicting objectives of minimizing energy consumption and execution time while ensuring that workflow deadlines are met. The proposed DRL technique demonstrates significant improvements over baseline algorithms, achieving 56% better energy efficiency and 46% faster execution times. Key innovations include a hierarchical action space that distinguishes between edge and cloud nodes, as well as a multi-actor framework that enhances the learning process by allowing separate networks to manage task allocation. The results indicate that this approach is particularly effective for latency-sensitive applications, such as video surveillance, where efficient resource management is critical. Overall, the research highlights the potential of DRL in optimizing resource allocation and scheduling in edge-cloud environments, providing valuable insights for future advancements in this rapidly evolving field.

The researchers of study [11] address the crucial issue of resource allocation in cloud computing, particularly in the context of increasing energy consumption and performance demands on data centers. The authors propose a hybrid model that combines Genetic Algorithms (GA) and Random Forest (RF) techniques to optimize the allocation of VMs to physical machines (PMs). The GA is employed to generate an optimized training dataset that maps VMs to PMs, which is then utilized by the RF for classification and allocation tasks. This approach aims to minimize power consumption while maximizing resource utilization and maintaining load balance across the data center. The effectiveness of the proposed model is evaluated using real-time workload traces from PlanetLab, showing significant improvements in energy efficiency and execution time compared to traditional methods. The study contributes to the existing body of knowledge by demonstrating the potential of hybrid optimization techniques in enhancing cloud infrastructure management. However, the authors acknowledge the need for further research to assess the model's adaptability to diverse workloads and its scalability in heterogeneous cloud environments.

The research in [10] introduces an Energy-Efficient Task Offloading Strategy (ETOS) aimed at enhancing energy efficiency in Mobile Edge Computing (MEC) environments for resource-intensive mobile applications. The study formulates the task offloading problem as a non-linear optimization challenge, proposing a hybrid approach that combines Particle Swarm Optimization (PSO) and Grey Wolf Optimizer (GWO)

to effectively allocate resources while considering capacity and latency constraints. The proposed ETOS leverages the collaborative capabilities of MEC servers to minimize energy consumption during task execution. Extensive simulations demonstrate that ETOS outperforms existing baseline methods in terms of energy utilization, response delay, and offloading utility, particularly under limited resource conditions. Despite its promising results, the research highlights the need for real-world validation and addresses the potential complexity of implementing the hybrid optimization approach in practical scenarios, suggesting directions for future work to enhance applicability and effectiveness in real-world MEC systems.

The research in study [12] focuses on developing a novel multi-classifier algorithm aimed at optimizing energy-efficient task offloading in Fog Computing environments for IoT applications. As the number of connected devices increases, efficient resource management becomes crucial to minimize energy consumption and enhance service quality. The proposed algorithm evaluates various attributes related to tasks, network conditions, and processing capabilities of Fog nodes to determine the most suitable node for task execution. By leveraging machine learning techniques, the algorithm aims to improve decision-making processes regarding task offloading, thereby reducing execution time and energy usage. The study emphasizes the importance of balancing energy efficiency with performance metrics, demonstrating that the multi-classifier approach can significantly enhance Quality of Service (QoS) parameters. In summary, this research contributes to the ongoing efforts to optimize Fog Computing frameworks, making them more effective in handling the computational demands of IoT applications while addressing energy constraints.

The authors of study [44] propose a novel framework to optimize energy consumption and computational efficiency in IoT environments. It introduces a three-layer architecture comprising sensor, edge, and cloud layers, facilitating effective task offloading and resource management. The study employs Long Short Term Memory (LSTM) networks for accurate workload prediction, enabling the system to adapt to dynamic conditions. Additionally, it utilizes Lyapunov optimization methods to address the non-convex nature of resource allocation problems. Simulation results demonstrate significant improvements in energy efficiency and processing rates. However, the research acknowledges limitations, including concerns about scalability, the assumptions made regarding user behavior, and a lack of focus on security aspects. Therefore, the paper contributes valuable insights into mobile edge computing, highlighting the potential for enhanced performance in IoT networks while suggesting areas for further exploration and refinement.

The research of [22] presents the Edge Intelligent Energy Consumption Model (ECMS) aimed at optimizing energy usage in MEC environments. As energy consumption in edge data centers becomes increasingly critical, the ECMS model provides a framework for predicting and managing energy needs based on varying workloads, including CPU-intensive, Web transactional, and I/O-intensive tasks. The authors validate the model through experimental results, demonstrating its superior performance in accuracy and training time compared to existing models like TW BP PM and FSDL. The study categorizes energy consumption modeling into two main approaches: system resource utilization and Performance Monitor Counter (PMC)-based modeling. The ECMS model leverages a simpler network topology and lower input dimensions, resulting in reduced training time and CPU workload during execution. The findings indicate a strong correlation between energy consumption and CPU utilization, emphasizing the need for precise energy models to inform optimization algorithms. The research concludes with future directions, suggesting the extension of the ECMS model to mixed workloads and integration with advanced AI/ML techniques, such as reinforcement learning, to further enhance energy efficiency in edge computing environments, ultimately contributing to sustainable practices in the industry.

A technical analysis on service placement approaches in the context of edge computing has been focused by the authors [45] with the aim of addressing energy efficiency in edge computing paradigm in IoT systems. The main objective of this research work has been to identify the effective and efficient strategies for service placement in IoT environments along with a taxonomy to categorize the studies in this field and in terms of cloud edge service placement approaches and algorithms that have been utilized. In addition to the technical analysis, a statistical analysis has also been provided by the authors along with evaluation factors to which the research findings provide further insights on future research in this paradigm. The results suggest that the server placement approaches fall under three types of categories, namely, decentralized, centralized and hierarchical while Genetic Algorithm has been widely utilized by researchers compared to other machine learning algorithms such as Greedy, Markov, BSAP, Topsis and Polynomial algorithms. Furthermore, time, cost, and latency evaluation metrics have been identified as the most concerned evaluation metrics in the context of service placement. Finally, the authors provide insights on to open issues and challenges in the context of service placement that is vital for future research focusing on service placement.

The research in study [19] presents a heterogeneous cluster-based wireless sensor network (WSN) model aimed at optimizing task allocation to minimize energy consumption and balance load. The network consists of clusters, each with a cluster center and several sensor nodes, where the cluster center collects data from the nodes and communicates with a central processor. The study establishes a task model where complex tasks are divided into independent subtasks, each requiring specific resources, data sizes, and computation times. To address the task allocation problem, the authors propose a Fusion Algorithm (FA) that integrates Genetic Algorithm (GA) and Ant Colony Optimization (ACO) techniques. This algorithm features a novel mutation operator and a new population initialization method, enhancing its effectiveness in reducing energy consumption and balancing the load across the network. Experimental results demonstrate that the FA outperforms traditional GA, achieving 8.1% lower energy consumption and significantly reducing the load on both sensor nodes and cluster centers. The proposed approach ensures all sensors remain operational throughout task execution, thereby increasing the reliability and longevity of the WSN. Therefore,

the research contributes valuable insights into efficient task allocation strategies in edge computing environments.

The researchers of study [46] investigate an RIS-assisted Non-Orthogonal Multiple Access (NOMA) Mobile Edge Computing (MEC) network, focusing on minimizing energy consumption for users. The authors propose a joint optimization approach that includes RIS phase shifts, data transmission rates, power control, and transmission time. Due to the non-convex nature of the problem, the authors decompose it into two sub-problems: firstly, utilizing a dual method for a closed-form solution with a fixed RIS phase vector, and the other employing a penalty method for suboptimal power control solutions. The optimization process alternates between these sub-problems until convergence is achieved. To demonstrate the effectiveness of their proposed NOMA-MEC scheme, the authors compare it against three benchmark schemes: TDMA-MEC partial offloading, full local computing, and full offloading. These researchers have also introduced an alternating 1-D search method for optimizing RIS phase shifts in the TDMA-MEC scheme. Numerical results indicate that the proposed scheme significantly reduces overall energy consumption and highlights the impact of user distance on performance. The paper concludes by acknowledging the potential for future work on robust transmission design to address channel state information estimation errors.

Another group of researchers in [47] have worked on a deep reinforcement learning (DRL) approach for delay-aware and energy-efficient computation offloading in dynamic MEC networks with multiple users and servers. The primary objective is to maximize the number of tasks completed before their deadlines while minimizing energy consumption. The proposed DRL model operates in an end-to-end manner, eliminating the need for post-action optimization functions, and can handle a large action space without relying on traditional optimization methods. The study formulates the offloading problem as a Markov Decision Process (MDP), capturing the complexity of the MEC system by incorporating time-varying channel conditions and various task profiles. Extensive simulations demonstrate that the proposed DRL model significantly outperforms existing DRL models and greedy algorithms in terms of task completion and energy efficiency. The results indicate that the DRL model learns optimal policies over time, effectively managing the trade-off between exploration and exploitation during training. The conducted research highlights the potential of DRL in enhancing the performance of MEC systems, making it a valuable contribution to the field of IoT and edge computing.

The research in [48] presents a novel approach to enhance task offloading in dynamic vehicular environments. It addresses the limitations of existing centralized and decentralized Deep Reinforcement Learning (DRL) algorithms, which often struggle with computational constraints and coordination issues. The proposed framework introduces a multi-layer Vehicular Edge Computing (VEC) architecture that optimizes task management across vehicles, edge servers, and cloud resources. Key contributions include the development of an energy-efficient VEC framework that considers the diverse computing capabilities of network entities and introduces a utility function to enhance energy efficiency. Additionally, a decentralized Multi-Agent Deep Reinforcement Learning (MADRL) algorithm is proposed, which effectively adapts to changing conditions while minimizing latency and maximizing task completion rates. The research also provides a comprehensive performance evaluation using simulations in a realistic environment, demonstrating the effectiveness of the proposed solution in managing varying traffic densities. The conducted research highlights the potential of decentralized approaches in improving the efficiency and responsiveness of vehicular networks, paving the way for advancements in autonomous vehicle applications and real-time data processing.

The research in [24] presents a novel cloud-edge cooperative content-delivery strategy aimed at minimizing network latency in asymmetrical Internet of Vehicles (IoV) environments. By leveraging Deep Reinforcement Learning (DRL), the authors propose a Deep Q Network (DQN) policy that optimizes content caching and request routing based on perceptive request history and current network states. The study formulates the joint allocation of heterogeneous resources as a queuing theory-based delay minimization objective, addressing the challenges of computation complexity and dynamic network conditions. Extensive simulations demonstrate that the proposed strategy significantly reduces network latency compared to existing solutions, showcasing its adaptability to varying user requirements and network states. The findings indicate that the DQN model achieves fast convergence and improved performance across different scenarios. The paper concludes with a discussion on future work, including the exploration of end-user mobility and deeper collaboration among mobile users, edge, and cloud networks to enhance overall Quality of Experience (QoE) while balancing network delay and energy consumption. This research contributes valuable insights into optimizing resource allocation in IoT-edge-cloud systems, particularly in the context of intelligent transportation systems.

Table I illustrates a summary of the recent work that were discussed in detail under objective, approach, key findings and remarks of the particular research work.

TABLE I. SUMMARY OF THE LITERATURE REVIEW

Reference	Objective	Approach	Findings	Remarks
[43]	To evaluate and compare energy consumption of Cloud, Fog, and Edge computing infrastructures	A taxonomy of different cloud architectures and a generic energy model	Fully distributed architectures consume 14%-25% less energy than centralized ones	Model may not account for real-world variables and simulator constraints
[13]	Energy-efficient resource scheduling in edge cloud environment	Deep Reinforcement Learning	• Energy consumption (56% of improvement) • Execution time (46% of improvement)	The proposed reinforcement learning framework is designed to operate in a centralized manner
[11]	Optimize virtual machine allocation in cloud infrastructure, aiming to minimize power consumption while maintaining load balance and maximizing resource utilization	Genetic Algorithm (GA) and Random Forest (RF) techniques	• Execution Time (37% of reduction) • Resource Utilization (11% Improvement)	Limited generalizability due to specific workload traces, complexity in real-world implementation, and potential oversight of other critical factors
[10]	Propose a task offloading scheme that minimizes the overall energy consumption along with satisfying capacity and delay requirements	Hybrid approach established based on Particle Swarm Optimization (PSO) and Grey Wolf Optimizer (GWO)	The proposed strategy considerably outperforms other baseline approaches, such as OEOS, ROA-DPH, ATO, and Local execution in terms of energy consumption, execution time, and offloading utility	Lacks real-world validation and may face implementation complexity in resource-constrained environments
[12]	Propose a novel energy-efficient task offloading method for IoT, Fog, and Cloud computing paradigms	Multi classifier-based approach	• Energy Consumption (11.36% of reduction) for Cloud-only • Energy Consumption (9.30% of reduction) for edge-ward • Network usage (67% of reduction) for Cloud-only • Network usage (96% of reduction) for edge-ward	Lacks extensive empirical validation and does not address decentralized approaches for dynamic environments
[44]	Propose a hierarchical communication and computation framework for jointly optimizing energy consumption and computation rate is proposed	The Long Short Term Memory (LSTM) network	The proposed method can greatly improve system performance by saving energy costs and achieving a high processing rate	Scalability concerns, assumptions about user behavior, limited security focus, and complexity in practical implementation
[22]	Predicting energy consumption and monitor edge servers	Intelligent energy modeling approach that combines Elman Neural Network (ENN)	The proposed ECMS outperforms the baseline power models (FSDL, CMP, TW_BP_PM, AEC, CUBIC, Power regression)	The research primarily focuses on specific workloads, limiting its applicability to broader, mixed workload scenarios in MEC environments
[45]	Identify studies related to service placement strategies to categorize the relevant studies as a knowledge source for further research	Perform a technical analysis on the cloud edge service placement approaches	• Methods and algorithms of the existing service placement approaches • Evaluation metrics for service placement approaches • Tools and environments developed for service placement approaches	Lacks any further implementation towards the service placement paradigm
[19]	Develop an efficient task allocation strategy for heterogeneous wireless sensor networks that minimizes energy consumption and balances load to extend network lifetime and enhance reliability	Fusion Algorithm combining Genetic Algorithm and Ant Colony Optimization for effective task allocation in WSNs	• Load on sensors was reduced by 58% with the FA, while the load on cluster centers decreased by 30.8%. • FA achieved an 8.1% reduction in energy consumption compared to the traditional GA.	The research may not address complex task dependencies and real-world scenarios requiring dynamic resource allocation and execution order
[46]	Minimize energy consumption in RIS-assisted NOMA-MEC networks	Jointly optimize RIS phase shifts, transmission rates, and power control	Significant energy savings compared to benchmark schemes.	Non-convex optimization and CSI estimation errors affect performance
[47]	Maximize task completion before deadlines while minimizing energy consumption in MEC systems	Deep Reinforcement Learning model	Proposed model outperforms existing methods in task completion and energy efficiency through extensive simulations	Model's performance may affect the complexity of real-world environments
[48]	Optimize task offloading and resource management in dynamic vehicular environments using a decentralized framework	A multi-layer edge computing architecture and a decentralized multi-agent deep reinforcement learning algorithm	Significant reduction in energy consumption and improved task completion rates when compared to existing algorithms in simulations	Scalability issues in highly dynamic vehicular networks
[24]	Minimize network latency in asymmetrical IoV environments through optimized resource allocation	Deep Reinforcement Learning	• Network Delay (44% reduction) • Reward per episode (39% improvement)	Future work needed on end-user mobility and deeper collaboration among network components and the tradeoff between network delay

				and energy consumption have not been focused to compromise among multiple network indicators

IV. DISCUSSION

The conducted literature review provides insights into future research that aims at energy efficiency in the paradigms of both cloud and edge computing along with the approaches that are utilized concerning the reduction of energy consumption. Nevertheless, it also noted that the researchers utilize a combination of techniques in their work towards optimizing energy efficiency for sustainable and efficient systems with reduced operational costs. Moreover, it is noted that the techniques widely spread towards the AI-driven approaches with the advancements in machine learning.

Furthermore, it is also vital to identify the challenges that are encountered when focusing on the energy-efficient aspects in edge computing due to the proliferation of IoT devices and advancements in modern computing. Among the challenges to optimizing energy efficiency in the edge computing paradigm, distributed dynamic workloads among edge nodes with vast range of heterogeneity, distributed, and resource constrained nature is much prominent since accurate modeling would be complicated due to the fluctuating workloads based on user demands. In addition, different and unpredictable workloads have imposed a lot of issues towards the edge computing paradigm. Nevertheless, the task scheduling techniques employed by contemporary research are more towards the independent task-oriented workloads while few studies have focused on complex workloads [13].

Moreover, delayed critical applications that run on devices in the mobile edge computing paradigm also impose challenges to this arena [10] that directly leads to the insufficient quality of experience for the end users and high cost of energy and bandwidth utilization that are unfavourable. Moreover, limited power sources, processing and storage capabilities also impose challenges to energy efficiency optimization strategies for a sustainable edge computing paradigm [49], [50]. Resource management is key to optimizing energy efficiency and has also been a challenging task owing to the highly dynamic nature of IoT traffic. Furthermore, many tasks have dependencies that dictate the order of execution. Managing these dependencies while optimizing resource allocation adds another level of complexity to the task allocation process.

Ensuring that the network meets specific QoS requirements, such as latency and reliability, while performing task allocation is a critical challenge that must be addressed. In addition, striking a balance between energy efficiency and QoS awareness has also been a challenging aspect where the QoS is highly impacted by the majority of mechanisms that are utilized in distributed computing environments [51]. Furthermore, energy efficiency with application performance and user experience is crucial, as overly aggressive energy-saving measures may negatively affect user satisfaction. Addressing these challenges is essential for advancing research and developing effective energy management strategies in MEC environments.

Additionally, the need for extensive data collection for relevant energy-related parameters can introduce overhead and impact performance, while selecting the most pertinent features for modeling remains a challenge. Real-time processing requirements further complicate the development of accurate models, and integrating advanced AI/ML techniques introduces complexities in training and deployment.

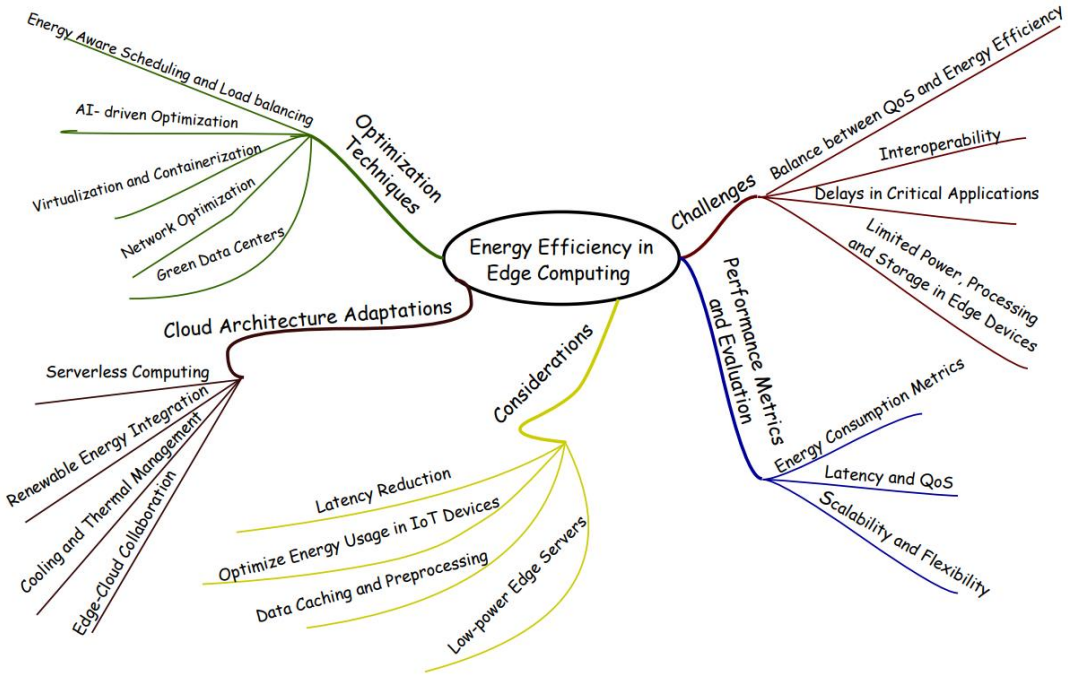

Fig. 1. Mind map with key findings from the conducted review.

With the scalability concerns in both edge and cloud computing, as the number of nodes and tasks increase, maintaining efficient communication and coordination among nodes becomes more difficult. Algorithms must be scalable to handle larger networks without significant performance degradation. Moreover, interoperability also could be a major challenge where a diverse range of IoT devices and platforms can lead to compatibility issues, making it difficult to implement a unified mechanism. Fig. 1 provides a mind map of the key findings from the conducted literature review comprising of energy optimization techniques, cloud architecture adaptations, major considerations and challenges to the energy efficiency aspect of the edge computing paradigm that provides further insights into research in this domain.

Therefore, when the above aspects are concerned, it is apparent that there is a lack of unified metrics and benchmarks for assessing energy efficiency across different edge computing environments, which makes it difficult to compare solutions. In addition, the use of AI/ML models for decision-making in edge computing often introduces significant energy overhead that urges need of optimized lightweight AI/ML algorithms for edge environments without compromising accuracy or efficiency. Heterogeneity of Edge devices also necessitates the scalable, device-agnostic optimization models that can adapt to heterogeneous edge environments. Moreover, real-time applications such as autonomous vehicles, healthcare monitoring systems, etc., have strict latency and reliability requirements, which complicate energy optimization efforts. Therefore, developing solutions that balance energy efficiency with real-time performance guarantees has also been a critical consideration in this research paradigm.

V. Conclusion

The research findings are indicative of the current approaches to energy efficient edge computing systems with reduced energy consumption and costs to provide further insights into future research in this arena. In addition, the different strategies that were identified as the key techniques to energy efficient systems in cloud computing further assists future research while a combination of different strategies has also been noted in contemporary research. Furthermore, AI-driven energy optimization techniques have been widely focused and researched and this approach has been able to provide better mechanisms for optimizing energy efficiency in both edge and cloud computing paradigms.

In conclusion, this comprehensive review on optimizing energy efficiency for edge computing highlights the growing importance of balancing performance and sustainability in modern cloud systems since as edge computing gains prominence in reducing latency and improving data processing efficiency, the need for energy optimization becomes critical. Moreover, various approaches, including workload distribution, resource allocation, and hardware improvements, have demonstrated the potential to significantly reduce energy consumption while balancing the quality of service. As future research, the authors are to refine these strategies and explore innovative methods to further enhance energy efficiency, ensuring sustainable cloud-edge ecosystems that meet the rising demands of modern applications.

Malicious Traffic Detection Algorithm for the Internet of Things Based on Temporal Spatial Feature Fusion

Linzhong Zhang
School of Electronic Information Engineering, Tianjin Vocational Institute, Tianjin, 300410, China

***Abstract*—With the rapid development of the Internet of Things, the security issues of its network environment have gradually attracted attention. To enable faster and more accurate identification and detection of malicious traffic attacks in the Internet of Things, an optimized malicious traffic detection algorithm based on fusion of temporal and spatial features is proposed. This method improves the feature extraction performance of traffic data and increases the accuracy of traffic detection. The test results showed that the comprehensive performance of the fusion algorithm was superior to the other four algorithms used for comparison. On the KDD99-CUP dataset, the F1 of the feature fusion algorithm reached 93.16%, while the F1 of algorithms 1-4 were 81.36%, 67.89%, 90.56%, and 92.24%, respectively. On the test set, 182 traffic samples were accurately identified, including 139 correctly identified malicious traffic and 43 correctly identified normal traffic, with recognition accuracy of 98.73% and 97.65%, respectively. Experimental results revealed that the use of fused feature extraction in traffic detection systems could improve detection efficiency and accuracy, providing a safer and more reliable guarantee for the interaction process of the Internet of Things network, and safeguarding the rapid development and application of the Internet of Things.**

***Keywords*—Internet of Things; network security; temporal-spatial characteristics; traffic detection; fusion algorithm**

I. Introduction

With the rapid development of the Internet, the Internet of Things (IoT) has also been widely used in a series of intelligent building systems such as smart cities, smart offices and smart homes [1-2]. However, because some IoT devices are directly exposed to the Internet, they face more security problems than other network interaction methods [3]. IoT based network attacks may affect communication quality, and even cause signal loss, network paralysis, and other phenomena, seriously threatening users' privacy and security [4]. For traditional anomaly traffic detection techniques, due to the concealment and complexity of existing IoT network attacks, and the fact that traffic attacks exhibit different characteristics with different network environments, there are problems with imbalanced traffic datasets and difficult feature extraction [5]. These issues have increased the difficulty of designing malicious traffic identification algorithms. In current traffic detection systems, the main focus is on identifying and analyzing a single type of traffic to achieve abnormal alerts. However, due to the different types and characteristics of attacks, and some attacks being of unknown types, the accuracy of traffic detection systems is not ideal, making it difficult to predict unknown attacks. To solve the above problems, a traffic detection algorithm based on temporal feature fusion is proposed, and malicious traffic analysis and detection in the IoT are completed on this basis.

II. Related Works

In today's era of rapid development of information technology, network traffic analysis has become an important means to ensure network security, optimize network performance, and improve user experience. Furthermore, with the explosion of Internet users and the popularization of various network applications, the complexity and diversity of network traffic are also increasing. Therefore, in-depth analysis of the characteristics and detection methods of malicious traffic is of great importance for network management and security protection. Yang H et al. proposed a fast strategy hill-climbing learning method to optimize the power allocation for malicious traffic detection in intelligent malicious traffic controllers. Therefore, the malicious traffic detection system could quickly achieve the optimal strategy when the malicious traffic model was unknown. The test results showed that the transmission rate of this malicious traffic detection method increased by 12.28% compared to the original, which made the malicious traffic detection system perform better [6]. Salem A et al. proposed an adaptive adaptation scheme that could make the detection of malicious traffic techniques constructive for legitimate users and destructive for eavesdroppers. Based on the average symbol error probability in different scenarios, this method used a finite rate to represent the overall retention rate. Malicious traffic detection technology could achieve an additional gain of 17dB in transmission signal-to-noise ratio and a gain of 10dB in total secrecy rate [7]. Su N et al. used joint design to transmit and receive beamforming and destructive malicious traffic techniques to weaken the eavesdropping signals of eavesdropping radar in wireless networks. The experimental results showed that this technology performed better than dual function radar network technology in terms of secure transmission [8]. Many radars and networks work in a coordinated manner, but Du Z et al. proposed using a non coordinated approach to study the impact of malicious network traffic on radar target detection. The study solved the maximum likelihood estimation in homogeneous clutter to optimize detection performance. Through verification, it was found that the improved target detection system showed significant improvement in performance in network

environments with high levels of malicious traffic [9]. Hosseinali J et al. proposed an improved adaptive algorithm to address the issue of malicious attacks on high-power ranging devices. The algorithm optimized power allocation for each reliable subcarrier, while subcarriers subjected to highly malicious traffic were deactivated. This adaptive technology could reduce the bit error rate to 10-7 under malicious traffic in high-power ranging devices, improving the reliability of network systems [10]. In the scenario of multi-user and multi-transceiver simultaneous network, to eliminate malicious traffic on reconfigurable intelligent surfaces, the Jiang T team proposed an alternating projection algorithm, which took the solution obtained by the algorithm approaching 0 as the initial value for subsequent optimization, and changed the phase of the reconfigurable surface components accordingly. Tests showed that the improved algorithm could detect malicious traffic on reconfigurable surfaces within the experimental range [11].

The malicious traffic detection performance of network systems is largely influenced by algorithms. Some scholars have conducted more in-depth research and experiments on the optimization of deep learning algorithms. Lin J et al. proposed an improved genetic algorithm based on four quadrant photodetectors to improve the accuracy and stability of visible light positioning. This algorithm enabled the detector to locate the measurement point based on the received illuminance value. The average positioning error of the positioning system using optimization algorithms was 4.023cm [12]. Mahmoud B et al. proposed a hybrid model of deep learning algorithm and tabu search to achieve balanced coverage of all targets in sensor networks. The optimized algorithm required the use of multiple sensors for coverage. Several experiments showed that this fusion algorithm outperformed algorithms based on automatic learning [13]. To extend the lifespan of wireless sensor networks, Rajan L et al. proposed a new optimization algorithm based on the grey wolf algorithm using Na deep learning algorithm, which selected the optimal cluster head under constraints such as separation distance and energy consumption. Compared to the classical grey wolf algorithm and particle swarm optimization algorithm, the improved grey wolf algorithm improved overall performance by 28.6% and 31.5%, respectively [14]. Shaikh M et al. proposed using optimized deep learning algorithms to achieve higher accuracy in the calculation of parameters for overhead transmission lines. This optimization algorithm was applied to single-phase and three-phase transmission lines, achieving optimal solutions for the vast majority of benchmark functions. The accuracy and computational efficiency of the optimized deep learning algorithm had been improved [15].

In conclusion, despite the numerous inferences and experiments conducted by scholars on optimizing detection algorithms and enhancing traffic detection performance, the intricate neural network structure inherent to deep learning algorithms results in a slow convergence speed and a notable decline in detection accuracy. To further enhance the performance of malicious traffic detection, an optimized malicious traffic detection algorithm based on the fusion of temporal and spatial features is proposed. This is achieved through the use of a mixed sampling and variational autoencoder data augmentation algorithm, which enables more intelligent and efficient detection results in complex environments.

III. Methods and Materials

A. Flow Detection Algorithm Integrating Temporal and Spatial Features

When faced with malicious traffic attacks, intrusion detection systems can use detection algorithms that continuously learn traffic information characteristics to identify them. When attacked, the detection system can determine the traffic attack behavior [16]. The process of traffic detection mainly consists of network status detection and traffic detection. The former is to detect the operating status of network and host and monitor the fluctuation of network system in real time, while the latter is to extract the characteristics of traffic data and complete the detection and analysis. The characteristics of traffic data can be analyzed from both temporal and spatial dimensions. For the temporal dimension, there is correlation between historical traffic data, while for the spatial dimension, there is local spatial correlation between traffic characteristics [17]. By integrating these two different types of features, traffic detection can simultaneously capture feature information from different dimensions, identify different traffic activities, and make the results of detection algorithms more accurate and reliable. The architecture of the data traffic detection system is depicted in Fig. 1.

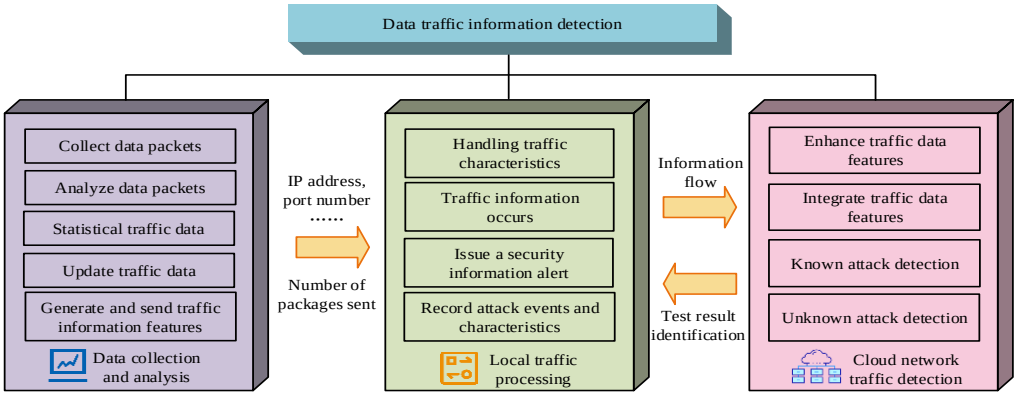

Fig. 1. The architecture of data traffic detection system.

In Fig. 1, the system mainly includes a data collection and analysis module, a local traffic processing module, and a cloud network traffic detection module. A traffic detection method based on temporal and spatial feature fusion has been proposed, and the main detection process is shown in Fig. 2.

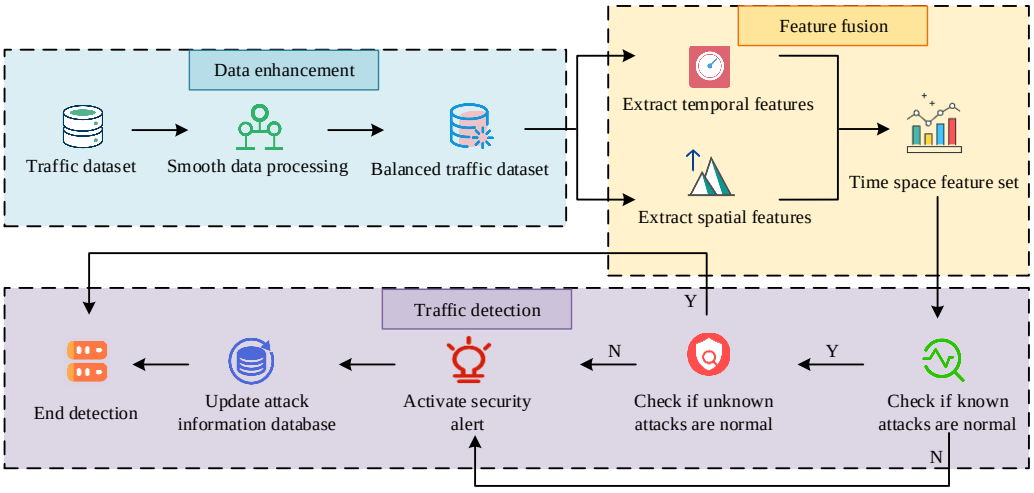

Fig. 2. Main process of detection.

Probability can be mainly divided into parametric estimation and nonparametric estimation, mainly used to estimate the potential probability density function of target information that is invisible [18]. The condition for parameter estimation is that the target information needs to follow a probability distribution and its parameters are unknown, so the corresponding parameters need to be solved through known data. Non parameter estimation requires the target information to have a probability density function, which is solved through observation data. Although it is mainly data-driven and does not require a probability distribution, its computational complexity is relatively high. If the one-dimensional random variable is the probability density function x of $f(x)$ can be represented by Eq. (1).

$$f(x)=\lim_{h\to 0}\frac{F(x+h)-F(x-h)}{2h} \tag{1}$$

In Eq. (1), x represents a one-dimensional random variable, h is the bandwidth width parameter, $F(x)$ is the probability distribution function, and the definition of $F(x)$ can be seen in Eq. (2).

$$F(x)=P(X\le x) \tag{2}$$

Frequency estimation probability can be applied to the dataset. If a one-dimensional random variable has n samples $\{x_1,x_2,x_3,....,x_n\}$, its probability distribution function $\hat{F}(x)$ can also be expressed as Eq. (3).

$$\hat{F}(x)=\frac{k}{n} \tag{3}$$

In Eq. (3), k represents the number of samples smaller than x, and the number of samples is set as m, thus obtaining the estimated equation for the probability density function $\hat{f}(x)$ as shown in Eq. (4).

$$\hat{f}(x)=\frac{m}{2nh} \tag{4}$$

If a uniformly distributed function is defined as $K(x)$, the estimation of the probability density function can also be called a kernel function, which can be represented by Eq. (5).

$$\hat{f}(x)=\frac{1}{nh}\sum_{i=1}^{n}K(\frac{x-x_i}{h}) \tag{5}$$

Multidimensional kernel density estimation can be obtained through univariate kernel density estimation. If a p-dimensional continuous random variable x is set, its multidimensional kernel density estimation equation can be represented by Eq. (6).

$$\hat{f}(x)=\frac{1}{n|H|^{1/2}\,0}\sum_{i=1}^{n}K(H^{-1/2}(x-xi)) \tag{6}$$

Among them, K is a multidimensional kernel function, and H is a symmetric bandwidth matrix. Analysis Eq. (6) shows that the influencing factors of kernel density estimation are mainly determined by the selection of kernel function K and the size of bandwidth width h. When the cloud receives data information, it needs to first enhance the data before completing data feature extraction and fusion. The process flow of the data collection and analysis module can be seen in Fig. 3.

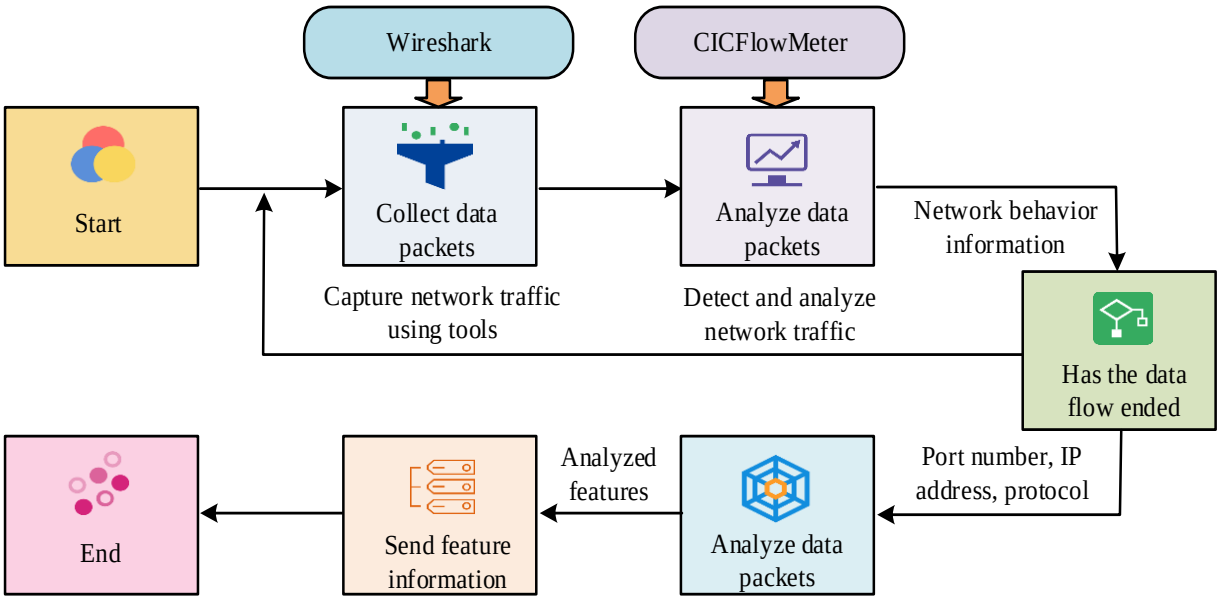

Fig. 3. Data collection and analysis module process.

The extracted and fused feature information will be used for known attack detection. If the detection result is abnormal traffic, further determination of the specific type of abnormal attack is required. If it is detected as normal traffic, further unknown attack detection will be carried out to prevent the IoT from being attacked by unknown traffic. The encoder is mainly composed of an input layer and a fully connected layer. Set the n dimensional feature vector received by the system as x, compress x to obtain a low dimensional latent space z of m dimension, set the neural network parameters of the encoder as f, and the compression function as $h()$, then the encoder can be expressed as Eq. (7).

$$z = h(x, \varphi) \tag{7}$$

The decoder consists of a fully connected layer and an output layer. Nonlinear computation can be used to reconstruct the low dimensional representation of m dimensional latent space as z into n as the eigenvector x. If the $\hat{x}$ neural network parameters of the decoder are set to θ and the reconstruction function is set to $g()$, the decoder can be expressed as Eq. (8).

$$\hat{x} = g(z, \theta) \tag{8}$$

The autoencoder compresses the input by using the encoder to obtain a low dimensional latent space, which preserves the effective features of the input data and enables the decoder to complete the reconstruction process of the original input data. The optimization objective can be represented by Eq. (9).

$$\varphi, \theta = \arg\min_{\varphi,\theta} \sum_{i=1}^{n} L(x_i, \hat{x}_i) \tag{9}$$

In Eq. (9), x_i is the original feature vector input to the autoencoder, and $\hat{x}_i$ is the reconstructed feature vector output by the autoencoder. The function for measuring vector differences is set as $L()$, which can generally be measured using the mean square loss function. The loss function can be expressed as Eq. (10).

$$s = \sum_{i=1}^{n} L(x_i, \hat{x}_i) \tag{10}$$

The compression network is represented by z, and the reconstruction loss of the input layer u and output layer v can be used as a low dimensional representation of the input features, as expressed in Eq. (11).

$$\begin{cases} u = [educlidean\_loss, \cos ine\_loss] \\ v = [z, u] \end{cases} \tag{11}$$

When extracting traffic features, the extraction process can be completed through time and space. Temporal feature extraction mainly targets multiple traffic data, while spatial feature extraction targets individual traffic data, and there are significant differences between these two extraction methods [19]. A feature fusion encoder is proposed by studying the fusion extraction method of temporal and spatial features. It is mainly divided into bidirectional attention temporal encoder and asymmetric multi-scale spatial encoder. The former is mainly responsible for extracting temporal features from spatial features, while the latter is responsible for extracting spatial features from raw traffic data. Through two different extraction methods, different dimensional fusion effects are achieved. The structure of the feature fusion encoder can be seen in Fig. 4.

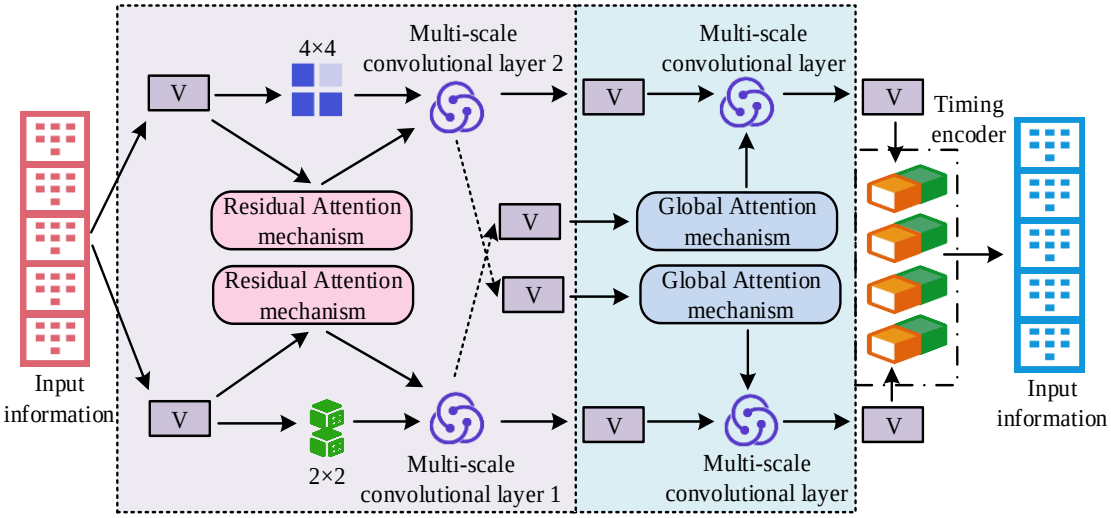

Fig. 4. Structure of fusion encoder.

B. Analysis and Detection of Malicious Traffic in the IoT

For malicious traffic anomaly detection, the balance between the number of normal and abnormal data in the dataset cannot be achieved, so its performance cannot be measured solely by accuracy. Accuracy and recall are two important measurement indicators [20]. If the accuracy is set to Acc, its calculation can be represented by Eq. (12).

$$Acc = \frac{TP + TN}{FN + TN + FP + TP} \tag{12}$$

In Eq. (7), TP represents the number of normal traffic samples detected by the detection model as normal, and TN represents the number of abnormal traffic samples detected by the model as abnormal. FN indicates the total number of samples is represented by the number of normal abnormal traffic samples detected by the detection model, and FP represents the number of normal samples detected as abnormal. The sum of these four types of samples is the total number of samples. If the accuracy of the detection is $\Pr e$, the calculation equation is shown in Eq. (13).

$$\Pr e = \frac{TP}{TP + FP} \tag{13}$$

The recall rate represents the proportion of correct predictions in the normal records of the predictive model. If $\mathrm{Re}c$ is used to represent the recall rate, its expression is shown in Eq. (14).

$$\mathrm{Re}c = \frac{TP}{FN + TP} \tag{14}$$

The relationship between accuracy and recall is quite conflicting. If the accuracy is increased by raising the threshold during detection, the recall rate will decrease. Therefore, when evaluating the performance of detection models, it is necessary to comprehensively evaluate the accuracy and recall rates for a more accurate assessment. If F represents the weighted harmonic of precision and recall, its expression can be seen in Eq. (15).

$$F = \frac{(1+\varepsilon)(\Pr e * \mathrm{Re}c)}{(\alpha^2 * \Pr e) + \mathrm{Re}c} \tag{15}$$

In Eq. (15), in general, the value of α is 1. After determining the evaluation criteria for detection performance, the interaction design between the traffic detection system and external modules is first completed. When the traffic detection system is attacked, the corresponding attack behavior can be detected, and the message can be transmitted to other functional modules through alarm information [21]. The architecture of Dbus is client service, which is a simple and fast communication method that supports point-to-point communication and can send messages to specific processes in a directed manner. Research has chosen Dbus as the mechanism for message notification to facilitate information exchange between the detection system and the external environment. The relationship between the system and external modules can be seen in Fig. 5.

After receiving relevant information, the local processing module completes the processing of information data, alarms and related records. When data information is received from the data acquisition module and the data analysis module, appropriate numerical and normalization processing of the feature data is required. The preprocessed information is sent to the cloud processing module, and after analysis and recognition by the cloud processing module, it is sent back to the local processing module [22]. The local processing module completes the parsing and judgment. If it is judged as normal traffic, it waits for the next traffic information from the data collection and analysis module. If it is judged as malicious attack traffic, a security alarm will be triggered and the traffic event will be sent to the corresponding module for recording. The process flow of the local processing module can be seen in Fig. 6.

The cloud network traffic detection module is mainly responsible for analyzing and judging traffic information. The traffic detection system can be divided into three parts: data collection and analysis, local processing, and cloud network traffic detection. The data collection and analysis module is mainly responsible for parsing traffic packets, attacking and updating traffic messages, and extracting and sending traffic characteristics. The collection and parsing of data packets is the process of parsing the data packets captured by the gateway and generating the specified data format. The statistics and updates of traffic messages involve updating traffic information. The process of generating traffic information features mainly involves transforming the parsed traffic into features such as address, number of packets, duration, port number, etc.

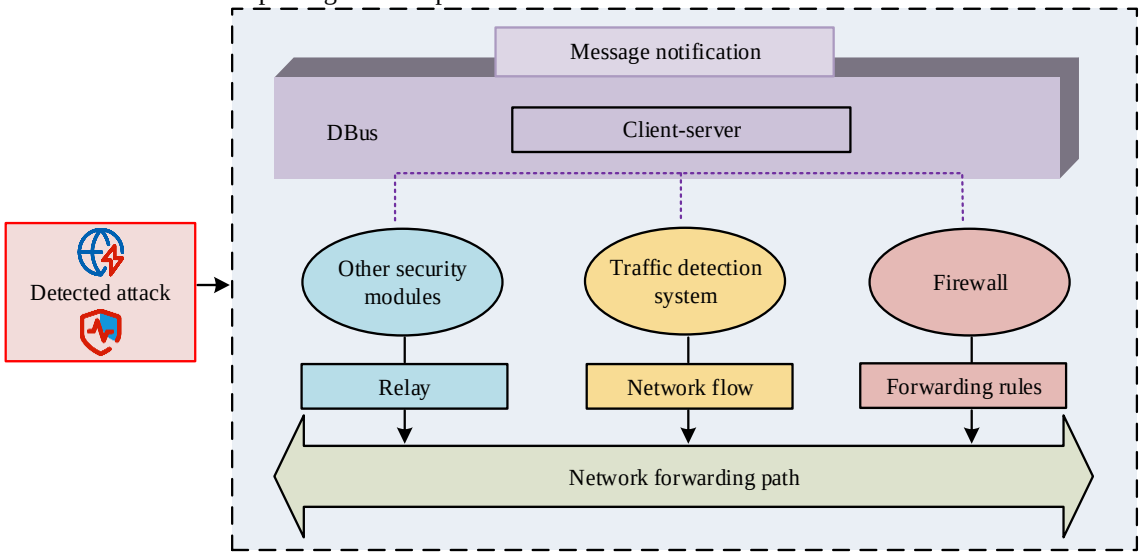

Fig. 5. Relationship between system and external modules.

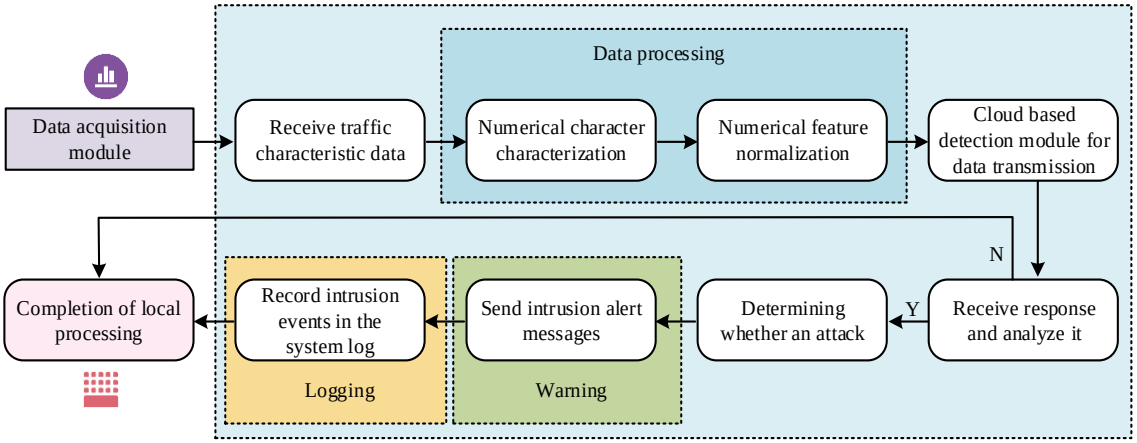

Fig. 6. Flow chart of data local processing module.

IV. Results

A. Performance Testing of Traffic Monitoring Algorithms

To verify the consistency between the original traffic information and the generated traffic information features based on feature fusion detection, the experiment analyzed the fitting situation before and after balancing from two aspects: actual forwarded data packets and packet length. The feature probability density distribution of the dataset was shown in Fig. 7.

In Fig. 7, the horizontal axis represented features, while the vertical axis represented the corresponding probability density. From Fig. 7(a), when the actual number of forwarded packets was less than 10, the probability density values of both the original data traffic and the preprocessed data traffic fluctuated between 0 and 0.4. When the number of forwarded packets was 2 and 5, the corresponding probability density could reach its maximum value. The probability densities of the original data traffic were 0.31 and 0.32, respectively, and the probability densities of the preprocessed generated data traffic were 0.38 and 0.35, respectively. In Fig. 7(b), when the probability density of the original data flow reached its maximum value of 0.45, the probability density of the generated data flow also reached its maximum value of 0.35. By observing the traffic feature distribution of the original data and the generated data, the feature distribution of the dataset was basically consistent before and after balancing. The data preprocessing method used in the study could ensure

that the data features remained consistent before and after processing. The experiment referred to the single class support vector machine detection algorithm, autoencoder detection algorithm, and isolated forest detection algorithm as detection algorithms 1-3, respectively. The feature fusion detection algorithm proposed in the study was trained on traffic data on both IoTID20 and XIoTID datasets. The IoTID20 dataset was based on smart home environments and mainly collected data from terminal IoT devices corresponding to smart speakers, smartphones, and smart cameras. In simulated attack scenarios, smart speakers and smart cameras were targeted. This dataset contained 83 rich features, with over 70% of the features scoring over 0.5, which could improve the classification ability of detection algorithms and techniques and reduce training time. The XIoTID dataset contained 19 categories, with the majority accounting for 55.24% and the minority accounting for over 0.01%, respectively. From this, the comparison of training effects of different algorithms can be obtained as shown in Fig. 8.

On the IoTID20 dataset in Fig. 8(a), as the number of iterations increases, the accuracy of the four detection algorithms gradually improved and eventually stabilized. The feature fusion detection algorithm proposed in the study showed an increase in accuracy from the initial 77% to 98.3% after the 40th iteration. At this point, the accuracy of the compared detection algorithms 1, 2, and 3 was 95.7%, 94.2%, and 88.2%, respectively. After increasing the number of iterations to 50, the accuracy of the four algorithms remained basically unchanged. On the XIoTID dataset in Fig. 8(b), the accuracy of the four algorithms reached stability after the 45th iteration. At the 60th iteration, the accuracy of the feature fusion algorithm was the highest, at 84.2%. At this time, the accuracy of detection algorithms 1-3 were 79.5%, 76.8%, and 82.6%, respectively. The aforementioned outcomes may be attributed to the proposed spatial and temporal feature fusion methodology, which enabled the comprehensive integration of the original feature map and the deep feature map, and facilitates a thorough examination of the interrelationship between historical data from both temporal and spatial perspectives. This approach enhanced the informativity of the extracted feature data and markedly improved the detection performance. To conduct a more accurate analysis of the detection performance of feature fusion algorithms, the deep autoencoder algorithm was added to the existing comparison algorithms as comparison Algorithm 4 in the experiment. The accuracy, precision, recall, and F1 of each algorithm were recorded and analyzed. The comparison results could be seen in Fig. 9.

From Fig. 9, the comprehensive performance of the fusion algorithm was superior to the other four algorithms. On the KDD99-CUP dataset in Fig. 9(a), the F1 of the feature fusion algorithm could reach 93.16%, while the F1 of algorithms 1-4 were 81.36%, 67.89%, 90.56%, and 92.24%, respectively. On the MTA-KDD dataset in Fig. 9(b), the accuracy of the fusion algorithm was 92.91%, the recall rate was 88.12%, and the F1 was 91.54%, still higher than other algorithms. In Fig. 9(c), Algorithm 2 had the lowest F1 on the N-BaIoT dataset, at 65.02%, while the feature fusion algorithm had the highest F1, at 98.21%. On the MedBIoT dataset in Fig. 9(d), the recall rate of the feature fusion algorithm was 95.08%, and the F1 was 97.33%, which was the highest among the five algorithms. The above results were due to the tendency of the research method to lead to precise resolution of feature roots in low-dimensional feature spaces, thereby optimizing the fitting effect of the data distribution.

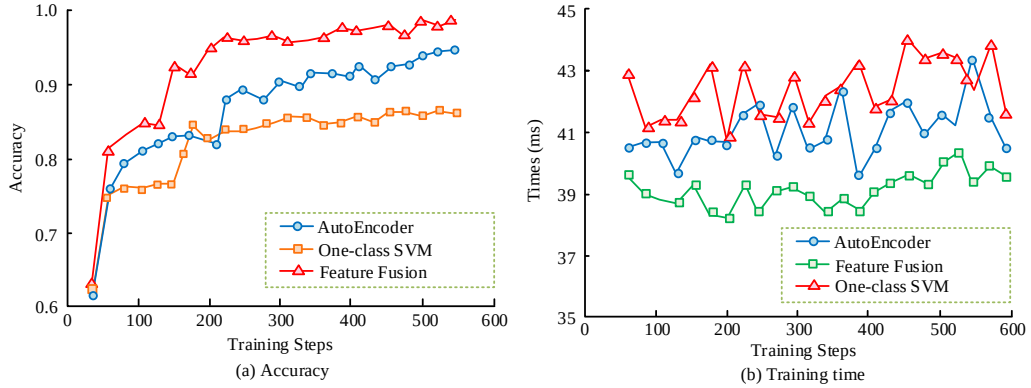
B. IoT Malicious Traffic Detection Experiment

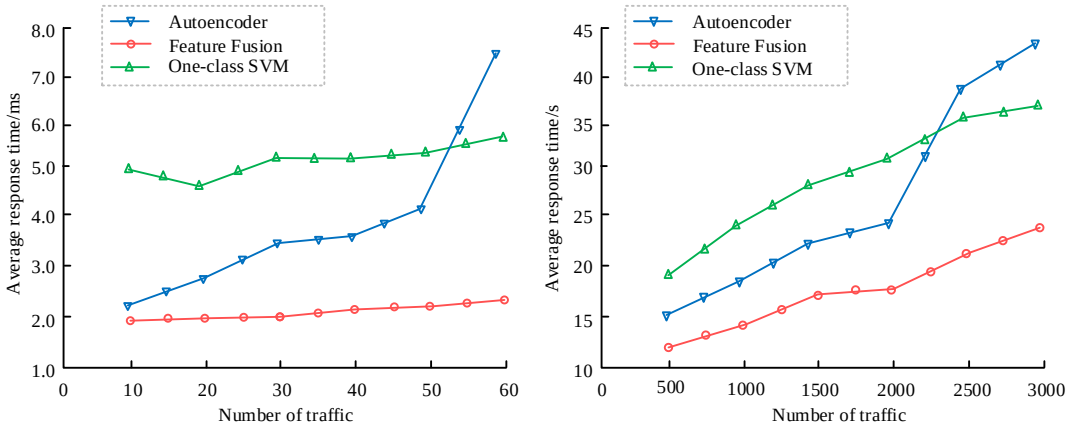
In the experiment on accuracy and model training time, the training steps were set to 600, and the automatic encoding detection model and single classification detection model were selected as controls. The comparison of accuracy and training time of the three models can be seen in Fig. 10.

In Fig. 10(a), when the training steps of the three models were less than 60, the difference in accuracy among the three models was small, and the accuracy of the feature fusion detection model was also below 0.8. As the number of training steps gradually increased, the accuracy of the three models begun to show significant differences. The detection accuracy of the feature fusion detection model proposed in the study was significantly higher than that of the other two models. When the training steps were 500, the accuracy of the feature fusion model reached 0.98, while at this time, the accuracy of the automatic encoding detection model and the single classification detection model were 0.91 and 0.84, respectively. In Fig. 10(b), there was not much difference in training time among the three models. The training time of the feature fusion detection model was slightly shorter than the other two detection models. After calculation, it was known that the average training time of the feature fusion detection model was reduced by 14.3% compared to the automatic encoding detection model and 17.43% compared to the single classification detection model. To verify the detection time of the model in the face of traffic attacks, the control model remained unchanged and the traffic quantity was divided into small-scale and large-scale tests. The comparison of traffic detection time for the three models was shown in Fig. 11.



(a) Accuracy (b) Training time

Fig. 10. Comparison of accuracy and training time.



(a) Small number of traffic (b) Large number of traffic

Fig. 11. Comparison of traffic detection time for various models.

In Fig. 11(a), when the number of attack traffic was small, the average detection time of the feature fusion detection model was relatively stable, and slowly increased with the increase of attack traffic. During the process of increasing the number of attack traffic from 10 to 60, the average detection time fluctuated between 2ms and 2.3ms. The growth rate of autoencoder detection models was relatively large, with the average detection time increasing from the initial 2.1ms to 7.8ms as the number of attack traffic increases. In Fig. 11(b), as the number of attack traffic increased significantly, the average detection time of the three detection models also increased significantly. When the number of attack traffic was 500, the average detection time of the feature fusion detection model was 12ms. When the number of attack traffic increased to 3000, the average detection time also increased to 23ms. At this time, the average detection time of the automatic encoding detection model and the single classification detection model were 43ms and 37ms, respectively. The malicious traffic detection time of the feature fusion detection model was shorter and the detection efficiency was higher than the other

two types of detection models. To further verify the detection performance of the feature fusion detection model, 400 samples were selected for the experiment. 40% of the samples were used as the test model, and 60% of the samples were used as the training model. The analysis and recognition results of the fusion detection model on traffic types were shown in Fig. 12.

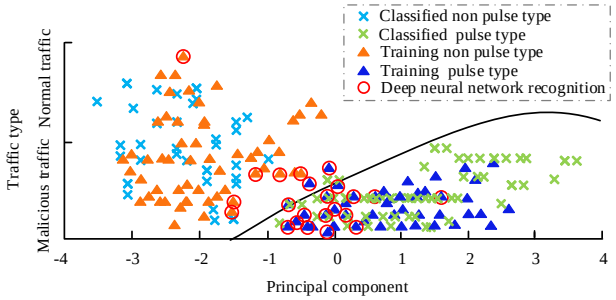


Fig. 12. Analysis and identification results of traffic types by fusion detection model.

In Fig. 12, the probability of correctly identifying the traffic samples used as training models was relatively high. Calculations showed that the accuracy of identifying malicious traffic on the training set was 96.89%. On the test set, 182 traffic samples were accurately identified, including 139 correctly identified malicious traffic and 43 correctly identified normal traffic, with recognition accuracy of 98.73% and 97.65%, respectively. Experimental results showed that both the training set for identifying attack traffic types and the test set for analyzing and judging traffic sample types had excellent performance, with high recognition rates and accuracy for traffic. It also proved that the detection algorithm that integrated temporal and spatial features could efficiently and reliably extract and judge traffic data features, with strong stability in detection and recognition.

To scientifically validate the performance of research methods, the latest malicious traffic detection algorithms were introduced for comparative experiments, namely convolutional neural networks and bidirectional gated space recurrent units (CNN-BiGSRU) based on convolutional neural networks and bidirectional gated space recurrent units, improved k-nearest neighbor based on cost sensitivity (IKN-CS) based on cost sensitivity, stacking and multi feature fusion (SMFF) based on multiple feature fusion, and a hybrid model based on deep learning algorithms and tabu search (DLTS). From this, the performance comparison of different malicious traffic detection algorithms can be obtained, as shown in Table I.

According to Table I, the research method had the best F1 score, accuracy, precision, and recall results, which were 99.2%, 99.5%, 99.6%, and 99.7%, respectively. In addition, the latest mainstream malicious traffic detection algorithms performed well, with all indicators exceeding 95%. The performance of the SMFF method was the worst, which may be due to the fact that the dataset used for testing contained normal and malicious traffic that were not of the same magnitude. However, this method was more suitable for detecting normal and malicious traffic of the same order of magnitude, but in practical application scenarios, normal and abnormal traffic were usually unbalanced. In summary, compared with mainstream methods, the research method still maintained excellent detection performance.

TABLE I. PERFORMANCE COMPARISON OF DIFFERENT MALICIOUS TRAFFIC DETECTION ALGORITHMS

Algorithm	F1 value/%	Accuracy/%	Precision/%	Recall/%
Feature fusion algorithm	99.2	99.5	99.6	99.7
DLTS	98.3	98.3	97.2	98.1
CNN-BiGSRU	97.9	98.1	98.4	97.6
IKN-CS	96.6	97.5	96.7	96.4
SMFF	95.8	96.4	96.3	95.7

V. DISCUSSION

To solve the problem of massive IoT data being vulnerable to attacks, an optimized malicious traffic detection algorithm is studied and designed, which integrates temporal and spatial features and enhances algorithm performance through mixed sampling and variational autoencoder data.

Tests on the IoTID20 dataset revealed that the accuracy of all four detection algorithms increased with the number of iterations and eventually stabilized. After the 40th iteration, the accuracy of the research algorithm increased from the initial 77% to 98.3%. The accuracy results of the XIoTID dataset were as follows, and the research method achieved the highest accuracy of 84.2% at the 60th iteration. Tang D et al. proposed a low-frequency DDOS attack detection algorithm based on multifeature fusion and sperm donation neural network, which could accurately detect DDOS attacks similar to normal traffic. The research results showed that fusing various network features into a feature map to represent the state of the network could effectively help improve the performance of the detection algorithm [23]. The above findings were consistent with this study due to the fact that the feature fusion algorithm integrally considered the correlation of the historical data before and after, which enriched the information content of the extracted feature data.

Compared with the current state-of-the-art malicious traffic detection methods, the results showed that the research method had the best F1 score, accuracy, precision, and recall rate, corresponding to 99.2%, 99.5%, 99.6%, and 99.7%, respectively. In addition, the latest mainstream malicious traffic detection algorithms perform well, with all indicators exceeding 95%. Liu Z et al. proposed a Bayesian meta-learning technique for the detection of encrypted malicious traffic to solve the problem of small sample size. The experimental results showed that when the sample size of malicious traffic was reduced to 100, the detection accuracy of the research model was 96.35% [24]. The study demonstrated that the accuracy of 98.3% can be achieved even with a limited sample size through the incorporation of a data augmentation processing method based on mixed sampling and variational autoencoder. This approach could effectively enhance the accuracy of research methods.

In summary, the research method can effectively improve the security level of IoT access devices, and ensure the security of information data processing and protection.

VI. Conclusion

To improve the detection capability of traffic detection systems for malicious traffic and achieve real-time security checks on IoT devices to achieve system security protection, an optimized malicious traffic detection algorithm was proposed. This research analyzed and identified traffic data by integrating temporal and spatial features, and used hybrid sampling and variational autoencoders to improve algorithm performance. As a result, in both the KDD99-CUP dataset and the XIoTID dataset, the performance of the proposed feature fusion algorithm was the highest, with an F-value of 93.16% in the former dataset and the highest accuracy of 84.2% in the latter dataset. Compared with the latest algorithms, the research method had the best F1, accuracy, precision, and recall results, which were 99.2%, 99.5%, 99.6%, and 99.7%, respectively. It also performed well against the latest mainstream malicious traffic detection algorithms, with all metrics exceeding 95%. Experimental results showed that the detection accuracy and efficiency of the IoT malicious traffic detection model based on feature fusion are high. However, the study only analyzed and identified normal and abnormal traffic, without conducting more in-depth identification and classification of abnormal traffic. Future research will further analyze the identified abnormal traffic to distinguish the types of unknown traffic attacks and achieve more favorable warning effects.

Abstract*—The existing gesture-based operating systems can only simply operate a single piece of software or a specific system, and are not compatible with other applications of mainstream operating systems. In this paper, based on the MediaPipe gesture recognition framework, we design HandMouse, a virtual mouse system that operates using hand gestures. It has the following characteristics: 1. The user does not have contact with the computer hardware when using the system; 2. It requires only one hand to operate, and the design of the gesture considers the ergonomics of the hand; 3. It has most of the functions commonly used in a physical mouse; 4. It can locate the operating area with relative precision. We invited 27 participants to use and evaluate the virtual mouse and then conducted an experiment to compare the performance of the virtual mouse with the physical mouse. The results show that this virtual mouse has a good learning effect and is a great alternative to the physical mouse in public places. The demonstrated operation video is available on *https://github.com/wanzhuxie/HandMouse-IJACSA.

***Keywords*—Virtual mouse; ergonomics; gesture; MediaPipe**

I. Introduction

Gesture recognition has been the subject of research for several decades. As early as 1997, paper [1] has provided a comprehensive summary of the accumulated technology of gesture recognition at that time, and it has experienced rapid development over the past 20 years. There are approximately four research directions for gesture recognition. The first direction involves the use of physical sensors to transmit information. For example, papers [2, 3] described sensor gloves with gesture recognition capabilities, while the system proposed in paper [4] processes finger pressure signals, and a virtual keyboard was designed in paper [5]. The second direction involves the use of cameras to extract finger information. Although physical sensors are not in direct contact with the computer, the recognition process requires the assistance of gloves of different colours to help the computer identify gestures, as described in papers [6, 7]. The third direction focuses on processing images without external elements to assist the computer. Advanced algorithms are used to extract hand images from gestures and infer their meaning, as demonstrated in papers [8-10]. The fourth direction involves inferring the coordinates of the key points of the hand and leaving the recognition of gestures to the specific gesture designers. This allows designers to consider more details and design a wider range of gestures. Deep learning techniques are commonly used for this purpose, for example, in 2016, paper [11] presented a gesture recognition system based on recursive 3D convolutional neural networks, achieving an accuracy of 83.8%. In 2017, a paper [12] trained a hand recognition model using 18,000 stereo hand images and the 3D key points in each image in different scenes, demonstrating a good tracking performance. In 2019, Google Artificial Intelligence Laboratory released an open-source gesture recognition framework called MediaPipe Hands [13], which continues to be maintained. MediaPipe Hands was trained using 300 million real-life hand gesture images with the corresponding 3D key point coordinates of the hand, achieving an overall recognition accuracy of 95.7%.

Thanks to the increasing efficiency and accuracy of gesture recognition technology, it has a wide range of applications in areas such as sign language recognition, remote-controlled robots, and human-computer interaction (HCI) [14-16]. Compared with the traditional mouse click or touch screen operation, it is more popular to add gesture operation into human-computer interaction system [17]. Gesture operation has significant appeal to customers due to its novelty, and the potential purchasing power of customers may be stimulated by the exploration or trial of gesture control. Gesture operation enables humans to have no physical contact with the machine, allowing users to be at a greater distance from the device, which enables a better layout planning for venue managers, prevents accidental damage caused by customers touching the device, and prevents the spread of diseases caused by touching. In paper [18], preliminary research on gesture output of Chinese was conducted. In paper [19], a gesture-based image viewer software was designed and applied to touchless operations in surgical room scenarios. The study in [20] proposed a gesture recognition method for controlling in-car devices. Furthermore, gesture recognition has been applied in gaming interactions as discussed in papers [21, 22], and an interesting study conducted in paper [23] explored the use of gestures for simple coding purposes.

Since the gesture commands have been used to realize the simple control of specific software, can they be further developed by using gestures to realise the functions of the physical mouse, such as the commonly used left-clicking, left-double-clicking, right-clicking, etc.? The answer is yes. At present, the gesture-based system can realize all or some of the

functions of the physical mouse and allow the operator to have no direct contact with the machine hardware, for what we can call it a virtual mouse. The virtual mouse has been the subject of extensive research by many researchers over the last decade. Although the result presented in paper [24] focused on the virtual keyboard input, its techniques are still relevant to the virtual mouse and serve as a valuable reference. Paper [25] employed a two-layered Bayesian network technique for gesture recognition and designed a virtual mouse system. Paper [26] designed a gesture-based virtual controller for manipulating 3D objects, taking into account the 3D data of finger movements. In paper [27], used convolutional neural network technology to recognise finger and fist gestures, and then developed a simple virtual mouse control system.

However, current gesture operations are specific to particular systems or software, where each gesture represents a specific command for a particular software. Unlike a physical mouse, these gestures are tailored to specific software and lack universality.

Based on existing gesture recognition technology, combined with the physiological structure of the human hand, this paper designs a set of simple and easy-to-use mouse operation gestures. On this theoretical basis, this paper presents an absolutely contactless, entirely gesture recognition-based virtual mouse system. The virtual mouse is independent of the software that is being operated and has a high degree of versatility. With relatively comprehensive functions, the virtual mouse is like a physical mouse, and most of the functions that can be achieved with a physical mouse can also be achieved with the virtual mouse. The general flow of the system is shown in Fig. 1, where the video frame image is captured by the camera, and the key points of the hand are detected by MediaPipe. The gesture recognition module analyses the coordinates of the key points and identifies the current gesture. When a pre-defined gesture is made, the mouse operation module immediately releases the mouse signals to operate any software.

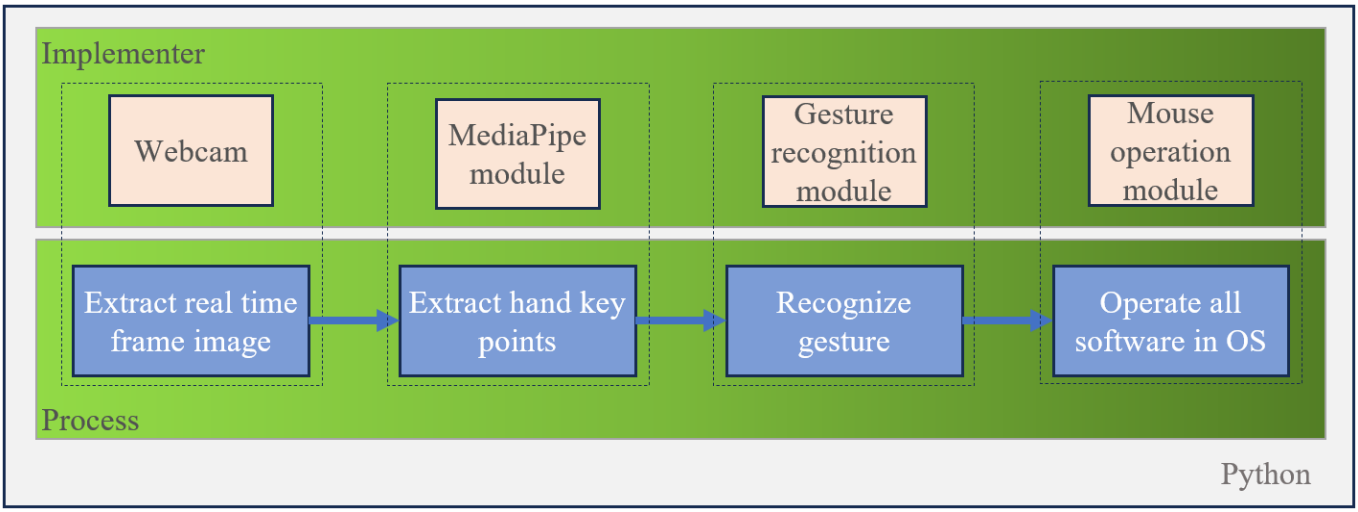

Fig. 1. The system architecture of the virtual mouse system.

II. FOUNDATIONS

A. Key Points of a Hand

There are many ways to recognize various gestures, such as feature matching, extraction of hand key points, and so on. Feature matching can only recognize the pre-defined hand postures, while key points extraction supports all kinds of hand posture, which has stronger speculation ability. As shown in Fig. 2, the 21 key points can basically describe the gesture information of a hand, and the recognition of gesture can be transformed into the analysis of the key points and further into the conversion of abstract image information into specific mathematical information. In this paper, P_n is used to represent the key points at a specific position, where $n \in [0, 20]$, and the sequence number of the starting key point is 0.

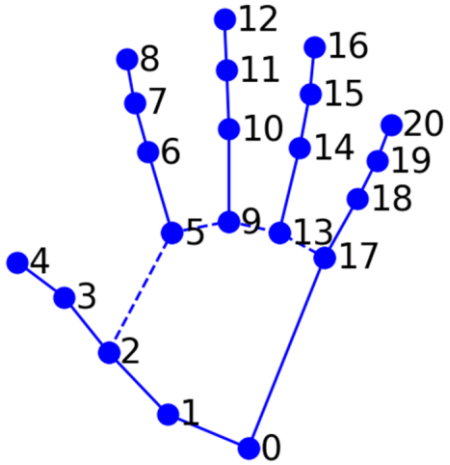

Fig. 2. Key points of a hand.

B. MediaPipe

MediaPipe is a cross-platform machine learning framework [28] that includes a number of sub-frameworks such as gesture recognition, face recognition, whole-body posture recognition, 3D object coordinate inference and so on. It has been widely used in many areas of life and industry. Papers [29-31] apply MediaPipe to home sports equipment, gesture language expression system, and human posture simulator. With the assistance of MediaPipe, papers [32, 33] developed the measurement system for some human rehabilitation movements and the abnormal gesture detection system for patients with the nerve injury. Paper in [34] developed a human emotion detection system using MediaPipe.

MediaPipe Hands is one of the frameworks of MediaPipe, which supports five fingers and gesture tracking, and can infer 21 stereo nodes of one hand from a frame image. Even if the palm is partially displayed or the hands are self-occluded, it can achieve high robustness, high performance, and low time consumption, so it has been applied in a variety of fields. Paper [35] designed a sign language expression system for Japanese; paper [36] captured the motion trajectory of fingers by analyzing the 3D coordinates of the key points of hand, and then designed an air-writing system; paper [37] used MediaPipe to identify the driver's hand information in a driver distraction warning system.

The system described in this paper also uses MediaPipe Hands to extract the coordinate information from the 21 key points of the hand. It reads each frame image captured by the camera and provides three coordinate values of the key points. Since the image can be scaled to meet the needs of image analysis, information transmission, image display and so on, when it is processed, the original coordinate values of the key points are normalised values, i.e. each coordinate value is a proportional value relative to the image size. The normalized datum of the X and Z coordinate value is the width of the image, and the normalized datum of Y coordinate value is the height of the image. Therefore, before using the coordinate value of key points, it is necessary to calculate the pixel coordinates of key points according to the frame image size obtained by the camera.

Although the performance of the MediaPipe Hands was excellent, there is a drop in recognition accuracy when the background colour is similar to the hand colour, or when the overall lighting is poor. The user may also make errors. The system therefore optimises the recognition reliability of MediaPipe. When recognising the current gesture, it is only considered to have changed if the camera captures the same gesture three times in a row. Otherwise, it is considered a single misrecognition by MediaPipe or the user, and the recognition result of the previous frame is returned.

C. Coordinate System

The default coordinate system of the display screen of the system takes the upper left corner as the origin, the horizontal right direction along the screen is the positive direction of the X axis, and the vertical downward direction along the screen is the positive direction of the Y axis. The coordinates (X_{max}, Y_{max}) of the bottom right corner of the screen are related to the screen resolution. When analyzing gestures, the larger the Y coordinate of the hand key point, the lower the position of the point.

III. Basic Design of Gesture Operations

A. Design Principles

First of all, we give three design principles:

1) Single-handed operating. Although two-handed operation can express more information, as in the application scenarios in [38-40], it also increases the demands on the operator. Compared with single-handed operation, it has two disadvantages. Firstly, the operator has to raise both hands at the same time to make gestures during the operation and may feel tired after a short time. Secondly, when two hands are operating together, they may be required to make different gestures, so the error rate of two-handed operation may be higher than that of single-handed operation or the operation of two hands making the same gesture.

2) Simple gestures considering. Due to the physiological structure of the hand, most people can't stretch out their ring finger alone as easily as their index finger. They need to work with other adjacent fingers to make gestures quickly and accurately. Therefore, the system does not use the ring finger alone as an indication signal, which reduces the probability of error gestures.

3) Multiple postures of hand supporting. In the process of specific operation, many scholars have studied the palms parallel to the display screen as a condition for gesture recognition [8, 25, 39, 41]. Meeting this condition can indeed improve the accuracy of detection, but it is not a small challenge to the user's physical strength and patience. In fact, if the palm plane is kept parallel to the screen all the time, the user's arm and wrist will feel tired in a short time and will not be able to perform gesture operations, which will reduce the user's use experience and may also cause the user's resistance. What can be determined is that people would prefer the system to be compatible with multiple postures of the same gesture, so that different postures can be changed during a long period of operation to alleviate the fatigue caused by gesture operation. Therefore, the system supports any angle between the palm plane and the screen plane, and users can make gesture signals according to their customary posture. All postures shown in Fig. 3 indicate that only the index finger is extended. It should be noted that, for ease of expression and understanding, all the gesture images in this paper are generated from the perspective of the operator. The gesture image captured by the camera should be the image observed in the opposite direction. However, this does not affect the design of the algorithm. As mentioned above, the system supports multi-position operation.

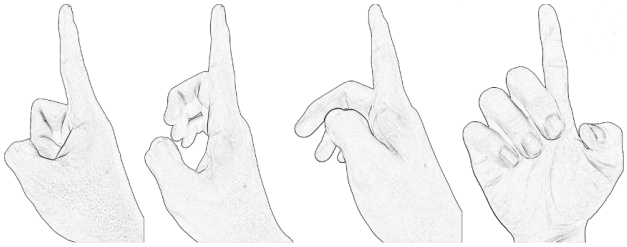

Fig. 3. Multiple gestures express that only the index finger is extended.

B. Gesture Unit Judgment

In this paper, the gesture of a single finger is called a gesture unit. The gesture unit has two states, the extension and closed of the finger. Each gesture signal is a combination of the states of each finger. To improve versatility and fault tolerance, this system does not consider the angle between fingers, but only whether each finger extends. We use five binary numbers to represent gestures for the convenience of display. Each number represents the extension and closed of the corresponding finger, with 1 representing the extension and 0 representing the closed. The numbers from left to right represent the status of the thumb, index finger, middle finger, ring finger, and little thumb. For example, [01000] means that only the index finger is extended.

For the other four fingers except the thumb, the extended condition is that the fingertip's key point is above its corresponding three other key points as shown in Fig. 2, as

$$Y\left(P_i\right) < Y\left(P_j\right) \tag{1}$$

where, $i \in \{8,12,16,20\}$ is the key point indexes of the fingertip and $j \in [i-3, i)$ is one of three other key points indexes.

This determination method is suitable for the scenario where multiple fine-tuned gestures are used to express the same signal, reducing the fatigue caused by the user making the same gesture for a long time.

For the thumb, the relationship between the thumb and the other four fingers is determined first, and then its extension and closed are determined based on the coordinate relationship between the thumb tip key point and the other key points of the thumb. If $X\left(P_2\right) > X\left(P_{17}\right)$, we define the handedness to be the right, and if $X\left(P_3\right) > X\left(P_4\right)$, then the thumb is closed, otherwise it is extended. Similarly, if $X\left(P_2\right) \le X\left(P_{17}\right)$, we define the handedness to be the left, and if $X\left(P_3\right) < X\left(P_4\right)$, then the thumb is closed, otherwise it is extended.

C. Gesture Operation Area

Mouse movement is the most common operation, and in terms of the difficulty of making gestures, it is easier to extend the index finger alone. In addition, using the index finger to guide the mouse pointer is also in line with the public's understanding of the habit. Therefore, this system uses the extension of the index finger as the signal to set the mouse position, and the mouse pointer moves with the movement of the tip of the index finger.

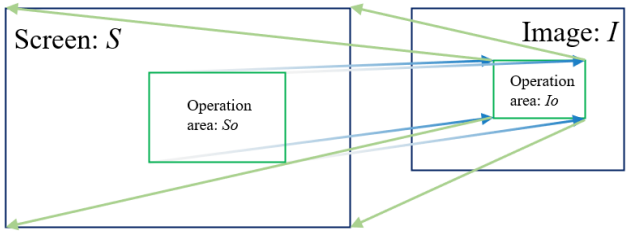

Fig. 4. The correspondence between the screen area and image area.

As shown in Fig. 4, *S* indicates the display screen area, *So* indicates the active area of the index fingertip on the screen *S*, which should be significantly smaller than *S*, otherwise it will cause two problems. Firstly, the components at the bottom of the screen cannot be operated because when the index fingertip is at the bottom of the screen, the hand is outside the screen area, and the recognition rate of a hand is very low, or even impossible. Similarly, when using the right hand, the components on the right side of the screen cannot be manipulated, and when using the left hand, the components on the left side of the screen also cannot be manipulated. Secondly, if the active area of the index fingertip is larger, the active area of the human hand will also be larger, and the range of activity of the arm will increase, which not only tires the arm, but also takes time to position the pointer. In fact, when the physical mouse is positioned, it will move much less than its pointer. Therefore, the size of *So* should be consistent with the motion range of the index fingertip when only the wrist is active. It is therefore necessary to map the fingertip coordinates in *So* to *S* in order to set the pointer coordinates.

In fact, there is another intermediate area between *So* and *S*, which is the corresponding area *Io* in the image of *So* on the screen, as shown in Fig. 4, where *I* is the area of the image captured by the camera. It should be noted that the height-width ratio of the image may not be the same as that of the screen. The coordinates of each key point of the hand are captured from the image, so the operation area in the image should be considered initially. But when the system is working, it is not necessary to display the image area, shown at the top right of Fig. 5, on the screen. The operator is not obliged to calculate the mapping relationship between the image and the screen, but only needs to customize the operation area on the screen. Depending on the size of the image, the system first maps the user-defined operation area So onto the operation area *I*o and then maps *I*o onto the screen, so that the index fingertip can wander around the entire screen and operate on target objects at any position. The above mapping process is also shown in Fig. 4.

It needs to consider multiple factors when setting the area of *S*o. If the area is too large, the swing range of the user's arm needs to increase, which will increase the user's fatigue. If the area is too small, because the area is mapped to the entire screen area, the slight movement of the fingers in this area may produce a large mouse pointer movement effect on the entire screen, which will affect the positioning accuracy. By default, the system sets the size of *S*o to a quarter of the screen size and places it in the centre of the screen. In fact, the size and

position of the operation area depend on the relative position of people and cameras. In order to adapt to cameras with different parameters or different installation positions of cameras with the same parameters, the system supports the operators to adjust the operation area.

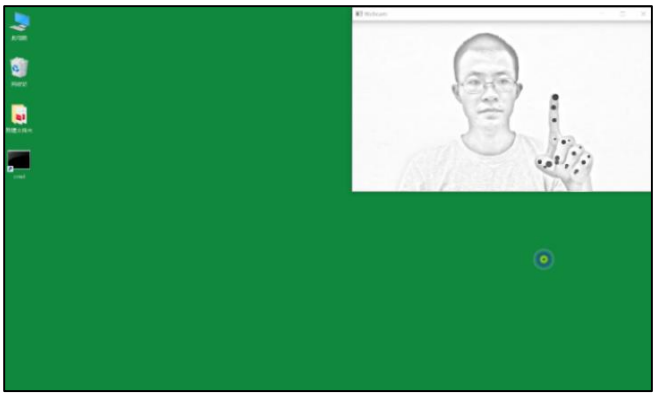

Fig. 5. The real screen area and the image area.

D. Mouse Position Calculation

Before performing mouse operations, the operator needs to use the tip of their index finger to locate the target position on the screen. We use $f(x,y)_s$ representing the coordinates of the index fingertip on the screen, and then we will derive and calculate it.

If R_{io} indicates the size of the operation area in the image, R_i indicates the size of the image, R_{so} indicates the size of the operation area in the screen, and R_s indicates the size of the screen. They have the following corresponding relationship.

$$R_{io} / R_i = R_{so} / R_s \tag{2}$$

The width and height of each of the four areas satisfy the above relationship, i.e., the four dimensions above can represent both width and height.

From the mapping relationship between S_o and I_o we can see that any position in S_o (the image operation area) $f(x,y)_{io}$ and the corresponding position $f(x,y)_{so}$ in I_o (the screen operation area) have the relationship.

$$f(x,y)_{io} = \frac{R_{io}}{R_{so}} f(x,y)_{so} \tag{3}$$

From the mapping relationship between I_o and S, the position of the fingertip in S (the screen) $f(x,y)_s$ has the following relationship with the corresponding position $f(x,y)_i$ in I (the image).

$$f(x,y)_s = \frac{R_s}{R_{io}} \left(f(x,y)_i - f(x,y)_{iom} \right) \tag{4}$$

Where, $f(x,y)_{iom}$ is the upper left corner of I_o (the image operation area), which can be obtained by the following equation.

$$f(x,y)_{iom} = \frac{R_{io}}{R_{so}} f(x,y)_{som} = \frac{R_i}{R_s} f(x,y)_{som} \tag{5}$$

Where, $f(x,y)_{som}$ is the upper left corner of S_o (the screen operation area).

From above equations, we can express the relationship between $f(x,y)_s$ and $f(x,y)_i$ as

$$f(x,y)_s = \frac{R_s^{\,2}}{R_i R_{so}} \left(f(x,y)_i - \frac{R_i}{R_s} f(x,y)_{som} \right) \tag{6}$$

Where, the screen size R_s is fixed; the image size R_i is depends on the camera settings and is also known. The size of the screen operation area R_{so} and its upper left corner $f(x,y)_{iom}$ are user defined or system default given values, which are also known. So $f(x,y)_s$ varies with the variable $f(x,y)_i$, and the latter can be calculated by the logic of the image processing section described above, up to this point we obtain an expression for the coordinates of the index fingertip.

In order to ensure that the value of the index fingertip's coordinate $f(x,y)_s$ does not have a negative value or a value that exceeds the screen area, we place a restriction on the final mouse pointer coordinate value, and the X-coordinate of the mouse pointer satisfies the following equation.

$$P_x = \begin{cases} 0 & , f(x,y)_s|_x \in (-\infty, 0) \\ R_s|_x & , f(x,y)_s|_x \in (R_s|_x, +\infty) \\ f(x,y)_s & , f(x,y)_s|_x \in [0, R_s|_x] \end{cases} \tag{7}$$

Similarly, the Y-coordinate of the mouse pointer satisfies

$$P_y = \begin{cases} 0 & , f(x,y)_s|_y \in (-\infty, 0) \\ R_s|_y & , f(x,y)_s|_y \in (R_s|_y, +\infty) \\ f(x,y)_s & , f(x,y)_s|_y \in [0, R_s|_y] \end{cases} \tag{8}$$

where, $R_s|_x$ is the width in pixels of the screen, $R_s|_y$ is the height in pixels of the screen, $f(x,y)_s|_x$ is the theoretical X-coordinate of the mouse pointer in the screen and $f(x,y)_s|_y$ is the theoretical Y-coordinate of the mouse pointer in the screen.

E. Mouse Sensitivity Design

Due to the hand inevitable tremor in front of the camera, the mouse pointer on the screen often frequently jump caused by the small movement of the hand. Hand tremor is unavoidable, and we can only minimise the effect caused by it [42]. The position can be recorded and compared with the last recorded position, and if the difference is within a certain error range, it is considered to be an invalid signal caused by hand tremor. In fact, this method filters out the effect of hand tremor, but it also ignores the signals that occur when the user actually

intends to move the mouse to another near position. Additionally, when the mouse is moved using gesture signals, the movement of the mouse pointer is not smooth, but rather jumps in discrete steps, with the step size depending on the error value. This may result in a less smooth user experience.

For mouse pointer positioning, this system detects the coordinates of the index fingertip on the screen and calculates a weighted value by combining the fingertip coordinates with the current mouse pointer position as the new pointer position.

The specific algorithm is as follows:

Step 1: Record the last mouse pointer coordinates $P(x_l, y_l)$.

Step 2: Detect the coordinates of the index fingertip in real time and calculate the weighted result of the fingertip coordinates and the last mouse pointer coordinates.

$$P(x_r, y_r) = P(x_l, y_l) + P(a(x_c - x_l), b(y_c - y_l)) \quad (9)$$

where, $P(x_r, y_r)$ is the weighted coordinates, x_c, y_c are the X and Y coordinates of the current index fingertip point respectively, a and b are constants, their range is all (0,1], when $a = b = 1$, it is equivalent to using the current fingertip coordinates as the coordinates of the mouse pointer.

The system correlates the value with the screen resolution, i.e.

$$\frac{a}{b} = \frac{R_s|_x}{R_s|_y} \quad (10)$$

Step 3: The weighted result of the fingertip coordinates and the last mouse pointer coordinates may have values that are outside the screen area, so the weighted result is constrained similarly to the "(8)" and "(9)" to ensure that the mouse pointer coordinate values are not outside the screen area.

IV. Gesture Design

A. Signal Categories and States

The Fig. 6 is the logic flow chart of the system operation, the blue rectangle indicates the system state, we define three states for the system, respectively, the *Ready* state, which is the first state after the system initialisation, the *Pressing* state during the mouse pressing process, and the *Adjusting* state during the operation area adjustment process.

The solid rounded rectangle represents the operation signals. Considering the mouse operations commonly used in the operating system, the operation signals of this system are left click, left double click, right click, scroll wheel up, scroll wheel down, left button press, and left button release, which are seven signals in total. Except for the two operations of scroll wheel, the other operations need to accurately locate the target area before the operation actions, so we call them locating operations, and the two operations of scroll wheel are called non-locating operations. In addition to mouse operations, the system supports customisation of the operation area, including setting its size and position. After initialization, if the system detects that only the index finger is extended [01000], it enters the *Ready* state, in which the mouse pointer follows the tip of the index finger.

The dashed rectangular rectangles indicate the indication signals, which are used to support the state switching and operation signaling.

The design of the gesture signals is the core of this system. For the Locating operations, the first step is to move the mouse pointer to the target object. Once the mouse pointer is placed, it should be held still while the corresponding gesture signal is performed. When making a gesture signal, the index finger should be extended as it plays a role in the composition of the gesture signal. If the index finger needs to be closed during this time, the spatial position of the index finger would change from extended to closed, making it difficult for the system to recognise the actual purpose of the index finger movement. It could be interpreted as a signal for an operation or simply as a movement of the mouse pointer. Therefore, the index finger should remain extended for positioning operations.

Indeed, if someone wants to keep the index finger away from the next action signal, an intermediate state can be introduced before the Locating operation. In this state, the mouse pointer no longer moves with the movement of the index fingertip, but remains stationary on the target object until the next signal action. During this time, the index finger can move freely to perform gestures. However, using this approach would require at least two actions to simulate one operation of the physical mouse, including a state transition action and a mouse operation action, which may introduce inconvenience in the operation process. Therefore, this system adopts the method that the index finger participates in the gesture signal composition for the locating operations.

Furthermore, it should avoid making gestures that may cause significant changes in the position of the index fingertip for the next operation. For example, extending the ring finger may cause an obvious change in the position of the index fingertip. As mentioned earlier in the discussion of mouse sensitivity, any change in the position of the index fingertip will have a larger impact on the screen. Due to this change, the mouse pointer may have moved beyond the intended target area. In fact, the extension and closing of the thumb have minimal impact on the other four fingers. Therefore, the system does not utilize an intermediate state but directly uses the thumb to send the operation signal.

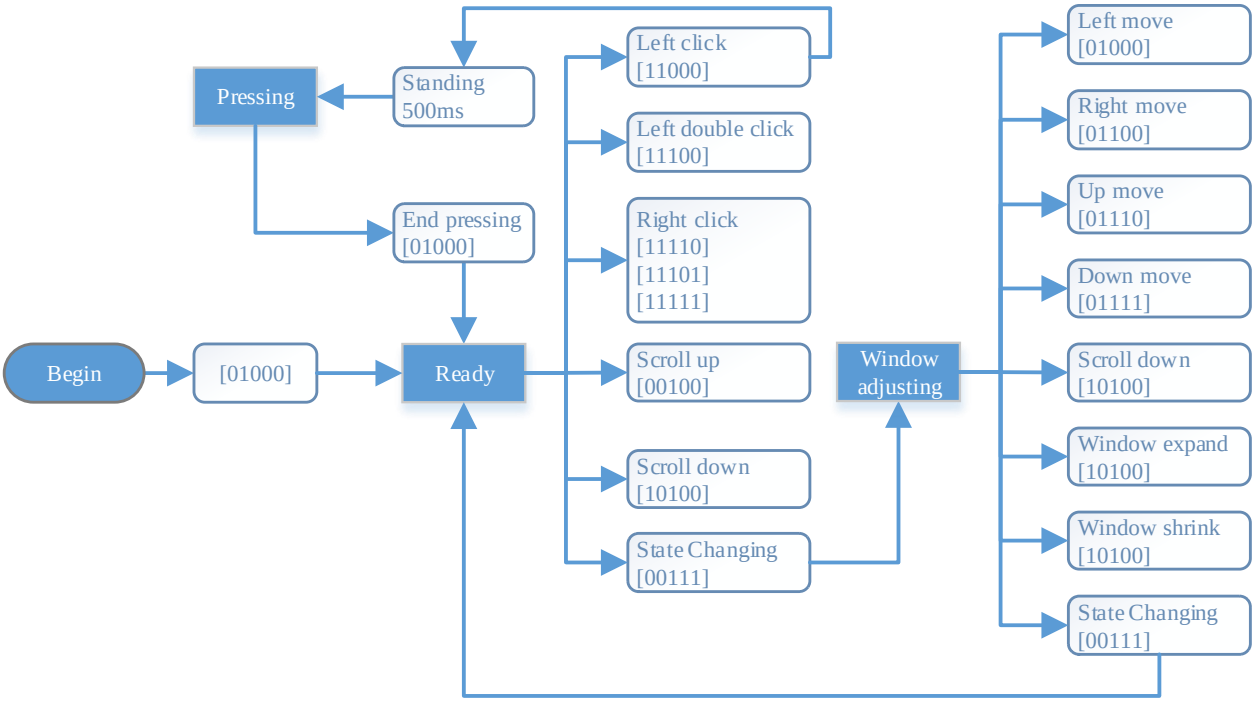

Fig. 6. System flow chart.

B. Operation Signal Design

1) Left clicking, pressing and releasing: Precision control and user comfort are two essential considerations in gesture operations [42, 43]. When designing the signals, the frequency of use of each operation is an important consideration. The more frequently an operation is used, the simpler the corresponding gesture should be. Left-clicking is the most frequently used mouse operation, and we use the index finger as the corresponding gesture for it, similar to the approach used in the references [44, 45]. When users want to left-clicking on an object, they first extend their index finger [01000] and place the mouse pointer over the target area. Keep the index finger stationary, the thumb can be extended. Then the system will detect the [11000] gesture, which represents the execution of a left-clicking. After the click, the thumb should immediately close, maintaining the [01000] gesture to guide the mouse pointer for the next operation. If the thumb remains extended in the target position for more than 0.5 seconds, the system performs a pressing operation on the target position.

The Pressing state is a specific state designed for dragging files. In the Ready state, if the gesture [11000] is held for 0.5 seconds, the system switches from the Ready state to the Pressing state. Similar to the logic of a physical mouse, the pressing action is executed by the system regardless of whether there is a target object under the mouse pointer. In the Pressing state, the mouse pointer drags the file along with the movement of the index finger until the thumb is retracted, at which point the system releases the left button and stops dragging, and the system immediately return to the Ready state.

To provide clearer feedback on the current state of the system, a semi-transparent coloured halo can be displayed around the mouse pointer in the Ready state. Fig. 7 shows the effect of the halo on the target position with four different background colours. This halo not only serves as an indicator but also helps visualize the position of the mouse pointer. When the system transitions to the Pressing state, the halo is hidden to prompt the user for the current drag operation. This is, of course, optional, and unless the scene has a complex background, it is recommended not to use a coloured halo as it may affect the activity of the pointer.

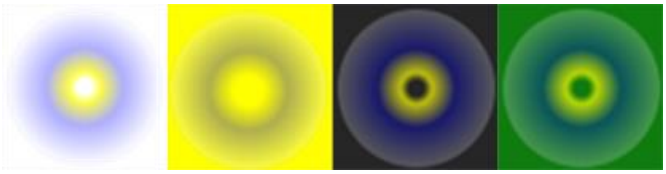

Fig. 7. The halo effect with different background colours.

2) Left-double-clicking: The left-double-clicking operation is also commonly used. From a conventional standpoint, a double-clicking consists of two single-clicks operations, as is the case for the physical mouse. However, when sending a signal, gesture-operated systems generally have a much larger range of motion than the physical mouse. As a result, the time required to perform a double-clicking operation is significantly longer than that of a physical mouse operation. In addition, performing a left-clicking gesture in this system

requires the thumb to be extended and closed once respectively, which can lead to hand fatigue after multiple operations. Therefore, our system uses a combination of the index and middle fingers as the gesture signal for the left double-click. In this case, the user only needs to extend and close the thumb once. When the user wants to make a left double-click on a target area, they can extend both the index finger and middle finger, and the mouse pointer will still follow the movement of the index fingertip. Once the pointer is over the target area, extending the thumb completes the double-click. This approach is similar to the method described in study [45].

3) Right-clicking: Similarly, the gesture corresponding to the right click is the combination of the index, middle and ring fingers. However, due to the physiological structure of the human hand, the ring finger has less dexterity than the other fingers, so the system accepts that the little finger can also act as the ring finger, and the ring finger can of course act on its own. Therefore, there are three gestures corresponding to the right-clicking, respectively [01110], [01101] and [01111].

4) Wheel scrolling and pausing: In most scenarios, scrolling operations with the mouse wheel do not require precise positioning of the mouse pointer. This system uses the gesture [00100] as the signal for scrolling the mouse wheel forward, and uses the gesture [10100] for scrolling the mouse wheel backward. In the *Ready* state, any gesture other than those mentioned above can temporarily pause the current scrolling operation.

C. Operation Area Adjusting

As mentioned above, the size and position of the work area can be adjusted. In order to still be able to operate with single hand, some of the gestures used to adjust the work area will inevitably be the same as those used to operate the mouse pointor, which is why the Adjusting state is raised. The states between Adjusting and others can be switched using the [00111] gesture (OK gesture). In order to minimise the risk of incorrect operations caused by hand movements or tremors, static gestures are used to adjust the operating area instead of dragging. In the Adjusting state, users can easily perform adjusting gestures without worrying about unintended operations. The corresponding gestures for these adjustment operations are listed in Fig. 6.

V. System Test and Discussion

We invited participants to test this virtual mouse system to measure its performance, learning curve and user acceptance. We first determined the unit of measurement of the target area for mouse clicks during the test. The size of the target area operated by the mouse is determined by the desktop application to which the operated object belongs. The smaller the target, the longer it takes to locate it with the mouse. Most UI controls are sized in pixels, so resizing a UI control requires adjusting the pixel values of its width or height accordingly. For mouse controls, however, the physical size of the target area is more important than its pixel size. For example, at resolutions of 1920×1080 and 800×600, an 80×80 target area at the former resolution is smaller than a 60×60 target area at the latter resolution, making it slightly more difficult to focus on using the mouse. Therefore, the target size here refers to the actual physical length, not the number of pixels.

A. User Experience Test

In order to test the learning effect of this virtual mouse system and its acceptance by new users, 27 participants were invited to take part in an experience and learning evaluation of the system. The test was conducted with 2 randomly varying items, the target area to be operated by the mouse and the specific action for each mouse operation. We randomly placed a square target area with sides in the range [30,80] on a 340×195 monitor screen, and randomly appeared an instruction in the square area that required the participant to operate the area. We set up only some of the most commonly used left-clicking, left-double-clicking and right-clicking instructions. The user operated on these target areas according to the instructions, and the next target area to be operated appeared only if the current operation was correct; otherwise the current target area was kept waiting for the user's correct operation. Each test consisted of 20 mouse operations. The operator first performed two tests with the physical mouse to use its average time as a comparison with the virtual mouse, then five tests were performed with the virtual mouse.

Based on the temporal data of the 27 participants' tests, we plotted the learning curve of the system, as shown in Fig. 8, which mainly expresses the mean value of the participants' time for each operation as well as its standard deviation.

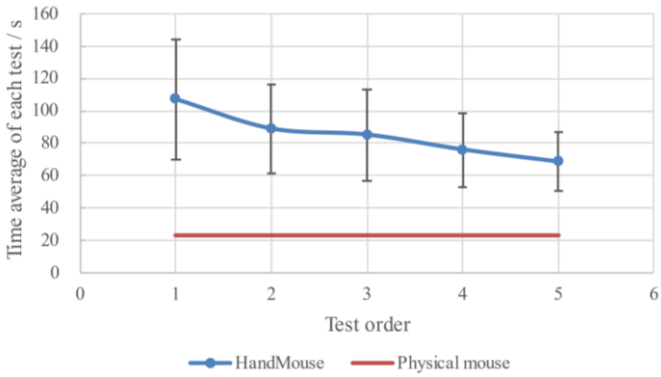

Fig. 8. The learning curve for the system. The blue curve is the learning curve based on the average time taken by the participant to perform the actions using HandMouse, and the red line is the referenced time taken to perform the actions using a physical mouse.

The time curves of the five virtual mouse tests for most participants did not always show a downward trend, but rather significant fluctuations. However, as we can see from Fig. 8, the average value of the test time has an overall decreasing trend, indicating that it still has a relatively positive learning effect. During the testing process, most of the new users would gradually understand and master the use of the system, although not very skillfully. At the same time, however, we can see that the standard deviation of each group's operation is relatively large, indicating that there are relatively large individual differences among the participants. A small number of participants experience a brief period of confusion and disorientation.

B. Subjective User Evaluation

After two physical mouse tests and five virtual mouse tests, each participant was asked to complete a survey to obtain a subjective evaluation of the gesture mouse system from new users. The survey questions were divided into two parts, one based on the NASA-TLX (NASA Task Load Index, https://humansystems.arc.nasa.gov/groups/TLX/) evaluation method, which asked questions about the feel of the operation. The second part compared the virtual mouse with the physical mouse to determine the user's preference between the two and the acceptance of the virtual mouse.

We collected the subjects' feelings from 6 aspects of Mental Demand, Physical Demand, Temporal Demand, Effort, Frustration Level, and Performance, and each of them has a corresponding question. Each item of the NASA-TLX is rated with a score of 20 points, and for each question, we counted the average of the 27 values that subjects rated, and the results are shown in Fig. 9.

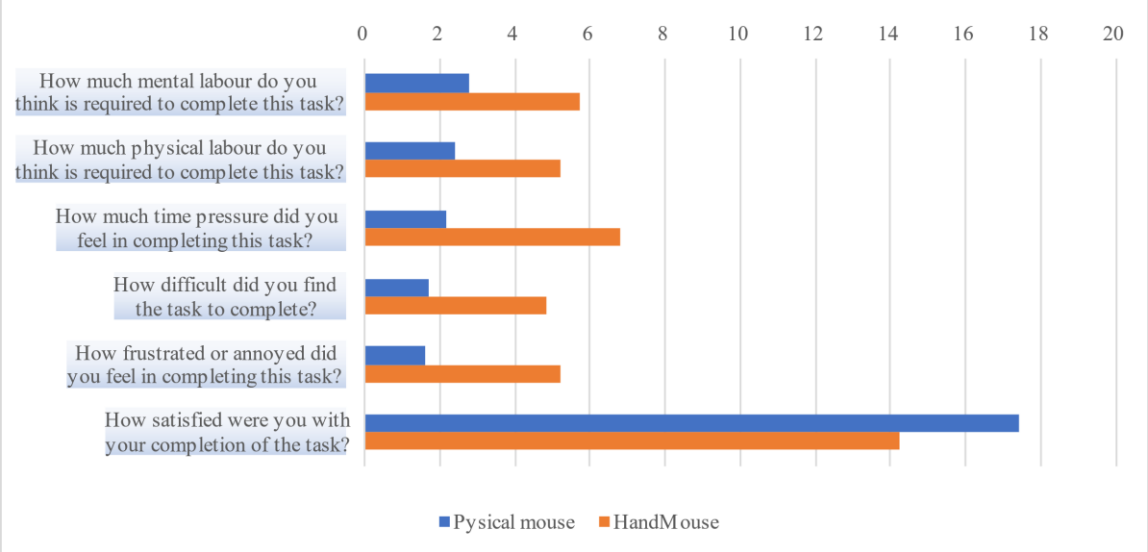

Fig. 9. Evaluation results on NASA-TLX.

The results of the second part of the survey content are shown in Table I, where 22 participants indicated that they would prefer to use this virtual mouse in an HCI system in a public environment, but unfortunately none of them preferred to use it in a work environment. Although this system has tried its best to perform as well as it can, it still has more mental and physical work in using it than a physical mouse. With the need for more precise results in the workplace, this virtual mouse system really isn't a good choice for new users. However, considering its performance, interesting, and technological effects, most of the participants gave it a relatively good rating as a whole.

TABLE I. AVERAGE TIME SPENT ON DIFFERENT OPERATIONS. THE UNIT OF ELAPSED TIME IS MILLISECONDS

Questions	Results
Do you prefer to use a physical mouse or this HandMouse during work or study?	0/27 body selected by HandMouse
Do you prefer to use a physical mouse or this HandMouse in public places such as shopping malls and museums?	22/27 bodies selected by HandMouse
How reasonable do you think the design of the gesture mouse is? (Score [0,20])	15.5 / 20
How satisfied are you with the gesture mouse compared to the physical mouse? (Score [0,20])	15.4 / 20
What is your overall score for this gesture mouse? (Considering rationality of design, technology, interesting, difficulty of operation, etc., Score [0,20])	16.8 / 20

C. Expert Test

To see how the HandMouse is used by experienced users and to explore the limits of its operation, we tested it with smaller target areas. We set the side lengths of the test squares to [6, 8, 12, 16, 20, 25, 30, 40, 50, 60]. Each square was randomly placed on the screen and appeared 20 times in succession. We performed 20 left-clicking operations on each square area and recorded the time taken to perform each operation. We obtained the average test results for different target areas, as shown in Table II and Table III. The open source code repository also contains the test program and the source data.

As can be seen from Table II and Table III, the efficiency of completing a mouse operation is related to the size of the target area and has an overall negative correlation. For the physical mouse, the maximum value of the time spent is about three times the minimum value. The median, mean, and average of Q1-Q3 (values in the middle 50%) are also close to each other, indicating that the physical mouse has great stability when operating on the target area. However, for the gesture mouse, when the target area is less than 12mm, the maximum value is more than 10 times the minimum value because it has one or two obviously large outliers. The overall average is significantly larger than the median and average of Q1-Q3 for the gesture mouse, and the median or average of Q1-Q3 is more representative, but at the same time, the instability of the gesture mouse's functionality should not be ignored.

TABLE II. TIME TAKEN OF PHYSICAL MOUSE OPERATIONS IN DIFFERENT AREAS

Object width / mm	Time taken / ms				
	Max	Min	Average	Median	Average of Q1-Q3
6	1,399	530	1,104	1,092	1,106
8	2,192	639	1,204	1,103	1,111
10	1,423	792	1,020	931	951
12	1,443	712	1,021	1,016	1,017
16	1,483	633	875	823	814
20	1,947	583	868	784	776
25	999	546	717	688	690
30	2,274	450	838	776	777
40	971	527	724	702	706
50	937	454	635	620	617
60	1,208	430	591	516	519

TABLE III. TIME TAKEN OF HANDMOUSE OPERATIONS IN DIFFERENT AREAS

Object width / mm	Time taken / ms				
	Max	Min	Average	Median	Average of Q1-Q3
6	35,464	2,690	7,278	3,991	4,114
8	17,009	1,624	4,884	4,034	4,037
10	18,390	1,876	5,271	3,952	3,889
12	18,526	1,799	4,873	2,957	2,964
16	3,822	1,369	2,412	2,374	2,330
20	8,997	1,512	3,094	2,465	2,516
25	6,693	1,203	2,538	2,289	2,345
30	6,513	1,323	2,391	2,280	2,198
40	2,803	930	1,838	1,876	1,832
50	35,464	2,690	7,278	3,991	4,114
60	17,009	1,624	4,884	4,034	4,037

When the target area is small, the standard deviation of the overall mean is larger for both the physical mouse and the gesture mouse, especially for the gesture mouse, and there are even 1-2 obvious outliers. There are two main reasons for the outliers: firstly, when the target area is small, it is really not easy to position the mouse pointer, and at this point the disadvantage of the gesture mouse is more obvious. Secondly, when the target area appears randomly, the user probably does not know where the target area is, and has to spend a certain amount of time to locate the target area, and then go to locate it.

The total interaction time with the gesture mouse is almost 3.2 times that of the physical mouse. The performance of the virtual mouse is significantly lower than that of the physical mouse. However, these differences may not be as pronounced when using the virtual mouse. The above data was obtained under the premise of assessing mouse performance, where the subject's attention was focused solely on the mouse operations and they aimed to perform the corresponding operations as quickly as possible to achieve the maximum performance of the mouse. In actual use, the mouse is merely a tool for performing specific tasks, and the mental effort required for these tasks may far outweigh the attention devoted to clicking on specific locations. Users often think about the logical steps or considerations in moving the mouse to the target position, without paying excessive attention specifically to mouse operations. However, speculation may not be accurate when the target area is smaller than 12-20 mm. In the course of testing the virtual mouse, subjects may have noticeable difficulty in focusing on the small target area, requiring considerable concentration on the target and repeated attempts to focus. In such cases, the efficiency of using the virtual mouse will be noticeably lower than that of a physical mouse, which may cause some anxiety.

Fortunately, as shown in Table III, the efficiency gap between the virtual mouse and the physical mouse decreases as the size of the target area increases. When operating on larger target areas, it becomes easier to achieve the same ease of use as with a physical mouse. Scenarios in which smaller target objects are manipulated are typically found in work-related environments, where people generally choose to use a physical mouse. The virtual gesture mouse is more suitable for HCI scenarios such as tourist attractions, shopping mall navigation and electronic exhibits in museums. In these cases, the size of the target objects should be larger, even up to 200mm, and then the efficiency gap between using a virtual mouse and a physical mouse or touch screen operation will be smaller. Therefore, the actual efficiency of this gesture mouse in practical use will be higher than in the test.

VI. CONCLUSIONS

Although AI has rapidly developed, gesture-based operations, as one of its applications, have not yet permeated various aspects of people's daily lives. They are only found in specific software or systems, such as intelligent car controls or sign language systems, with limited applications. Moreover, a universal gesture mouse applicable to all software is even rarer. This paper presents a set of gestures designed to replace the physical mouse, resulting in a gesture mouse system that achieves the basic functionality of a physical mouse. On personal computers, it can partially replace the physical mouse, but its performance is significantly lower than a physical mouse. While in public places with larger displays, it can serve as a viable alternative to physical mouse and touch screen operations.

However, the system also has noticeable disadvantages. Firstly, the efficiency of operating smaller target areas is significantly lower compared to a physical mouse, limiting its practical use in work scenarios. Additionally, the system currently only supports recognition of a single hand and does not consider the allocation of operating privileges in multi-user scenarios. For example, in situations where multiple users simultaneously give different control commands, the system does not know whose instructions to follow. While optimizing the former disadvantage may be difficult due to inherent human physiological characteristics, as hand tremors on the screen might already exceed the size of the target object, optimization is not currently prioritized. Nevertheless, there is

great potential for optimizing the latter disadvantage. In the future work, facial recognition of the operators may be implemented to determine the owner of the hand currently in control, thereby automatically allocating operating privileges.

***Abstract*—This paper introduces deepnetguard, an innovative deep learning algorithm designed to efficiently identify potential security threats in large-scale network traffic.deepnetguard achieves automated feature learning by fusing basic, statistical, and behavioral features through a multi-level feature extraction strategy, and is capable of identifying both short-time patterns and long-time dependencies. To adapt to the dynamic network environment, the algorithm introduces a dynamic weight adjustment mechanism that allows the model to self-optimize the importance of features based on real-time traffic changes. In addition, deepnetguard integrates auto-encoder (ae) and generative adversarial network (gan) technologies to not only detect known threats, but also recognize unknown threats. By applying the attention mechanism, deepnetguard enhances the interpretability of the model, enabling security experts to track and understand the key factors in the model's decision-making process. Experimental evaluations show that deepnetguard performs well on multiple public datasets, with significant advantages in accuracy, recall, precision, and f1 scores over traditional ids systems and other deep learning models, demonstrating its strong performance in cyber threat detection.**

***Keywords*—Network security; threat detection; defense; multilevel feature extraction; dynamic weight adjustment mechanism; interpretability**

I. Introduction

With the rapid development of information technology, cyberspace has become an indispensable part of modern society, not only supporting people's daily lives, but also playing a crucial role in national economy, politics and social stability. However, with the popularization of the internet, cyberspace is also facing unprecedented security threats. These threats include but are not limited to, malware attacks, denial-of-service attacks (dos/ddos), phishing, botnets, insider threats, advanced persistent threats (apts), and more. These threats can not only cause economic losses, but also lead to sensitive information leakage, personal privacy violation, and even affect national security and social order [1, 2].

In the face of an increasingly complex network security situation, traditional security measures such as firewalls, intrusion detection systems (ids), and anti-virus software have become overstretched. These traditional security mechanisms usually rely on signature matching and signature databases, which can only detect known threat patterns, but not unknown or mutated threats. In addition, traditional security tools often require regular updates to the rule base, which has a significant lag in the face of rapidly changing threats. To make matters worse, modern cyber attackers often exploit zero-day vulnerabilities, which are not yet publicized and thus cannot be protected in a timely manner [3, 4].

Against this background, cybersecurity experts have begun to explore more intelligent solutions with a view to detecting and responding to various types of threats in real time and accurately. Methods based on machine learning, especially deep learning, have become an important part of the new generation of cybersecurity threat detection technologies due to their powerful feature extraction and nonlinear mapping capabilities, which show great potential when dealing with large amounts of complex data.

Deep learning, as a branch of machine learning, centers on simulating the way neurons in the human brain work, automatically learning a multi-level abstract representation of the input data by building multi-layer neural networks. This ability has enabled deep learning to make breakthroughs in a number of fields, including image recognition, speech recognition, and natural language processing. Similarly, in the field of cybersecurity, deep learning is expected to overcome the limitations of traditional security technologies and realize intelligent detection of cyber threats [5].

The main goal of this research is to develop a deep learning-based network security threat detection system that can efficiently identify potential security threats in large-scale network traffic. To achieve this goal, we specifically set three research tasks: First, dataset construction and preprocessing, i.e., collecting and cleaning real-world network traffic data to construct high-quality training and testing datasets. Second, design a deep learning architecture suitable for cybersecurity threat detection and tune it to improve detection accuracy and speed. Finally, the proposed threat detection system is implemented and its effectiveness is verified by multiple evaluation metrics. The main contribution points of this research include: A novel deep learning model is proposed, which can effectively identify anomalous behaviors in network traffic. Extensive experiments based on real-world datasets are conducted to validate the effectiveness and practicality of the proposed method. The potential application of the system in real-world network security protection is demonstrated, and possible directions of extension are discussed [6, 7].

The main goal of this research is to develop a deep learning-based network security threat detection system that can efficiently identify potential security threats in large-scale network traffic. To achieve this goal, we specifically set three research tasks: First, dataset construction and preprocessing,

i.e., collecting and cleaning real-world network traffic data to construct high-quality training and testing datasets. Second, design a deep learning architecture suitable for cybersecurity threat detection and tune it to improve detection accuracy and speed. Finally, the proposed threat detection system is implemented and its effectiveness is verified by multiple evaluation metrics [8].

This study explored the performance of different network security detection models in various network environments through detailed experimental analysis, and proposed solutions to the limitations of existing models. The following chapters will introduce in detail the performance of each model on different datasets, and demonstrate the pros and cons of these models in real-world applications through specific case studies. Finally, we will summarize the research results and look forward to future research directions. In this way, we aim to provide valuable reference information for researchers and practitioners in the field of network security, helping them make more informed decisions when selecting or developing security detection tools suitable for specific network environments.

II. Related Work

A. Overview of traditional network security threat detection techniques

Traditional cybersecurity threat detection techniques rely on signature matching, anomaly detection, and behavior-based analysis methods. Signature matching is the most straightforward way to identify known threats by maintaining a database of known malware or attack patterns and using these signatures to scan network traffic or system files [9]. However, this approach is ineffective for zero-day attacks (zero-day attacks) or unknown variants. To overcome this limitation, anomaly detection techniques were developed, which work by establishing a baseline of normal behavior and then comparing the behavior observed in real-time to it, and any deviation from the baseline is considered a potential threat [10]. Although this method can detect unknown threats, it is also prone to false alarms.

Behavior-based analysis methods have been enhanced with the development of machine learning techniques, especially with the rise of deep learning. Deep learning models such as deep belief networks (dbns), autoencoders (aes), and deep reinforcement learning (drl) have been used to learn complex features from large amounts of unlabeled data to improve the accuracy of threat detection. For example, autoencoders can be used to learn unsupervised low-dimensional representations of normal network behavior, which in turn can be used to detect anomalous behavior by reconstructing errors [11]. Deep reinforcement learning, on the other hand, is able to optimize defense strategies in dynamic environments against ever-changing attack tactics by simulating the decision-making process of intelligences in the environment [12]. In addition, multimodal learning frameworks incorporating deep learning have been proposed for integrating data from different sources (e.g., logs, traffic, emails, etc.) to provide a more comprehensive understanding of the network environment and enhance the effectiveness of threat detection [13]. By leveraging the powerful generalization capabilities of deep learning, these techniques are able to not only detect known threats, but also identify new types of attacks, which improves the overall level of protection for network security.

B. Application of Deep Learning in Cyber Security

Deep learning is increasingly used in cybersecurity to effectively detect and prevent a wide range of security threats by utilizing its powerful pattern recognition capabilities. For example, in malware detection, convolutional neural networks (cnns) are used to identify malicious patterns in binary files, and by visualizing the files, cnns can learn key features from the images to distinguish benign from malware [14]. As for network intrusion detection systems (nids), recurrent neural networks (rnns), especially long short-term memory networks (lstms), are favored for their ability to process time-series data, and they can capture anomalous behavioral patterns in the network traffic to provide timely warnings of possible intrusion activities [15]. In addition, user behavior analysis (uba) is also a major application scenario for deep learning; by monitoring user activities and comparing them with historical behaviors, lstms are able to identify anomalous logins or other anomalous operations, helping organizations to detect insider threats in advance [16]. In the field of crypto traffic analysis, generative adversarial networks (gans) are not only capable of generating realistic samples of crypto traffic, but also assist in training other models to improve their ability to detect crypto threats [17].

Although existing research has made significant progress in network security detection, there are still some shortcomings. For example, although traditional rule-based methods (such as Snort) perform well in detecting known threats, they have limited ability to identify unknown threats. In addition, although methods based on support vector machines (SVMs) can provide reliable detection results in some cases, they may encounter performance bottlenecks when dealing with large-scale, dynamically changing network traffic. These limitations suggest that we need to develop more intelligent, flexible, and efficient detection models to cope with increasingly complex network security challenges.

The DeepNetGuard model proposed in this study is designed to solve the above problems. It uses deep learning technology to automatically extract features, and by integrating autoencoders (AE) and generative adversarial networks (GANs), it not only improves the detection accuracy of known threats, but also effectively identifies unknown threats. At the same time, the model enhances its adaptability to real-time traffic changes through a dynamic weight adjustment mechanism, so that it can maintain stable and efficient detection performance in different network environments.

III. Research Methodology

A. Problem Modeling

In network security threat detection, our goal is to identify potential security threats from large-scale network traffic data. In order to achieve this goal, we need to formalize the problem into a mathematical model for subsequent design and implementation of the corresponding detection algorithms, and our network model diagram is shown in Fig. 1 [18, 19].

First, we need to define how to represent network traffic data. Suppose we have a series of network traffic records, each of which can be represented as a vector $\mathbf{x} = [x_1, x_2, \ldots, x_n]$, where x_i represents the i th feature in the traffic record. These features can include source ip address, destination ip address, protocol type (tcp, udp, etc.), packet size, timestamp, and port number [20].

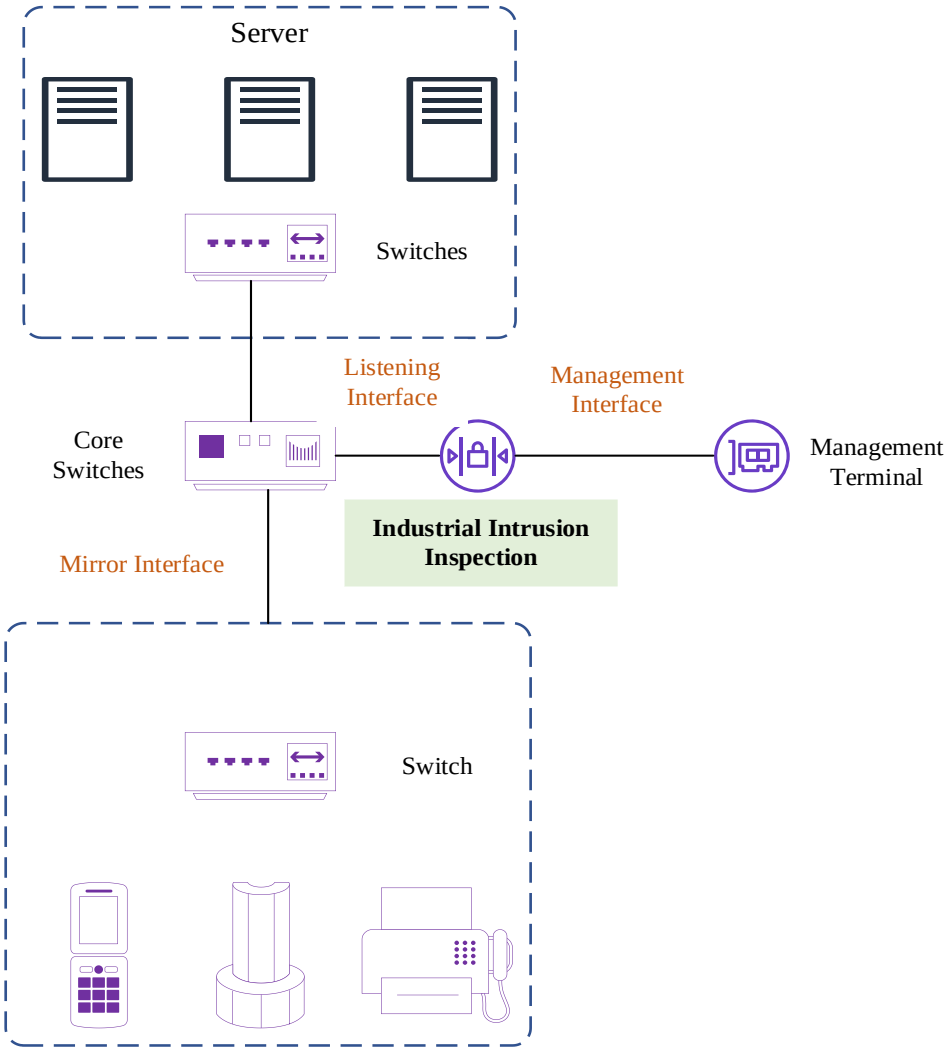

Fig. 1. Security threat detection and defense.

Assuming that we have m network traffic records, the entire dataset can be represented as a matrix $\mathbf{X} = [\mathbf{x}_1, \mathbf{x}_2, \ldots, \mathbf{x}_m]^T$.

For each traffic record, we need a label y_i to indicate whether this record contains threats. If the record contains threats, then $y_i = 1$. Otherwise $y_i = 0$. Thus, the entire set of labels can be represented as a vector $\mathbf{y} = [y_1, y_2, \ldots, y_m]^T$ [21].

Our goal is to construct a classifier $f : \mathbb{R}^n \rightarrow \{0,1\}$ that outputs a binary classification result of the presence or absence of a threat based on a given traffic record $\mathbf{x}$ [22, 23].

To train this classifier, we need to define a loss function L to measure the difference between the model predictions and the actual labels. Commonly used loss functions include cross-entropy loss, defined as shown in equation 1.

$$L(f(\mathbf{x};\theta), y) = -y \log(f(\mathbf{x};\theta)) - (1-y)\log(1-f(\mathbf{x};\theta)) \quad (1)$$

Where $f(\mathbf{x};\theta)$ is the output probability of the classifier and θ are the parameters of the model [24].

In order to find the optimal parameter θ^*, we need to minimize the average value of the loss function L over all the training samples as in Eq. (2) [25].

$$\theta^* = \arg\min_\theta \frac{1}{m} \sum_{i=1}^{m} L(f(\mathbf{x}_i;\theta), y_i) \quad (2)$$

In addition, in order to prevent overfitting, we can also add the regularization term $R(\theta)$ to penalize larger parameter values to obtain the final objective function as shown in Eq. (3). Where λ is the regularization intensity factor [26, 27].

$$\theta^* = \arg\min_\theta \frac{1}{m}\sum_{i=1}^{m} L(f(\mathbf{x}_i;\theta), y_i) + \lambda R(\theta) \quad (3)$$

B. Modeling Ideas

Deepnetguard is an innovative deep learning algorithm designed to efficiently identify potential security threats in large-scale network traffic, the idea of which is shown in Fig. 2. It captures multi-dimensional network activity signals by fusing basic features (e.g., ip addresses and ports), statistical features (e.g., traffic patterns), and behavioral features (e.g., login attempts) through a multi-level feature extraction strategy. Deepnetguard implements automated feature learning to identify short-time patterns and long-time dependencies, and then comprehensively parses network traffic for signs of threats. In order to adapt to the dynamic network environment, the algorithm introduces a dynamic weight adjustment mechanism, which allows the model to self-optimize the importance of features based on real-time traffic changes, improving the flexibility and accuracy of detection [28, 29].

C. Modeling Framework

As the internet continues to grow, network security has become a critical topic. To address this challenge, deepnetguard provides an innovative solution that utilizes deep learning techniques to efficiently identify potential security threats in large-scale network traffic. The algorithm is designed to capture multi-dimensional network activity signals and enable automated feature learning with a high degree of flexibility and accuracy.

Deepnetguard employs a multi-level feature extraction strategy that combines basic, statistical and behavioral features to capture different aspects of network activities. This is shown in Table I [30].

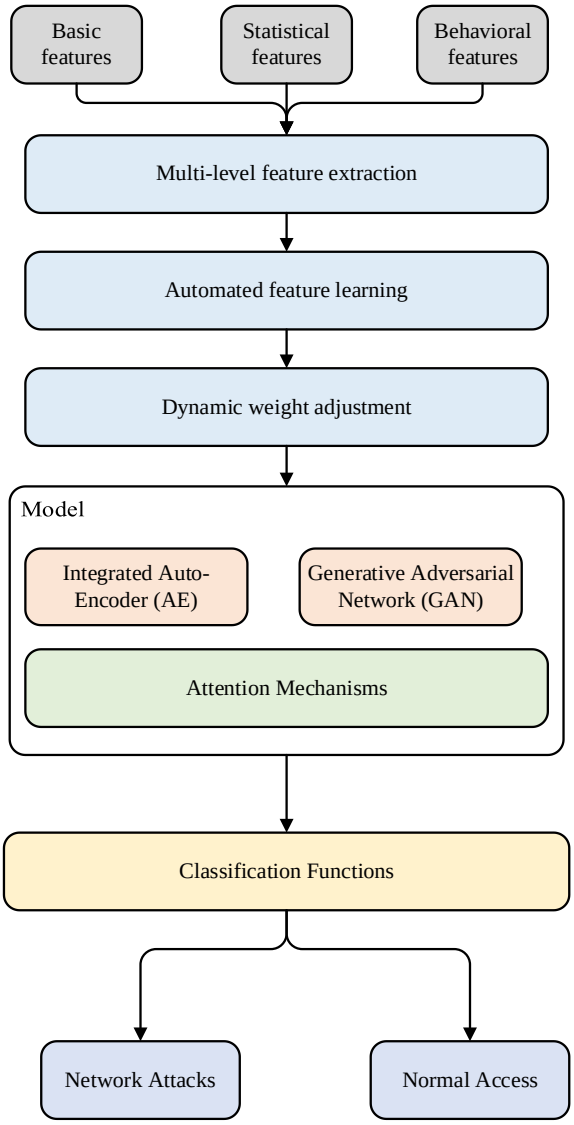

Fig. 2. Deepnetguard.

TABLE I. SUMMARY OF NETWORK DATA ANALYSIS CHARACTERISTICS

Feature category	Descriptive	Typical example
Basic features	Includes basic information about network communication, usually extracted directly from the packet header.	- ip address - port number - protocol type (tcp, udp, icmp, etc.)
Statistical characteristic	Characteristics obtained by statistical analysis of network traffic reflecting communication patterns and traffic characteristics.	- packet size distribution - packet delivery frequency - session duration
Behavioral characteristics	Reflects patterns of user behavior in network activities involving specific application layer interactions.	- number of login attempts - document access modalities - request type (get, post)

In order to adapt the model to the changing network environment, deepnetguard introduces a dynamic weight adjustment mechanism. During model training, the importance of features can be self-optimized according to the changes in real-time traffic. This adjustment is realized by introducing a learnable weight matrix $\mathbf{W}_{dyn}$ as shown in Eq. (4)

$$\mathbf{F}_{adjusted} = \mathbf{W}_{dyn} \cdot \mathbf{F}_{combined} \quad (4)$$

Among them, $\mathbf{F}_{combined}$ is the integrated feature vector after integrating the extracted features from cnn and lstm, which is a weight matrix dynamically adjusted according to the training data.

Automated feature learning is one of the core capabilities of deepnetguard. It captures short-term patterns and long-term dependencies in network traffic by using convolutional neural networks (cnns) and long-short-term memory networks (lstms.) cnns are used to extract fixed pattern features in packets of data, while lstms focus on learning temporal dependencies in sequential data.

For cnn feature extraction, define the convolution kernel $\mathbf{W}_{cnn}$ and the bias term $\mathbf{b}_{cnn}$, and the convolution operation can be expressed as Eq. (5).

$$\mathbf{F}_{cnn} = f(\mathbf{W}_{cnn} * \mathbf{x}_{base} + \mathbf{b}_{cnn}) \quad (5)$$

Where f is usually a nonlinear activation function such as relu. The state update equation for lstm is shown in Eq. (6)-(10).

$$i_t = \sigma(\mathbf{W}_{xi} x_t + \mathbf{W}_{hi} h_{t-1} + b_i) \quad (6)$$

$$f_t = \sigma(\mathbf{W}_{xf} x_t + \mathbf{W}_{hf} h_{t-1} + b_f) \quad (7)$$

$$c_t = f_t \circ c_{t-1} + i_t \circ \tanh(\mathbf{W}_{xc} x_t + \mathbf{W}_{hc} h_{t-1} + b_c) \quad (8)$$

$$o_t = \sigma(\mathbf{W}_{xo} x_t + \mathbf{W}_{ho} h_{t-1} + b_o) \quad (9)$$

$$h_t = o_t \circ \tanh(c_t) \quad (10)$$

Deepnetguard integrates auto-encoder (ae) and generative adversarial network (gan) techniques to detect known and unknown threats. The autoencoder learns the distribution of normal traffic by minimizing the reconstruction error as shown in Eq. (11).

$$E = \frac{1}{m} \sum_{i=1}^{m} || \mathbf{F}_{adjusted}^{(i)} - \mathbf{F}^{(i)} ||^2 \quad (11)$$

Where $\mathbf{F}$ is the reconstructed feature vector. Anomalous traffic is considered to exist when the reconstruction error exceeds a certain threshold.

Gan discovers potential security threats by adversarial training of a generator G and a discriminator D . The generator tries to generate realistic network traffic samples, while the discriminator tries to distinguish real traffic from generated traffic.

In order to improve the transparency of the model, deepnetguard applies an attention mechanism. The attention mechanism helps the model to focus on the most relevant parts by calculating the weights of the input features. The attention weight α is calculated as shown in Eq. (12).

$$\alpha = softmax(\mathbf{a}^T \tanh(\mathbf{W}_{att} \mathbf{F}_{adjusted} + \mathbf{b}_{att})) \quad (12)$$

Where $\mathbf{a}$ is the learnable vector, and $\mathbf{W}_{att}$ and $\mathbf{b}_{att}$ are the weights and biases of the attention layer. The attention weighting feature can be expressed as Eq. (13).

$$\mathbf{F}_{att} = \alpha \circ \mathbf{F}_{adjusted} \quad (13)$$

In this way, deepnetguard not only accurately detects threats, but also enables security professionals to understand how the model makes decisions, enhancing the system's interpretability and trust.

D. Interpretability

Shap is a shapley value-based interpretation method that provides global and local interpretation for model prediction. In deepnetguard, shap is mainly used in the following ways:

Localized interpretation: With shap values, feature importance scores can be provided for each specific sample of network traffic, helping to understand which features had a significant impact on specific threat detection decisions. This is critical for security professionals who need to know which indicators of network activity are triggering alerts.

Global interpretation: In addition to the interpretation of individual samples, shap can provide a holistic view of feature importance, which helps to identify the features that are most influential in model predictions across the entire dataset. This global view aids in feature engineering and model optimization.

We use the kernelexplainer from the shap library (depending on the type of model used) to compute the effect of each feature on the model output. For a given input $\mathbf{x}$, the shap value can be defined as in Eq. (14)

$$\phi_i = \sum_{S \subseteq F,\ \{i\}} \frac{|S|!(|F|-|S|-1)!}{|F|!}[E[f(X)\,|\,do(X_S = x_S)] - E[f(X)]] \quad (14)$$

Where F is the set of features, S is the subset of features, and ϕ_i is the shap value of the feature i . The shap value indicates the magnitude of the contribution of each feature to the prediction result of a particular sample.

Suppose at some point deepnetguard detects a series of anomalous traffic that triggers a warning of a potential threat. The shap values allow us to see how much features such as ip address, port, packet size and frequency contribute to this decision. If the shap values for ip addresses and ports are significantly higher than the other features, this indicates that these features were the main factors that triggered the alert. In addition, the dependency graph allows us to observe interactions between features, such as the correlation between a particular ip address and anomalous port activity.

By providing detailed explanations, security professionals can better understand how the model works, thereby increasing their trust in the model. Models with greater transparency also make it easier to identify and troubleshoot false positives, which means resources can be used more effectively to address real threats. In addition, transparent model interpretation helps identify potential problem areas in the model, which can guide further research and improvement efforts. Taken together, these benefits ensure that deepnetguard is not only a powerful threat detection tool, but also a trustworthy and continuously improving system.

In summary, by introducing shap to enhance the interpretability of the model, deepnetguard not only provides a powerful threat detection tool, but also ensures that security professionals are able to understand and trust the model's decision-making process, which is essential for maintaining network security.

IV. Experimental Design

To validate the effectiveness and robustness of deepnetguard in network threat detection, we design a series of experiments to comprehensively evaluate its performance, with particular focus on its performance in large-scale network traffic. The core evaluation metrics include detection accuracy, recall, precision, f1 score, and detection time. Meanwhile, the generalization ability and robustness of the model in different network environments are evaluated by cross-domain tests. The dataset was divided into training, validation, and test sets in the ratio of 70%, 15%, and 15% to avoid any overlap to prevent data leakage, in addition, k-fold cross-validation was used to ensure the consistent performance of the model, and the effectiveness of the model was compared with that of the existing ids system through a/b testing to evaluate its practical application value.

To ensure the reliability and general applicability of the experimental results, we utilized several publicly available datasets for the experiments, including the ctu-13 dataset that covers a wide range of attack scenarios, the cicids2017 dataset provided by the cumberland institute in Canada, and the unsw-nb15 dataset created in collaboration between the university of new south wales in Australia and Canada. Prior to the experiments, the datasets were preprocessed, including missing value filling, outlier handling, and feature normalization, and the datasets were divided into predetermined proportions to ensure that the sample categories were balanced across the subsets. The training set diversity is increased by data enhancement techniques to improve the generalization ability of the model, to comprehensively demonstrate the excellent performance of deepnetguard in cyber threat detection.

V. Results

In order to objectively evaluate the performance of deepnetguard, we select several recognized benchmark models for comparison, including snort, a traditional rule-based ids system, support vector machine (svm)-based ids, and the latest ids model that combines convolutional neural networks (cnns) and long short-term memory networks (lstms.) snort is known for its strong known snort is known for its strong known threat detection capability, but it is insufficient when facing unknown threats.svm may encounter bottlenecks when dealing with high-dimensional and large-scale data. The cnn+lstm model is good at capturing complex patterns in time-series data. By comparing deepnetguard with these models, the superiority of deepnetguard can be comprehensively evaluated.

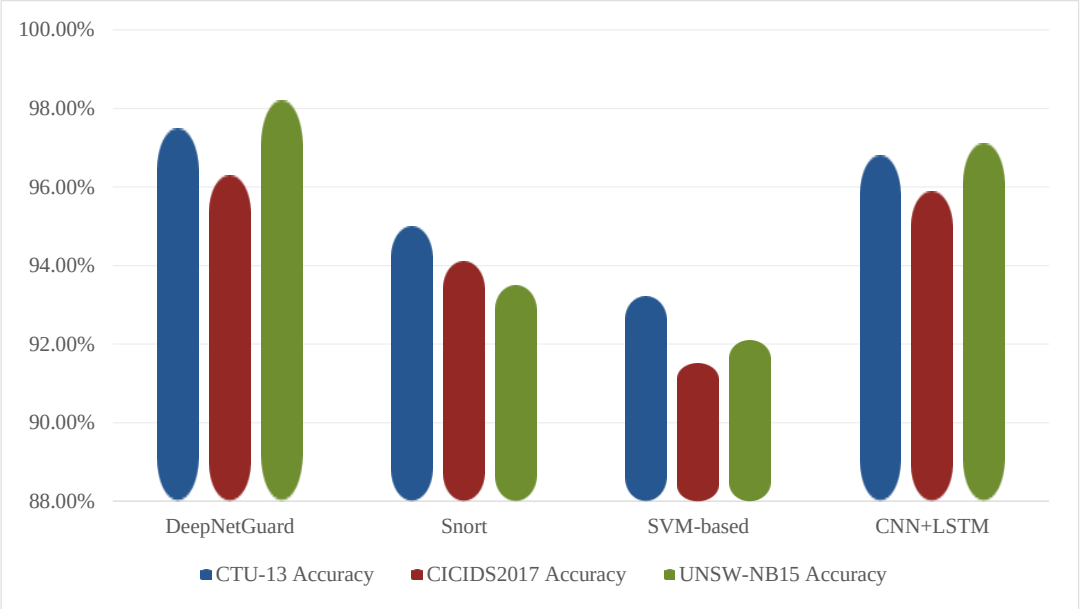

Fig. 3. Model performance comparison - detection accuracy.

In Fig. 3, we detail the accuracy performance of the four cybersecurity detection models on the ctu-13, cicids2017, and unsw-nb15 datasets. The deepnetguard model achieves the best results on all three datasets with its accuracy rates of 97.5%, 96.3%, and 98.2%, showing its the cnn+lstm model follows with accuracy rates of 96.8%, 95.9%, and 97.1%, proving the potential of deep learning technology in the field of cybersecurity. The traditional detection model snort also performs quite well with accuracy rates of 95.0%, 94.1% and 93.5%, showing its stable application value. In contrast, the svm-based model has slightly lower accuracy rates of 93.2%, 91.5% and 92.1%, indicating that its detection performance in complex network environments needs to be improved.

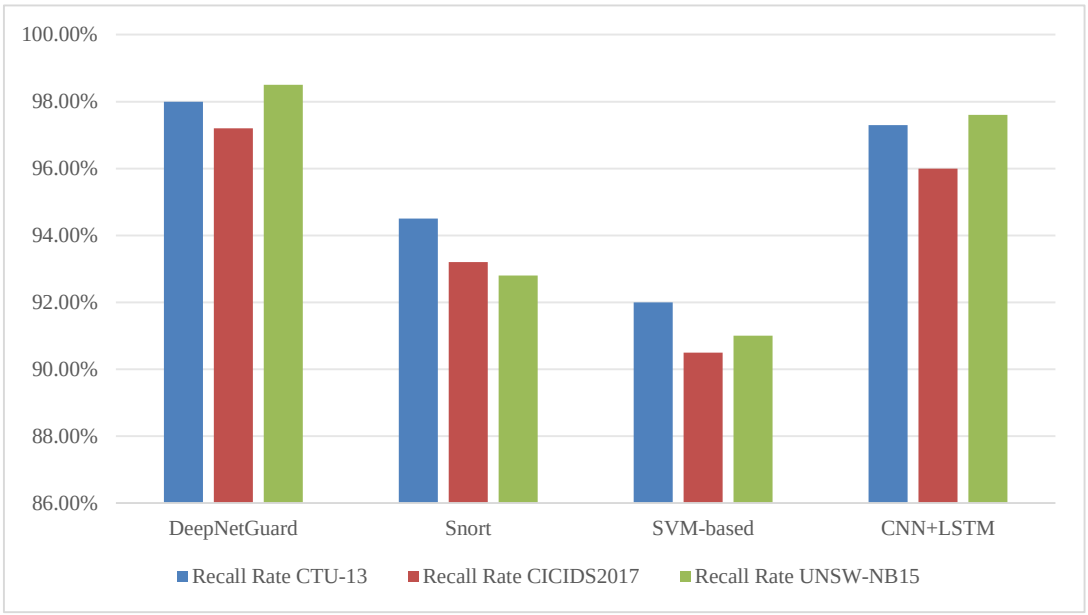

Fig. 4. Comparison of model performance - recall rate.

Based on the data in Fig. 4, we can see the performance of the four models in terms of recall. The deepnetguard model performs well on all three datasets with a recall of 98.0%, 97.2%, and 98.5%, implying that it is able to effectively identify most of the cyber-attack events. The cnn+lstm model has a recall of 97.3%, 96.0%, and 97.6%, again showing its effectiveness in capturing cyber threats. The snort model has recall rates of 94.5%, 93.2% and 92.8%, indicating that it is able to cover the attack events well. The svm-based model, on the other hand, has the lowest recall rates of 92.0%, 90.5% and 91.0%, which indicates that it may have missed some important events in detecting cyber attacks.

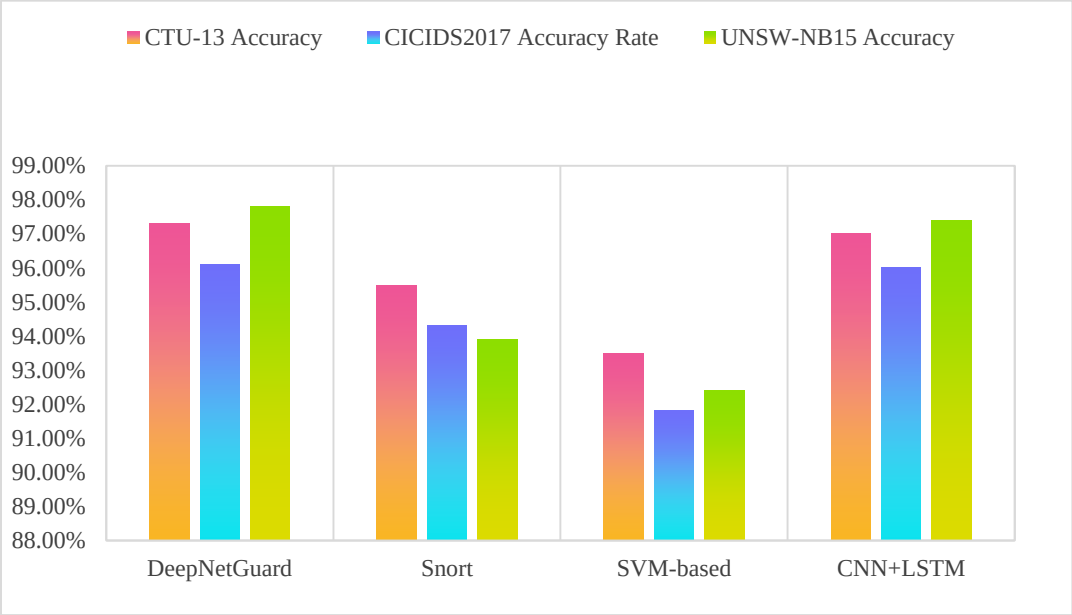

Fig. 5. Model performance comparison – accuracy.

Fig. 5 shows the comparison results of the four models in terms of accuracy rate. The deepnetguard model tops the list with accuracy rates of 97.3%, 96.1%, and 97.8%, indicating its high accuracy in the detection process. The cnn+lstm model also performs well, with accuracy rates of 97.0%, 96.0%, and 97.4%, showing its good detection capability. The accuracy rates of the snort model are 95.5%, 94.3% and 93.9%, indicating its advantage in avoiding false alarms. The accuracy rates of svm-based model are 93.5%, 91.8% and 92.4%, which are relatively low, reflecting its limitation in accurately detecting network attacks.

TABLE II. MODEL PERFORMANCE COMPARISON - F1 SCORES

Mould	Ctu-13 f1 score	Cicids 2017 f1 score	Unsw-nb15 f1 score
Deepnetguard	97.8%	96.7%	98.0%
Snort	95.2%	93.6%	93.1%
Svm-based	92.8%	91.0%	91.7%
Cnn+lstm	97.1%	95.9%	97.5%

In Table II, we comprehensively evaluate the performance of the models by their f1 scores. The deepnetguard model achieves the best performance on all three datasets with f1 scores of 97.8%, 96.7%, and 98.0%, showing a good balance between accuracy and recall. The f1 scores of the cnn+lstm model are 97.1%, 95.9%, and 97.5%, again demonstrating its excellent overall performance. The f1 scores for the snort model are 95.2%, 93.6% and 93.1%, showing its stable but not optimal performance. The svm-based model has the lowest f1 scores of 92.8%, 91.0% and 91.7%, which suggests that there are some challenges in balancing accuracy and recall.

TABLE III. MODEL PERFORMANCE COMPARISON - DETECTION TIME

Mould	Ctu-13 detection time (ms)	Cicids2017 detection time (ms)	Unsw-nb15 detection time (ms)
Deepnetguard	2.5	2.7	2.6
Snort	1.2	1.3	1.3
Svm-based	3.0	3.2	3.1
Cnn+lstm	2.8	3.0	2.9

Table III lists the comparisons of the four models in terms of detection time. The detection times of deepnetguard model are 2.5ms, 2.7ms and 2.6ms, showing its efficient detection ability. The detection times of cnn+lstm model are 2.8ms, 3.0ms and 2.9ms, which are slightly higher than deepnetguard, but still in the fast response range. The snort model has the shortest detection time of 1.2ms, 1.3ms and 1.3ms, proving its advantage in real-time detection. The svm-based model, on the other hand, has the longest detection time of 3.0ms, 3.2ms and 3.1ms, which may limit its application in real-time network monitoring.

TABLE IV. MODEL PERFORMANCE COMPARISON - CROSS DOMAIN TESTING

Mould	Ctu-13 to cicids2017 declining accuracy rate	Cicids2017 to unsw-nb15 declining accuracy rates	Unsw-nb15 to ctu-13 decrease in accuracy
Deepnetguard	1.2%	1.9%	0.7%
Snort	1.5%	2.3%	1.3%
Svm-based	2.5%	3.0%	2.1%
Cnn+lstm	1.5%	2.2%	1.0%

Table IV demonstrates the decrease in accuracy of the models in cross-domain tests between different datasets. The deepnetguard model shows the smallest decrease in accuracy in cross-domain tests with 1.2%, 1.9% and 0.7%, indicating its good generalization ability. The cnn+lstm model's accuracy decreases with 1.5%, 2.2% and 1.0%, which also shows its robustness on different datasets. The accuracy of the snort model decreases to 1.5%, 2.3%, and 1.3%, indicating its fair performance in cross-domain detection. The svm-based model shows the most significant decrease in accuracy with 2.5%, 3.0%, and 2.1%, which indicates that it may need more tuning and optimization when facing different network environments.

A. Case Studies

Case 1: Intra-enterprise network environment

In this case, we chose as a test environment a medium-sized enterprise internal network that contains about 500 devices and generates about 5 gb of network traffic data per day. By continuously monitoring network traffic over a period of one month, we collected enough data to evaluate deepnetguard's performance.

TABLE V. ENTERPRISE INTERNAL NETWORK ENVIRONMENT TESTING PERFORMANCE

Mould	Accuracy	Recall rate	Accuracy	F1 score	Detection time (ms)
Deepnetguard	97.0%	98.1%	97.5%	97.8%	2.4
Snort	94.5%	93.5%	94.8%	94.1%	1.3
Svm-based	92.0%	91.5%	92.5%	92.0%	3.0
Cnn+lstm	96.5%	97.0%	96.8%	96.9%	2.8

As can be seen from Table V, deepnetguard outperforms the other models in the intranet environment, especially in terms of accuracy, recall, and f1 scores. Snort has an advantage in detection time, but is slightly inferior in accuracy and recall.

Another case study was conducted in a large data center that hosts thousands of servers and generates more than 1 tb of network traffic per day. Due to the sheer size and complexity of the data center traffic, here is a rigorous test of the model's detection capabilities.

TABLE VI. DATA CENTER NETWORK ENVIRONMENT TESTING PERFORMANCE

Mould	Accuracy	Recall rate	Accuracy	F1 score	Detection time (ms)
Deepnetguard	98.2%	98.5%	98.3%	98.4%	2.6
Snort	93.0%	92.5%	93.5%	93.0%	1.5
Svm-based	91.0%	90.5%	91.5%	91.0%	3.2
Cnn+lstm	97.5%	97.8%	97.6%	97.7%	3.0

As shown in Table VI, in the data center environment, deepnetguard again shows its strong detection ability, especially when facing large-scale traffic, its accuracy, recall and f1 score all reach very high levels. Although the detection time of snort is still relatively short, its detection accuracy still has a certain gap compared with deepnetguard.

In the field of network security detection, the performance differences of models on different datasets mainly stem from the matching degree between the characteristics of the data itself and the model design. This paper compares the performance of four network security detection models (DeepNetGuard, CNN+LSTM, Snort, and SVM-based models) on three public datasets (CTU-13, CICIDS2017, and UNSW-NB15) to show the differences in model performance and their applicability.

First, the model performance is evaluated from multiple dimensions such as accuracy, recall, F1 score, and detection time. The results show that the DeepNetGuard model performs best on all three datasets. Its high accuracy (97.5%-98.2%), high recall (98.0%-98.5%), and high F1 score (97.8%-98.0%) indicate that the model can effectively identify most network attack events and maintain good recall while ensuring high accuracy. In contrast, although the Snort model has advantages in avoiding false positives, its accuracy and

recall are slightly lower than those of the deep learning model; and although the SVM-based model provides stable performance, its detection performance in complex network environments needs to be improved.

Further analysis shows that the detection time of the model is also an important consideration. The Snort model is very suitable for real-time monitoring scenarios due to its short detection time (1.2ms-1.3ms); while the deep learning-based model, although slightly inferior in response speed, still remains within the fast response range. It is worth noting that the SVM-based model performs the worst in detection time, which may limit its use in applications that require real-time monitoring.

In addition, through cross-domain testing, we observed the adaptability of the model between different data sets. Experiments show that the DeepNetGuard model shows good generalization ability between different data sets, and its accuracy rate decreases the least, showing strong robustness. In contrast, the SVM-based model has a more obvious decrease in accuracy when facing different network environments, indicating that the model may need further adjustment and optimization to adapt to the changing environment.

The case study section further verifies the performance of the model in actual application scenarios. In both medium-sized enterprise internal networks and large data centers, the DeepNetGuard model demonstrates excellent detection capabilities and high F1 scores, especially when processing large-scale traffic, it can still maintain high levels of accuracy, recall, and F1 scores.

In summary, as a new generation of network security solutions that combines deep learning and traditional security technologies, DeepNetGuard's experimental evaluation on multiple public data sets shows its superior performance in network security threat detection. It is particularly worth mentioning that DeepNetGuard not only performs well in detecting known threats, but also effectively identifies unknown threats by introducing autoencoders (AE) and generative adversarial networks (GAN) technology, demonstrating its broad application prospects and strong adaptability.

VI. Conclusion

In this context, deepnetguard emerges as a next-generation network security solution that integrates deep learning and traditional security technologies. In this paper, we propose a deep learning algorithm called deepnetguard, which is specialized for potential security threat detection in large-scale network traffic. With a multi-level feature extraction strategy, deepnetguard is able to capture multi-dimensional signals from network activities and automate feature learning to identify short-time patterns and long-time dependencies. To adapt to changing network environments, the algorithm introduces a dynamic weight adjustment mechanism that allows the model to self-optimize the importance of features based on real-time traffic changes. In addition, deepnetguard integrates auto-encoder (ae) and generative adversarial network (gan) techniques, which not only improves the detection of known threats, but also effectively recognizes unknown threats. By introducing an attention mechanism, deepnetguard also enhances the interpretability of the model, enabling security experts to better understand the key factors in the model's decision-making process to validate the effectiveness of the detection results. Deepnetguard has demonstrated its superior performance in cyber threat detection through experimental evaluations on multiple publicly available datasets. Compared with traditional rule-based ids systems (e.g., snort) and other deep learning models, deepnetguard demonstrates significant advantages in terms of accuracy, recall, precision, and f1 score. In particular, deepnetguard's detection capability is fully validated in both internal and data center network environments, demonstrating its broad applicability and robustness in different application scenarios. In addition, through cross-domain testing, we found that deepnetguard has good generalization ability and can maintain stable detection performance in different network environments.

In future work, we will continue to optimize the DeepNetGuard model and explore more feature extraction methods and technology combinations to further improve the detection efficiency and accuracy of the model. At the same time, we plan to expand the scale of experiments and collect more types of data sets for testing to ensure the reliability and stability of the model in various complex network environments. In addition, we will also conduct in-depth research on the interpretability of the model so that security experts can better understand the decision-making process of the model and enhance the transparency and trust of the system. The ultimate goal is to build a comprehensive, intelligent and trustworthy network security protection system.

Development of Fuzzy Logic CRITIC Coupling Coordination Degree Evaluation Algorithm

Practice of Cultural and Tourism Integration Development in the Yangtze River Economic Belt, China

Fangfang Hu
School of Humanities and Tourism, Zhejiang Institute of Economics and Trade, Hanzhou 310018, Zhejiang, China

***Abstract*—The integrated development of culture and tourism in the Yangtze River Economic Belt refers to a strategic initiative to push economic development and regional coordinated development with culture and tourism as the core. The purpose of this paper is to evaluate the coupling coordination degree of the integrated development of culture and tourism in the Yangtze River Economic Belt, by analysing the integrated development of culture, tourism and economy, and constructing an evaluation index system based on culture and tourism, in which 5 normative indicators and 19 basic indicators are constructed under the cultural perspective, and 4 normative indicators and 10 basic indicators are constructed under the tourism perspective, and its role and impact on regional economic development is explored based on the construction of the index system. Based on the construction of the indicator system, the role and influence of the indicators in regional economic development are explored. The CRITIC algorithm is used to calculate the importance of stratified indicators and stratified evaluation results, and finally, the coupling coordination degree of the research object is calculated through the coupling coordination degree model, which shows that the 13 provinces (municipalities directly under the central government) along the Yangtze River Economic Belt have a slightly different degree of coordination, but the least of them have reached the primary level of coordination, but it also proves that this paper proves the feasibility and necessity of the research method, and it can provide a good solution for the integrated development of culture and tourism in the Yangtze River Economic Belt. However, it also proves the feasibility and necessity of the research method of this paper, which can provide theoretical and practical guidance for the integrated development of culture and tourism in the Yangtze River Economic Belt, and provide new ideas and methods for the development of local tourism along the way.**

***Keywords*—Cultural and tourism integration; Yangtze River Economic Belt; coupling coordination degree; CRITIC algorithm**

I. INTRODUCTION

In China, the integrated development of culture and tourism has become a topic of great concern and has made some progress in academic research and practice. As a country with a long history and rich cultural heritage, China is endowed with unique cultural and tourism resources. Therefore, the integrated development of culture and tourism has become an important way to promote the development of tourism, cultural heritage and cultural industry, and domestic research on the integrated development of culture and tourism has gradually gained attention and importance [1-3]. Scholars have explored the theoretical basis, practice mode, policy support and other aspects of the integrated development of culture and tourism through field research, literature analysis and case studies, not only focusing on the impact of tourism on cultural heritage and the role of cultural resources in promoting tourism, but also putting forward a series of valuable ideas and suggestions [4-6]. Secondly, government departments and related institutions have also begun to pay attention to the integrated development of culture and tourism, and have issued a series of policies and measures to support the integration of culture and tourism, which aim to promote the sharing, complementation and integration of cultural and tourism resources, to promote the development of cultural and tourism industries, and to enhance the quality of tourism experience and cultural heritage. At the same time, some regions and scenic spots in China have begun to explore the development mode of integrating culture and tourism by organising cultural festivals, traditional performances, cultural experience activities, etc., integrating cultural elements into tourism products and services, which enriches the tourism experience, attracts more tourists, and promotes the development of the local economy [7-8].

It is believed abroad that such integrated development of culture and tourism can not only promote economic growth but also enrich people's spiritual lives and enhance international mutual understanding and friendship. In foreign countries, many scholars and research institutions have conducted in-depth research on the integrated development of culture and tourism and put forward many theoretical and practical results, which have made important contributions to the development of this field. Therefore, in foreign countries, many universities and research institutions have established interdisciplinary research teams to conduct in-depth research on the integrated development of culture and tourism, which has promoted the academic development of this field [9-10]. Foreign scholars have put forward many theoretical frameworks and models for the integrated development of culture and tourism, such as the theory of cultural tourism industry chain, the theory of cultural creative industry, the theory of cultural heritage protection, etc. [11-12]. These theoretical explorations have provided theoretical support and guidance for the integrated development of culture and tourism, and theoretical guidance for the relevant practices, and so along with this, many foreign research institutes have carried out in-depth studies on the practical cases of the integrated development of culture and tourism, and summarised the successful cases. In-depth study, summed up the

successful case experience and failed lessons, these practice case studies for the integration of culture and tourism development in other regions to provide reference and warning. Relevant research tasks cultural and creative industries as an important support for the integrated development of culture and tourism, so they have conducted in-depth research on the development path, innovation mode and policy support of cultural and creative industries, which provides important ideas for the integrated development of culture and tourism [13-15].

However, how to promote the deep integration and sustainable development of culture and tourism, and determine the degree of integration of culture and tourism at this stage, especially the degree of coordinated development of regional culture and tourism has become a new research hotspot, this paper considers that the Yangtze River Economic Belt, as one of the most important regions of China's economy, and the integration of culture and tourism development is of great significance to its economic development, so it adopts the CRITIC algorithm [16] to carry out a study on the degree of significance of the basic indicators in the indicator system of culture and tourism integration. Based on the coupling coordination degree [17] to determine the degree of cultural and tourism integration. In order to provide in-depth exploration and expansion of the concept of cultural and tourism integration, and to promote the continuous improvement and innovation of the theory of cultural and tourism integration.

II. Evaluation Model Construction

A. Overview of the Study Area and Sources of Data

1) Study area: In this paper, the study area is selected as provinces and municipalities along the route, mainly considering that the Yangtze River Economic Belt is located in the economically developed areas of China, with rich resources and good industrial foundation, which is one of the important pillars of China's economy, and the study of the coupling and coordination degree of the development of culture and tourism fusion in this region can make full use of the economic advantages of the Yangtze River Economic Belt, and promote the development of the culture and tourism industry [18]. Secondly, the Yangtze River Economic Belt spans across the developed provinces and cities in eastern China, and is connected to the upstream, midstream and downstream areas of the Yangtze River Basin, with an advantageous geographic location, which in turn provides rich regional cultural and tourism resources for the integrated development of culture and tourism, as well as broad market space for the integrated development of the culture and tourism industry [19-20]. At the same time, the Yangtze River Economic Belt has rich natural and human resources, but also faces the challenge of ecological environmental protection and governance, the study of the coupling and coordination degree of the integrated development of culture and tourism can help to promote the green development of the Yangtze River Economic Belt, and achieve the coordinated development of the economy and ecology. In addition, the government has put forward the development strategy of the Yangtze River Economic Belt in recent years, which provides policy support and financial guarantee for the development of the region, so the study of the degree of coupling and coordination of the integrated development of culture and tourism can be in line with the government's strategy, and better realise the integrated development of the regional economy and the culture and tourism industry [21]. The Yangtze River Economic Belt is a densely populated region in China, and its economic and social development level has an important impact on the whole country. By studying the coupling and coordination degree of the integrated development of culture and tourism, we can promote the economic and social development of the Yangtze River Economic Belt, and drive the development of the whole country's culture and tourism industry [22].

Studying the coupling and coordination degree of the integrated development of culture and tourism in the Yangtze River Economic Belt is of great practical significance and strategic significance, which helps to promote the regional economic development, cultural inheritance and the prosperity of the tourism industry, and fully demonstrates that the Yangtze River Economic Belt is suitable to be an ideal choice for studying the integrated development of culture and tourism.

2) Research data sources: Considering that this paper studies the development status of culture and tourism integration in the Yangtze River Economic Belt over the years, which is spatial in nature, the data for the indicators come from China Statistical Yearbook, China Environmental Statistical Yearbook, China Tertiary Industry Statistical Yearbook, China Tourism Statistical Yearbook, China Culture and Related Industries Statistical Yearbook, China Cultural Relics and Culture Statistical Yearbook, China Regional Economy Statistical Yearbook China Informatisation Statistical Yearbook", as well as the official website of the Ministry of Culture and Tourism, the database of the National Research Network, the Dawei Patent Search Engine, the official website of the State Civil Aviation Administration, the statistical yearbooks of provinces and districts along the Yangtze River Economic Belt and the annual statistical bulletin of national economic and social development, the mean value of the research data of the indexes is used to characterise the degree of development of the study area over the years, and at the same time it is dimensionless. The model is utilised to the extent that it can be utilised.

B. Constructing a System of Research Characterisation Factors

Through relevant research, it can be seen that the coupling coordination degree evaluation of cultural and tourism integration development needs to consider the richness and characteristics of tourism resources such as natural landscape, human landscape, historical and cultural heritage, and the degree of development and utilisation of tourism resources, because tourism resources are an important factor in attracting tourists, and also the main support for the development of cultural and tourism integration. Secondly, the development level of the regional economy and industrial structure has a direct impact on the coupling coordination degree of the integrated development

of culture and tourism, mainly in the economic prosperity, industrial diversification will provide more support and demand for the integration of culture and tourism; in addition, the government's support for the integrated development of culture and tourism policies and regulations have a profound impact on the evaluation of the degree of coordination, the soundness of the policy or not, the support, guidance, etc., will have a direct impact on the coordination degree of the integrated development of culture and tourism. However, relevant scholars believe that national policy considerations can be weakened in the study of the Yangtze River Economic Belt, because the importance of the cities along the line for its development can be seen. Of course, the social and cultural background of the region, customs and traditions, cultural heritage, etc. will have an impact on the degree of coordination of the integrated development of culture and tourism, cultural heritage and innovation, social inclusion and sharing are for cultural recognition, tourism integration of the details of the factors. The slogan of "green water and green mountains are golden mountains" is familiar, so it can be considered that the overall quality of the regional environment, ecological protection and governance, resource utilisation and sustainable development is the basis for the integrated development of culture and tourism.

Based on the above, the influencing factor indicator system can be constructed initially, but for the evaluation model, the following principles need to be considered when constructing the influencing factor indicator system for evaluating the coupling coordination degree of culture and tourism integration and development:

1) The principle of multi-dimensionality: Consider the influence of multiple factors. The integrated development of culture and tourism involves culture, tourism, economy, society and other fields, so the evaluation indicator system should be multi-dimensional, including cultural value, tourism resources and other aspects of the indicators, in order to comprehensively evaluate the degree of coordination of the integrated development of culture and tourism.

2) Principle of operability: The indicators should be operable and measurable. Evaluation indicators should be measurable and observable for assessment and monitoring in practical application. At the same time, the design of the indicators should take into account the feasibility of practical operation and be easy to be used by the government, enterprises and research institutions.

3) Principle of uniformity: The indicator system should have a certain degree of uniformity, and the evaluation indicators should have a certain degree of coordination and consistency in the whole, in order to ensure the objectivity and comparability of the evaluation results, therefore, this paper has carried out a dimensionless processing for the collected data of the research objects in section 2.1.2 to complete the consistency of the measurements.

4) Principle of sustainability: Consider the sustainability factors of development. The integrated development of culture and tourism needs to consider long-term sustainability, and the evaluation index system should take into account sustainability factors such as environmental protection, resource utilisation, social benefits, etc., in order to promote the sustainability of the integrated development of culture and tourism.

5) Participatory principle: Promote the participation of relevant stakeholders. The construction of the evaluation indicator system should take into account the opinions and needs of all stakeholders, and encourage them to participate in the selection of indicators and the evaluation process, in order to enhance the fairness and rationality of the evaluation.

The role of these principles is to ensure that the evaluation index system for integrated cultural and tourism development is scientific, practical and fair, so that it can comprehensively and objectively evaluate the degree of coordination of integrated cultural and tourism development and provide a scientific basis for decision-making and planning. At the same time, these principles also help to promote the participation and consensus of all stakeholders and promote the sustainability and coordination of integrated cultural and tourism development.

Based on this, this paper finally constructs the indicator system as shown in Table I.

As seen through Table I, based on the current research results, construction principles and visit records, this paper constructs a total of 29 basic indicators, of which a total of 19 indicators are constructed in the field of culture, and a total of 10 indicators are constructed under the tourism perspective, which can be seen that the indicators under the cultural perspective are higher than those under the tourism perspective, and analysed that the main reason is that how culture is embedded in the development of tourism is more concerned at the present time, i.e., how to promote the tourism Evolution into a harmonious win-win situation of culture and tourism is the current issue, which is not only a challenge to the inclusiveness of the tourism industry, but also a great challenge to the penetration and friendly integration of the cultural industry. And this also proves that it is more appropriate to adopt the degree of coupling coordination to analyse the degree of win-win between the two.

C. Degree of Impact and Evaluation based on the CRITIC Approach

The CRITIC algorithm is a risk assessment methodology for evaluating and managing risk in projects and decisions. CRITIC is an acronym for "Criticality, Recoverability, Inherent Risk, Time Criticality, Impact, and Controllability", and it includes the following six risk factors:

- Criticality: The degree of importance of the event and its impact on the project objectives.
- Recoverability: The ability of a project or organisation to return to a normal state after a risk event.
- Inherent Risk: The likelihood of a risk event occurring and the magnitude of its impact, regardless of the controls already in place.
- Time Criticality: The degree to which a risk event affects the timetable and schedule of a project or organisation.
- Impact: The degree of impact on the project or organisation following the occurrence of a risk event, including financial, environmental and social impacts.

- Controllability: The degree of control and ability of a project or organisation to control risk events.

TABLE I. EVALUATION INDEX SYSTEM OF COUPLING COORDINATION DEGREE OF CULTURAL AND TOURISM INTEGRATION DEVELOPMENT IN THE YANGTZE RIVER ECONOMIC BELT [22, 23]

Target level	Normative layer	Indicator layer	Interpretation of indicators
Cultures	Cultural Services Facilities	Number of public libraries	For assessing the distribution and coverage of cultural and educational resources.
		Number of performing arts venues	The number of performing arts venues in a city or region, which is used to assess the abundance of performing arts activities and opportunities for cultural exchange.
		Number of museums	Number of museums in the city or region, used to assess the preservation and presentation of historical and cultural heritage.
		Number of mass cultural institutions	Number of mass cultural institutions in the city or region for assessing the transmission and development of cultural traditions and intangible cultural heritage.
	Cultural services staff	Public Library Practitioners	The number of staff in public libraries, which is used to assess the quality and efficiency of library services.
		Museum practitioners	The number of staff in museums is used to assess the level of heritage conservation and display management in museums.
		Practitioners of mass cultural institutions	The number of staff in mass cultural institutions is used to assess the transmission of cultural traditions and the implementation of intangible cultural activities.
		Performing arts organisations	The number of staff of performing arts organisations, which is used to assess the scale and professionalism of performing arts activities.
	Cultural Services Benefits	Museum income	The museum's income is used to assess the museum's own operations and economic performance.
		Income from mass cultural institutions	The income of mass cultural institutions is used to assess the economic efficiency and sustainability of cultural activities.
		Revenue from performances at performing arts venues	The performance income of performing arts venues is used to assess the market performance and audience feedback of performing arts activities.
	Cultural service recipients	Public library circulation	Circulation of books in the public library collection is used to assess the library's reading service and the utilisation of book resources.
		Audience at arts performance venues	Audience size of performing arts venues, which is used to assess the audience size and social impact of performing arts activities.
		Museum Visit	Visits to museums, which are used to assess the social engagement and cultural impact of museums.
	Inputs to cultural services	Training in mass cultural institutions	Information on training activities provided by mass cultural institutions is used to assess the transmission of cultural traditions and the teaching of intangible cultural skills.
		Total expenditure on public libraries	The total expenditures of public libraries are used to assess the operating costs and funding of libraries.
		Total expenditure on mass cultural institutions	The total expenditure of the mass cultural institutions is used to assess the efficiency of financial expenditure and management of cultural activities.
		Total museum expenditure	The total expenditure of the museum is used to assess the museum's financial commitment and heritage conservation work.
		Expenditure on performing arts venues	Expenditure on performing arts venues, which is used to assess the operating costs and management efficiency of performing arts activities.
Journey	Tourism Service Facilities	Travel agents	Number and services of travel agencies in the city or region, used to assess the level of coverage and quality of tourism services.
		Starred hotel	The number and services of star-rated hotels in the city or region are used to assess the quality and reception capacity of tourism accommodation services.
		Scenic area	The number of attractions and visits within a city or region, which are used to assess the attractiveness of the attraction and the visitor experience.
	Tourist service staff	Travel agents	The number of staff in travel agencies, which is used to assess the level of professionalism and service attitude of travel services.
		Star-rated hotel workers	The number of staff in star-rated hotels is used to assess the scale of the service and the level of management of the hotels.
		Scenic Area Practitioners	The number of staff in the scenic area is used to assess the level of scenic area management and visitor services.
	Revenue from tourism services	Operating income from star-rated hotels	The operating income of star-rated hotels is used to assess the economic efficiency and market competitiveness of hotel operations.
		Gross tourism income from scenic spots	The total tourism revenue of the scenic spot is used to assess the economic efficiency and tourism attractiveness of the scenic spot.
	Tourism service recipients	Number of domestic and foreign tourists received by travel agencies	The number of domestic and foreign tourist arrivals received by travel agencies is used to assess the capacity and market demand for tourism services.
		Scenic Area Reception	The number of tourists received by the scenic spot is used to assess the flow of tourists and tourism impact of the scenic spot.

This paper considers adopting the CRITIC algorithm, mainly because it can comprehensively consider the importance and interconnectedness of multiple criteria or factors, so as to comprehensively assess the degree of tourism integration and development, which can help to avoid one-sided and localised evaluations, and improve the comprehensiveness and comprehensiveness of the assessment. Moreover, the CRITIC algorithm is based on mathematical models and quantitative analysis, which can provide objective evaluation results and reduce the influence of subjectivity and personal bias. At the same time, for diverse samples, this paper also proposes in section II.B that it is necessary to consider a clear evaluation process and calculation method, so that the evaluation process is operable and replicable, and the evaluator using the CRITIC algorithm can carry out standardised processing according to the standards and data, so as to carry out effective evaluation and comparison. In addition, the CRITIC algorithm can flexibly adjust and weigh different criteria or factors according to the actual situation, which helps to provide a flexible and comprehensive assessment of different aspects of integrated tourism development.

Taken together, the CRITIC algorithm, as a multi-criteria decision analysis method, has the advantages and strengths of comprehensiveness, objectivity, operability, flexibility and visualisation in assessing the degree of coupled coordination of tourism integration and development. The calculation steps are shown below.

1) Standardisation: Let the number of objects to be evaluated be *m*, the number of evaluation indicators be *n*, and the matrix of data elements be denoted as $X = (x_{ij})_{m\times n}$.

$$x_{ij}^{`} = \frac{x_{ij} - min \quad x_j}{max \quad x_j - min \quad x_j} \tag{1}$$

In Eq. (1), where: x'_{ij} - Data matrix elements after normalisation;

x_{ij} -Initial element of the data matrix.

2) Indicator variability

$$\sigma_j = \sqrt{\frac{1}{N}\sum_{i=1}^{N}\left(x_i - \mu\right)^2} \tag{2}$$

In Eq. (2), where: σ_j - standard deviation;

x_i -*i* data for the *jth* indicator;

N - The number of x_i ;

μ - Arithmetic mean of x_i .

3) Calculation of quantitative indicators of the conflicting nature of the indicators.

$$R_{ij} = \sum_{i=1}^{n}(1 - r_{ij}) \tag{3}$$

In Eq. (3), where: R_{ij} - correlation coefficient;

r_{ij} -Evaluate the correlation coefficient between indicators *i* and *j*.

4) Calculation of the combined informativeness of the indicators.

$$C_j = \sigma_j \sum_{i=1}^{n}(1 - R_{ij}) \tag{4}$$

In Eq. (4), where: C_j - the amount of information for the jth indicator;

σ_j -standard deviation;

R_{ij} -correlation coefficients.

N -Number of quantities for the ith indicator.

5) Calculation of indicator weights

$$\omega = \frac{C_j}{\sum_{j=1}^{N} C_j} \tag{5}$$

In Eq. (5), where: ω - Objective weight of the jth indicator;

C_j -The amount of information in the jth indicator;

N -Number of quantities of the jth indicator.

6) Calculation of scores

$$S_i = \sum_{j=1}^{n}\left(\omega_j x'_{ij}\right) \tag{6}$$

In Eq. (6), Where: S_i - Score.

D. Degree of Coupling Coordination

The Coupled Coordination Degree Evaluation Model (CCDEM) is a model used to assess the degree of coordination and coupling between parts of a system. It is usually used to analyse the degree of interaction and coordination between different parts of a complex system in order to identify potential problems and opportunities for improvement. In the coupled coordination degree evaluation model, three aspects are usually considered: degree of coupling, degree of coordination, and degree of coupled coordination [17, 27].

Coupling degree refers to the degree of interdependence between the parts of the system, high coupling degree means high complexity of the system; Coordination degree refers to the degree of synergy between the parts of the system, high coordination degree can promote the overall performance and efficiency of the system; Coupling Coordination Degree Index: evaluate the coupling degree and coordination degree between the parts of the system through the quantitative index, so as to provide the overall performance of the system to assess and improve the direction.

Coupling C:

$$C = \left(\frac{\prod_{i=1}^{n} U_i}{\left(\frac{1}{n} \sum_{i=1}^{n} U_i \right)^n} \right)^{\frac{1}{n}} \quad (7)$$

In Eq. (7):U_i -Cultural System and Tourism System Score;

n-Number of systems.

Coordination T:

$$T = \sum_{i=1}^{n} \omega_i U_i \quad (8)$$

In Eq. (8):U_i -Cultural System and Tourism System Score;

n-Number of systems;

ω_i -System weighting, this paper considers two systems equally important each with 0.5.

Coupling coordination degree D, Eq. (9):

$$D = \sqrt{CT} \quad (9)$$

In this paper, the grading of the coupling coordination degree is listed in the following Table II.

TABLE II. CRITERIA FOR CLASSIFYING THE DEGREE OF COUPLING COORDINATION

Interval of D-values for coupling coordination	Level of coordination	Degree of coupling coordination
[0.0~0.1)	1	extreme disorder
[0.1~0.2)	2	severe disorder
[0.2~0.3)	3	moderate disorder
[0.3~0.4)	4	mild disorder
[0.4~0.5)	5	on the verge of becoming dysfunctional
[0.5~0.6)	6	sue for coordination
[0.6~0.7)	7	primary coordination
[0.7~0.8)	8	intermediate level coordination
[0.8~0.9)	9	good coordination
[0.9 to 1.0]	10	quality coordination

III. EMPIRICAL ANALYSES

A. Impact Level Analysis Based on the CRITIC Approach

This paper collects data from a total of 11 provinces (municipalities directly under the central government) in the study area to be analysed, and the degree of importance of the indicators is calculated by the equation (1-5) as shown in Table III and the evaluation scores are calculated according to the Formula (6) as shown in Table IV.

TABLE III. RESULTS OF THE CALCULATION OF THE IMPORTANCE OF IMPACT FACTORS

Indicator layer	Weights	Combined weights	Normative layer	Weights	Combined weights
Number of public libraries	0.0289	0.2028	Cultural Services Facilities	0.1427	0.2188
Number of performing arts venues	0.0374	0.2622

TABLE V. CALCULATION OF EVALUATION SCORES AT THE TARGET LEVEL

Target level	Cultures	Journey
1. Shanghai	86.4791	85.6362
2. Jiangsu Province	84.0455	85.7647
3. Zhejiang Province	85.9233	86.6861
4. Anhui Province	83.4487	88.4296
5. Jiangxi Province	84.2203	84.1592
6. Hubei Province	87.1058	84.9243
7. Hunan Province	85.8589	79.0361
8. Chongqing	84.0469	88.7207
9. Sichuan Province	84.3610	83.9527
10. Yunnan Province	85.6311	82.7800
11. Guizhou Province	86.3462	87.6728

B. Analysis of the Results of the CRITIC Method

From Table VI, it can be seen that in the guideline layer results, the better development belongs to Shanghai Municipality and Guizhou Province, closely followed by Zhejiang Province and Hubei Province.

Observation of the economic zone research curve graph can be seen, the cultural perspective, to the best development of Hubei Province, based on the tourism perspective can be seen, Anhui Province, Sichuan Province, the development trend is better, to the worst development of Hunan Province, but the overall score is greater than 75, proving that the development of although compared with the high and low points, but there is no development of the bad provinces (municipalities).

C. Coupled Coordination Degree Model

The model evaluation of the study area is carried out according to Eq. (7-9), and the degree of coupling, coordination, and coupling co-ordination are now listed in the Table VI shown.

TABLE VI. EVALUATION RESULTS OF COUPLING COORDINATION DEGREE

Target level	Cultures	Journey	Coupling C-value	Harmonisation index T-value	D-value of coupling coordination	Level of coordination	Degree of coupling coordination
1. Shanghai	86.4791	85.6362	0.9940	0.7640	0.8710	9	good coordination
2. Jiangsu	84.0455	85.7647	0.7720	0.5890	0.6880	7	Primary coordination
3. Zhejiang	85.9233	86.6861	0.9990	0.7560	0.8690	9	good coordination
4. Anhui	83.4487	88.4296	0.7240	0.5690	0.6420	7	Primary coordination
5. Jiangxi	84.2203	84.1592	0.9790	0.4380	0.6550	7	Primary coordination
6. Hubei	87.1058	84.9243	0.9710	0.7980	0.8800	9	good coordination
7. Hunan	85.8589	79.0361	0.8530	0.5530	0.6910	7	Primary coordination
8. Chongqing	84.0469	88.7207	0.8520	0.6500	0.7440	8	Intermediate level coordination
9. Sichuan	84.3610	83.9527	0.9900	0.4430	0.7440	7	Primary coordination
10. Yunnan	85.6311	82.7800	0.9660	0.5250	0.7120	8	Intermediate level coordination
11. Guizhou	86.3462	87.6728	0.9990	0.8520	0.9230	10	Quality coordination

Based on Table VI, the coupling coordination degree of the Yangtze River Economic Belt as a whole does not appear coordination degree imbalance phenomenon, but Jiangsu Province, Anhui Province, Jiangxi Province, Hunan Province, Sichuan Province only for the primary coordination, which indicates that the degree of integration of culture and tourism still needs to be further strengthened; at the same time, only the degree of integration of culture and tourism in Guizhou Province to achieve a high quality degree of coordination, which indicates that at this stage, the local culture, tourism, the degree of collaboration is relatively high, and the development of the development presents a good trend.

According to Table VI, although different provinces (municipalities directly under the central government) of the degree of coupling, degree of coordination, coupling degree of coordination there is a certain degree of variability, all show a high value of coupling degree, which indicates that the integration of culture, tourism is an extremely complex system, perhaps there are certain differences, but also just show the degree of difficulty of the differences between the places, but the degree of coordination exists there is a low phenomenon, indicating that the system's synergistic operation efficiency Low, especially in Jiangxi Province, but the coupling degree in Jiangxi Province is very high, which indicates that the more complex the system is, the less easy it is to coordinate the operation, so Jiangxi Province must put forward reasonable and feasible measures to strengthen the integration of culture and tourism.

IV. CONCLUSION

As an important support region for China's economic development, the coupling and coordination degree of the integrated development of culture and tourism in the Yangtze River Economic Belt plays a crucial role in its development. By evaluating the coupling coordination degree of culture and tourism integrated development in the Yangtze River Economic Belt, it can be seen that the coupling coordination degree of culture and tourism integrated development in the Yangtze River Economic Belt presents a good trend as a whole, and the coordination and cooperation and resource sharing among regions make the culture and tourism industry develop better and provide strong support for the comprehensive development of the economic belt. However, there are some problems and challenges in the evaluation of the coordination degree of culture and tourism integrated development in the Yangtze River Economic Belt. Some areas in the integrated development of culture and tourism still have deficiencies in the synergistic development between culture and tourism industries, the combination of cultural resources and tourism products is not high, and the depth and breadth of the integration of culture and tourism need to be strengthened. This requires strengthening the integration and sharing of resources for the integrated development of culture and tourism, increasing investment, optimising resource allocation, promoting the integration and sharing of culture and tourism resources, and improving the quality and level of integration of culture and tourism. At the same time, the coordination and cooperation among regions of the Yangtze River Economic Belt should be strengthened, the regional coordination of the integrated development of culture and tourism should be promoted, and the sharing and complementation of resources among regions should be facilitated, so as to achieve the synergistic development of the integrated development of culture and tourism.

In summary, the evaluation of the coupling coordination degree of the integrated development of culture and tourism in the Yangtze River Economic Belt is of great significance, and in the future, it is necessary to continuously strengthen the coordination and cooperation to promote the synergistic development of the integrated development of culture and tourism, to inject new vitality into the economic and social development of the Yangtze River Economic Belt, and to achieve the goal of high-quality development

Performance Comparison of Pretrained Deep Learning Models for Landfill Waste Classification

Hussein Younis[1], Mahmoud Obaid[2]
Department of Computer System Engineering, Arab American University, Jenin, Palestine[1, 2]

***Abstract*—The escalating challenge of waste management, particularly in developed nations, necessitates innovative approaches to enhance recycling and sorting efficiency. This study investigates the application of Convolutional Neural Networks (CNNs) for landfill waste classification, addressing the limitations of traditional sorting methods. We conducted a performance comparison of five prevalent CNN models—VGG-16, InceptionResNetV2, DenseNet121, Inception V3, and MobileNetV2—using the newly introduced "RealWaste" dataset, comprising 4,752 labeled images. Our findings reveal that EfficientNet achieved the highest average testing accuracy of 96.31%, significantly outperforming other models. The analysis also highlighted common challenges in accurately distinguishing between metal and plastic waste categories across all models. This research underscores the potential of deep learning techniques in automating waste classification processes, thereby contributing to more effective waste management strategies and promoting environmental sustainability.**

Keywords*—Waste management; deep learning; waste classification; real-waste dataset; performance comparison

I. Introduction

The increase in waste generation, particularly in developed countries, poses a significant challenge to effective waste management and recycling efforts. By 2050, it is projected that developed nations will experience a 19% increase in per capita daily waste production, emphasizing the critical need for more efficient waste management strategies [1]. Traditional waste sorting methods, such as manual sorting and visual inspection, have limitations in terms of subjectivity, scalability, and labor requirements [1]. To address these challenges, the integration of deep learning techniques, particularly Convolutional Neural Networks (CNNs), into waste sorting processes can enhance automation and improve waste classification based on its features [2], [3].

CNNs are a class of deep learning models that excel in processing visual data, making them well-suited for tasks like waste classification [3]. These networks automatically extract relevant information from input data through their layers, with convolutional layers specifically extracting spatial features from images, making CNNs highly efficient for image-related tasks [4]. By leveraging advanced technologies like deep learning, waste sorting processes can be optimized, recycling rates can be increased, and a more sustainable waste management system can be achieved [5].

Automated waste classification systems, powered by deep learning models like CNNs, have become essential for addressing the global waste problem and promoting sustainable development [6]. These systems offer a more objective and scalable approach to waste sorting compared to traditional methods, contributing to more efficient recycling processes and waste management overall [7]. The incorporation of deep learning methods in waste classification not only streamlines the sorting process but also plays a crucial role in achieving environmental sustainability by reducing waste and promoting recycling efforts [8].

In conclusion, the adoption of deep learning techniques, particularly CNNs, in waste classification is pivotal for enhancing automation, improving waste sorting accuracy, and ultimately aiming to create a waste management system that is more effective and sustainable in light of the rising amount of garbage produced worldwide.

This paper presents a performance comparison of five common CNN pre-trained models applied on a dataset called "RealWaste" and provides a critical analysis of the results to see the impact of the quality of the dataset and more detailed classes of the waste. Hence, the main contributions of this paper are as follows:

- Provide a performance comparison of five common CNN models in landfill waste classification.
- Evaluate the performance of the selected models when the type of material over different items is important to be detected.
- Employ transfer learning and fine-tune the learning process using the scheduling of the learning rate.
- Achieve superior classification accuracy compared to previous work.

The remainder of this paper is structured as follows: Section II discusses the related works. The RealWaste dataset and the proposed models for evaluation are detailed in Section III and Section IV. Section V discusses the results and outcomes, and Section VI concludes the paper.

II. Literature Review

Table I presents the top accuracies achieved by different datasets in waste classification tasks. It includes datasets such as RealWaste and DiversionNet, Waste dataset, Custom dataset, Sekar's waste classification, OrgalidWaste, Waste Classification data, and the proposed work using RealWaste. The accuracy values range from 49.69% to 99.43%, highlighting the varying performance levels of the datasets in accurately classifying waste materials.

TABLE I. COMPARATIVE ANALYSIS OF DATASETS AND TOP ACCURACIES IN WASTE CLASSIFICATION

Ref.	Dataset	Top Accuracy
[9]	RealWaste and DiversionNet	49.69% using DiversionNet and 89.19% using RealWaste
[10]	Waste dataset	70%
[11]	Custom dataset	99.43%
[12]	Sekar's waste classification	80.88%
[13]	OrgalidWaste	88.42%
[14]	Waste Classification data	96.7%
Our proposed work	RealWaste	96.31%

In study [9], the authors propose a new dataset called RealWaste and evaluate the performance of five deep learning models (VGG-16, InceptionResNetV2, DenseNet121, Inception V3, and MobileNetV2) for waste classification using the "RealWaste" dataset and the existing "DiversionNet" dataset. The classification accuracy for the "DiversionNet" dataset was limited to 49.69% for the "RealWaste" dataset, the models were able to achieve much higher classification accuracy where Inception V3, reached 89.19% classification accuracy on the full spectrum of labels required for accurate waste modeling.

In research [10], the authors use a custom CNN model architecture with four and five convolution layers to classify four categories of solid waste including plastic, glass, organic, and paper materials. They use a "Waste dataset" that contains 100 RGB images for each category. The five-layer DCNN architecture achieved a 70% accuracy rate in distinguishing the different waste types, while the four-layer architecture had a 61.67% accuracy rate. Plastic waste was the most challenging to classify accurately, with 37% and 56.7% accuracy rates in the four-layer and five-layer architectures, respectively. The key limitations were around classification accuracy, particularly for plastic waste, as well as the need for further optimization and exploration of a broader range of waste types and real-world application considerations.

In study [11], the authors use a custom CNN model with two, six, and eight convolutional layers with a custom dataset of 878 carrot images captured in-house, which they preprocessed and augmented to train and evaluate their proposed CNN models. The authors found that the eight convolutional layers model with the mixed pooling layer achieved the best performance, reaching 99.43% accuracy in classifying regular and irregular carrot shapes on 24x24 pixel images. The study was conducted using a dataset of 878 carrot images, which may be considered a relatively small dataset for training deep learning models. Also, the study was conducted in a controlled laboratory setting using images captured under specific lighting conditions. The authors acknowledge that while the proposed CNN-based approach showed promising results in the laboratory setting, further research and real-world validation would be needed to fully assess the practical applicability and limitations of the system.

In study [12], the authors developed a bespoke 5-layer CNN architecture and trained it on two different image resolutions (80x45 and 225x264 pixels) of the augmented "Sekar's waste classification" dataset consisting of 25,077 images of organic (13,966) and recyclable (11,111) waste objects. The research aims to explore the possibility of training an efficient lightweight model with high accuracy and less computational demand compared to standard CNN architectures. The smaller model (80.88%) outperformed the larger model (76.19%), but the larger model seems more generalizable based on the observed behavior of loss and accuracy during training, validation, and testing. The key limitations include the data paucity and limited categories.

In study [13], the authors use various CNN models for waste classification, including AlexNet, GoogLeNet, EfficientNet-B0, and ResNet-50 with a transfer learning approach. Also, they use a custom four-layer CNN. They used a dataset called "OrgalidWaste" which comprises approximately 5,600 images categorized into four waste classes: organic, glass, metal, and plastic. The performance evaluation of the models in the study was based on accuracy and cross-entropy loss observed during training, validation, and testing. The VGG16 model achieved the highest accuracy of 88.42%, outperforming other CNN architectures like VGG19, Inception-V3, and ResNet50. The study highlighted the need to further enhance classification accuracy for practical deployment despite the promising results obtained.

In study [14], the authors use convolutional neural networks (CNNs) and faster region-based convolutional neural networks (R-CNNs) to classify e-waste. The proposed system aims to facilitate communication between individuals requesting WEEE pickup and waste collection companies, enabling efficient collection planning based on the identified type and size of the e-waste items. They used a dataset called "Waste Classification data" containing 24,705 images of refrigerators, washing machines, and monitors/TVs. The geometric transformations were used as data augmentation with 13 transformations such as rotation, color transformation, zoom, and blur. The proposed CNN model achieved an average accuracy of 90-96.7% and the faster R-CNN network provided slightly lower accuracy, around 90% on average, but had the advantage of being able to detect and determine the size of the objects in the images. The key limitations were around the limited e-waste categories.

III. DATASET

The study leveraged the newly developed landfill waste dataset, "RealWaste," which comprises 4,752 raw and fully labeled RGB images. This dataset was meticulously collected during the biannual residential waste audit at the Wollongong Waste and Resource Recovery Centre's landfill [9]. The collection process involved capturing images of various waste items as they were sorted, ensuring a representative sample of the types of materials commonly found in residential waste.

Fig. 1 shows samples of RealWaste images with their label.

(a) (b) (c) (d)

Fig. 1. Sample images from the dataset for: (a) Cardboard; (b) Food Organics; (c) Glass; (d) Metal.

The RealWaste dataset includes samples across nine distinct labels representing different landfill waste categories including Cardboard, Food Organics, Glass, Metal, Miscellaneous Trash, Paper, Plastic, Textile Trash and Vegetation.

An analysis of the dataset reveals that it exhibits some degree of imbalance in the distribution of images across the labels. Table II presents the count and percentage of images for each label, highlighting the variations.

TABLE II. LABELS AND IMAGE COUNT IN DATASET

Label	Images Count	Percentage Of Each Label in The Dataset
Cardboard	461	9.69%
Food Organics	411	8.65%
Glass	420	8.83%
Metal	790	16.62%
Miscellaneous Trash	495	10.41%
Paper	500	10.51%
Plastic	921	19.38%
Textile Trash	318	6.69%
Vegetation	436	9.17%

This imbalance may pose challenges for model training, particularly in ensuring that the model generalizes well across all categories. The predominance of plastic images, for instance, could lead to bias in classification outcomes if not adequately addressed.

IV. METHODOLOGY

This section addresses a significant gap in waste classification literature, focusing on dataset limitations and inadequate labeling in waste auditing studies. To enhance the accuracy and practicality of waste classification models, data is preprocessed and augmented for use by the pre-trained CNN models EfficientNet, GoogLeNet, ResNet-152, ShuffleNet, and VGG-19. The objectives include evaluating the use of clean material datasets for training models in real waste classification, comparing dataset approaches by training on real waste samples, and identifying the best model for waste classification in real-world scenarios.

As shown in Fig. 2, the proposed methodology consists of the following main steps:

- Data Splitting: The dataset was split into training, validation, and testing subsets using a standard split ratio, where 50% of the data was used for training, 20% for validation, and 30% for testing. This ensures that the model is trained on a diverse set of data, validated on a separate subset, and finally tested on unseen data [15].
- Hyperparameter tuning: Hyperparameters–such as batch size, learning rate, number of epochs, momentum, and learning rate decay–are set. These hyperparameters play a crucial role in the training process and should be carefully chosen through experimentation and validation [16].
- Training and Validation: Each model is trained and validated using a stochastic gradient descent optimizer. Additionally, the use of automatic mixed precision (auto-cast) is considered to accelerate training without sacrificing model accuracy. Furthermore, a learning rate scheduler is employed to adjust the learning rate during training [17].
- Model Evaluation: Each model uses metrics such as accuracy, precision, recall, F1 score, receiver operating characteristic curve, and confusion matrix analysis. These metrics provide a comprehensive understanding of the model's performance, such as correctly classifying instances, handling imbalanced classes, and discriminating between classes [18].

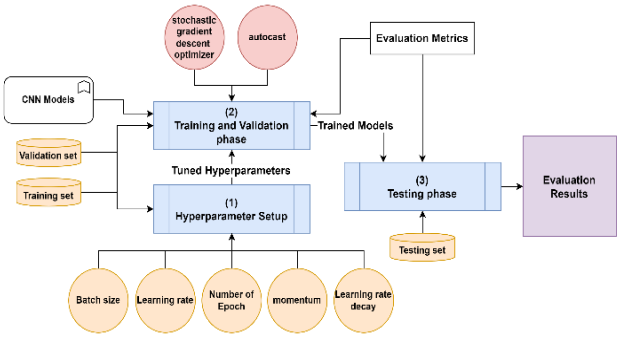

Fig. 2. The proposed methodology.

A. Data Preprocessing and Augmentation

CNNs typically require input images to be of a fixed size to avoid issues with model training and performance. Variations in image dimensions can be addressed by resizing images before inputting them into the CNN. This can be done using techniques like Bicubic interpolation, which involves averaging 16 neighboring pixels to determine pixel values in the resized image [19], [20]. Data augmentation techniques, which improve models' ability to generalize and perform well on diverse datasets and solve unbalanced dataset issues such as:

- Color Jitter which introduces random variations in the hue and saturation levels of images to augment the dataset. The hue indicates the range of random hue adjustments applied to the image, while saturation represents the range of random saturation adjustments.

- Randomly rotates images within the specified range of degrees.

The incorporation of augmented images with diverse textures and appearances enhanced the diversity and richness of the dataset. As a result, this contributed to an improved generalization of models and enhanced their performance across all classes. Each image in the dataset was used to generate two new images: The first was generated by adding Color Jitter with a hue value of 0.05 and a saturation of 0.05 to the original image. The second was generated by applying random rotations to images in the dataset with a range from 0 to 180 degrees.

B. The Selected Models

The CNN models including EfficientNet, GoogLeNet, ResNet-152, ShuffleNet, and VGG-19 were selected for this experimental study to analyze the performance in classifying landfill waste due to their proven capabilities in image classification tasks. EfficientNet is renowned for its efficiency in balancing model size and accuracy. GoogLeNet introduces the inception module for feature extraction. ResNet-152 utilizes residual connections to tackle the vanishing gradient problem. ShuffleNet emphasizes computational efficiency through channel shuffling. VGG-19 is acknowledged for its deep architecture with small convolutional filters [21], [22], [23]. The strengths of these models in image classification position them as ideal candidates for accurately classifying landfill waste:

- EfficientNetV2, introduced in 2021 by Tan and Le, improves training speed and parameter efficiency compared to the original EfficientNet. It addresses slow training with larger image resolutions by combining MBConv and Fused-MBConv blocks through neural architecture search and model scaling. This optimization enhances training efficiency [24].
- GoogLeNet: GoogLeNet developed by Google in 2015, is a deep convolutional neural network for image classification. It uses multiple convolutional layers with different filter sizes and pooling operations to extract features at various scales. The architecture consists of 19 layers, featuring inception modules for feature extraction, auxiliary classifiers to address the vanishing gradient issue and overfitting, and ensuring computational efficiency. It also includes max-pooling layers, an average pooling layer, a dropout layer, and a linear layer for the final output [25].
- ResNet-152: ResNet-152 was introduced in 2015 by Microsoft. It is part of the ResNet (short for Residual Network) family of models, known for their deep structure and the use of residual connections. ResNet-152 specifically has 152 layers, making it a very deep network, and it has been widely used for various computer vision tasks, such as image classification and object detection [26].
- ShuffleNet V2: Introduced in 2018 as an evolution of the original ShuffleNet, focuses on enhancing computational efficiency and model performance. By integrating channel shuffling and pointwise group convolutions, it improves performance while preserving computational efficiency. These elements enhance its effectiveness in feature extraction and representation learning. With 164 layers, ShuffleNet V2 incorporates operations like depthwise separable convolutions, concatenation, and channel shuffling to facilitate efficient information exchange and feature extraction within the network [27], [28].
- VGG19: VGG19, a deep convolutional neural network that comprises 19 layers, was developed in 2014. It is known for its simplicity and effectiveness in image recognition tasks. The network architecture consists of a series of convolutional layers that are followed by max pooling layers and culminates in three fully connected layers [29].

C. Hyperparameters and Optimization Technique

Hyperparameters are parameters that govern the learning process and dictate the values of the model parameters acquired by a learning algorithm. The use of the prefix "hyper" indicates the significance of the parameters in determining both the learning process and resulting model parameters [30]. Specifically, hyperparameters are settings or configurations that are not learned from the data but are set before training the model, and in the proposed methodology, the following hyperparameters were used: learning rate, loss function, number of epochs, and batch size.

Optimizers are essential for adjusting model weights and learning rates to minimize errors or maximize efficiency. For instance, stochastic gradient descent is a popular optimization algorithm in deep learning, a variation of gradient descent. It minimizes loss functions by training models. Unlike traditional gradient descent, stochastic gradient descent computes gradients using data subsets, known as "mini-batches," making it faster and more scalable for large datasets. This approach accelerates convergence, especially beneficial for handling extensive datasets [31], [32]; therefore, it was used in the proposed methodology. The objective function $f(x)$, which is the average loss function, is given by the following equation:

$$f(x) = \frac{1}{n}\sum_{i=1}^{n} f_i(x) \quad (1)$$

where n is the number of input data taken from the training dataset. The gradient of the objective function is computed for each iteration of the training phase by the following equation:

$$\nabla f(x) = \frac{1}{n}\sum_{i=1}^{n} \nabla f_i(x) \quad (2)$$

The stochastic gradient descent algorithm reduces the computational cost at each iteration by randomly shuffling the training data to ensure that the mini-batches used for computing the gradients are representative of the entire dataset and compute the gradient $\nabla f_i(x)$ to update x by the following equation [33]:

$$x \leftarrow x - \eta \nabla f_i(x) \quad (3)$$

where η is the learning rate.

D. Evaluation Metrics

Various evaluation metrics were utilized to appraise the performance of the selected models, including the confusion matrix, accuracy, F1 score, precision, recall, and receiver operating characteristic (ROC) curve [34]. The confusion matrix evaluates the classification performance of the CNN model by juxtaposing actual and predicted values. In this matrix, rows correspond to actual values while columns represent predicted values. The results obtained from this evaluation encompass four potential outcomes: True Positive (TP) - denoting correct prediction of the positive class, False Positive (FP) - indicating incorrect prediction of the positive class, True Negative (TN) - signifying accurate prediction of the negative class, and False Negative (FN) - representing erroneous prediction of the negative class [35].

Accuracy refers to the extent to which the model effectively categorizes all instances within a dataset. It is computed by dividing the total number of correct predictions by the overall number of predictions made [36]. The following equation calculates accuracy:

$$Accuracy = \frac{(TP + TN)}{(TP + TN + FP + FN)} \quad (4)$$

The F1 score is a numerical measure of the balance between precision and recall [37]. It is calculated by taking the harmonic mean of precision and recall using the following equation:

$$F1\ score = 2 * \frac{(precision * recall)}{(precision + recall)} \quad (5)$$

Where precision is the ratio of true positives to the sum of true positives and false positives, measuring the accuracy of positive predictions. Recall, on the other hand, is the proportion of true positives to the sum of true positives and false negatives, indicating the ability to identify actual positives accurately.

The ROC curve evaluates a CNN model's ability to distinguish labels by examining the true positive rate (TPR) and false positive rate (FPR) at different thresholds. It assesses the model's accuracy in classification by graphing TPR against FPR at various threshold levels [38]. The TPR and FPR are calculated using the following equations:

$$TPR = \frac{TP}{(TP + FN)} \quad (6)$$

$$FPR = \frac{FP}{(FP + FN)} \quad (7)$$

V. Results and Discussions

A. Experimental Setup

The original dataset was cleaned, preprocessed, and enhanced as outlined in Section III to prepare it for training CNN models. The image quantity was increased to 19,008 labeled images, with each label representing around 3% of the dataset, totaling 9 unique labels. One-hot encoding was utilized for label encoding. Various hyperparameters such as learning rate, loss function, epochs, batch size, optimizer, momentum, learning rate decay, and weight initialization were set for training the CNN models as shown in Table III. The selected models' weights were initialized by loading pre-trained weights from ImageNet, enhancing their performance and efficiency while reducing the need for extensive training on the dataset.

TABLE III. Hyperparameters and their Values Tuning

Hyperparameters	Value
Learning rate	0.001
Loss function	Cross-entropy loss
Number of epochs	50
Batch sizes	64
Optimizer	Stochastic gradient descent
Momentum	0.9
Learning rate decay	0.0005
Weight initialization	Transfer learning

All experiments were carried out locally on a computer with the following specifications:

- Processor: AMD Ryzen 9 5900HX, 3301 MHz, 8 Core(s), 16 Logical Processor(s).
- Physical Memory (RAM): 32.0 GB.
- Graphics Card: NVIDIA GeForce RTX 3080 Laptop GPU.

B. Models Training Performance

All models were trained using the same dataset and with hyperparameter values as listed in Table III to analyze the learning behavior of each model. Table IV presents the average training and validation accuracy, as well as the average training and validation loss for various models including EfficientNet, GoogLeNet, ResNet-152, ShuffleNet, and VGG-19. ResNet-152 has the highest average training among the models listed, with a value of 99.07%.

TABLE IV. Hyperparameters and their Values Tuning

#	Model	Average Training Accuracy	Average Validation Accuracy	Average Training Loss	Average Validation Loss
1	EfficientNet	98.82%	95.57%	0.036	0.174
2	GoogLeNet	98.93%	92.93%	0.035	0.234
3	ResNet-152	99.07%	94.63%	0.029	0.198
4	ShuffleNet	92.83%	86.42%	0.270	0.430
5	VGG-19	97.94%	91.22%	0.063	0.343

ShuffleNet has the lowest average training accuracy at 92.83% but still demonstrates strong performance. EfficientNet and GoogLeNet demonstrate competitive performance in terms of accuracy and loss, while VGG-19 shows slightly lower accuracy, but relatively lower loss compared to ResNet-152.

Overall, the analysis shows that ResNet-152 performs exceptionally well in terms of both accuracy and loss, while ShuffleNet appears to face challenges in generalizing to validate data. This comparative analysis can provide valuable

insights for selecting the most suitable model based on specific performance criteria.

Fig. 3 to Fig. 7 visualize the loss values and average accuracy percentage for all models per epoch.

C. Models Testing Performance

Table V provides a comprehensive overview of the performance metrics including accuracy, precision, recall, and F1 score for different models. Among these models, EfficientNet stands out with the highest Average Testing Accuracy of 96.31%, highlighting its effectiveness in classification tasks. This exceptional performance can be attributed to Efficient Net's sophisticated architecture that incorporates compound scaling and efficient model scaling methods, allowing it to achieve superior accuracy.

TABLE V. HYPERPARAMETERS AND THEIR VALUES TUNING

#	Model	Average Testing Accuracy	Average Precision	Average Recall	Average F1 Score
1	EfficientNet	96.31%	0.9342	0.9631	0.9643
2	GoogLeNet	94.25%	0.8965	0.9425	0.9432
3	ResNet-152	95.49%	0.9183	0.9549	0.9555
4	ShuffleNet	89.11%	0.8113	0.8911	0.8924
5	VGG-19	92.91%	0.8727	0.9291	0.9296

ResNet-152 and GoogLeNet also demonstrate strong performance with accuracy rates of 95.49% and 94.25% respectively. ResNet-152, known for its deep architecture with residual connections, excels in capturing intricate features within the data, leading to high precision, recall, and F1 scores. On the other hand, Google Net's inception modules and efficient use of parameters contribute to its competitive performance across all metrics.

ShuffleNet and VGG-19, while slightly lower in accuracy compared to the top performers, still exhibit respectable results. Shuffle Net's emphasis on computational efficiency through channel shuffle operations enables it to achieve a balance between accuracy and resource utilization. VGG-19, with its deeper architecture comprising multiple convolutional layers, maintains a strong performance across precision, recall, and F1 score metrics.

D. Models Performance Analysis

To gain a deeper understanding of the models' classification performance, a detailed analysis was conducted using the AUC, as shown in Fig. 8.

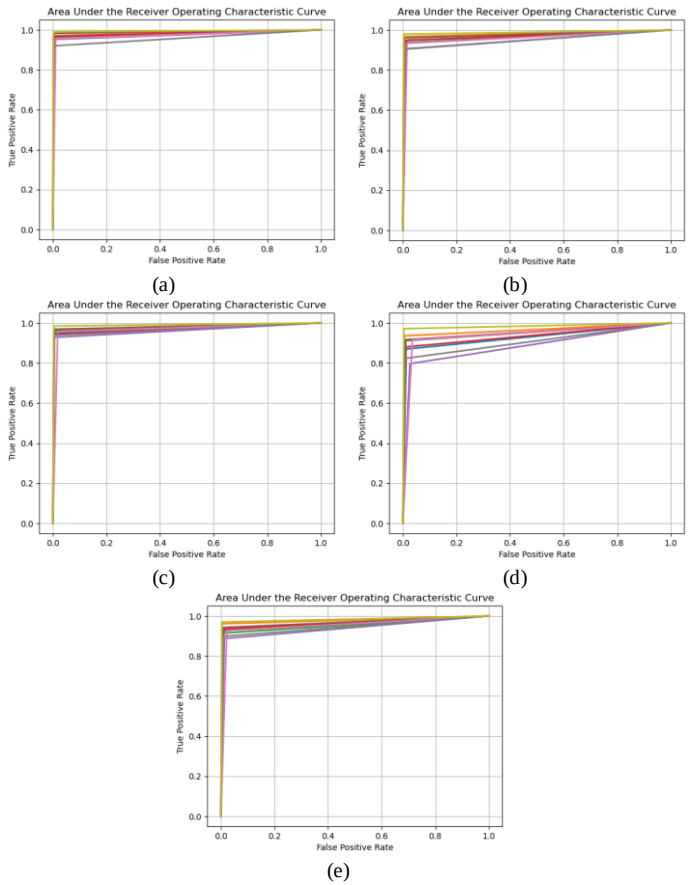

Fig. 8. AUC values for different Labels across various models including (a) EfficientNet (b) GoogLeNet (c) ResNet-152 (d) ShuffleNet and (e) VGG-19.

EfficientNet demonstrates strong performance across most classes with consistently high AUC values, particularly excelling in classes such as Food Organics and Vegetation where it achieved AUC scores of 0.99. This suggests that EfficientNet is effective in distinguishing these classes from others with high accuracy. GoogLeNet also performs well overall, with notable AUC scores for classes such as Glass and Vegetation. However, it shows slightly lower performance compared to EfficientNet in some classes like Metal and Miscellaneous Trash. ResNet-152 showcases consistent performance across various classes, with competitive AUC values for most categories. It performs particularly well in distinguishing classes like Cardboard and Paper. ShuffleNet exhibits varying performance across different classes, with lower AUC scores for categories such as Miscellaneous Trash and Textile Trash compared to other models. VGG-19, similar to GoogLeNet, demonstrates strong performance in classes like Glass and Vegetation but shows lower AUC values for categories like Miscellaneous Trash and Textile Trash.

In summary, EfficientNet stands out as a top performer in this analysis, followed closely by ResNet-152 and GoogLeNet. These models show effectiveness in classifying diverse classes accurately, with variations in performance observed across different models and classes.

Also, the confusion matrix was utilized to analyze the model's classification performance in correctly classifying different waste categories and reveal the presence of false negatives and false positives. Fig. 9 to Fig. 13 visualize the confusion matrix for the five models.

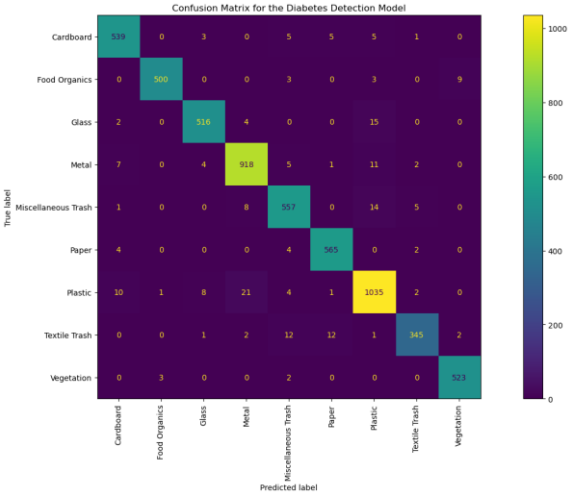

Fig. 9. Confusion Matrix for EfficientNet model in classifying landfill waste.

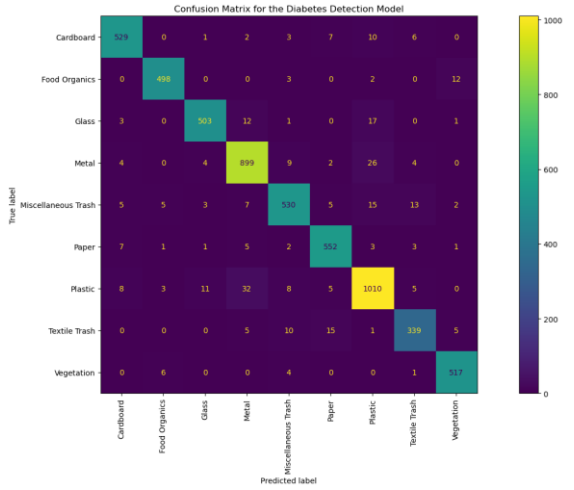

Fig. 10. Confusion Matrix for GoogLeNet model in classifying landfill waste.

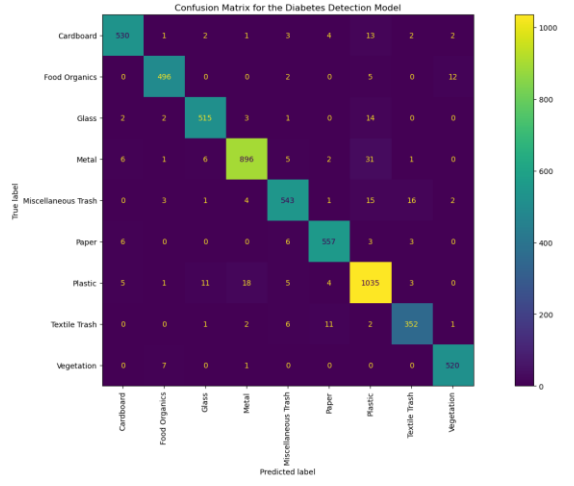

Fig. 11. Confusion Matrix for ResNet-152 model in classifying landfill waste.

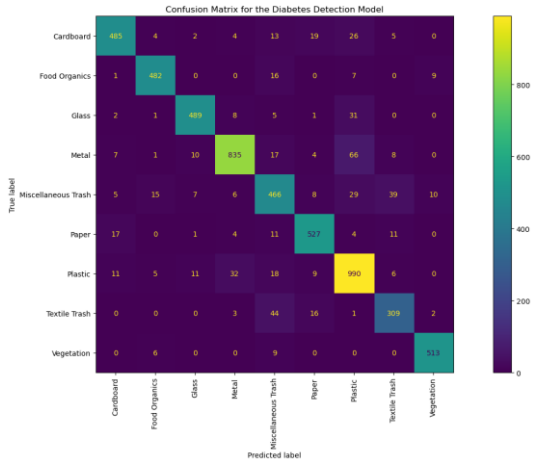

Fig. 12. Confusion Matrix for ShuffleNet model in classifying landfill waste.

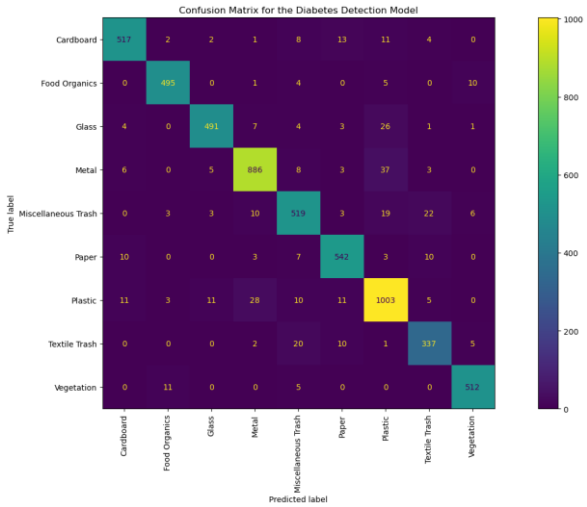

Fig. 13. Confusion Matrix for VGG-19 model in classifying landfill waste.

The confusion matrix for all models shows that the model's performance reveals notable confusion among various waste labels, particularly between metal and plastic categories. For EfficientNet, the model achieved a high accuracy rate of 92.41% in correctly identifying metal objects but misclassified four items as plastic. The accuracy of the plastic label was slightly lower at 84.78%, with six items mistakenly classified as metal and one item as cardboard. For GoogLeNet, the model's performance metrics show a similar trend with notable confusion between metal and plastic categories. Similarly, the ResNet-152 model exhibited challenges in distinguishing between metal and plastic categories, leading to misclassification. VGG-19 model's performance also indicated confusion between metal and plastic labels, impacting the accuracy of classification. In summary, all models struggled with distinguishing between metal and plastic waste categories, highlighting a common challenge across the different models in accurately classifying these materials. The difficulty in distinguishing between metal and plastic waste categories in the models could be attributed to several factors:

- Multi-Structured Shapes and Textures: Both metal and plastic items have varied shapes and textures, which further complicates the classification problem for the models.
- Data Variability: The reason why models fail to differentiate between waste materials made of metal and those that are made of plastic may partly be attributed to the lack of diversity in examples used during training concerning these two classes.

To address the challenges faced by models in accurately classifying metal and plastic waste, several strategies can be implemented:

- **Diverse Data Sources**: Where the current dataset is established, further research could explore the utilization of other sources of images taken in different surroundings and conditions of light. This would help create a more comprehensive dataset that captures a wider range of metal and plastic items.
- **Improved Image Augmentation**: While augmentation has been done, checking out advanced augmentation techniques, such as changes in brightness, contrast, and adding artificial noise, might yield a better generalization performance across different conditions.

E. Comparison with State-of-the-Art

To ensure an unbiased comparison, we have chosen to evaluate our work by benchmarking it against other studies that have utilized the same dataset. This approach allows for a fair assessment of the effectiveness and performance of our methodology within the context of the specific dataset, promoting a more accurate evaluation of our contributions in the field.

In study [9], they achieved an accuracy of 49.69% using DiversionNet and 89.19% using RealWaste. The accuracy of using RealWaste was notably higher compared to DiversionNet, indicating the effectiveness of RealWaste in the classification process. However, our work demonstrated a higher accuracy of 96.31% using the RealWaste dataset. It showed a significant improvement in accuracy compared to Work 1's results with RealWaste.

In summary, our proposed work exhibited superior performance in waste classification using the RealWaste dataset compared to study [9], showcasing advancements in accuracy and potentially innovative approaches in the classification process.

VI. Conclusion

Incorporating deep learning techniques, especially Convolutional Neural Networks (CNNs), into waste classification processes is crucial for enhancing automation, improving waste sorting accuracy, and striving towards a more sustainable and efficient waste management system amidst the escalating global waste production. The performance evaluation of five common CNN pre-trained models on the RealWaste dataset not only demonstrated advancements in accuracy but also highlighted potential innovative approaches in waste classification methodologies. This study contributes to the continuous enhancement of waste management strategies and the promotion of environmental sustainability through the

utilization of cutting-edge technologies like deep learning. Notably, EfficientNet emerged as the top performer with the highest Average Testing Accuracy of 96.31%, underscoring its effectiveness in classification tasks. Additionally, the performance of five well-known CNN pre-trained models was compared in this research using the RealWaste dataset as a test. The evaluation aimed to understand the impact of the dataset quality and the inclusion of more detailed waste classes, shedding light on the importance of data quality in achieving accurate waste classification outcomes. By addressing these aspects, the research contributes to advancing waste management practices and fostering environmental sustainability through advanced deep-learning methodologies. Looking ahead, future work will focus on expanding the dataset to include more diverse samples and exploring advanced data augmentation techniques to address class imbalances. These efforts aim to further enhance model robustness and improve waste classification systems, ultimately contributing to more effective waste management practices and fostering environmental sustainability.

***Abstract*—Object detection is a fundamental task in gesture recognition, involving identifying and localising human hand or body gestures within images or videos amidst varying environmental conditions. To address the inadequate recognition rate of gesture detection algorithms in intricate surroundings caused by issues such as inconsistent illumination, background colors resembling skin tones, and diminutive gesture scales, a gesture recognition approach termed HD-YOLOv5s is presented. An adaptive Gamma image enhancement preprocessing technique grounded in Retinex theory is employed to mitigate the effects of lighting variations on gesture recognition efficacy. A feature extraction network incorporating an adaptive convolutional attention mechanism (SKNet) is developed to augment the network's feature extraction efficacy and mitigate background interference in intricate situations. A novel bidirectional feature pyramid architecture is implemented in the feature fusion network to fully leverage low-level features, thereby minimizing the loss of shallow semantic information and enhancing the detection accuracy of small-scale gestures. A cross-level connection strategy is employed to enhance the model's detection efficiency. To assess the efficacy of the suggested technique, experiments were performed on a custom dataset featuring diverse lighting intensity fluctuations and the publicly available NUS-II dataset with intricate backdrops. The recognition rates attained were 99.5% and 98.9%, respectively, with a detection time per frame of about 0.01 to 0.02 seconds.**

Keywords*—Gesture recognition; Yolov5; object detection; attention mechanism; bidirectional feature pyramid

I. INTRODUCTION

With the continuous development of human-computer interaction (HCI) technology, people's lives are becoming increasingly intelligent [1-2]. Traditional HCI methods rely on contact-based devices such as a mouse, keyboard, and joystick. However, with the advancement of technologies like voice recognition and gesture recognition, contactless interaction has become one of the main research directions. Gesture recognition, as a form of body language, is simple, direct, and convenient. It enables HCI in various fields such as in-vehicle cabin control, aerospace, smart homes, and intelligent education, making it a research hotspot in HCI technology. For example, using gesture recognition in smart homes allows for remote control with simple gestures, greatly enhancing convenience in people's lives. However, in practical applications, gesture recognition algorithms still face many challenges in complex environments due to factors like lighting, background, distance, and skin tone. Gestures can be categorized as either static or dynamic, where dynamic gestures can be viewed as a sequence of interrelated static gestures. Therefore, static gesture recognition serves as a fundamental basis for studying dynamic gestures and their applications. This paper focuses on static gesture recognition. Gesture recognition [3] technology has undergone multiple phases of development to date. Conventional gesture recognition is often investigated via sensor-based techniques or computer vision methodologies. Gesture recognition reliant on sensors generally necessitates hardware devices to gather and interpret gesture data, like wearable data gloves, Leap Motion, and Kinect. While these approaches are rapid and precise and exhibit less sensitivity to fluctuations in intricate external surroundings, they depend on hardware devices, which may be cumbersome and costly to utilize. Gesture identification based on computer vision predominantly uses depth cameras, color spaces (RGB [4], HSV [5], YCbCr [6]), or skin color detection to delineate the gesture area. Following segmentation, recognition approaches such as template matching [7] and support vector machines (SVM) [8-9] are employed. These approaches depend on manually crafted feature extraction, rendering them vulnerable to external influences and leading to diminished robustness and suboptimal identification rates.

In recent years, the advent of deep learning has prompted numerous academics to implement deep learning techniques for gesture detection in intricate contexts, with the objective of enhancing recognition accuracy. For instance, the Yu et al. [10] utilized a skin color model to identify gesture regions and applied convolutional neural networks (CNN) for feature extraction and detection. This approach is susceptible to fluctuations in lighting and skin color in complicated situations, diminishing its generalizability and robustness. The Diba et al. [11] directly utilized CNN to identify motions from raw photos; however, when the image features analogous skin and background hues, the CNN is unable to extract pertinent information, resulting in elevated false detection rates. The swift advancement of deep learning-based object detection algorithms has led many academics to recognize that utilizing these techniques for gesture recognition in intricate contexts can enhance performance. For example, the Gao et al. [12] employed the Faster R-CNN algorithm for gesture identification, utilizing Gaussian filters for image pre-processing. The Fan et al. [13] used neural networks with the SSD (single shot multibox detector) to extract essential points in motions. Despite enhancements in gesture recognition [14] in tough conditions such lighting and skin tone fluctuations, the substantial model sizes and prolonged detection times hinder real-time identification in intricate environments. To tackle this

issue, Huang et al. [3] enhanced the YOLO (You Only Look Once) algorithm and introduced the DSN algorithm for gesture detection, employing CNN for recognition. This system improved recognition rates under uneven lighting and skin-tone background interference while enhancing detection speed, attaining real-time target detection. Nonetheless, it exhibited subpar performance in identifying little actions inside intricate settings.

In terms of recognition accuracy, speed, and real-time performance, the YOLOv5 algorithm, which was recently introduced, surpasses other algorithms in the YOLO series. Although the YOLOv5 model has demonstrated satisfactory performance on extensive public datasets, it is still necessary to make specific enhancements in order to optimize the model's performance for specific target objects based on the characteristics of the selected datasets. For instance, the detection capability of small objects such as traffic lights was enhanced by Premaratne et al. [15] and colleagues through the modification of the backbone convolution network and the construction of a feature fusion network. The following challenges are presented when the YOLOv5 model is explicitly applied to gesture recognition in complex environments, despite the significance of high gesture recognition rates:

- The algorithm's generalization and robustness are subpar when recognizing gestures in uneven lighting.
- When skin tones blend with background colors, high false detection rates occur.
- The algorithm experiences high miss rates and low recognition accuracy when recognizing gestures at a distance or on a small scale.

To address the current challenges in gesture recognition, such as missed detection, false detection, and low recognition rates caused by uneven lighting, skin-tone backgrounds, small-scale gestures, and complex environments, this paper proposes an improved YOLOv5-based gesture recognition method, HD-YOLOv5s. The main contribution of this paper is as follows:

- First, an adaptive Gamma image enhancement method is used to pre-process the dataset, mitigating the effects of lighting variations in complex environments on gesture recognition.
- To tackle background interference in complex environments, the attention mechanism module SK from the dynamic selection network is incorporated into the final feature extraction layer of the feature extraction network.
- This allows for adaptive adjustment of the convolution kernel size for different scales of images, which helps in extracting effective features and improving feature extraction capabilities.
- Finally, the PANet structure in the feature fusion network is replaced with an adjusted bidirectional feature pyramid structure (BiFPN), which improves the recognition rate of small-scale gestures in complex environments.

II. YOLOv5s Network Structure

YOLOv5 is a neural network architecture employed for object detection. As network depth and weights increase, YOLOv5 is categorized into four variants: YOLOv5s, YOLOv5m, YOLOv5l, and YOLOv5x. The YOLOv5s model is the smallest and exhibits the highest inference speed among these options. The YOLOv5 architecture comprises three components: the feature extraction network (Backbone), the feature fusion network (Neck), and the detection network (Prediction).

A. Feature Extraction Network (Backbone)

The Backbone comprises the CSPDarknet, Focus, and SPP (Spatial Pyramid Pooling) modules, which primarily operate to extract high (deep), intermediate, and low (shallow) level features from images. The backbone network of YOLOv5 is CSPDarknet53. In contrast to the Darknet53 network, the $C3_X$ module partitions the feature mappings of the base layer into two segments and subsequently integrates them via partial local cross-layer fusion. This not only mitigates the problem of excessive computation due to duplicated gradient information during network optimization, but also guarantees precision while diminishing computational burden. The Focus module enhances feature extraction efficiency by segmenting and recombining input feature maps within the backbone network, hence reducing the number of network layers. This significantly decreases computational burden and enhances detection velocity while preserving precision. The SPP module is incorporated following the CSPDarknet53 architecture to extract prominent characteristics from photos. The SPP architecture enhances the receptive field of the prediction box, addresses the alignment discrepancy between the target box and the feature map, and guarantees both effective feature extraction and the operational speed of the network.

B. Feature Fusion Network (Neck)

The fundamental components of the Neck are feature pyramid networks (FPN) [16] and path aggregation networks (PAN) [17], which primarily enhance the model's capacity to recognize objects across various scales. Deep feature maps possess enhanced semantic features but diminished localization information, whereas shallow feature maps have superior localization information but reduced semantic features. FPN segments the feature maps into various scales and integrates them. It transmits profound semantic information to the superficial layers, augmenting semantic representation across various scales.

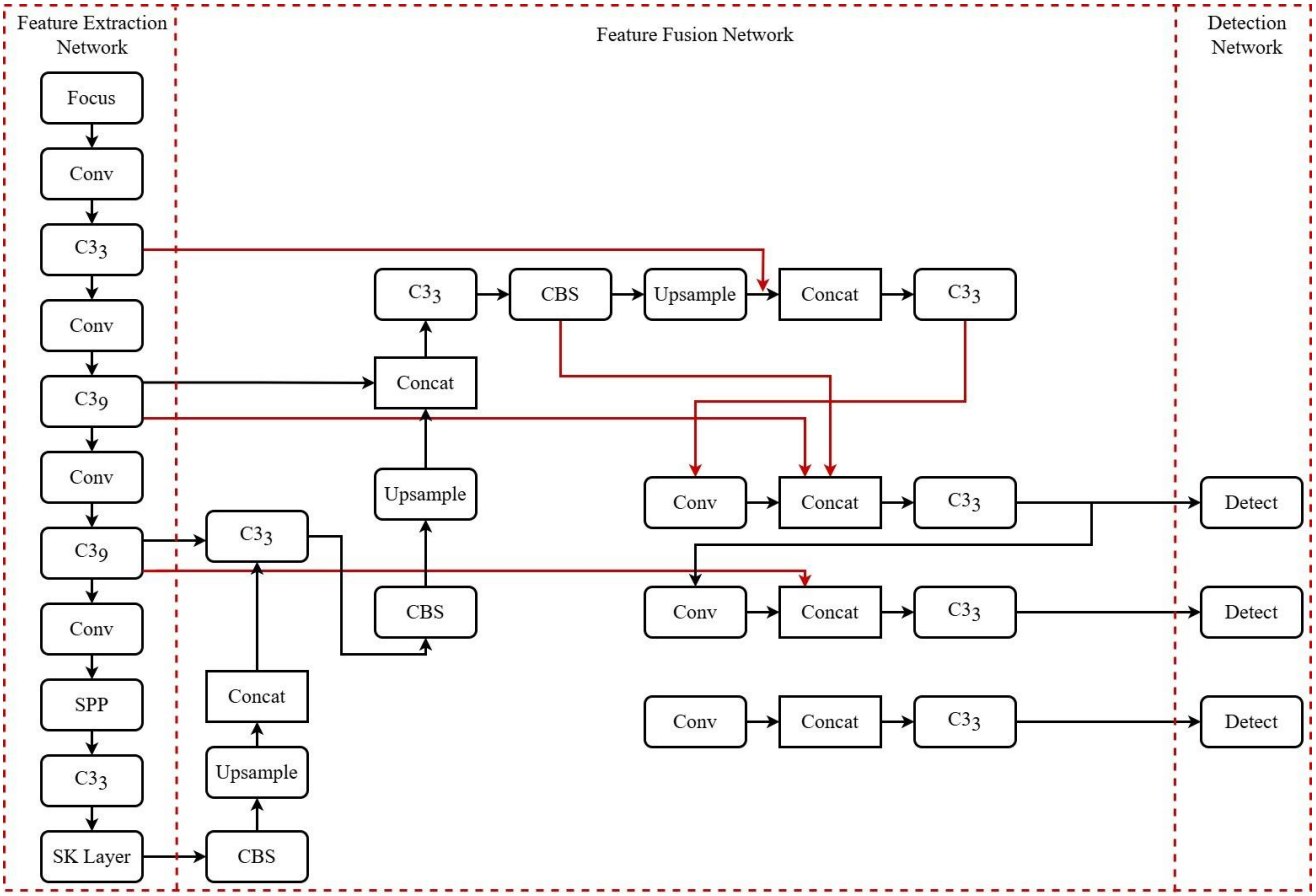

Fig. 1. HD-YOLOv5s network structure.

Conversely, PAN conveys superficial localization data to the deeper layers, enhancing localization proficiency across various scales. The PANet feature pyramid architecture incorporates a bottom-up pathway structure in addition to the Feature Pyramid Network (FPN) [18-19]. FPN improves object detection by integrating characteristics from both deep and shallow layers, particularly enhancing the identification of small objects. Object identification involves pixel-level categorization, and shallow features, which often capture edges and forms, are essential for this process. The bottom-up path architecture effectively employs shallow layer characteristics for segmentation. Incorporating this upgrade into FPN, PANet enables deep feature maps to leverage the extensive localization information from shallow layers, hence enhancing the detection of huge objects.

C. Detection Network (Prediction)

Traditional neural networks only input the deepest layer of network features into the detection layer, leading to the loss of small object features as they are passed from lower layers to higher layers. This results in difficulty in recognizing small objects and a low detection rate. YOLOv5 adopts a multi-scale detection method, dividing the feature maps into three scales through 32x, 16x, and 8x down sampling. By utilizing different receptive fields, larger feature maps detect small objects and smaller feature maps detect large objects, overcoming the limitations of top-layer features.

III. HD-YOLOv5 Network Structure

The gesture recognition technique introduced in this research, HD-YOLOv5s, represents an enhancement of the YOLOv5s model. Fig. 1 illustrates the architecture of the HD-YOLOv5s model, whereas Fig. 2 depicts the configuration of each module within the HD-YOLOv5s model. In Fig. 1, the newly incorporated features relative to the original YOLOv5s model are distinguished by various colors.

A. Feature Extraction Network with SKNet

In complex background environments, gesture targets may be small in size or have backgrounds similar in color to skin, which makes it challenging to recognize targets of varying scales. This requires higher feature extraction capabilities from the network model. Attention mechanisms can enhance the network's ability to express model features by strengthening important features and weakening general features. Therefore, this paper adopts an attention mechanism to enhance the network's feature extraction capability.

The selective kernel neural network (SKNet) employs an adaptive selection method.

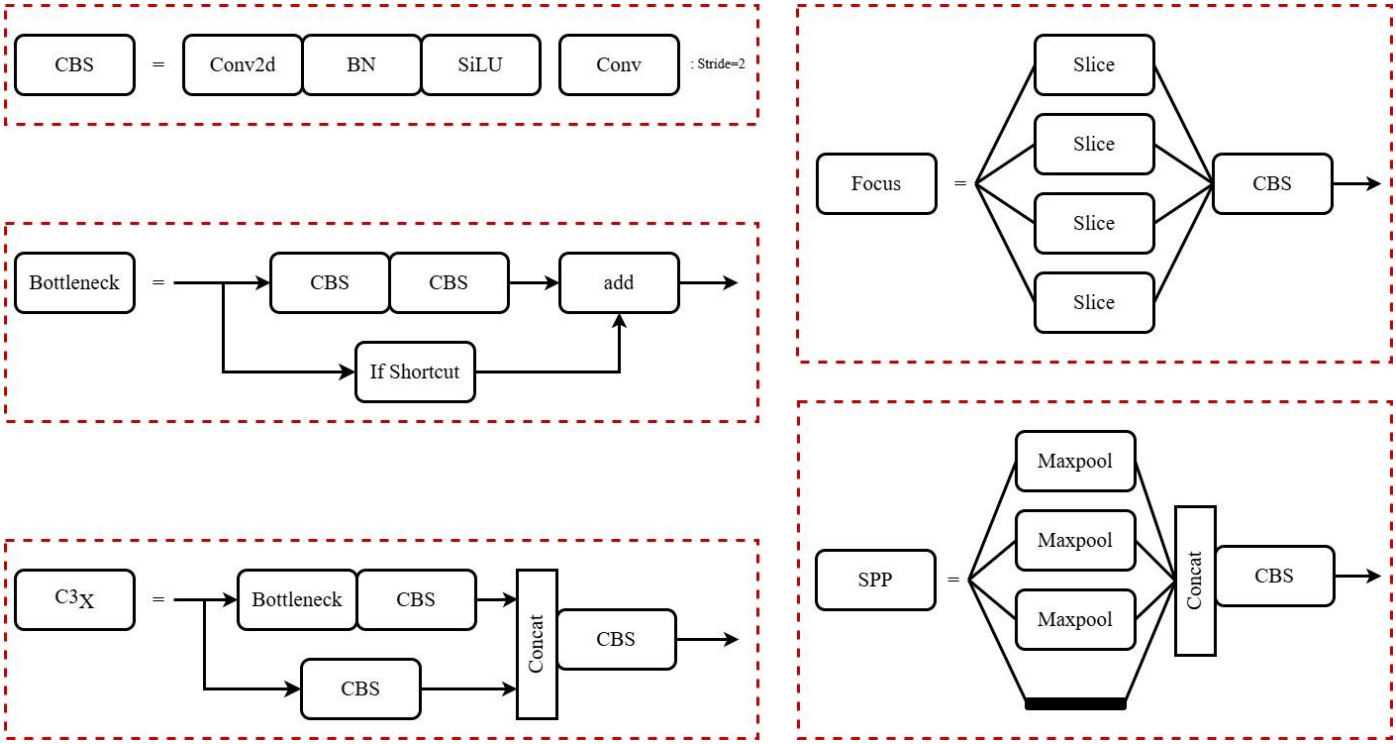

Fig. 2. HD-YOLOv5 module structure.

The advantage resides in its consideration of several convolutional kernels, enabling neurons to select the suitable kernel size according to input information of varying scales, so efficiently modifying the receptive field size. This allows the network to concentrate on significant features. Conversely, conventional convolutional networks often employ a singular convolutional kernel per layer, and throughout feature extraction, the kernel size remains constant at each layer, resulting in a static receptive field. The dimensions of the receptive field directly affect the scale of the features, and the features derived from conventional convolutional networks are generally more homogeneous, which imposes specific constraints. Structures such as Inception incorporate numerous convolutional kernels to accommodate multi-scale pictures; however, the weights of these kernels remain constant, and post-training, the parameters are immutable. This leads to the indiscriminate utilization of all multi-scale information. Undoubtedly, employing a dynamic selection method such as SKNet offers greater advantages.

SKNet, an enhancement of the SENet network, incorporates multi-branch convolutional networks, dilated convolutions, and group convolutions. It examines the interactions among channels while also addressing the function of convolutional kernels. SKNet enables the network to prioritize channels beneficial for recognition during feature extraction and autonomously identifies the ideal convolutional operator, hence enhancing recognition performance. SKNet operates through three phases: splitting, fusing, and selecting, as illustrated in Fig. 3.

The specific steps are as follows:

1) Split: Given an input feature $X \in R^{G\times Z\times C}$, two convolution operations are performed with convolutional kernels of sizes 3×3 and 5×5, resulting in two outputs: $\tilde{F}: X \to \tilde{V} \in R^{G\times Z\times C}$ and $\hat{F}: X \to \hat{V} \in R^{G\times Z\times C}$. To further improve efficiency, dilated convolution with a dilation rate of 2 is used in place of the 5×5 convolution.

2) Fuse: To adaptively adjust the receptive field size, the two branch results are first fused by element-wise summation, expressed as follows:

$$V = \tilde{V} + \hat{V} \tag{1}$$

Secondly, use the global pooling operation on the integrated information to obtain the global information, as shown in the following formula:

$$T_c = F_{\mathrm{hQ}}(V_c) = \frac{1}{G\times Z}\sum_{i=1}^{G}\sum_{j=1}^{Z} V_c(i,j) \tag{2}$$

In the formula, F_{hQ} represents the global average pooling operation function, T_c represents the output of the c channel, and $V_c(i,j)$ represents the coordinates of the c channel. G Is the height of the feature map, and Z is the width of the feature map, where i and j are the coordinate values for the height and width of the feature map, respectively.

Finally, $T_c$is reduced in dimension by the fully connected layer to obtain U, as follows:

$$U = F_{\mathrm{fc}}(T) = \delta\big(\beta(Z_T)\big) \tag{3}$$

$$d = \max\left(\frac{c}{r}, L\right) \tag{4}$$

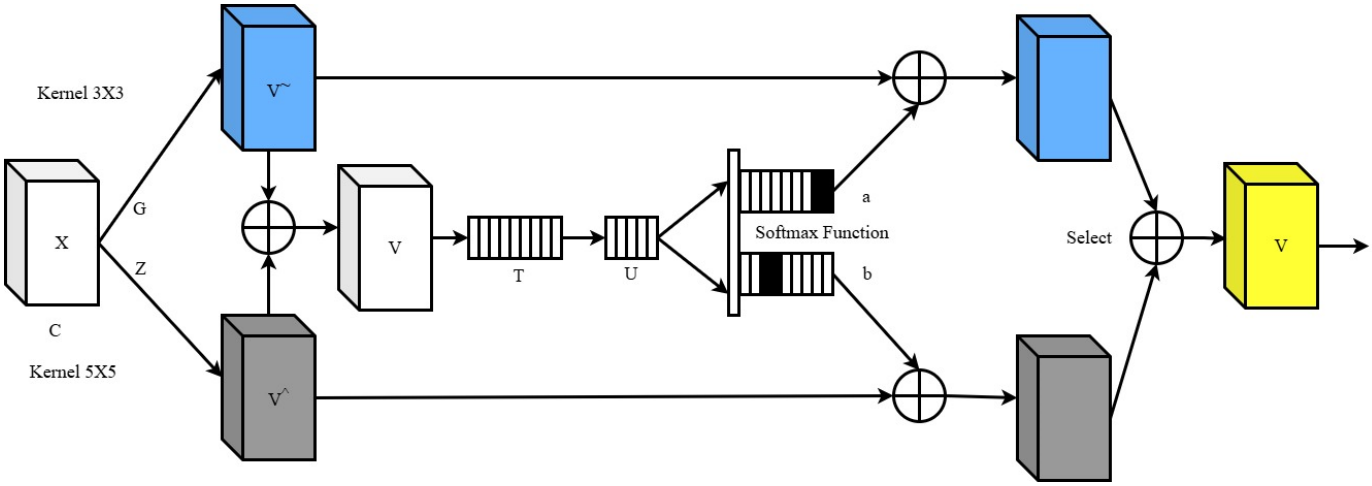

Fig. 3. SKNet network structure.

In the equation, F_{fc} denotes the fully connected operation function, δ signifies the non-linear activation function, β represents the batch normalization (BN) layer, and d indicates the fully connected layer regulated by the reduction ratio. L represents the minimum value of d, where $Z \in \mathrm{R}^{d\times c}$, $U \in \mathrm{R}^{d\times 1}$.

3) Selection: First, the channel attention is generated, and then adaptive selection of information at different scales is made, as expressed below:

$$\begin{cases} a_c = \frac{e^{A_c U}}{e_c A_c + e^{B_c U}} \\ b_c = \frac{e_c U}{e_\varepsilon U} + e^{B_c U} \end{cases} \quad (5)$$

In the formula, $A, B \in \mathrm{R}^{c\times d}, a_c, b_c$ represent the attention vectors corresponding to $\tilde{V}$ and $\hat{V}$ respectively, where A_c represents the c row and a_c represents the c element of a.

Finally, the features output by the two branches are weighted and fused to obtain V_c, as follows:

$$W_c = a_c \tilde{V}_c + b_c \hat{V}_c; a_c + b_c = 1 \quad (6)$$

In, $W = [W_1, W_2, \cdots, W_c], W_c \in \mathrm{R}^{G\times Z}$.

SKNet is a lightweight embedded module composed of multiple SK (Selective Kernel) convolutional units. In this paper, the SK convolution layer is added to the C3 module at the end of the HD-YOLOv5s backbone network, enabling the network to focus more on extracting effective features. The process is as follows: the initial feature map size is set to 640×640×3, and the channel scaling factor is set to 0.5. After one Focus operation and four CBS operations, the output feature map size of the final C3 module is 20×20×512, which is used as the input for the SK module.

First, the feature map is passed through two convolution kernels, 3×3 and 5×5, using grouped convolution, outputting two feature maps of different scales, each with 512 channels, denoted as $\tilde{V}$ and $\hat{V}$. Then, the results of the two branches are added element-wise. After global average pooling, the output is a 1×1×512 feature map. Next, after two fully connected layers for dimensionality reduction and expansion, a feature map of size 1×1×d is obtained. This is then dynamically and adaptively adjusted using the softmax activation function, automatically selecting the optimal convolution operators a and b, which control the receptive field feature maps of the two branches. Finally, the two branches are weighted and fused as $W = \tilde{V} \times a + \hat{V} \times b = 20 \times 20 \times 512$ to produce the output of this network layer, allowing the network to focus more on the gesture information that is useful for recognition.

Abhishesh Pal et al. [20] and Prabu Selvam et al. [21] was integrated SKNet into YOLOv3 and SSD networks, enhancing the feature extraction capability and improving the mean average precision (mAP) of the networks to varying degrees. Therefore, SKNet is added to the HD-YOLOv5s algorithm proposed in this paper to improve the network's detection performance.

B. Feature Fusion Network

This work focuses on hand gesture recognition, encompassing small and varied-sized objects. The YOLOv5s network model employs the PANet (Path Aggregation Network) architecture to tackle the challenge of multi-scale input. Nonetheless, because to the disparate resolutions of the gesture region features, PANet frequently amalgamates features indiscriminately while integrating various input features. This may nevertheless result in false positives and overlooked detections, particularly with little objects. This research proposes utilizing a modified weighted bidirectional feature pyramid network (BiFPN) to supplant PANet for feature fusion, hence augmenting the model's detection efficiency and expanding the network's capability to identify hand gesture targets across varying scales.

The Google Brain team introduced BiFPN in the EfficientDet object detection algorithm [22], characterized by efficient bidirectional cross-scale connections and weighted feature fusion. The BiFPN feature fusion technique assigns weights to features derived from the bidirectional feature pyramid and aggregates them pixel-wise, while the original YOLOv5s algorithm concatenates features along the channel dimension. This study integrates the bidirectional feature pyramid network (BiFPN) into the feature fusion network of the YOLOv5s model, employing channel-wise concatenation for

feature fusion and implementing cross-level cascade to augment the network's feature fusion efficacy. Fig. 4 illustrates the feature fusion network of the original YOLOv5s method. In the diagram, $Ci(i = 2 \sim 5)$represents the multi-scale features extracted by the feedforward network. F represents the $C3_3$ operator, Qi represents the output features, where 2× refers to two-fold up sampling achieved via bilinear interpolation, and 0.5× refers to down sampling. The features of different scales $\{C2, C3, C4, C5\}$, extracted by the backbone network, are input into the feature fusion network. With the original image resolution set to 640×640, after bidirectional cross-scale connections and weighted feature fusion, three different scale features $\{Q3, Q4, Q5\}$ are obtained as the detection layers of YOLOv5s, with resolutions of $20 \times 20, 40 \times 40, 80 \times 80$, respectively.

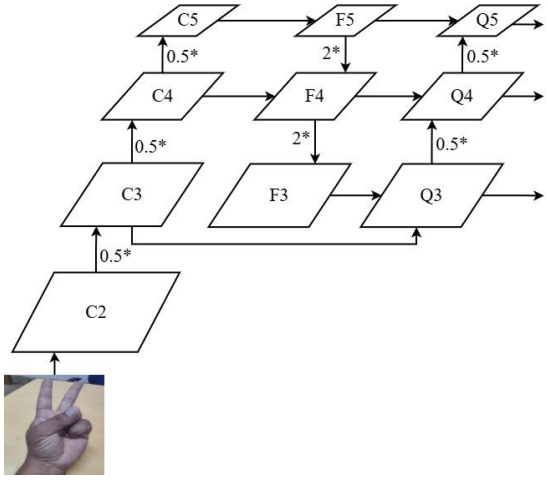

Fig. 4. Feature fusion network of the original YOLOv5s algorithm.

The specific improvements are as follows:

- **To enhance the accuracy of small object detection**, this paper proposes a feature fusion method that fully utilizes low-level features. It makes full use of the Q2 feature by incorporating high-resolution Q2 information into the feature fusion process. By establishing a connection between the small object detection feature Q3 and the previous level feature C2, it alleviates the loss of the F3 feature caused indirectly by network down sampling, thus further improving the network's supervision ability over small objects.
- **To improve the model's efficiency**, while performing bidirectional feature fusion from top to bottom and bottom to top, a cross-scale lateral connection is added between the input and output nodes at the same scale. This cross-level connection allows surface-level details, edge information, and contour information to be integrated into the deeper layers of the network, enabling precise edge regression of the target without increasing computational costs. This reduces the feature loss caused by having too many layers. The improved feature fusion network structure is shown in Fig. 5.

In Fig. 5, the dashed lines represent cross-level connections. Cross-level connections refer to adding a skip connection between the input and output nodes at the same scale. Since they are at the same level, this allows for more feature fusion without significantly increasing computational cost. As shown in Fig. 5, to reduce computation and shorten inference time, cross-level weighted fusion was not applied to the low-level Q2 feature. Instead, cross-level weighted fusion was used only when obtaining the Q3 and Q4 features for final detection. The low-level Q2 feature was fully utilized by introducing high-resolution feature information into the feature fusion process, improving the model's performance in small object detection and enhancing the backbone network's learning ability for target detection across different scale gesture regions.

The weighted feature fusion uses a fast normalization fusion formula, as shown in Eq. (7). The normalization process is achieved by dividing each weight by the sum of all weights, with the normalized weights constrained between [0, 1], which improves GPU processing speed and reduces additional time costs.

$$O = \sum_i \frac{z_i}{\varepsilon + \sum_j z_j} \cdot I_i \quad (7)$$

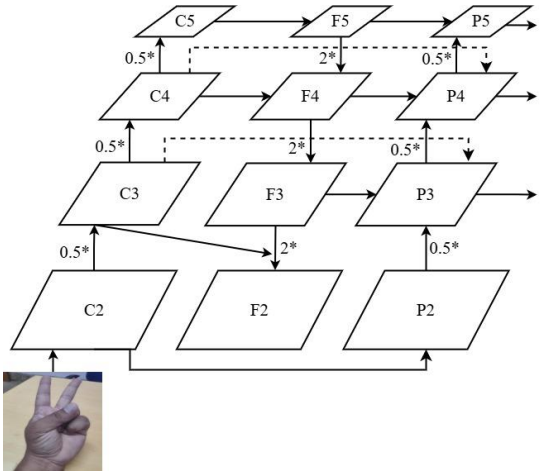

Fig. 5. Improved feature fusion network.

C. Image Enhancement Preprocessing

During the collection of gesture datasets, issues such as uneven lighting or background colors similar to skin tones often occur. These issues can degrade image quality, affecting the model's ability to recognize gestures and leading to missed or incorrect detections. To address these problems, this paper introduces an adaptive contrast adjustment image enhancement method based on the original network, specifically an adaptive Gamma enhancement algorithm improved from the Retinex (Retina and Cortex) theory [22-23]. This algorithm is effective in addressing uneven lighting, providing better contrast, naturalness, and efficiency. Common image enhancement algorithms, such as histogram equalization and Retinex, tend to cause over-enhancement, color distortion, and halo effects during the enhancement process [24].

The Retinex-based adaptive Gamma enhancement algorithm adapts to the brightness level of different regions of an image, reducing the brightness in overexposed areas and increasing it in underexposed areas. This helps minimize over-enhancement issues during image processing, resulting in better contrast. Moreover, this algorithm retains more detailed

information after adaptive correction, reducing color distortion and halo effects. Additionally, when processing images with uneven lighting, the algorithm can adjust the Gamma parameter adaptively based on the distribution characteristics of the lighting component, saving the time required for manually setting the Gamma value. The main steps of this image enhancement algorithm are as follows:

- Use the Retinex theory to separate the brightness component and reflection component of the image.

$$R^c(x,y) = \frac{I^u(x,y)}{L(x,y)}, c \in \{r,h,b\} \quad (8)$$

where, $R^c(x,y)$ represents the separated reflection component, $I^u(x,y)$ represents the brightness of each RGB channel, and $L(x,y)$represents the brightness component of the image.

- Apply the adaptive Gamma correction algorithm to the brightness component.

$$L_{\text{en}}(x,y) = L(x,y)^{\gamma(x,y)} \quad (9)$$

$$\gamma(l) = 1 - \sum_{v=0}^{l} \frac{Q_\omega(v)}{T_q} \quad (10)$$

$$T_q = \sum_{i=0}^{l} Q_\omega(l) \quad (11)$$

where, $L_{\text{en}}(x,y)$ is the corrected brightness component, $\gamma(x,y)$is the coefficient matrix, $\sum_{v=0}^{L} Q_\omega(v)$is the cumulative distribution function of the brightness component, and $Q_\omega(l)$ is the distribution function of the brightness values.

$$Q_\omega(l) = \frac{Q(l) - q_{\min}}{p_{\max} - q_{\min}} \quad (12)$$

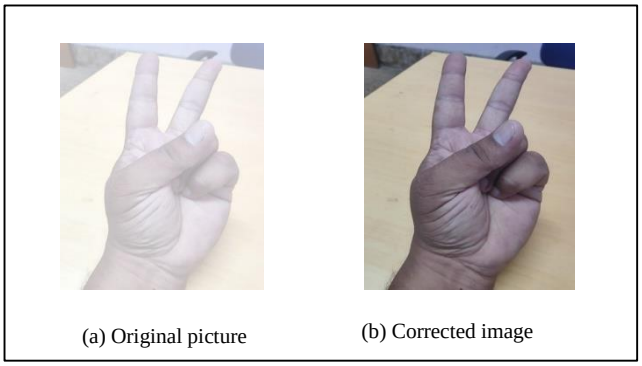
$$Q(l) = \frac{n_l}{n_q} \quad (13)$$

where, $Q(l)$ is the probability density function of the brightness component, n_l represents the number of pixels with a corresponding brightness, and n_q represents the total number of pixels in the brightness component.

- By merging $L_{\text{en}}(x,y)$ and $R^c(x,y)$the final enhanced image $I^c_{\text{en}}(x,y)$ is obtained, restoring the original image's color and details.

$$I^c_{\text{en}}(x,y) = R^c(x,y) \cdot L_{\text{en}}(x,y), c \in \{r,\text{h},b\} \quad (14)$$

The experimental comparison of the corrected images is shown in Fig. 6.



(a) Original picture (b) Corrected image

Fig. 6. Comparison of images before and after Gamma correction

Experimental results show that correcting images with uneven lighting not only significantly improves the clarity of the pre-processed images but also increases the diversity of lighting conditions in the dataset. By performing lighting enhancement pre-processing on the dataset, the quality of gesture images is improved, which in turn increases the accuracy and recall rate of gesture recognition. The flowchart of the HD-YOLOv5s gesture recognition method with the added image enhancement algorithm is shown in Fig. 7.

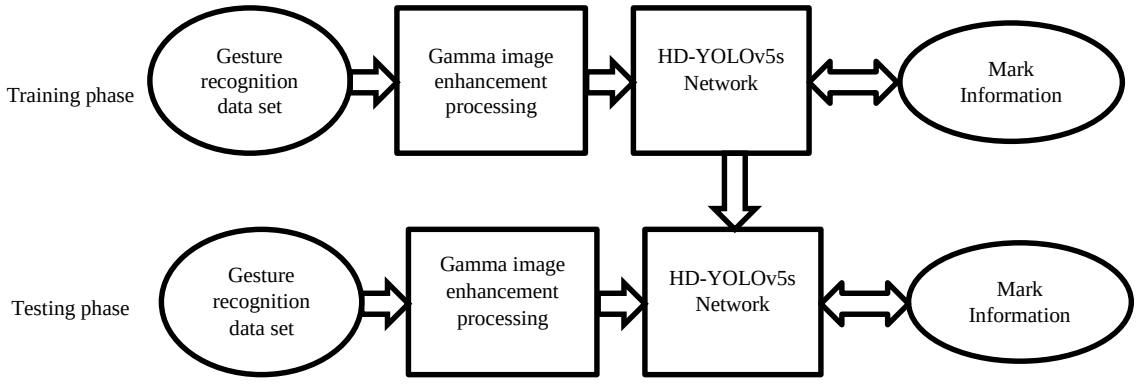


Fig. 7. Flowchart of the HD-YOLOv5s gesture recognition method.

IV. Experimental Detail and Results Analysis

A. Gesture Dataset Preparation

This paper uses the NUS-II dataset [25], which contains 2,750 samples divided into 10 categories. The dataset was collected from 40 participants of different hand shapes and ethnicities in various complex indoor and outdoor environments. The gesture images in this dataset vary in size, dimension, and skin tone, with complex backgrounds, meeting the research criteria of this paper. Some examples from the dataset are shown in Fig. 8.

Fig. 8. NUS-II dataset examples.

A custom gesture dataset was collected using an infrared camera, capturing the gestures of five participants under different lighting conditions and at various distances. Each participant performed seven different gestures, including numerical gestures 0-5 and the "OK" gesture. To augment the dataset, data augmentation techniques such as flipping, scaling, and shifting were applied to the images. The expanded dataset contains 300 samples per class, resulting in a total of 2,100 images.

Fig. 9. Custom dataset examples.

The gesture datasets used in this paper are formatted according to the VOC dataset format. For the custom dataset, images in JPEG format were manually annotated using the label image tool. The 2,100 samples were then split into a training set and a test set at a 9:1 ratio. Some examples from the custom dataset are shown in Fig. 9.

B. Evaluation Metrics

To better assess the model's detection performance before and after the comparative experiments, the evaluation metrics commonly used in mainstream object detection algorithms were adopted. The specific detection metrics used in this paper are as follows:

1) Precision (P): The proportion of correctly predicted targets out of all predicted targets.

$$\text{Precision} = \frac{TP}{TP+FP} \tag{15}$$

Recall (R): The proportion of targets predicted correctly by the model among all true targets.

$$\text{Recall} = \frac{TP}{TP+FN} \tag{16}$$

In the formula:

- TP (True Positives) refers to the number of correctly recognized gesture images.
- FP (False Positives) refers to the number of incorrectly identified gesture images.
- FN (False Negatives) refers to the number of missed gesture images.

2) Average Precision (AP): The precision value for a single category in the dataset, with a range from 0 to 1. Since using the 11-point interpolation sampling method can lead to a loss of precision, this paper adopts the AP calculation method introduced after VOC 2010, defined as follows:

$$AP = \int_0^1 P_{\text{smooth}}(r)\mathrm{d}r \tag{17}$$

$$P_{\text{smooth}}(r) = \max_{r'r' \geqslant r} P(r') \tag{18}$$

In the equation, average precision (AP) is the mean of the precision values over the Precision-Recall (P-R) curve. The P-R curve is a graphical representation of recall values on the horizontal axis and precision values on the vertical axis, creating a curve on the coordinate plane. The P-R curve is initially smoothed by utilizing all real recall values as thresholds. For each threshold when the recall r′ surpasses a specified value, the maximum accuracy value is designated as $P_{\text{smooth}}(r)$. The ultimate AP value is determined by integrating the area beneath the smoothed curve.

3) Mean Average Precision (mAP): The mean of the Average Precision (AP) values over all categories in the dataset, sometimes referred to as the recognition rate. The formula for computation is presented in Eq. (19), where k represents the total number of target categories detected.

$$mAP = \frac{1}{k}\sum_{i=1}^{k} AP_i \tag{19}$$

C. Experimental Setup

All comparative experiments in this study were performed on a Windows 10 operating system with an NVIDIA GTX970 GPU. The experimental setup comprised the deep learning framework PyTorch 1.10.0, CUDA version 10.2, and cuDNN version 8.2.4. The learning rate was established at 0.01 to facilitate rapid convergence in localized areas, while the batch size was determined to be 16 to enhance training efficiency.

D. Result Analysis

1) Comparative experiments: To address the low recognition rate of small-scale gestures in complex environments, this paper improved the feature fusion network of the YOLOv5s model. The accuracy and parameter counts of mainstream feature fusion networks, including FPN, PANet,

and BiFPN, were compared to select the best-performing multi-scale fusion network.

As shown in Table I, FPN only performs unidirectional feature fusion from top to bottom, resulting in low detection accuracy. PANet, which adds a bottom-up path to FPN, integrates strong localization information from lower-level features and shows significant improvement in detection accuracy. BiFPN further enhances PANet by adding bidirectional cross-scale connections. Although the parameter count of BiFPN increases by 13.2% compared to PANet, the computational cost (FLOPs) remains nearly unchanged, and the mAP value increases by 1.4 percentage points. Therefore, adding cross-scale connections enables the network to fuse more features without significantly increasing computational costs, making its detection accuracy superior to other networks.

TABLE I. COMPARISON OF FEATURE FUSION NETWORK PERFORMANCE

Feature Fusion Network	mAP/%	M/106	FLOPs/10^9
FPN	94.5	6.52	15.2
PANet	95.9	7.03	15.9
BiFPN	97.3	8.1	16.3

To better demonstrate the advantages of the improved model in this paper, a comparison was made with several classic object detection algorithms, including the two-stage model Faster R-CNN, and the one-stage models SSD, YOLOv3, and YOLOv5s. All models were trained and validated using the NUS-II dataset, as shown in Table II**.**

TABLE II. COMPARISON BETWEEN MAINSTREAM TARGET DETECTION ALGORITHMS AND THE PROPOSED METHOD

Model	mAP/ %	M/10 6	Model size/106	Inference time/ms
Faster R-CNN	94.5	60.1	159	44
SSD	92.3	24.2	92.1	20.73
YOLOv3	93.9	61.9	235	16.06
YOLOv5s	95.9	7.03	15.9	9.07
HD-YOLOv5s	99.5	13.6	17.8	10.51

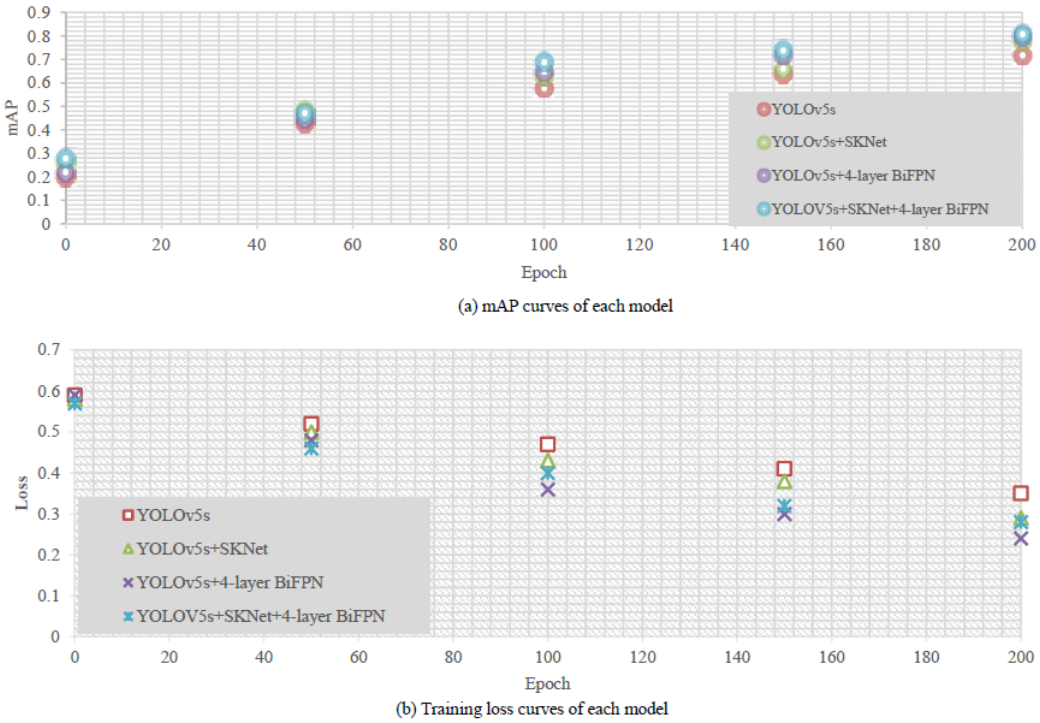
From Table II, it can be seen that the sizes of the Faster R-CNN, SSD, and YOLOv3 models are 6 to 10 times larger than that of the HD-YOLOv5s model, and the number of parameters is 3 to 10 times that of HD-YOLOv5s. Therefore, HD-YOLOv5s can be considered a lightweight network compared to these models. The size of the HD-YOLOv5s model is not significantly different from that of YOLOv5s, although HD-YOLOv5s adds a feature layer to the original YOLOv5s feature fusion network, resulting in increased computational complexity and a 1.44 ms. slower inference time than YOLOv5s. Nonetheless, the detection accuracy has increased by 3.6 percentage points relative to YOLOv5s. HD-YOLOv5s surpasses Faster R-CNN, SSD, and YOLOv3 in detection accuracy and inference speed, achieving detection speeds for a single frame image between 0.01 and 0.02 seconds, thereby fulfilling the real-time criteria for gesture recognition. To comprehensively confirm the efficacy of the gesture recognition approach presented in this research, it was compared with alternative gesture recognition methods utilizing the public NUS-II dataset, with the experimental findings displayed in Table III.

TABLE III. COMPARISON BETWEEN MAINSTREAM GESTURE RECOGNITION ALGORITHMS AND THE PROPOSED METHOD

References	Recognition method	mAP/%
Wang et al. [26]	Bayesian attention + multi-class SVM	93.7
Yi Li et al. [27]	Skin color detection + CNN	95.6
Yi Tan et al.[28]	Deep convolutional neural network	96.2
Fatma M. et al.[29]	Dual channel convolutional neural network (DC-CNN) + Softmax classifier	98
Proposed Model	HD-YOLOv5s	99.5

During the segmentation and detection phase, gestures were classified directly, resulting in a recognition rate of 96.2%. Fatma M. et al. [29] introduced a gesture identification technique utilizing a dual-channel convolutional neural network (DC-CNN), wherein the gesture picture and edge image were input independently into two distinct channels. Following the pooling processes, the characteristics were integrated in the fully connected layer to derive more profound categorization insights, yielding a recognition rate of 98.0%. From these results, the subsequent conclusions may be inferred:

- Yi Li et al. [27] employed gesture segmentation and skin color detection techniques, which are susceptible to contextual influences, resulting in diminished recognition rates in intricate settings. This paper presents a method that enhances feature extraction by incorporating image enhancement pre-processing and integrating the SKNet attention module into the feature extraction network, thereby augmenting the model's generalization and robustness in complex environments, which results in improved gesture recognition rates.
- Yi Tan et al. [28] identified gestures by direct classification or by augmenting network layers. This framework can mitigate the effects of inconsistent illumination and intricate backdrops, enhancing the model's adaptability to complicated surroundings. Nonetheless, its performance in recognizing small-scale movements is merely mediocre. This research presents an approach that, through the development of an innovative feature fusion network, augments the model's capacity to identify small-scale gestures from considerable distances, hence enhancing gesture recognition rates.



(a) mAP curves of each model

(b) Training loss curves of each model

Fig. 10. Training curves of each model.

2) Ablation experiment: To verify the effectiveness of each improvement module in the YOLOv5s network model, an ablation experiment will be conducted based on the YOLOv5s model, comparing the performance of different improved models. As shown in Table IV, '—' indicates not used, and '√' indicates used.

Table IV indicates that the mAP value of the enhanced network model HD-YOLOv5s attained 99.5%. In Improved Model 1, the SKNet attention mechanism was incorporated into the original backbone extraction network. The parameter count (M) remained rather stable, while the mAP enhanced by 1.5 percentage points in comparison to the previous model. SKNet, as a lightweight embedded module, produces more rational weight coefficients by autonomously picking the ideal operator, hence augmenting the network's feature extraction capability while maintaining a steady parameter count.

Improved Model 2 incorporated a novel bidirectional feature pyramid network (BiFPN) into the original feature fusion network. In comparison to the BiFPN in Table I, which has three levels of fusion feature layers, the BiFPN enhanced with low-level features exhibits superior fusion capability. By fully leveraging the low-level P2 characteristics, the model's efficacy in small item recognition was enhanced. In contrast to Improved Model 3, which has four detection layers, Improved Model 2 omits low-level features in the bidirectional feature fusion, leading to a 0.3 percentage point reduction in mAP, while decreasing the computational load by 0.5% and the parameter count by 4.9%. Consequently, to alleviate computational burden and decrease inference duration, bidirectional feature fusion was not utilized for the low-level P2 features in this study.

TABLE IV. PERFORMANCE COMPARISON OF EACH IMPROVED MODEL

Model	Feature layer	Detection layer	Gamma	SKNet	BiFPN	mAP/%	M/10^6	FLOPs/10^9
YOLOv5s	3	3	—	—	—	95.9	7.03	15.9
Improved model 1	3	3	—	√	—	97.4	7.24	16.2
Improved model 2	4	3	—	—	√	98	13.5	17.8

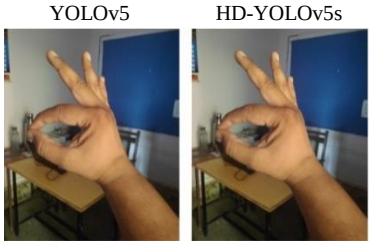
(b) Weak light with recognition rate 95-99% for two fingers



(c) Uneven lighting with recognition rate 95-99% for three fingers

Fig. 11. Recognition effect under different lighting conditions.

Enhanced Model 4 integrated the attention mechanism and the refined feature fusion module into the network. In comparison to Improved Model 2, the computational burden and parameter count exhibited no growth, while the mean Average Precision (mAP) rose by 1.3 percentage points. The mAP improved by 3.4 percentage points relative to the previous model. The enhanced HD-YOLOv5 model utilized Gamma image enhancement preprocessing on the dataset during the input phase, attaining a mAP value of 99.5%, representing a 3.6 percentage point increase compared to the original YOLOv5s network.

Fig. 10 illustrates the training result curves for the different models prior to and following enhancement on the custom training set. The iterations were established at 200, the learning rate at 0.01, and the momentum factor at 0.937. In Fig. 10(a), the horizontal axis denotes the training epochs, whereas the vertical axis indicates the mAP value at an IOU of 0.5. The performance of the enhanced models surpasses that of the pre-enhancement ones. In Fig. 10(b), the enhanced HD-YOLOv5s model exhibited a more rapid convergence and a reduced loss value relative to the YOLOv5 model, signifying superior convergence capabilities of the improved model.

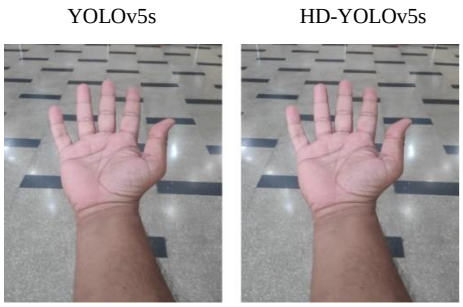
V. RESULTS AND DISCUSSION

This study utilizes the publicly available NUS-II dataset [30] for training, with validation findings presented in Table V. The NUS-II dataset, while encompassing a variety of intricate backgrounds, contains a limited number of gesture photos across different lighting situations. To enhance the verification of the universality and robustness of the new technique, validation experiments were undertaken on a bespoke dataset encompassing diverse illumination situations. The validation outcomes are presented in Table VI. The HD-YOLOv5s model demonstrated a notable enhancement in recognition accuracy on the custom dataset. This illustrates that the enhanced algorithm exhibits strong performance across diverse complicated backgrounds and increases resilience to interference.

To verify the feasibility of the improved HD-YOLOv5s model, several gesture images from the test set were selected for testing. Fig. 11 compares the gesture recognition results between the YOLOv5s and HD-YOLOv5s models under different lighting conditions. Fig. 11(a) and 11(b) show the recognition results in strong and weak lighting environments, while Fig. 11(c) shows the recognition results under uneven lighting. In these comparisons, the left images are from the YOLOv5s model, and the right images are from the HD-YOLOv5s model. The results show that the improved HD-YOLOv5s model achieves varying degrees of improvement in gesture recognition accuracy under different lighting conditions. In Fig. 11(c), the left image misclassifies the "OK" gesture and part of the windowsill as gestures "5" and "0," whereas the right image correctly identifies them with higher accuracy.

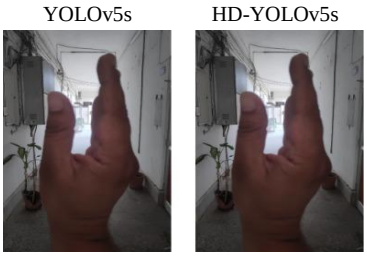
Fig. 12 compares the recognition results of the models before and after improvement in situations where the background color is similar to skin tone. Fig. 12(a) and 12(b) display the recognition of gestures in simple and complex backgrounds, respectively. In Fig. 12(a), the performance difference between the original and improved models is minimal in a simple background. However, in Fig. 12(b), the improved model achieves significantly higher accuracy in a complex background, showing a substantial improvement in recognizing gestures with backgrounds close to skin color.

(a) Simple background with 96-98% recognition rate

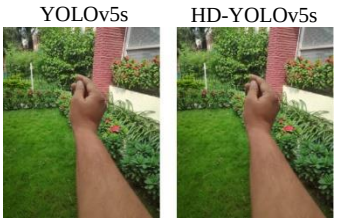


(b) Complex background with 93-99 recognition

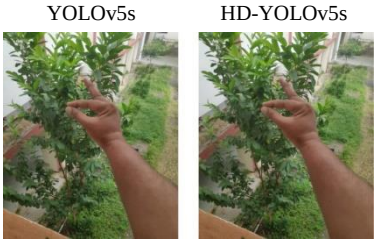
Fig. 12. Recognition effect when the background is close to skin color.



(a) Uneven lighting with 88-90% recognition rate



(b) Simple background with 95-98% recognition rate



(c) Complex background with 93-99% recognition rate

Fig. 13. Recognition effect of small-scale gestures in complex environments.

Fig. 13 shows the recognition performance of the models before and after improvement for small-scale gestures in complex environments. Fig. 13(a), 13(b), and 13(c) represent the detection of small gestures at a distance in different complex scenarios. Especially in Fig. 13(a), under uneven lighting and a complex background, the improved model shows a clear improvement in recognizing small gestures.

In summary, the improved HD-YOLOv5s model outperforms the original YOLOv5s model in recognition performance. The YOLOv5s model performs poorly in complex environments with uneven lighting or skin-tone-like backgrounds, leading to misdetections and weak performance in recognizing small gestures at a distance. In contrast, the HD-YOLOv5s model can accurately recognize gestures in complex environments with a higher recognition rate and resolves the original model's issue of low accuracy in detecting small gestures. The performance improvement of the improved model is not due to any single method but results from overall enhancements in feature extraction and feature fusion capabilities.

VI. Conclusion

This study presents a gesture recognition methodology, HD-YOLOv5s, which attains great precision even in intricate settings, hence enhancing human-computer interface technology. The adaptive Gamma image enhancement technique grounded in Retinex theory was employed to preprocess the dataset. The SKNet adaptive convolutional attention mechanism model was subsequently integrated into the feature extraction network to augment its feature extraction capabilities. The modified BiFPN structure was incorporated into the feature fusion network, enhancing the network's capacity to identify tiny objects. The experimental findings indicate that HD-YOLOv5s attained a mAP value of 99.5%. In comparison to the Faster R-CNN, SSD, and YOLOv3 models, the suggested technique identifies a single image in about 0.01 to 0.02 seconds. The model is compact and efficient, satisfying the real-time demands of gesture recognition in intricate situations. Accuracy increased by 3.6 percentage points vs to the previous YOLOv5s model. Furthermore, in comparison to other prevalent gesture recognition algorithms, our model demonstrates superior generalization and robustness. Validation trials performed on a proprietary dataset and the NUS-II public dataset with intricate backgrounds attained identification rates of 99.5% and 98.9%, respectively. This research presents an enhanced network model that demonstrates superior recognition ability and resilience against challenges such as inconsistent lighting, backdrops resembling skin tones, and diminutive gesture sizes. It fulfills the real-time demands of gesture recognition in intricate situations. Effective static gesture identification is a crucial basis for the examination of dynamic gestures and their applications. The results indicate that this technique exhibits strong robustness and real-time efficacy in intricate situations. This technology is intended for future application in dynamic gesture tracking amongst complicated background variations to resolve challenges associated with low identification rates, hence improving its utility in human-computer interaction domains.

Multi-Label Aspect-Sentiment Classification on Indonesian Cosmetic Product Reviews with IndoBERT Model

Ng Chin Mei[1], Sabrina Tiun[2], Gita Sastria[3]
Faculty of Information Science & Technology, Universiti Kebangsaan Malaysia, Malaysia[1, 2]
Jurusan Ilmu Komputer, Fakultas Matematika dan Ilmu Pengetahuan Alam, Universitas Riau, Indonesia[3]

***Abstract*—For an existing cosmetic company to expand, it is crucial to understand customers' opinions regarding cosmetic products through product reviews. Aspect-based sentiment classification (ABSC), which consists of text representation and classification stages, is typically employed to automatically extract the interested insights from review. Existing studies of ABSC primarily used single-label classification, which fails to capture relationships between multiple aspects in a review. Additionally, the use of contextual embeddings like IndoBERT for representing Indonesian-language cosmetic product reviews has been underexplored. This study addresses these issues by developing a multi-label classification model that leverages IndoBERT, including IndoBERT[b], IndoBERT[k], and IndoBERTweet, to better represent context and capture relationships across multiple aspects in a review. The model is trained and evaluated using a dataset of Indonesian-language cosmetic product reviews from Female Daily. The multi-label models can be constructed using IndoBERT directly as end-to-end model or employing IndoBERT solely as word embedding model. The latter model, also known as conventional multi-label model, needs to be coupled with problem transformation approach and classifier for classification. Single label classification model with Word2Vec serves as baseline to assess the improvement of multi-label model's performance on Female Daily cosmetic product reviews dataset. The empirical results revealed that the multi-label approach was more effective in identifying sentiments for pre-defined aspects in reviews. Among the models, end-to-end IndoBERT[b] achieved the highest accuracy (86.98%), while conventional multi-label models combining IndoBERT[b], Label Powerset (LP), and Support Vector Machine (SVM) performed best with 69.64%. This study is significant as it provides a more generalized understanding of the BERT embedding within the context of multi-labels classification and explores the effect of contextual embedding in the cosmetic domain.**

Keywords*—Aspect-based sentiment analysis; IndoBERT; multi-label classification; IndoBERTweet; problem transformation

I. Introduction

Recently, it can be observed that the worldwide cosmetic industry has generally experienced tremendous growth [1]. Specifically, in Indonesia, the cosmetic industry market size is anticipated to grow from USD 1.17 billion from 2020 to roughly double the amount, which is USD 2.38 billion within eight years period [2].

In order for cosmetic companies to capitalize on these future prospects, it is imperative to understand the customer's needs and opinion, and one of the methods to achieve this is through customer's product reviews, as these heavily influence purchasing decisions [3] [4]. Sentiment analysis is a suitable technique to extract the insights from reviews due to the nature of review itself, which is opinionated with a sentiment polarity, either positive, negative, or neutral. In sentiment analysis, classification of sentiment can be performed at three levels of extraction in terms of granularity, namely document level, sentence level and aspect level. Analyzing reviews at aspect level using aspect-based sentiment analysis (ABSA) is crucial since it identifies sentiments tied to specific product aspects, offering deeper insights than document or sentence-level analysis.

Aspect-based sentiment classification (ABSC) is one of the tasks in ABSA that involves solely sentiment classification. Typically, ABSC is implemented as a pipeline consisting of two stages, namely text representation and classification. The first stage involves the transformation of the text data into its numerical representation. Traditional text representation methods such as Term Frequency - Inverse Document Frequency (TF-IDF) and static word embedding model (e.g., Word2Vec) are relatively inaccurate in representing text as they fail to capture contextual meanings between words [5]. The emergence of contextual word embedding model addresses this limitation. One state-of-the-art contextual model is BERT (Bidirectional Encoder Representations from Transformers). The effectiveness of BERT is demonstrated by the findings of several studies [6] [7] [8] [38].

Subsequently, text representation enables the next stage which is classification. Classification is where sentiment for each aspect of an individual review text can be determined. A notable limitation in the classification stage of ABSC in prior research is the reliance on a single-label classification approach [28] [29] [30] [31] [32]. This method determines the sentiment for each aspect independently, failing to capture correlations between sentiments across different aspects of a review [9]. In real-world scenarios, multiple aspects in a customer review may have related sentiments, and ignoring these dependencies can reduce the performance of the classification model. Although [9] proposed a multi-label approach to account for these correlations, their work did not directly compare it with single-label models, and their dataset was from a different domain. Furthermore, there is a gap in exploring multi-label classification for Indonesian-language datasets, which have

been under-explored compared to more dominant languages like English.

This study focuses on investigating ABSC of cosmetic products reviews written in the Indonesian language. Several issues have been observed in this context. Firstly, there is a scarcity of prior ABSC research in Indonesian cosmetic products reviews. Secondly, none of the prior works have explored the effect of contextual embedding models such as BERT on this domain. Thirdly, existing studies primarily employed single label classification, but this classification approach presents limitations by disregarding possible relationship between multiple aspects within single review [9]. Thus, this study aimed to address these issues by developing a reliable multi-label ABSC model, at the same time, exploring the performance of contextual word embedding in representing words from cosmetic domain. As the focus is on the Indonesian language, IndoBERT, which is a BERT designed for Indonesian language, was employed as the contextual embedding model in this study.

In this study, this multi-label ABSC model was built with two alternative methods, one using IndoBERT as an end-to-end model, and the other built with a combination of text representation method, multi-label problem transformation approach, and machine learning classifier. The former method performs multi-label classification by directly processing the text and generating sentiment predictions within a single model, while the latter method analyses the word vectors transformed by IndoBERT, then combines the multi-label approach with a classifier to categorize the aspect-sentiment labels for each cosmetic product review. The second method was referred to conventional multi-label model. This study is organized as follows: Section II presents the background information and related works. Section III demonstrates the methodology. Section IV presents the results. Discussion is given in Section V. Finally, the paper is concluded in Section V.

II. Literature Review

A. IndoBERT

1) Variants of IndoBERT: There are three variants of IndoBERT, which are IndoBERT[k], IndoBERT[b], and IndoBERTweet. The key differences among IndoBERT variants lie in the training datasets used. IndoBERT[k], introduced by [10] was trained on the INDOLEM dataset, which consists solely of formal text, limiting its effectiveness with colloquial Indonesian. To address this, [11] introduced IndoBERT[b], trained on the mixed formal and informal dataset INDONLU. Additionally, IndoBERTweet was developed specifically for informal social media language [12].

2) Word embedding model: Previous comparative studies consistently highlight the superiority of IndoBERT variants when applied to Indonesian product review datasets across various domains. For example, [13] demonstrated that IndoBERT[b] outperformed Word2Vec when paired with a Convolutional Neural Network (CNN) classifier in categorizing restaurant customer reviews across four dimensions: Price, Food, Place, and Service. This finding is corroborated by study [14], who showed that IndoBERT[k] performed better than both Word2Vec and FastText in representing the reviews related to COVID vaccines. Moreover, the IndoBERT[b] showed more effectiveness than Word2Vec with all seven classifiers such as SVM, Naïve Bayes (NB), and Random Forest (RF) when dealing with hotel reviews in study [15], further supporting the superiority of IndoBERT as word embedding models in transforming the text.

3) End-to-end model: IndoBERT also plays a good role as end-to-end model in ABSC as shown in study [16]. In the study of [17], sentiment classification on online reviews was conducted using IndoBERT as end-to-end model, with the aim to investigate the satisfaction of customer towards ride-hailing company Gojek from seven aspects. A relatively high accuracy of 96% was achieved, suggesting the superiority of IndoBERT. Similar promising results were obtained in the study of [18]. Other studies such as [19] and [20] showed the effectiveness of IndoBERT implementations as an end-to-end model when comparing its performance to other deep learning language models and traditional machine learning method.

B. Multi-Label Classification

Existing research categorizes multi-label approaches into three categories: Problem transformations, algorithm adaptations, and pre-trained language model. Problem transformation methods, such as Binary Relevance (BR), Classifier Chain (CC), and Label Powerset (LP), convert multi-label problems into binary or multi-class problems for classification. BR treats each label as a separate binary problem, while CC predicts labels sequentially, and LP transforms labels into a multi-class problem. RAkEL D, an ensemble of LP, addresses LP's limitations by training on label subsets. Algorithm adaptation modifies existing algorithms, like ML-kNN and ML-DT, to handle multi-label tasks directly.

In most previous works on multi-label classification, emphasis was placed mainly on text categorization [21] [22] [23] [24]. The literature review reveals that there was only a limited of studies on ABSC that specifically address multi-labels classification. Related existing studies primarily assessed the multi-label aspect-sentiment model efficiency through multi-label metrics: Accuracy and Hamming Loss.

The study in [25] explored drug effectiveness using problem transformation methods (BR, CC, LP) combined with various classifiers, finding that SVM performed best, followed by DT and NB. Among the transformation methods, LP outperformed CC and BR. Despite this study evaluating all three popular problem transformation methods, there was a lacking exploration of the algorithms that specifically adapted for multi-label problems.

The research in [9] compared three categories of multi-labels approaches using customer reviews from restaurants, wine, and movies, demonstrating pre-trained language models such as BERT outperformed other categories, followed by problem transformation and algorithm adaptation. For problem transformation, the author obtained the same results as [25]: LP consistently outperformed CC and BR.

The study in [26] further confirmed the findings of [9], demonstrating BERT's superiority in sentiment classification

and showing that LP outperformed BR and CC within problem transformation approaches.

In the Indonesian context, BERT variants, IndoBERT has shown excellent performance in multi-label tasks, outperforming other models, as evidenced by studies like [27] and [15].

C. Aspect-based Sentiment Classification (ABSC) on Indonesian Cosmetic Product Reviews

Previous ABSC studies of cosmetic product reviews in Indonesian language, primarily using datasets from Female Daily, focused on determining the overall sentiment of user reviews. These studies explored various aspects, with most focusing on four predefined aspects: packaging, quality, scent, and price [28] [29] [30] [31].

Traditional text representation approaches like TF-IDF and NB yielded moderate performance, with studies like [28] achieving an average F1-score of 62.81% across these four aspects. Their results indicated room for improvement, potentially due to the limitations of TF-IDF and NB, which rely on word frequency for representation and independence assumptions for classification.

Subsequent research improved performance by employing Word2Vec static word embeddings and different classifiers, such as SVM, on similar datasets with the same aspects. [29] achieved a 68.25% F1-score using Word2Vec for text representation while maintaining NB as the classifier. The improvement is likely due to Word2Vec enhanced the contextual richness of sentiment representations compared to TF-IDF. The study in [30] demonstrated further improvements by using SVM with TF-IDF as the text representation method.

Other studies, like those by [32], explored additional aspects but found limitations in performance using approaches like Bag of Words (BOW), achieving only a 53.04% F1-score. The study in [31] employed a hybrid method of TF-IDF and semantic similarity, achieving a high accuracy of 90.33%, likely due to fewer predicted aspects.

Notably, none of these studies applied contextual embeddings or addressed multi-label classification in the cosmetic domain, highlighting areas for future improvement in ABSA methods.

III. Methodology

A. Research Methods Overview

Generally, there are two strategies that can be used to build a multi-label model using IndoBERT, as shown in Fig. 1. In the first strategy, IndoBERT was used as an end-to-end model to directly perform multi-label classification. In second strategy, IndoBERT was used solely as a word embedding model to transform text into dense word vectors, which were then passed to machine learning classifiers. The model from second strategy, known as the conventional multi-label model, involved using word embeddings for text representation, multi-label problem transformation methods, and classifiers.

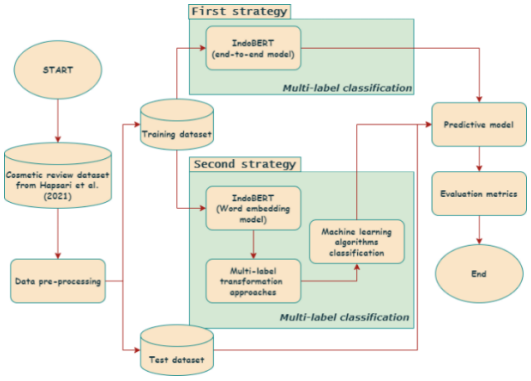

Fig. 1. General workflow for building multi-label models using IndoBERT.

In this study, three interconnected experiments were conducted: -

1) Experiment I: This experiment was focused on evaluating the performance of multi-label classification in ABSC context, with single-label model from [29] serving as the baseline. To rule out any external factors which might affect the results, the experiment established the baseline by replicating the literature experiment [29].

2) Experiment II: Experiment II concentrated on assessing the different variants of IndoBERT as word embeddings, alongside the promising multi-label approaches identified from experiment I. This experiment exploited Word2Vec as the baseline word embedding. The IndoBERT variants used were IndoBERT[b], IndoBERT[k], and IndoBERTweet.

3) Experiment III: Building upon the findings of Experiment I and II, this experiment further explored the performance of IndoBERT in multi-label classification by incorporating the multi-label capabilities into model, using IndoBERT directly as end-to-end model, serving as both text representation and classifier. Conventional multi-label models with classifiers such as Gaussian NB, SVM, Linear SGD, and RF were also employed for comparison.

B. Dataset

The study investigated a secondary dataset that was exclusively sourced from journal article published by [29]. The dataset consists of a total of 3960 customer reviews on cosmetic products collected from Female Daily website and written in Indonesian language. Each review was pre-annotated with sentiments across four different aspects, with the sentiment distribution summarized in Table I.

TABLE I. Sentiment Distribution Across Four Aspects in Cosmetic Product Reviews

Aspect	Sentiment Count		
	Positive	***Negative***	***Neutral***
Product	659	688	2612
Packaging	447	189	3323
Price	1056	716	2187
Scent	669	218	3072

C. Exploratory Data Analysis (EDA)

Before data modeling, a Chi-square test was conducted during the EDA stage to assess dependencies between the targeted aspects. This test provided insights into the relationships between aspect-sentiments, helping determine if single-label or multi-label classification would be more suitable. In this study, the null hypothesis claimed that there is no significant association between the targeted aspects in the investigated dataset. A p-value threshold of 0.05 was used; any value below this indicated significant associations between aspects, suggesting the need for a multi-label classification approach in the dataset.

D. Preprocessing

For multi-label classification, the aspect columns were transformed into aspect-sentiment labels for further analysis. Each aspect was further divided into three labels, following the patterns of 'aspect_pos,' 'aspect_neg,' and 'aspect_other', with the number 0 or 1 indicating the presence of each aspect-sentiment label.

E. Word Embedding (Text Representation) using IndoBERT

Before being processed by IndoBERT, the review text must first pass through the IndoBERT tokenizer to obtain special input format. In this stage, the input sentence was concurrently tokenized and added with special tokens of [CLS] and [SEP] tokens at the beginning and the end of tokenized sequence respectively. For the input length, the maximum sentence length was limited to 128 tokens in this study. After that, these modified sequences were fed into token, segment, and position embeddings sequentially to generate the initial input embedding, which in turn fed into encoder layers within IndoBERT for further processing.

In IndoBERT, the initial embedding of each token was passed through multiple sub-layers consisting of multi-head self-attention and Feed-forward Network to incorporate the contextual information. The final output contextualized embedding was extracted through a mean pooling strategy. The overview of the word embedding process for IndoBERT is illustrated in Fig. 2.

F. Multi-Label Classification

1) Conventional multi-label classification: To build conventional multi-label models, the output contextualized embeddings and target labels were transformed using problem transformation methods. Binary Relevance (BR), Classifier Chain (CC), and Label Powerset (LP) were used to convert the data into binary or multi-class problems. Classifiers such as Gaussian Naïve Bayes (NB), Support Vector Machine (SVM), Random Forest (RF), and Linear Stochastic Gradient Descent (SGD) were then applied for classification.

2) IndoBERT (As end-to-end model): To perform multi-label classification directly using IndoBERT, an additional classifier layer was added at the uppermost level of the model. Final output embedding from mean pooling layer was fed into the classifier layer directly for multi-label classification as shown in Fig. 3. In this strudy, the hyperparameters values of classifier layer mirrored the literature findings of [33], which set to "learning rate = 2e-5, batch size = 8, and epoch =5", optimizing with Adam optimizer. Because IndoBERT was designed to perform multi-label classification, sigmoid function was used rather than SoftMax in classification layer. The formula of sigmoid function is shown in (1). The output probability from sigmoid activation function for each aspect-label is a real number within the range of 0 to 1. Given that the study applied the default threshold value of 0.5, any predicted probability of the label greater than 0.5 was referred to present and less than 0.5 was considered as absent.

$$\sigma(x)= 1/(1+e^{(-x)}) \quad (1)$$

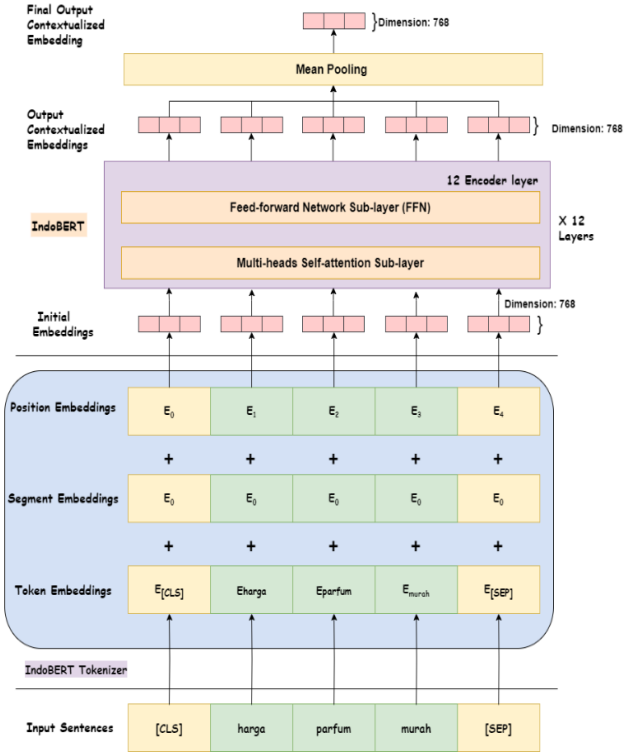

Fig. 2. Overview of word embedding process for input sentence by IndoBERT.

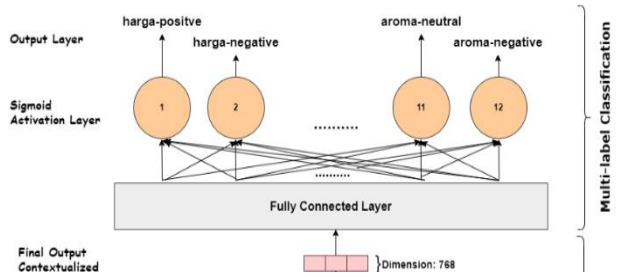

Fig. 3. Multi-label classification process within IndoBERT.

G. Evaluation Metrics

In this study, several evaluation metrics were employed to evaluate the sentiment classification model performance.

1) Accuracy per label: This metric assesses the number of correctly predicted labels over the total number of instances,

computing using (2), where TP and TN refer to True Positive and True Negative, respectively. Given that it evaluates the model's correctness on individual labels (column) independently, accuracy is commonly used in single label classification. In this study, this metric was utilized for comparing the performance of multi-label with single-label models in Experiment I.

$$\text{Accuracy per label} = (TP + TN) / Total \quad (2)$$

2) Accuracy: This accuracy metric calculates the probability of the correctly classified labels by considering the overlap between the true data, Y_i and predictive data, Z_i for each instance, as computed by the (3). In this study, this metric was used as one of the main references in assessing the multi-label sentiment classification model performance in Experiment II and III.

$$Accuracy = 1/N * \Sigma | Yi \cap Zi | / | Yi \cup Zi | \quad (3)$$

3) Hamming loss: Hamming Loss is the prominent evaluation metric of multi-label classification that measures the proportion of wrongly classified labels over all instances. In contrast with typical metrics, the lower the value hamming loss represents the higher performance of model. The formula for computing hamming loss is shown in (4). It was used to evaluate the multi-label model performance in this study.

$$\text{Hamming Loss} = 1/N * \Sigma | Yi \, \Delta \, Zi | \quad (4)$$

4) Micro-F1 score: Micro F1-score is a harmonic mean of precision and recall calculated based on classes, shown in (5), where P and R represent precision and recall respectively. Precision measures the proportion of the chosen items that are correct over the actual instances that are predicted as chosen while recall is a metric uses to gauge the percentage of correct items that are selected. The formula of precision and recall is shown in (6) and (7).

$$F1-score = 2PR/(P+R) \quad (5)$$

$$Precision = 1/N * \Sigma | Yi \cap Zi | / | Zi | \quad (6)$$

$$Recall = 1/N * \Sigma | Yi \cap Zi | / | Yi | \quad (7)$$

IV. Results

A. (EDA) Results

Table II presents the Chi-square test results between aspects, showing that most p-values were below 0.05, indicating variable dependency. From the results, it can be observed that nearly all the resulting p-values were less than threshold value 0.05.

TABLE II. Chi-Square Test Results Between Different Aspects of Cosmetic Product

Variable 1	Variable 2	p value	Null hypothesis
harga	pengeamsan	0.0147	Rejected
	produk	6.5113e-24	Rejected
	aroma	3.4954e-12	Rejected
pengemasan	produk	4.3069e-13	Rejected
	aroma	0.0689	Accepted
produk	aroma	1.2633e-25	Rejected

B. Experimental Results I

In this experiment, the baseline single label classification model was replicated based on the methodology from [29]. The method primarily employed Word2Vec to vectorize the text reviews and utilized Gaussian NB to classify the sentiment for each aspect independently. Given that there were four aspects, the model iterated four times to complete the prediction for all aspects. Table III presents the empirical outcomes of baseline from our experiment and [29].

TABLE III. Comparison of Accuracy Per Label of Baseline Single Label Model and Our Experiment

Source	Average Accuracy per Label (%)	Accuracy per Label (%)			
		Price	***Packaging***	***Product***	***Aroma***
[29]	68.17	70.96	68.79	56.36	76.57
Our experiment	62.47	60.33	74.39	48.18	66.99

From Table III, it shows that there was approximately 6% reduction in average accuracy when comparing the replicated model with [29]. The differences can be attributed to factors such as differences in the parameters setting of Gaussian NB as [29] did not include any details about their parameters while this study proceeded with default settings. To mitigate the influences from external factors, an accuracy of 62.47% is used as a reference value for comparing the performance of multi-label models.

Fig. 4 shows that multi-label models perform differently in determining sentiment for Indonesian cosmetic product reviews. Models using BR and CC problem transformation methods had performance comparable to the baseline. The BR model achieved the same accuracy of 62.47% as the baseline, likely due to their similar classification approach. However, the other two multi-models with LP and RAkEL D, exhibited notable enhancement in accuracy over the baseline single label model, achieving 70.18% and 70.16%, respectively.

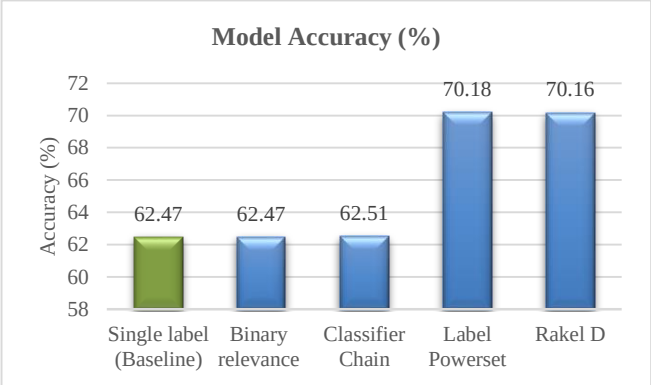

Fig. 4. Average of accuracy per label for single label and multi-label models.

C. Experimental Results II

In Experiment II, the study evaluates the performance of IndoBERT as word embeddings in representing the words from cosmetic domain, using Word2Vec as the baseline. Building upon the findings of Experiment I, LP and RAkEL D, each was used to transform the multi-label problem in the model while Gaussian NB classifier was utilized to classify the aspect-sentiment labels to each review, along with Word2Vec. The IndoBERT word embedding model was employed in parallel, aiming to determine its effectiveness compared to Word2Vec. The results are summarized in Table IV.

TABLE IV. PERFORMANCE OF MULTI-LABEL MODELS USING DIFFERENT EMBEDDING MODELS IN EACH MULTI-LABEL APPROACH

Transformation Approach	IndoBERT version	Accuracy (%)	Hamming Loss (%)	Micro F1-score (%)
Label Powerset	Word2Vec	54.75	22.27	66.66
	IndoBERT[b]	60.39	19.15	71.28
	IndoBERT[k]	47.70	26.18	60.73
	IndoBEETweet	61.10	18.72	71.91
RAkEL D	Word2Vec	53.60	24.96	66.12
	IndoBERT[b]	57.79	20.81	69.97
	IndoBERT[k]	41.86	31.87	56.21
	IndoBERTweet	57.55	21.09	69.76

Overall, both IndoBERT[b] and IndoBERTweet consistently outperformed the baseline Word2Vec embedding model, regardless of the problem transformation approaches used in classification model. For models with LP approach, there was an approximate 5% to 6% improvement in accuracy and micro F1-score when comparing the multi-label models with Word2Vec to IndoBERT[b] and IndoBERTweet. On the other hand, the models employing RAkEL D exhibited only a 2% to 3% enhancement in accuracy and micro F1-score. For hamming loss in the models employing both LP and Rakel D, an approximately range of 3% to 4% reduction was observed when comparing the baseline with each of the IndoBERT[b] and IndoBERTweet, indicating a decrease in misclassification occurrences in models employing both methods.

D. Experimental Results III

This experiment evaluated IndoBERT's performance in direct multi-label classification. Building on results from Experiments I and II, conventional multi-label models using IndoBERT[b] and IndoBERTweet were developed with various classifiers. The results are shown in Tables V and VI, while Table VII presents IndoBERT's empirical performance.

TABLE V. PERFORMANCE OF CONVENTIONAL MULTI-LABEL MODEL USING INDOBERT[B] AS TEXT REPRESENTATION METHOD

Model	Accuracy (%)	Hamming Loss (%)	Micro F1-score (%)
Label Powerset + NB	60.45	19.12	71.33
Label Powerset + SVM	69.64	14.20	78.69
Label Powerset + RF	63.3	17.45	73.82
Label Powerset + SGD	65.48	16.36	75.47
RakEL D + NB	56.81	21.43	68.90
RakEL D + SVM	68.31	14.26	78.59
RakEL D + RF	62.93	16.60	74.18
RakEL D + SGD	65.31	15.99	75.94

TABLE VI. PERFORMANCE OF CONVENTIONAL MULTI-LABEL MODEL USING INDOBERTWEET AS TEXT REPRESENTATION METHOD

Model	Accuracy (%)	Hamming Loss (%)	Micro F1-score (%)
Label Powerset + NB	61.15	18.70	71.95
Label Powerset + SVM	68.14	14.92	77.61
Label Powerset + RF	62.54	17.82	73.26
Label Powerset + SGD	63.38	17.54	73.69
RakEL D + NB	56.71	21.49	69.13
RakEL D + SVM	66.88	14.86	77.57
RakEL D + RF	61.94	17.42	73.26
RakEL D + SGD	64.71	16.35	75.75

TABLE VII. PERFORMANCE OF MULTI-LABEL MODELS WITH INDOBERT AS END-TO-END MODEL

Model	Accuracy (%)	Hamming Loss (%)	Micro F1-score (%)
IndoBERT[b]	86.98	5.45	91.70
IndoBERTweet	86.21	5.85	91.12

The results show that the end-to-end model significantly outperformed the conventional multi-label models. It can be observed that there was a significant enhancement in end-to-end model performance when using IndoBERT[b] and IndoBERTweet, with accuracy increasing by approximately 18% to 30% and the micro F1-score by 13% to 22%, compared to both the highest and lowest performing conventional models based on the same IndoBERT embedding. In terms of hamming loss, using IndoBERT[b] and IndoBERTweet directly for multi-label classification reduced significantly (8% to 16%) in classifying wrongly the aspect-sentiment label for cosmetic product review.

V. DISCUSSION

The results of p-values from EDA showed that most of the null hypotheses were rejected, suggesting that the variables are dependent on each other. These dependencies indicate the presence of an aspect's sentiment might affect the prediction of sentiment of another aspect. Given this dependency, it implies a need to explore the Indonesian cosmetic product review dataset with multi-label model.

There are three categories of multi-label classification methods: Problem transformation, algorithm adaptations, and pre-trained language model. For the problem transformation, the BR model transforms the multi-label task into 12 single-label problems, performing independent classification for each label, much like the baseline. Unlike BR, multi-label model with CC

problem transformation method considered label correlation into account. However, it still demonstrated comparable accuracy with 62.51% to baseline. One of the possible reasons might be the influences by the arbitrary arrangement of labels, which could lead to the poor performance in CC model [34] [35]. In contrast with BR and CC, the other two multi-models with LP and RAkEL D, exhibited notable enhancement in accuracy over the baseline single label model, achieving 70.18% and 70.16%, respectively. There was approximately 8% improvement of accuracy in multi-label models with LP and Rakel D methods over baseline. This suggests LP and RAkEL D are more suitable for multi-aspect sentiment classification. The improvement is probably due to both multi-label models considering label dependencies, with LP capturing co-occurrence relationships by converting the problem into combinations of labels, and RAkEL D enhancing performance by training Gaussian NB on distinct label subsets, improving label correlation handling.

In terms of text representation, as expected, IndoBERT outperformed Word2Vec as a word embedding model due to its architectural design. Word2Vec, using the CBOW architecture with a fixed window produces static embeddings, which lack contextual information. In contrast, IndoBERT generates contextualized embeddings by learning from masked tokens, capturing semantic relationships and nuances. This contextual richness allows IndoBERT to provide more refined input vectors, enabling the Gaussian NB classifier to more accurately classify aspect-sentiment labels. IndoBERT[k] performed worse than the baseline Word2Vec, indicating that contextualized embeddings don't always outperform static embeddings, as seen in study [36]. The varying performance among IndoBERT variants may stem from differences in pre-training datasets. IndoBERT[k], trained primarily on formal text, struggles with the informal language in product reviews. In contrast, IndoBERT[b] and IndoBERTweet, pre-trained on informal data like social media, are better equipped to handle the mixed linguistic style found in the reviews.

Given that multi-label classification can be performed directly using pre-trained language models as end-to-end model, this paper proposes using IndoBERT and IndoBERTweet for classification, as these two pre-trained language models have demonstrated high accuracy in terms of text representation. The results show that the proposed end-to-end model significantly outperformed the conventional multi-label models. These findings align with outcomes from [9] and [15], suggesting that IndoBERT generalizes multi-label classification tasks better than conventional models. This is likely due to the architectural differences between IndoBERT and traditional classifiers. IndoBERT, using neural networks, is more complex, flexible, and better equipped to handle intricate patterns in the dataset compared to simpler linear, tree-based, or probabilistic classifiers like SGD, SVM, RF, and Gaussian NB [37].

For conventional multi-label models, it can be observed that a similar trend of classifier performance was exhibited across multi-label transformation approach and word embedding. Notably, SVM consistently demonstrated superiority in correctly multi-classifying labels, followed by linear SGD, RF and Gaussian NB. These results aligned with classification results for two out of three datasets in the study of [9], which found that SVM outperformed linear SGD, followed by RF, regardless of whether LP or Rakel D was used.

VI. Conclusion

This study developed a reliable multi-label ABSC model while exploring the performance of contextual word embedding in representing words from the Indonesian cosmetic domain. Three experimental experiments evaluated different multi-label classification approaches. The results showed that IndoBERT[b] and IndoBERTweet provided more refined text representation, improving performance approximately by 2% to 6% compared to Word2Vec. The findings also demonstrated that multi-label models using IndoBERT as an end-to-end model outperformed conventional methods. IndoBERT[b] achieved the best accuracy of 86.98%, showing a 17.34% to 30.27% improvement over the baseline, confirming its superiority for multi-label classification in this domain. Although this study demonstrated notable improvements, certain limitations remain. The study investigated only one type of contextual embedding model, IndoBERT. To further enhance the multi-label model, future work could explore other contextual embeddings, such as DistilBERT and RoBERTa. Additionally, the hyperparameter settings for the end-to-end IndoBERT model were restricted to "learning rate = 2e-5, batch size = 8, and epoch = 5." Future research could experiment with different hyperparameter combinations, as there is no one-size-fits-all setting for optimizing the model.

***Abstract*—Plant disease diagnosis at an early stage enables farmers, gardeners and agricultural experts to manage and control the spread of illnesses in a timely and suitable manner. The traditional methods of plant disease diagnosis are expensive and might need significant manpower and advanced level machinery. In addition to that, conventional methods, such as visual inspections are prone to subjectivity, time constraints and error susceptibility. In comparison to that, computer based methods such as machine learning is accurately predicting plant diseases underscore the need for a transformative approach. However, by focusing solely on visualized contents and thermal images, these methods overlook the potential insights hidden within customer-posted images that may leads to low accuracy. This study is an attempt to addresses these gaps by proposing an alternative methodology which relies on a hybrid deep learning framework called CCNET. The core CCNET is the utilization of the superiorities of Convolutional Neural capsule network models to get better architecture for plant diseases diagnosis. The proposed CCNET effectively amalgamates the strengths of convolutional layers for spatial feature extraction and the sequential modelling capabilities of CNN and CapsNet for capturing temporal dependencies within image data. The performance of the CCNET has been evaluated through rigorous experimentation. The outcomes underscore the remarkable prowess of the proposed model with the accuracy of 94%. When it compared to the conventional methods, the CCNET surpasses all of them in terms of precision, recall, F-Score, and accuracy.**

***Keywords*—CapsNet; classification; CNN; feature extraction; plant disease; thermal images**

I. Introduction

The agricultural industry holds immense significance for numerous nations globally, serving as a crucial source of sustenance, materials and energy to support the expanding population. Apart from its economic value, agriculture plays a pivotal role in addressing pressing global issues such as climate change, ensuring food security, and promoting sustainable development. As per the Food and Agriculture Organization of the United Nations (FAO), agriculture engages over one billion individuals worldwide and contributes approximately 3% to the overall global gross domestic product (GDP) [1].

However, this sector encounters noteworthy obstacles, including the imperative to augment food production to fulfill the rising needs of the world's growing inhabitants. While concurrently mitigating the environmental impact associated with agricultural practices. Additionally, the prevalence of plant diseases poses a substantial menace to agricultural productivity, leading to crop losses that range from 10% to 40% on a global scale [2]. Plant diseases can cause extensive damage to crop, resulting in significant economic losses for farmers worldwide. Fig. 1 shows the typical leave disease that effect the production of plant. As per the Food and Agriculture Organization (FAO) of the United Nations, plant diseases account for the annual loss of approximately 20–40% of global crop production [3]. An efficient and effective plant disease management system is therefore essential for ensuring the sustainability and productivity of the agriculture sector.

Fig. 1. Leaf disease example adopted from study [5].

*Corresponding Author

The conventional farm management practices rely on human experts to monitor plants in the field for signs of disease, which can be time-consuming, labor-intensive and prone to errors. However, visual symptoms of plant diseases usually appear several days after infection, indicating that the illness has already disseminated and the quality of yield has declined, leading to significant losses in productivity [4]. Most of the disease control process usually adopted appropriate control measures, such as the utilization of resilient crop strains, farming techniques and chemical treatments. But due to the increasing number of diseases and expensive chemical, this job become quiet hectic and time consuming.

Alternative to the conventional methods, Smart farm management practices, which rely on vision technology and machine learning, have revolutionized plant disease management by allowing for early detection and prevention of crop losses. According to a study [6], smart farm management practices have led to increased agricultural productivity and improved food security in many countries. These technologies are particularly useful in remote areas where access to expert knowledge and resources is limited. By implementing these practices, farmers can detect plant diseases before visual symptoms appear, ultimately increasing crop yields and contributing to the overall economic growth of the country.

The development and adoption of new technologies, including the use of computer science and artificial intelligence, can be better attempt that helps in the timely identification and control of plant diseases. Vision technology, which is widely used in modern smart farm management practices, has the potential to address some of these challenges by processing and analysing images of infected plants to identify disease patterns [7]. However, this approach is limited in that it does not accomplish early detection, presuming that plants are still in the incubation phase prior to the disease's manifestation [8]. This highlights the need for alternative approaches that can detect diseases at an early stage, before visible symptoms appear, to prevent significant crop losses and increase productivity.

However, the variations of diseases at different of plants and temperature discrepancies in the infected plants that are imperceptible to the human eye may require more sophisticated mechanism [9]. The application of thermal imaging as depicted in Fig. 2, in plant disease management has emerged as a promising approach for early detection and control of diseases. By recording the temperature of plants, thermal imaging enables the identification of temperature changes that can indicate the presence of disease. These temperature changes are a result of internal chemical alterations that occur in plants following disease inoculation. Analysing these temperature variations allows for the early detection of diseases before visible symptoms manifest.

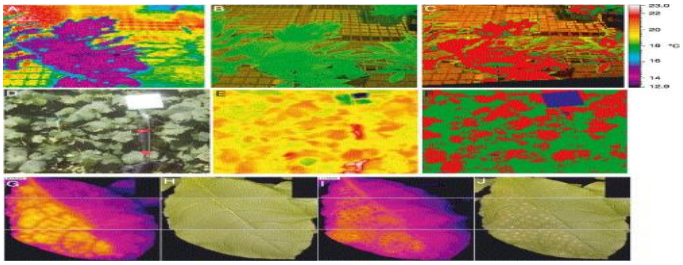

Fig. 2. The Geo-informatics-based view of plant thermal images.

It is concluded that thermal imaging and machine learning technologies have the potential to revolutionize plant disease management and increase crop productivity by predicting and preventing the spread of plant diseases. This research addresses the above discussed gaps by proposing an alternative methodology that is based on hybrid deep learning model called CCNET. The core CCNET is the utilization of the superiorities of Convolutional Neural Network-Gated Recurrent, Bidirectional Long Short-Term Memory and Conditional Random Field models to get better architecture for plant diseases diagnosis from thermal images. The proposed CCNET effectively amalgamates the strengths of convolutional layers for spatial feature extraction and the sequential modelling capabilities of CNN and CapsNet for capturing temporal dependencies within image data.

A. *Research Contribution*

The key contribution of the proposed research are as follows:

1) The proposed CCNET is an attempt to efficiently diagnosing plant disease by using thermal images that perform detection at early stage before visible symptoms appear that is not tackled in the previous literature to prevent significant crop losses.

2) The utilization of advance level deep learning methods such as CNN and CapsNet provide better identification as compared to machine learning algorithms that are based on static similarity measures.

3) Experimental evaluation on thermal imaging and comparative analysis with benchmark methods has proved that the performance of proposed CCNET surpasses the existing works by obtaining an accuracy of 94 %.

The rest of the paper is organized as follows: An overview of the relevant research is presented in Section II. The proposed CCNET is briefly described in Section III. The experimental evaluation and discussion has been discussed in Section IV. The conclusion and future work are given in Section V.

II. Related Work

The utilization of digital images for the categorization of plant diseases presents a significant hurdle. However,

advancements in machine learning techniques, particularly deep learning, have facilitated the identification, detection, and diagnosis of plant diseases. In the article [10], a combined model is proposed that merges two pre-trained convolutional neural networks (CNNs), specifically VGG16 and VGG19, to classify images of healthy and diseased leaves for the purpose of diagnosing plant diseases. CNNs are employed due to their capacity to overcome the technical intricacies associated with the classification of plant diseases. Nonetheless, CNNs pose a challenge in terms of hyper parameters, necessitating manual identification of specific architectures to attain optimal performance. To tackle this challenge, the paper utilizes the orthogonal learning particle swarm optimization (OLPSO) algorithm to optimize the hyper parameters by determining the optimal values instead of relying on traditional trial and error methods.

In another work, specifically focuses on charcoal rot, a fungal disease that affects soybean crops globally and is transmitted through soil [11]. In their study, the authors propose a unique 3D deep convolutional neural network (DCNN) that directly incorporates hyper spectral data and provides meaningful physiological explanations through model interrogation. Their proposed model achieves an impressive classification accuracy of 95.73% and an infected class F1 score of 0.87 when analysing hyper spectral images of both inoculated and mock-inoculated stem samples. By employing an explainable deep learning model, the study not only achieves high accuracy but also provides valuable physiological insights into the model's predictions, thereby increasing confidence in the reliability of these predictions.

The work of study [12] provide a comprehensive overview of the existing literature on neural network techniques that are employed for processing image data in the detection of crop diseases. They claim that predictions are particularly relevant for precision agriculture and research applications that utilize automated phenotyping platforms. The goal of this survey is to enhance the performance and accuracy of deep learning in detecting plant diseases, with the potential to significantly impact sustainable agriculture. Hyper spectral imaging has emerged as a potent tool for plant disease identification, but its effectiveness heavily relies on the choice of deep learning models. Convolutional neural networks (CNNs) have been identified as the most promising models for diagnosing and predicting crop infections.

TABLE I. COMPARATIVE ANALYSIS OF THE EXISTING RESEARCH METHODS

Reference	Methodology	Data Set	Accuracy	Limitations
[15]	Support Vector Machines (SVM)	Thermal images	90%	The study was only conducted on wheat crops under moisture stress conditions, which limits the generalizability of the findings to other crops and growing conditions.
[16]	Support vector machine (SVM), Gaussian kernel and Random Forest	High-resolution thermal image	82%	Only evaluates model accuracy for detecting decline, not effectiveness of management interventions, and is geographically specific.
[17]	Feature weighted random forest (FWRF)	27 olive orchards	92%	Study's insights on olive orchards affected by Xf and Vd outbreaks in 2011-2017 Italy and Spain may not apply to other regions or timeframes.
[18]	Multiple Linear Regression (MLR)	IoT-sensed crop Dataset	91%	Restricted to blister blight in tea plants, doesn't address other diseases, and relies on IoT sensor accuracy for environmental data.
[19]	Dual-stream hierarchical bilinear pooling model	Field-obtained dataset	84.71%	The study only demonstrates accuracy in identifying plants and diseases on a specific field dataset, with uncertain generalizability to other crops or datasets.
[20]	14-DCNN	147,500 images of 58 different healthy and diseased plant lea.	91.79%	Does not discuss the real-world application and the limitations that the proposed model may face when deployed in the actual environment.

Gadekallu et al. [13] emphasizes the importance of ensuring a consistent supply of healthy food for the growing global population, as well as the economic significance of agriculture in developing countries. To overcome these challenges, their study focuses on harnessing the power of machine learning models to classify tomato diseases, with the aim of proactively addressing agricultural crises. Their research utilized a publicly available dataset from plant-village to train and evaluate their model. They employed a hybrid approach that combines dimensionality reduction method. The extracted features were then fed into a deep neural network for the classification of tomato diseases. To demonstrate the effectiveness of their proposed model, they compared their work with traditional machine learning techniques, showcasing its superior performance in terms of accuracy and loss rate metrics.

The utilization of automated approaches, such as machine learning and deep learning, for the prediction of plant species and diseases has been explored in the work of study [14]. In addition to this they also proposed a novel multi-task learning strategy, which leverages shared representations between these related tasks to enhance overall performance. Their proposed approach utilizes a multi-input network that incorporates raw images and transferred deep features extracted from a pre-trained deep model to predict both the plant's type and disease. An end-to-end multi-task model is developed, enabling the simultaneous execution of multiple learning tasks by integrating Convolutional Neural Network (CNN) features and transferred features. This approach has the potential to address the challenges associated with plant species and disease prediction by providing accurate predictions, reducing the time and cost required for manual prediction, and guiding decision-making processes in the context of sustainable agriculture.

From the above discussion, it has been concluded that, instead of traditional diagnosis methods that are hectic, expensive, and time-consuming, machine learning models perform better disease diagnosis. However, the detection of diseases at an early stage is still challenging. By foreseeing and halting the development of plant illnesses, thermal imaging, and machine learning technologies hold the promise of revolutionizing plant disease management and boosting

agricultural output. This research tries to fills the gaps of previously mentioned literature by giving an improved architecture by utilizing the advantages of Convolutional Neural Network-Gated Recurrent, Bidirectional Long Short-Term Memory, and Conditional Random Field models.

III. MATERIALS AND METHODS

This section discusses the proposed CCNET's core methodology, which is composed of data collection, pre-processing, feature extraction, and final classification. Fig. 3 depicts the diagrammatic flow of the proposed CCNET.

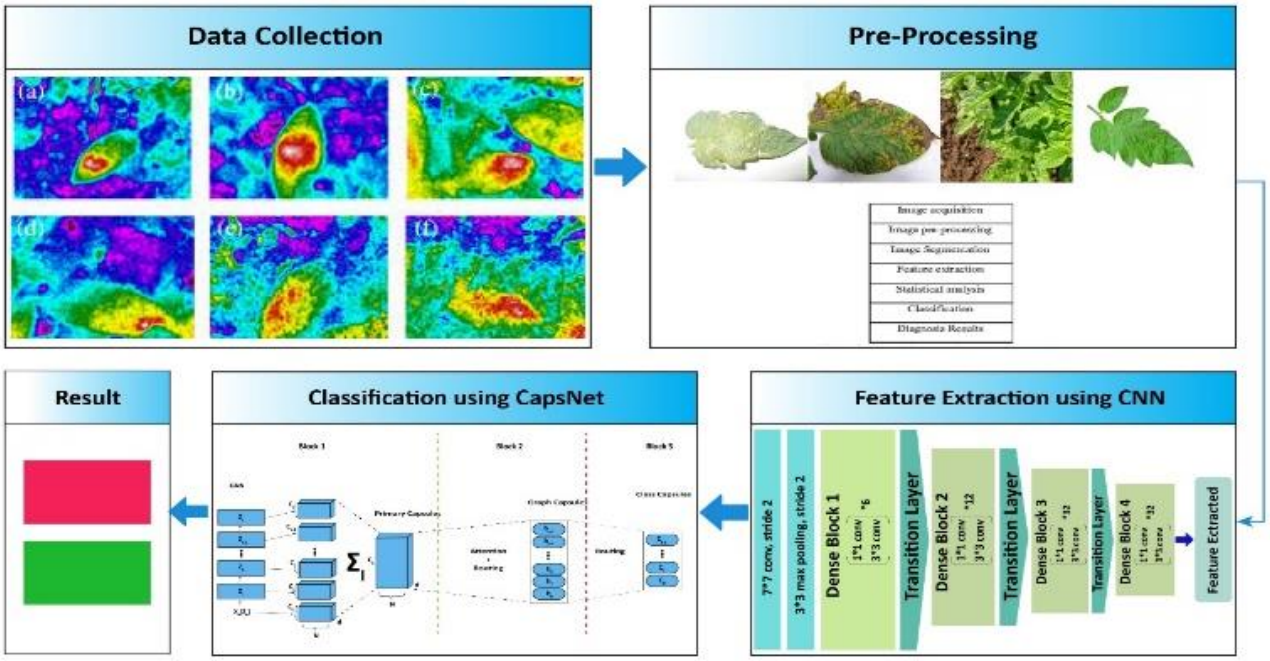

Fig. 3. The CCNET architecture for plant disease detection.

A. Data Collection and Description

In this research, thermal image-based datasets that are publicly available on the Kaggle repository have been used. The first dataset, DS-I, encompasses roughly 87,000 RGB images of plant leaves, categorized into 38 distinct health-related classes. Offline augmentation techniques were employed during its construction to ensure both authenticity and diversity. A separate collection comprising 33 test images was also established solely for predictive purposes. Another dataset that is DS-II, has 1132 images that focus on corn and maize leaf disease, derived from reputable sources like Plant Village and Plant Doc, meticulously tailored to address issues related to corn or maize leaf diseases.

The last dataset is DS-III, which contains 1401 images of rice leaf diseases. This dataset holds particular significance for regions characterized by low to lower-middle-income economies, where rice is crucial to food security. This dataset serves as a comprehensive compilation of crop leaf images, offering researchers in the agricultural science domain an opportunity to utilize it for further examination and exploration. The availability of such a dataset can facilitate the development of robust and precise models, aiding in the detection and classification of crop diseases and empowering farmers to identify such diseases at an early stage, thereby mitigating potential crop yield losses.

B. Pre-processing

After the formation of the dataset, the very next phase is the pre-processing. Algorithm 1 outlines the proposed pre-processing procedure. Initially, images are resized to a consistent dimension of 256x256 pixels. Pixel values are normalized via min-max normalization, representing pixel (x, y). Each image is randomly rotated within a defined angle range, and random horizontal or vertical flips are applied. A random zoom transformation is also employed. Additionally, images are converted to grayscale. Data is then organized into batches and shuffled using a randomized seed for training randomness assurance.

Algorithm 1: The Data Pre-Processing

```
def preprocess_image(image):
    resized = resize(image, (256, 256))
    normalized = (resized - np.min(resized)) / (np.max(resized) - np.min(resized))
    rotated = rotate(normalized, random.uniform(-30, 30))
    flipped = np.fliplr(rotated) if random.choice([True, False]) else np.flipud(rotated)
    zoomed = zoom(flipped, random.uniform(0.8, 1.2))
    grayscale = rgb2gray(zoomed)
    return grayscale
random.seed(42)
preprocessed_data = [preprocess_image(image) for image in original_data]
random.shuffle(preprocessed_data)
batches = [preprocessed_data[i:i+batch_size] for i in range(0, len(preprocessed_data), batch_size)]
```

By applying these pre-processing steps, the dataset is prepared in a format that can be effectively utilized for training deep learning models. Resizing the images ensures that the models can handle images of different sizes, while normalization and data augmentation techniques help enhance the dataset's diversity and reduce overfitting [21]. Finally, batching and shuffling the data enable efficient model training.

C. Feature Extraction

There exist too many deep learning models that are used for image based feature extraction. However, convolutional neural networks (CNNs) are the most demanding due to their exceptional ability to capture hierarchical patterns and spatial dependencies in images [22-26]. In the proposed CCNET, the CNN model starts with the convolution operation, where the dot product is calculated between input image patches and adaptable filter weights, uncovering specific attributes within localized areas as shown in Fig. 4. Subsequently, the Pooling operation comes into play, particularly Max pooling. This technique is renowned for its efficiency, selectively highlighting the highest value within a predefined window, distilling the essential information while retaining the core of the data. The process culminates with flattening, a transformative step that restructures pooled feature maps into a streamlined one-dimensional vector. This sequence effectively transforms raw images into compact yet enriched features, crucial for subsequent analytical processes.

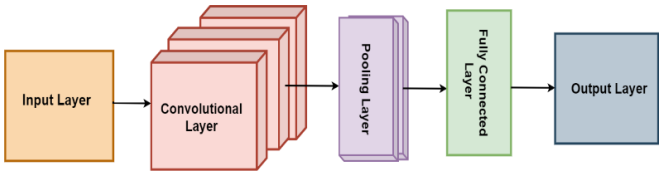

Fig. 4. The feature extraction workflow using CNN.

D. Classification

In comparison to the traditional CNN, Capsule Networks (CapsNet), is an alternative architecture for image classification. CapsNet was introduced by Geoffrey Hinton and his colleagues in 2017 [27-34] and was designed to address some of the limitations of CNNs, especially when it comes to handling spatial hierarchies, pose variations, and viewpoint changes. The CapsNet is a layered network in which the first layer of a Capsule Network typically consists of primary capsules. Each primary capsule is responsible for detecting a particular visual feature along with it numeric values in an image. Instead of using convolutional layers like CNNs, Capsule Networks use a combination of convolutional layers and capsules. These capsules output a vector representing a specific feature's presence along with its pose information. Whereas the pose estimation layer handles variations in the pose (position, orientation, etc.) of the detected features. Each capsule outputs a vector representing the probability of the feature's presence and pose parameters (such as position and orientation). The architecture is shown in Fig. 5.

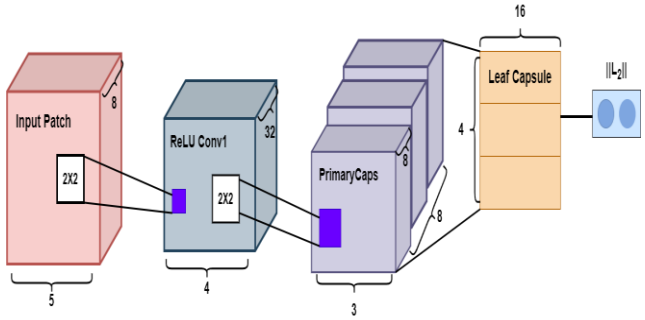

Fig. 5. The typical CapNet architecture for thermal image classification.

One of the key innovations of CapsNet is the routing algorithm. This algorithm aims to find the agreement between capsules in one layer and capsules in the subsequent layer. It ensures that capsules with similar features and poses "agree" with their predictions. This process helps to establish a more coherent and dynamic representation of hierarchical features. In addition to this, dynamic routing involves iterative updates of the coupling coefficients between capsules in different layers. This process encourages capsules that agree to have higher coupling coefficients, while capsules that disagree have lower coefficients. It allows the network to learn better feature hierarchies and spatial relationships. The final layer of capsules is used for classification. Each capsule in this layer represents a specific class, and the length of the capsule's output vector indicates the probability of the image belonging to that class.

IV. Experimental Results

This section thoroughly examines the experimental analysis and evaluates the proposed methodology. The proposed CCNET has been evaluated on three different datasets already discussed in the data collection section. It has also been compared with three baseline techniques and five machine learning models to test its accuracy and efficiency through a series of rigorous experiments.

A. Baseline Method

The following baseline reference models have been considered for comparison and evaluation of efficiency.

1) Banerjee et al. [24]: This study employed thermal imaging technology to capture images of wheat crop canopies and aimed to estimate the leaf area index (LAI) under varying moisture stress conditions. Their method was based on Maximum Likelihood Estimation, Box Classifier, and Support Vector Machines.

2) Poblete et al. [25]: They employed a Feature Weighted Random Forest (FWRF) classification model on olive orchards affected by specific outbreaks (Xf and Vd) in a limited timeframe and region might restrict the generalizability of its findings to other areas and time periods.

3) Zhiyan Liu [26]: This study focused on IoT-sensed crop fields, specifically addressing blister blight in tea plants with the utilization of multiple linear regression (MLR).

B. Results

Fig. 6 shows a comprehensive overview of the experimental results of CCNET on three distinct datasets—DS-I, DS-II and DS-III. On DS-I, the CCNET achieved 0.92 accuracy, 0.91 precision and 0.90 recall indicating that the model is enough capable to correctly predict plant disease. Whereas for DS-II, the accuracy remains high at 0.93, signifying the model's consistent ability to make accurate predictions across different datasets. In the last, the accuracy on DS-III is 0.94, indicating that the model remains robust in different plant health contexts. Whereas, the precision score is 0.92, suggesting that the model effectively predicts plant diseases without excessive false positives. Based on this measure, the predicted ROC curve is also demonstrated in Fig. 7 to clearly mention the superiority of CCNET.

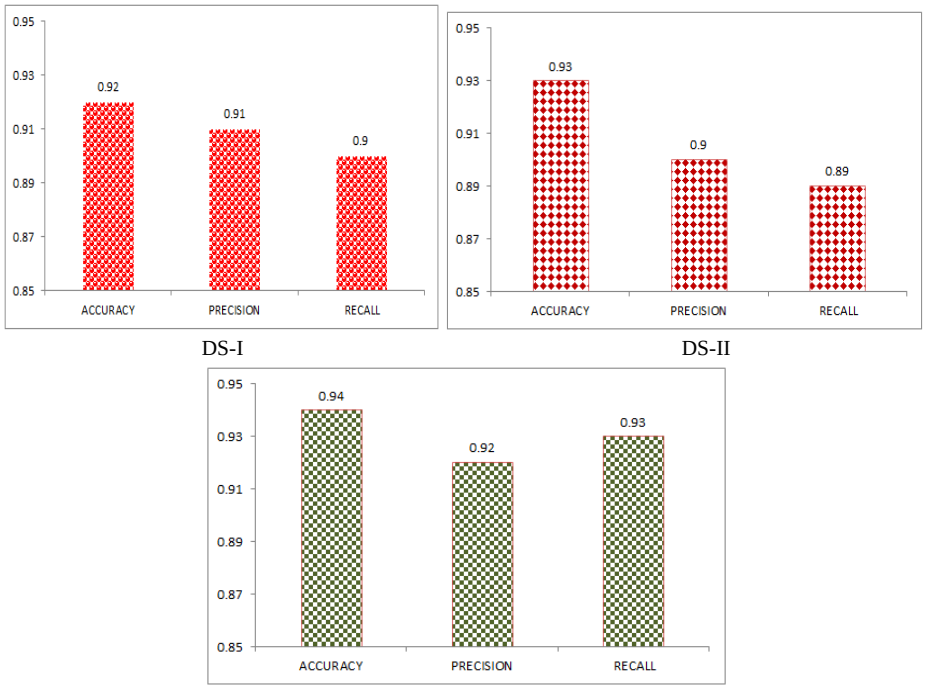

Fig. 6. Experimental results of CCNET in terms of precision, recall and accuracy.

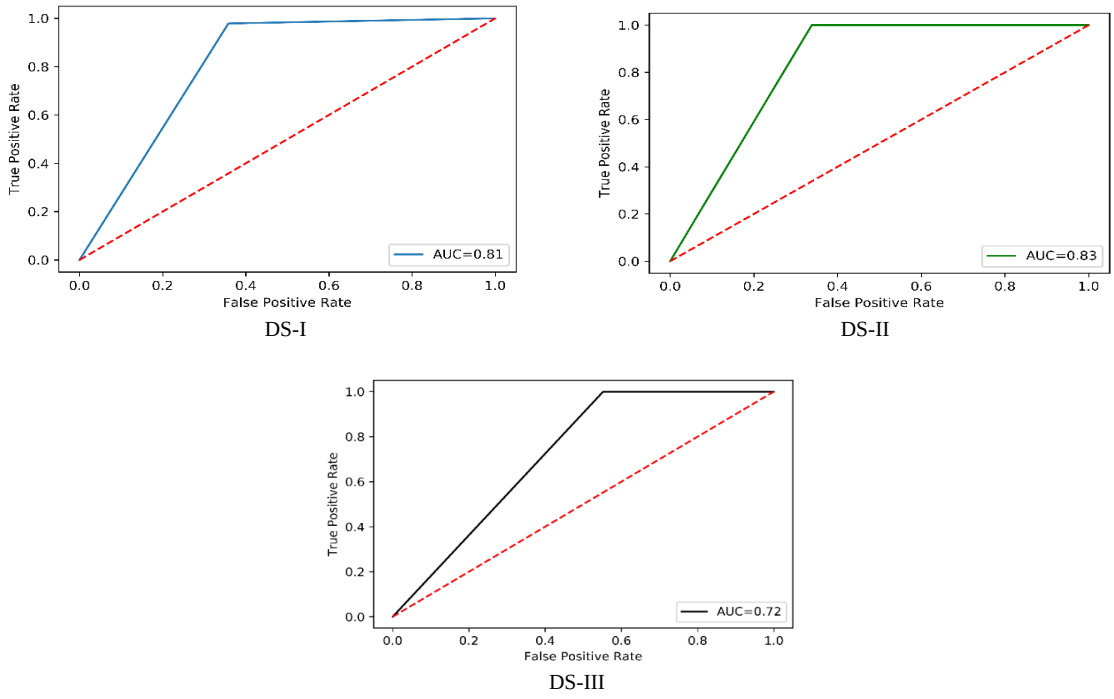

Fig. 7. ROC curves on DS 1, DS II and DS III.

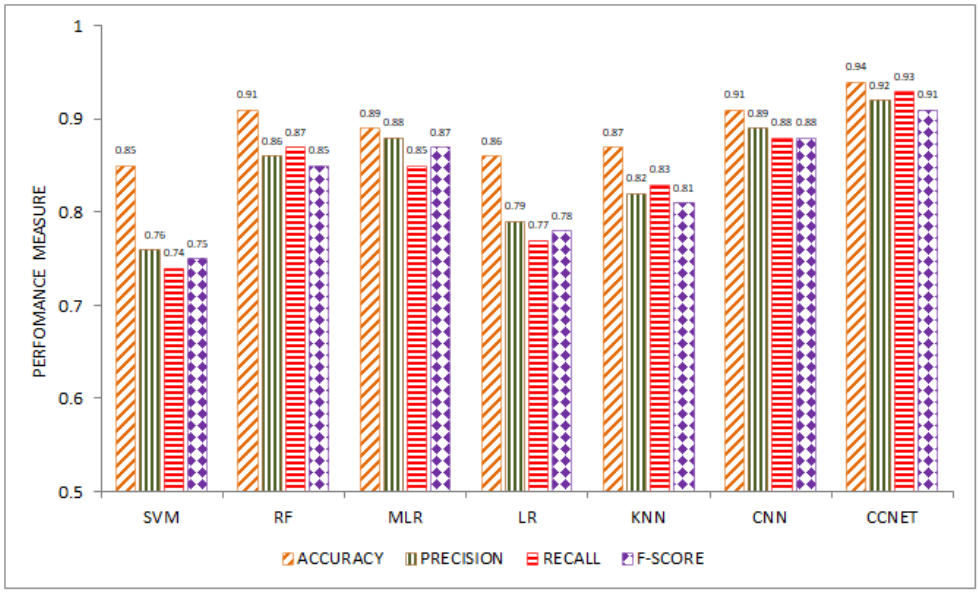

Fig. 8. Comparison of CCNET with machine learning models.

Fig. 8 presents a comprehensive comparative analysis between the proposed CCNET techniques and with standard machine learning model. The graphical values show that CCNET achieves a remarkable performance with 0.92 precision, 0.93 recall, 0.91 F1-Score and 0.94 Accuracy. This results shows that the CCNET gets a significant fraction of correctly identified positive instances in relation to the total actual positive instances.

In the last experiment, a thorough comparison of the CCNET with baseline methods was conducted by using DS-I, DS-II and DS-III to assess the accuracy. The graphical demonstration at Fig. 9 shows the superiority of the CCNET by beating the baseline with the variation of 6%, 7% and 9% respectively.

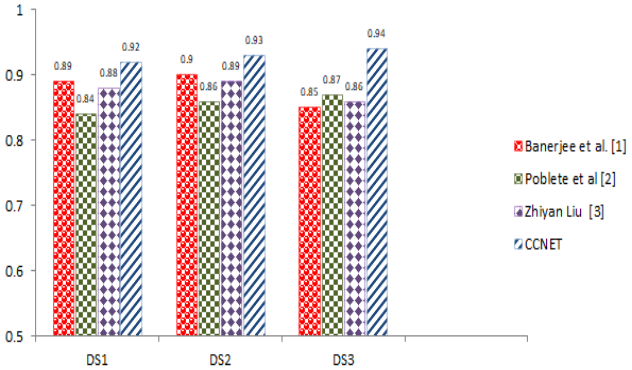

Fig. 9. Experimental analysis of CCNET with baseline models.

V. Conclusion

Plant disease diagnosis at early stages enables farmers to manage and control the spread of diseases in a timely and appropriate manner. Traditional methods for diagnosing plant diseases are costly and may necessitate a large number of personnel and sophisticated equipment. In addition, conventional methods, including visual inspections, are subject to subjectivity, time constraints, and error susceptibility. Whereas, the machine learning models based solution are limited to thermal images and leads to poor accuracy. In this research, a new model CCNET based on deep learning model has been proposed. The key steps of CCNET are data collection of thermal images, feature extraction and CapsNet based final classification. The evaluation of CCNET has been performed on three different datasets. The experimental results and comparative analysis provides a compelling evidence of the significant potential CCNET. The results demonstrate that the CCNET gets high accuracy with the value of 0.94, 0.93 and 0.92 on three different datasets and beat the base line methods with the variation of 6%, 7% and 9%. Looking forward, future research should concentrate on integrating multiple imaging modalities, such as hyperspectral or multispectral data, to further heighten disease detection accuracy. Expanding the training dataset to encompass a broader range of diseases and addressing class imbalances will bolster the model's generalization and robustness. Additionally, incorporating contextual information, developing interpretability techniques, and optimizing the model for real-time implementation are pivotal areas for advancement.

***Abstract*—Efficient virtual machine (VM) movement and task scheduling are crucial for optimal resource utilization and system performance in cloud computing. This paper introduces AMS-DDPG, a novel approach combining Deep Deterministic Policy Gradient (DDPG) with Adaptive Multi-Agent strategies to enhance resource allocation. To further refine AMS-DDPG's performance, we propose ICWRS, which integrates WSO (Workload Sensitivity Optimization) and RSO (Resource Sensitivity Optimization) techniques for parameter fine-tuning. Experimental evaluations demonstrate that ICWRS-enabled AMS-DDPG significantly outperforms traditional methods, achieving a 25% improvement in resource utilization and a 30% reduction in task completion time, thereby enhancing overall system efficiency. By merging nature-inspired optimization techniques with deep reinforcement learning, our research offers innovative solutions to the challenges of cloud resource allocation. Future work will explore additional optimization methods to further advance cloud system performance.**

Keywords*—Adaptive multi-agent; cloud-based; hybrid optimization; task scheduling; virtual machine migration; gradient technique

I. INTRODUCTION

Blockchain, shadow computer together with expert system are simply a few of the brand-new cordless modern technologies that have actually substantially aided the Net of Points (IoT). Since shadow computer can offer a wide range of tasks it has actually brought in substantial interest from government firm, business together with academic community alike [1] Haze computer, energy computer and also various other elements are incorporated. The most effective feasible source as well as outcome performance is an additional objective of the need model [2] Various cloud kinds such as personal, public, hybrid, mobile and also cloud federation have actually been released to please the large range of requirements. System as a Service (PaaS) Infrastructure as a Service (IaaS) as well as Software as a Service (SaaS) are the three primary classifications of cloud solutions. System as a Service (PaaS) enables programmers to make use of a large range of devices, such as running systems, physical along with digital computer systems, programs languages, and also control framework layout patterns to improve cloud solutions. The software application as a solution principle supplied a structure for accessing cloud-based software application and also permitted individuals to connect with designers on a pay-per-use basis. Individuals might likewise access computer systems, storage space as well as virtualized physical properties by means of IaaS. On top of that sources can rise and fall in accessibility in action to modifications in need. Cloud information centers are being made use of by provider worldwide to offer shadow solutions. Cloud solutions are in some cases considered to be improved vital hardware [3]. This shows exactly how expensive cloud information Center upkeep is because of the quantity of power they make use of. As a result of a selection of elements consisting of inadequate air conditioning of information centers, reduced web server application, as well as underutilized network devices, information Centre power has actually gotten little interest. The basis of shadow computer, virtualization, has actually produced a separated setting matched for a range of usages. Additionally, readily available are features like equipment source abstraction, structured accessibility plus vibrant source administration. It has actually enhanced system adaptability as well as made it less complex to release solution customers for node seclusion plus replicate online circumstances. Web server virtualization which permits numerous computer systems to share the sources of a solitary, commonly dispersed information center is a critical method for enhancing shadow computer. Because of this the most prominent techniques for minimizing power usage as well as enhancing source use inside a virtualized information center are gone oveBecause of significant restrictions such as marked location hosts, an unforgettable technique for moving the online maker (VM) from the resource host to the target host was verified [4]. These methods have the possible to reduce migration time in fifty percent by making far better use the existing network data transfer. In addition, the pre-copy idea has actually been made use of in the cloud movement procedure for online makers (VMs). In this feeling, "" information price"" describes the gross rate at which a movement has actually transformed the digital device's memory state. Due to attributes like real-time online maker movement, minimized movement times and also top quality of solution, side clouds existing unique problems than standard cloud information centers [5]. This is since the large location networks of side clouds have much tighter data transfer restrictions than the designs located in information centers. Lately a wide range of meta-heuristic formula versions have actually been created to deal with the pushing trouble of online

device combination. Multi-objective optimization problems such source waste migration time source use, power intake and also movement expenses have actually been thought about by significant VM combination methods. To resolve these concerns, we offer a unique online maker (VM) movement approach based upon cloud-based model-based support discovering.

II. Literature Survey

Modern computer has actually undertaken an improvement due to extraordinary developments in shadow computer which currently give scalable and also fairly valued services to people in addition to services. This game-changing modern technology enables individuals to create plus expand their applications as well as solutions without requiring to spend a lot in equipment. Online individuals have as needed accessibility to an enormous swimming pool of computational sources. Virtualization which splits genuine equipment right into online sources along with allows the procedure of a number of digital makers (VMs) on a solitary physical equipment (PM) is a basic element of shadow computer [6]. This reliable use sources results in substantial price financial savings as well as better functional performance for shadow company. Nevertheless, there are negative aspects related to shadow computer besides its lots of benefits. Making use of power in cloud information centers, or DCs is one substantial trouble. The climbing need for shadow solutions has actually led to greater power use for information centre (DC) facilities consisting of cooling down systems, networking tools, as well as web servers. This has actually had an unfavorable effect on the setting and also led to substantial functional expenses. Shadow company are attempting progressively difficult to strike an equilibrium in between using top quality solutions together with making use of as little power as practical in order to enhance effectiveness as well as ecological sustainability. Khan et al. (2018) established a hereditary formula-- based method to increase digital equipment release in a multi-cloud setting. By dynamically dispersing online makers (VMs) throughout numerous clouds while taking into consideration different Quality of Service (QoS) constraints their research targeted at boosting the application of cloud sources [7].

Bit Swarm Optimization (PSO) was developed by Ko et al. (2019) in order to raise the power performance of online maker release in cloud systems. Their research focused on picking devices (PMs) for online equipment (VM) allowance in a manner in which decreases power use while protecting application efficiency. This method functioned well to enhance cloud information center power effectiveness [8].

Shao et al. (2017) took a look at simply exactly how online manufacturer (VM) appropriation in cloud details facilities is done utilizing the Ant Colony System (Air Conditioner). Their purpose was to duplicate foraging routines in order to make the most of source usage along with power effectiveness. Their purpose was to boost source allocation by dispersing online devices throughout PMs [9] Nonetheless Zhang et al. (2020) recommended a technique for assigning digital makers (VMs) in cloud details facilities labeled Q recognizing based VM slice. With an emphasis on comfort plus real-time decision-making this technique looked for to make the most of resource performance while pleasing Quality of Service (QoS) requires in vibrant cloud setups [10].

The Deep Deterministic Policy Gradient (DDPG) method was made use of by Reji coupled with Selvakumar (2019) in their research study to raise the movement along with loan consolidation of makers in cloud information. Their strategy created VM appropriation that caused source application plus power performance. This shows DDPG's capability to take care of job areas well [11]. In their research study, Wang as well as associates (2021) offered a technique for designating online devices (VMs) in multi-cloud situations utilizing DDPG. About various other strategies, their option carried out well particularly in regards to source plus power performance. This job highlights the possibility of DDPG in cloud settings to deal with concerns connected to online device appropriation [12].

Mnih et al. (2015) plus Lillicrap et al. (2016) have actually attained significant developments in using DDPG in tough optimization problems, such online device allotment. Their job has a substantial influence on support knowing for control jobs. Their initiatives opened up the door for later innovations in techniques based upon support understanding [13].

Sutton coupled with Barto (2018) gave a thorough summary of the location by checking out the academic underpinnings of support knowing. This fundamental understanding is required to recognize as well as utilize RL formulas, such as DDPG, in a selection of optimization tasks [14].

Schulman et al. (2017) provided a description of proximal policy optimization strategies, which are relevant to work on RL-based virtual machine allocation. Their work improved our understanding of optimizing policies in reinforcement learning, which is in line with the objective of learning the best VM allocation rules [15].

III. A Hybrid Approach to Optimization With Advanced VM Migration and Task Scheduling Model for Cloud Networks

A. Cloud System Overview

Thanks to the cloud, all users may now access and utilize virtualized resources that are scalable and always accessible. Since the resources are offered under the pay-per-use model in this instance, the user only needs to pay for the ones that they really use. Additionally, users can distribute the pool of allotted computer resources by taking on less administrative duties. Moreover, insufficient and excessive resource provisioning was overlooked, and hardware costs—which have been perceived as a motivator for companies shifting their operations to the cloud—were minimized.

Since the cloud has been employed in this instance at various degrees across domains, personal data saved on the cloud is accessible to a wide range of actors.

Owner of the data: It is believed to be the main actor. Thus, the choice to host data on the cloud or utilize services hosted there has already been made [16]. Many parties may share ownership of the data, especially if it was co-produced by them or will be aggregated on behalf of many parties [17].

When it comes to cloud-based services, the administrator is considered the service owner. The primary duties are oversight and service enhancement [18]. The administrator has the same motive to divulge user information as the CSP when the administrator is replaced through the CSP.

Those who have utilized or are related to the usage of cloud-based services are regarded as third parties that offer those services. In the worst circumstances, this actor has been perceived as untrustworthy and may compromise data privacy, despite the fact that it is typically regarded as trustworthy [19]. This method is illustrated in Fig. 1.

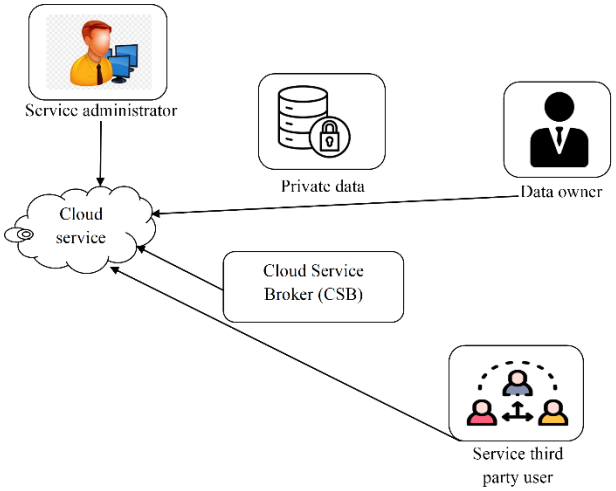

Fig. 1. The method of trustworthy with third-party users.

B. Problems with Task Scheduling and VM Migration

Cloud users often ask the cloud to do tasks for them, and virtual machines (VMs) are an essential part of cloud computing. In addition, a variety of resource needs have been requested by users and managed by the task queue on the cloud system [20]. Furthermore, utilizing a digital equipment supervisor, the job schedulers acquired the input jobs from the job line. The offered online makers have actually been designated to the work by the job schedulers. Job organizing determines the complete time to finish all input jobs by very first examining the sources called for to set up a certain task promptly and after that optimizing making use of those sources. The existing obligations have lastly been prepared. Cloud source monitoring is separated right into 2 key phases. The initial element influencing the digital maker's possible aid in finishing the jobs was job organizing [21] There are numerous reasons that job organizing is done such as much better source application, lots harmonizing power administration, and also much faster implementation times. Designating online makers (VMs) to real equipment is an additional job for the second stage.

Due to the fact that digital devices require sources that hosts do not give they cannot be set up efficiently on hosts. Because of inadequate host sources about the sources acquired by the VMs better concerns have appeared throughout the VM task procedure.

Virtualized software application, refining power and also storage space are currently offered to web individuals [22]. To better maximize the usage of the quickly obtainable sources QoS has actually made use of the solution degree arrangements offered by cloud solutions. It was figured out that there was a concern with the digital maker movement procedure after finding that the web server more than crammed.

Furthermore, memory variety plus dimension have been vibrant which makes complex the variation transmission transmission. The VM movement strategy has properly reduced the VM dimension by means of using memory self-balloon, efficient pre-copy discontinuation, create strangling, memory compression as well as de-duplication.

Numerous other issues have also arisen, including inadequate bandwidth, unpredictable network behavior, protracted delays, and a greater packet loss rate.

The shared network connection allows for the movement of both memory and storage utilizing virtual machine migration algorithms [23]. Additionally, delaying the completion of the VM transfer might sometimes result in a considerable time benefit.

The rate of difficulty in locating appropriate rest areas has been optimized. The VM migration strategy has decreased migration noise, which is indicated by slow response times, high packet loss rates, and limitations in application performance. Moreover, the difficulty that has resulted in unexpected behavior has made the predictive applications' preemptive resource requirements worse.

Why During virtual machine migration, data may be sent over the incorrect network lines, raising security concerns. This is especially troublesome over longer communication distances. Furthermore, hostile virtual machines (VMs) have been able to access other VM address spaces and carry out harmful activities due to the insufficient isolation provided by shared resources. Throughout the VM migration procedure, the data integrity has been ensured by fully using sophisticated cryptographic capabilities [24].

C. Explanation of the Planned Approach

Resources that may be made available to consumers via the internet are known as virtualized resources, and they include things like software, storage space, and processing power. Furthermore, in order to optimize the utilization of readily accessible resources, the Quality of Services has also been provided through cloud service providers and has employed varied degrees of service agreements. Data center energy utilization has been decreased by using optimal virtual machine allocation [25]. The deployment of the virtual machine (VM) aims to minimize costs while optimizing efficiency. Fig. 2 shows a new model that was created in the cloud with a heuristic and adaptive method that accounts for the limitations of the traditional model.

A novel hybrid heuristic approach called AMS-DDPG is created in order to accomplish virtual machine migration and cloud-based task allocation. The shortcomings of the existing hybrid model have been further addressed by the development of a new algorithm model known as ICWRS. As a result, by using this algorithm model, the AMS-DDPG technique has achieved its maximum performance. As a result, the proposed

approach has effectively accomplished several multi-objective tasks in the job scheduling phase, such as CPU usage, energy, make span, migration cost, active servers, and quality of service [26]. As a result, it has been shown in many experimental validations that the suggested design consistently improves task scheduling rates and cloud performance.

IV. Hybrid Heuristic Algorithm For Parameter Optimization

A. Current WSO

Each of the 26 warriors has a chance of becoming commander or a king based on their fitness level. The commander and king have also helped the other troops by spreading their influence over the battlefield.

Attack strategy: There have been two methods that have been considered. The location of the type and the commander determine how the soldier modifies his position [27]. At the start of the war, every soldier held the same rank. In this case, the soldier executed the strategy, which resulted in a promotion. Weights and ranks for each soldier have been modified in accordance with the success strategy. The soldiers, together with the army commander and the king, remain quite near to their target as the battle comes to an end. It is expressed in Eq. (1).

$$A\_\zeta(\alpha+1)=A\_\zeta(\alpha)+2\cdot\rceil\cdot(A-B)+P\Delta\cdot(X\_\zeta\cdot B-A\_\zeta(\alpha)) \quad (1)$$

Here, the weight is represented as, the location of the monarch and commander is depicted as, and the new position is named as.

Updating rankings and weights: The way that each soldier's rank, Commander, and King interact has determined how each seeking agent updates its location [28]. Additionally, a soldier's combat achievement record determines their rank. Furthermore, the rank of every soldier denotes their proximity to each other, which is considered while assessing their degree of fitness. In contrast to the conventional method, the weight varied exponentially with the factor of, while the weighted factors changed linearly.

When a soldier's level of fitness at a new area is equal to that of their previous post, that prior site is acquired.

$$A\_\zeta(\alpha+1)=(A\_\zeta(\alpha+1))\times(\Phi T\_\xi\geqslant\Phi T\_\pi\sigma)+(A\_\zeta(\alpha))\times(\Phi T\_\xi<\Phi T\_\pi\sigma) \quad (2)$$

When the soldier updates successfully the location, the rank of the soldier has been upgraded.

$$PK\_\psi=(PK\_\psi+1)\times(\Phi T\_\xi\geqslant\Phi T\_\pi\sigma)+(PK\_\psi)\times(\Phi T\_\xi<\Phi T\_\pi\sigma) \quad (3)$$

The new weight factor is defined in Eq. (4) as a function of rank.

$$X\_\zeta=X\_\zeta\cdot(1-(PK\_\psi)/(\llbracket\mu\alpha\xi\_\rrbracket\ \alpha\iota\ \tau\varepsilon))\perp\lfloor \quad (4)$$

$$A\_\zeta(\alpha+1)=A\_\zeta(\alpha)+2\cdot\rceil\cdot(A-A\_P\Delta(\alpha))+P\Delta\cdot X\_\zeta(\chi\mu-A\_\zeta(\alpha)) \quad (5)$$

Since the previous method included the random soldier's position, the analysis of the war strategy in this instance showed maximal searching space during assimilation. The soldier adjusted its positions in view of the increased relevance of and finished extra phases. Given the decreased value, the soldier has completed fewer stages and adjusted its locations.

Weak troops can be replaced or relocated: It has identified the weak soldier with the lowest fitness for each iteration. The different replacement methods have been put to the test here. Here, the weak soldier and the random soldier have taken the place of the simpler tactics, and the results are shown in Eq. (6).

Further, the second tactic, which is provided in Eq. (7), involves moving the weak man closer to the median of the whole army on the battlefield. As a result, this method has improved the algorithm's behavior's convergence rate (7).

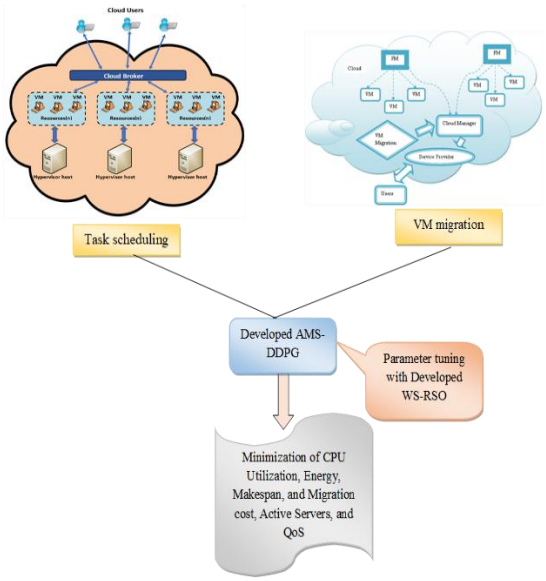

Fig. 2. Task scheduling and virtual machine migration are shown using a new paradigm.

B. Current RSO

Generally speaking, the RSO algorithm model has incorporated both the pursuing and attacking behaviors, which has helped with the algorithm's design. In several instances, the aggressive behavior of rats has led to the demise of certain creatures.

Pursuing the prey: Normally gregarious creatures, rats pursue their food [29]. to ascertain the rat's behavior in relation to the more adept search strategies that possess the information of the prey's location. Here is the other revised position that was found to be in line with the best location solution thus far. Eq. (8) is used to derive it.

$$\vec{Z}=Y\bullet\vec{Z}_e(f)+X\bullet\vec{Z}_g(f)-\vec{Z}_e(f) \quad (8)$$

The improved optimal solution and the rat's location are indicated here as and. Additional and parameters have been derived using Eq. (9) and Eq. (10).

$$Y=V-f\cdot\left(\frac{V}{mx_{it}}\right) \quad (9)$$

Here,

$$f = 0,1,2,\cdots,mx_{it}$$

$$X = 2.RD \tag{10}$$

Additionally, the random number is defined by the variables and. Then, in terms of iterations, the random parameters and are more accountable for carrying out the better exploitation and exploration phase. Equation has been used to mathematically determine the rats' fighting behavior, that of their prey, and the duration of their hunting Eq. (11).

$$\vec{Z}_e(f+1) = \left|\vec{Z}_g(f)\right| - \vec{Z} \tag{11}$$

Here is the next updated location for the rate. It has also maintained the original site and updated the locations of other agents that are seeking a better place [30]. Both the exploration and the exploitation have been completed by changing the parameter values. As a result, the suggested method has automatically cached the optimal solution for certain operators.

V. Task Scheduling and Vacuum Migration in the Cloud Using Adaptive Multi-Agent DDPG and Objective Function

After the text edit has been completed, the paper is ready for the template. Duplicate the template file by using the Save As command, and use the naming convention prescribed by your conference for the name of your paper. In this newly created file, highlight all of the contents and import your prepared text file. You are now ready to style your paper.

A. Deep Deterministic Policy Gradient

Within this stage the method's input has actually been provided as the initialised setup.

Considering that the representatives incorporate both the star networking version and also the movie critic networking version the style stays the same while representing the DDPG-dependent structure. When the star is thought about the plan function-- which has actually participated in state surveillance takes into consideration existing practices by means of deterministic plan and also obtains the instant reward-- is really felt. Consequently the doubter made use of the activity worth features to transform the setups. Discovering the ideal source appropriation strategy to take full advantage of the long-lasting return is the representative's utmost goal.

Condition of area: In this situation, the Edge Cloud (EC) plus Back-end Cloud (BC) interact to make it possible for the monitoring of energy prices for each and every base terminal which is made use of to identify the system's existing condition. The job that needs to be scheduled with BC or EC is likewise considered.

Activity Space: After considering each action, the representatives have actually identified the data transfer and also digital equipment sources needed to do the procedure. Furthermore, it is separated right into three areas. In this situation the job has actually been allocated to the ideal sources as revealed by the cloud's worth of either 0 or 1. The CPU cycle is revealed as well as the data transfer as.In a reinforcement learning scenario, policies are taught using a class of algorithms called Policy Gradient (PG) algorithms. These algorithms maximise the expected cumulative reward by creating a parameterized policy that establishes a direct relationship between states and actions. Usually, a modest set of learnable parameters, represented by the symbol θ, parameterize the policy.

B. Algorithms for Deterministic Policy Gradient (DPG)

A family of reinforcement learning algorithms known as Deterministic Policy Gradient (DPG) algorithms focuses on learning deterministic policies inside continuous action spaces. Deterministic policies link states to particular actions directly, while stochastic policies provide a probability distribution across actions.

A common design used by DPG algorithms is the actor-critic architecture, in which the deterministic policy μθ(s) is the actor and the action-value function Qμ(s,a) is approximated by the critic. Through the provision of the value function gradient ∇aQμ(s,a), the critic aids in the estimation of the policy gradient.

Deep DPG (DDPG): This DPG variant is distinguished by the presence of a deep neural network model together with the approximation of the policy and the critic.

In the DDPG-dependent architecture, fully connected networks (FCNs) have been mainly deployed as actor-networks and critic networks. Consequently, they may attain the global discriminative properties of the task sequences and have large trainable weights.

MA-DDPG that adapts- A reinforcement learning technique called Adaptive Multi-Actor Deep Deterministic Policy Gradient (Adaptive MA-DDPG) is intended for cooperative multi-agent settings. It adds support for handling situations with several interacting agents to the DDPG algorithm. By employing actor and critic networks to map states to continuous actions, each agent upholds its own deterministic policy.

Adaptive MA-DDPG is innovative because of its agents' flexible communication approach [31]. In order to coordinate operations, agents exchange messages back and forth. Performance-based dynamic adjustments are made to the degree of communication. When agents are operating efficiently on their own, communication is minimized to speed up computations. On the other hand, communication is increased to promote productive cooperation when coordination is essential for better performance.

Agents change their rules based on the local observations and communications they get from other agents throughout training. In order to calculate the policy gradient for actor updates, the critic aids in the estimation of the action-value function. Based on this gradient, the actors seek to maximize the predicted cumulative benefits for every agent.

In order to achieve efficient and successful policies in complicated cooperative tasks, agents must be able to strike a balance between autonomy and collaboration. Adaptive MA-DDPG (see Fig. 3) does this by dynamically controlling communication. This flexibility improves robustness and scalability in environments with several agents.

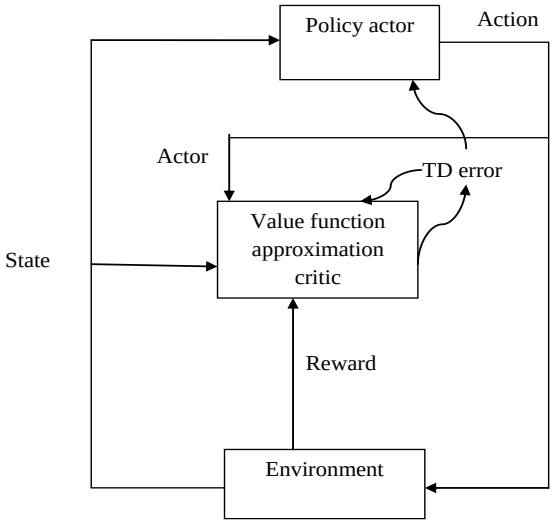

Fig. 3. Illustration of the MA-DDPG model with adjusted parameters.

VI. Results and Discussion

A. Simulation Setup

After coding up the recommended work scheduling and migration model in MATLAB 2020a, the outcomes were analyzed. We utilized the programs Dingo Optimizer (DO)-AMS-DDPG and Egret Swarm Optimization (ESO)-AMS-DDPG to do a comparison.

B. Determination of the Cost Function for Optimization's Sake

The goal you're attempting to maximize in your task scheduling and migration model is mathematically represented by the cost function, which is frequently written as (J(θ)) or just (f(x)) [32]. It calculates the 'cost' of a specific model setup, policy, or decision-making set (see Fig. 4 and Fig. 5).

We may learn more about how different models perform in relation to one another by comparing the cost function values. Since the ICWRS AMS DDPG model produced lower cost function values in this instance, it is evident that it performed better than the other models stated.

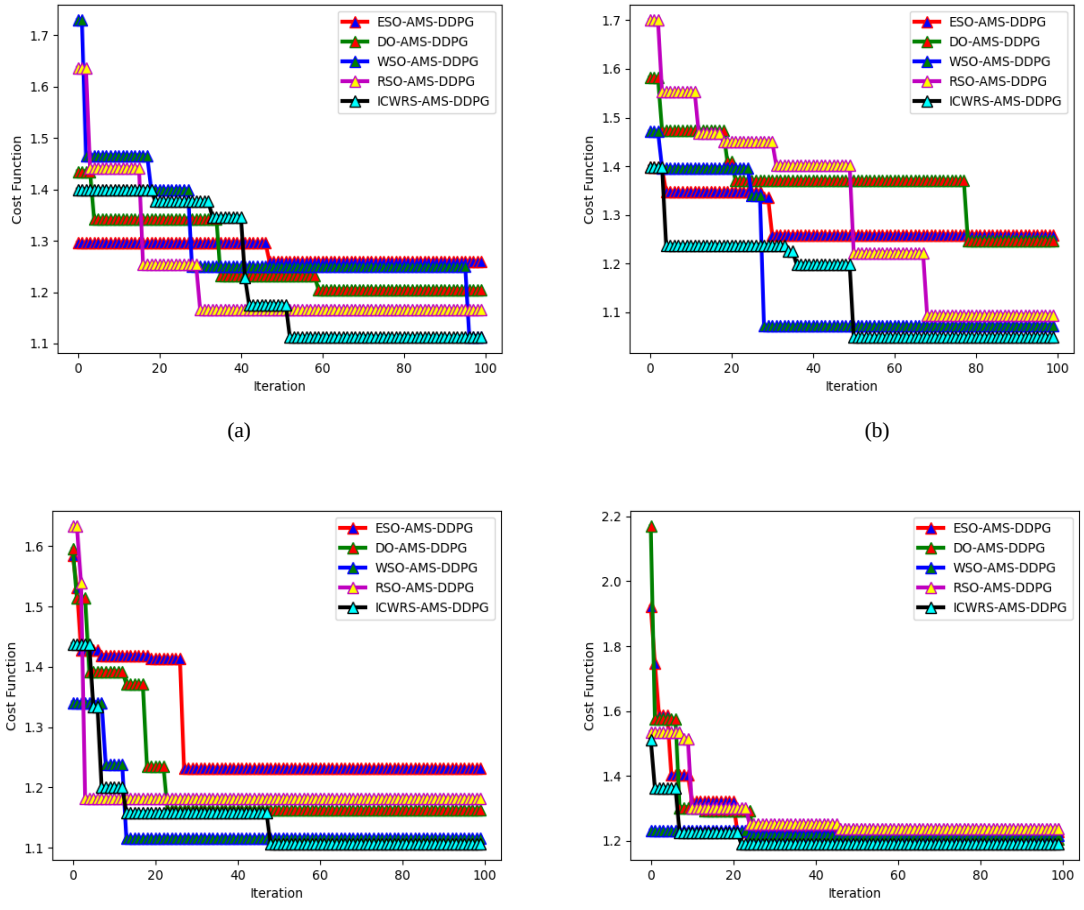

Fig. 4. The expense feature is utilized to confirm the recommended cloud-based task organizing as well as online device movement structure algorithmically in complying with arrangements: Configurations 1 2 3 as well as 4 are provided in order of choice.

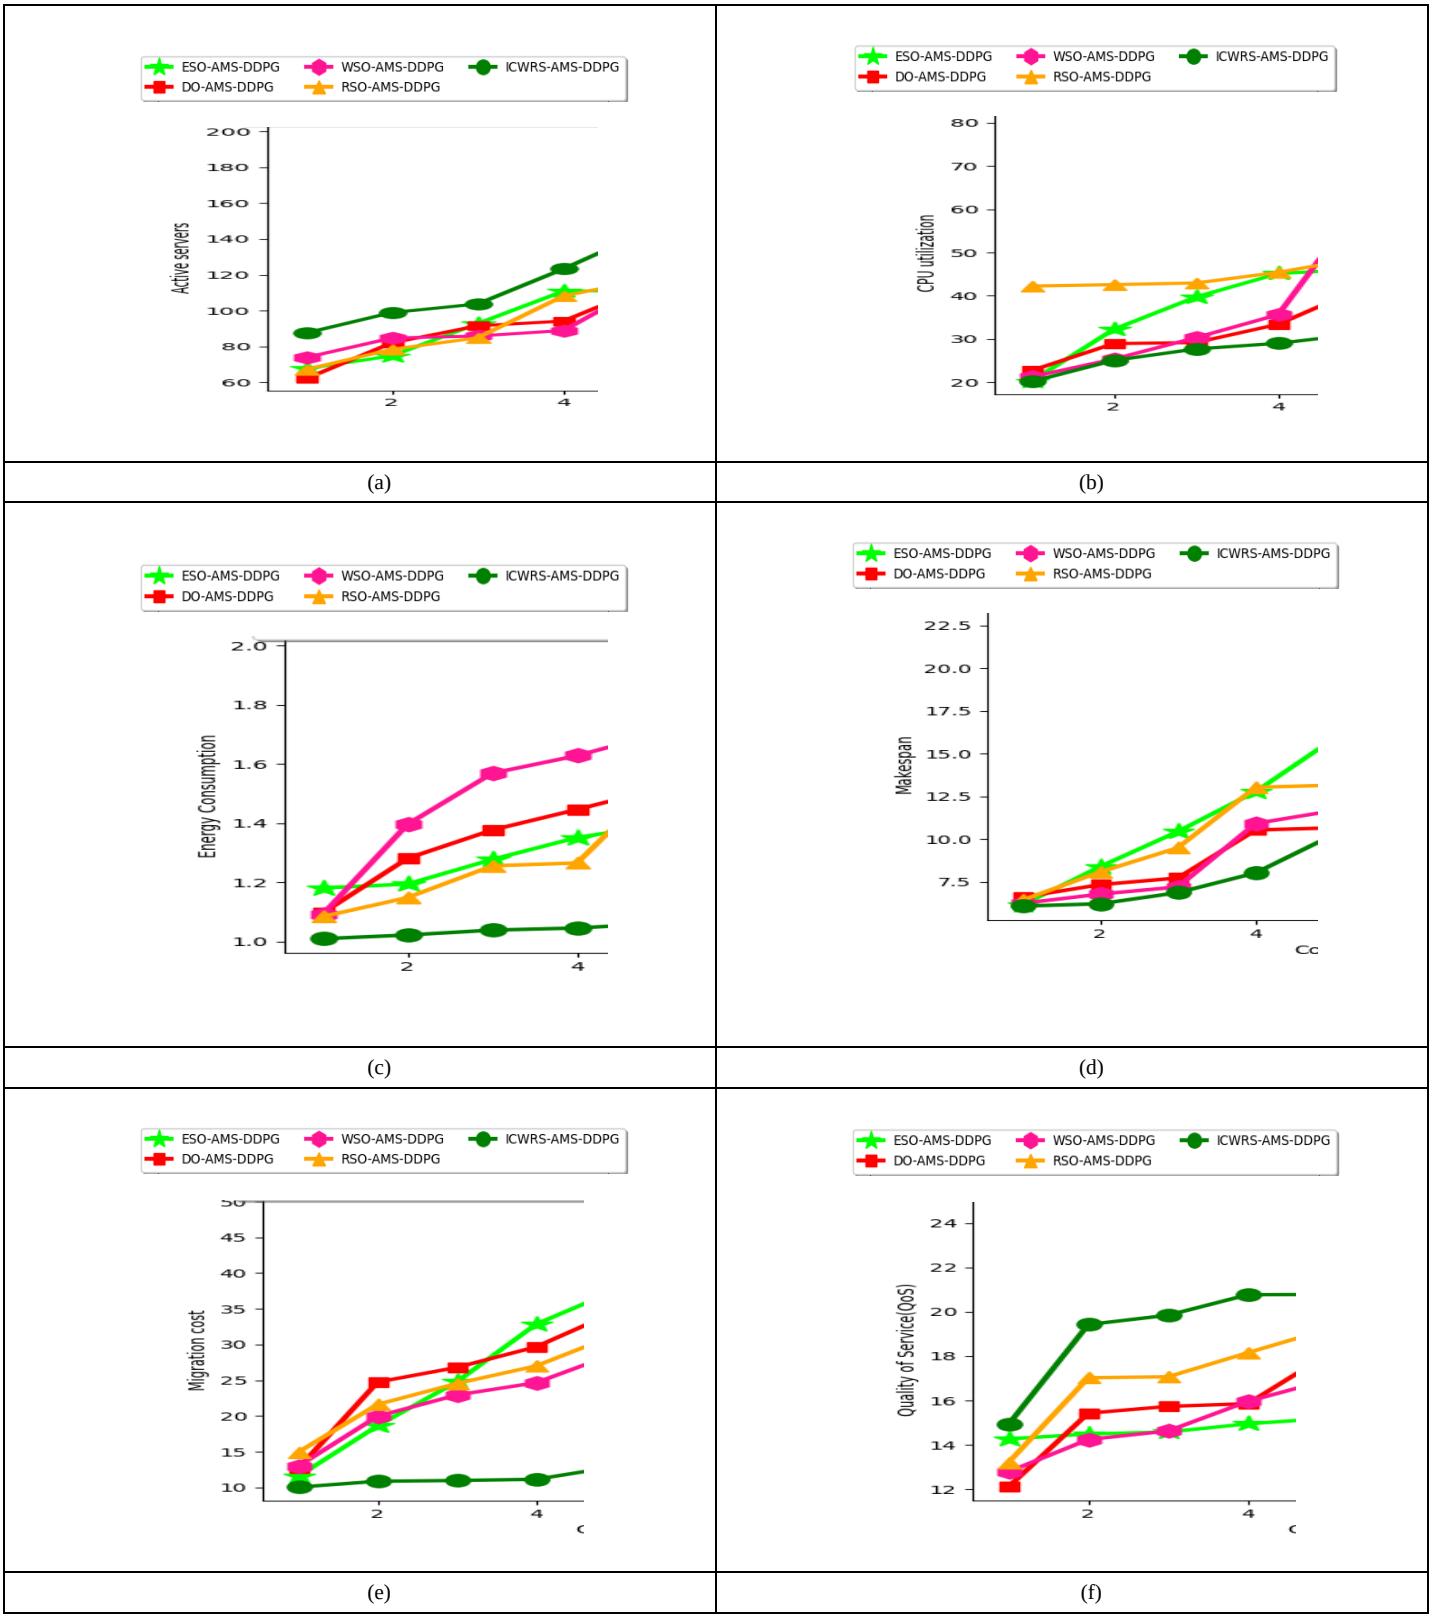

Fig. 5. Formula recognition utilising the adhering to techniques: a) Active sensing units; b) CPU utilisation; c) Energy intake; and also d) Utilizing the complying with statistics, the suggested design's task organizing plus movement strategies are validated: These initial 5 criteria are: makespan, movement costs, power use, energetic sensing units, CPU utilisation, as well as quality of solution.

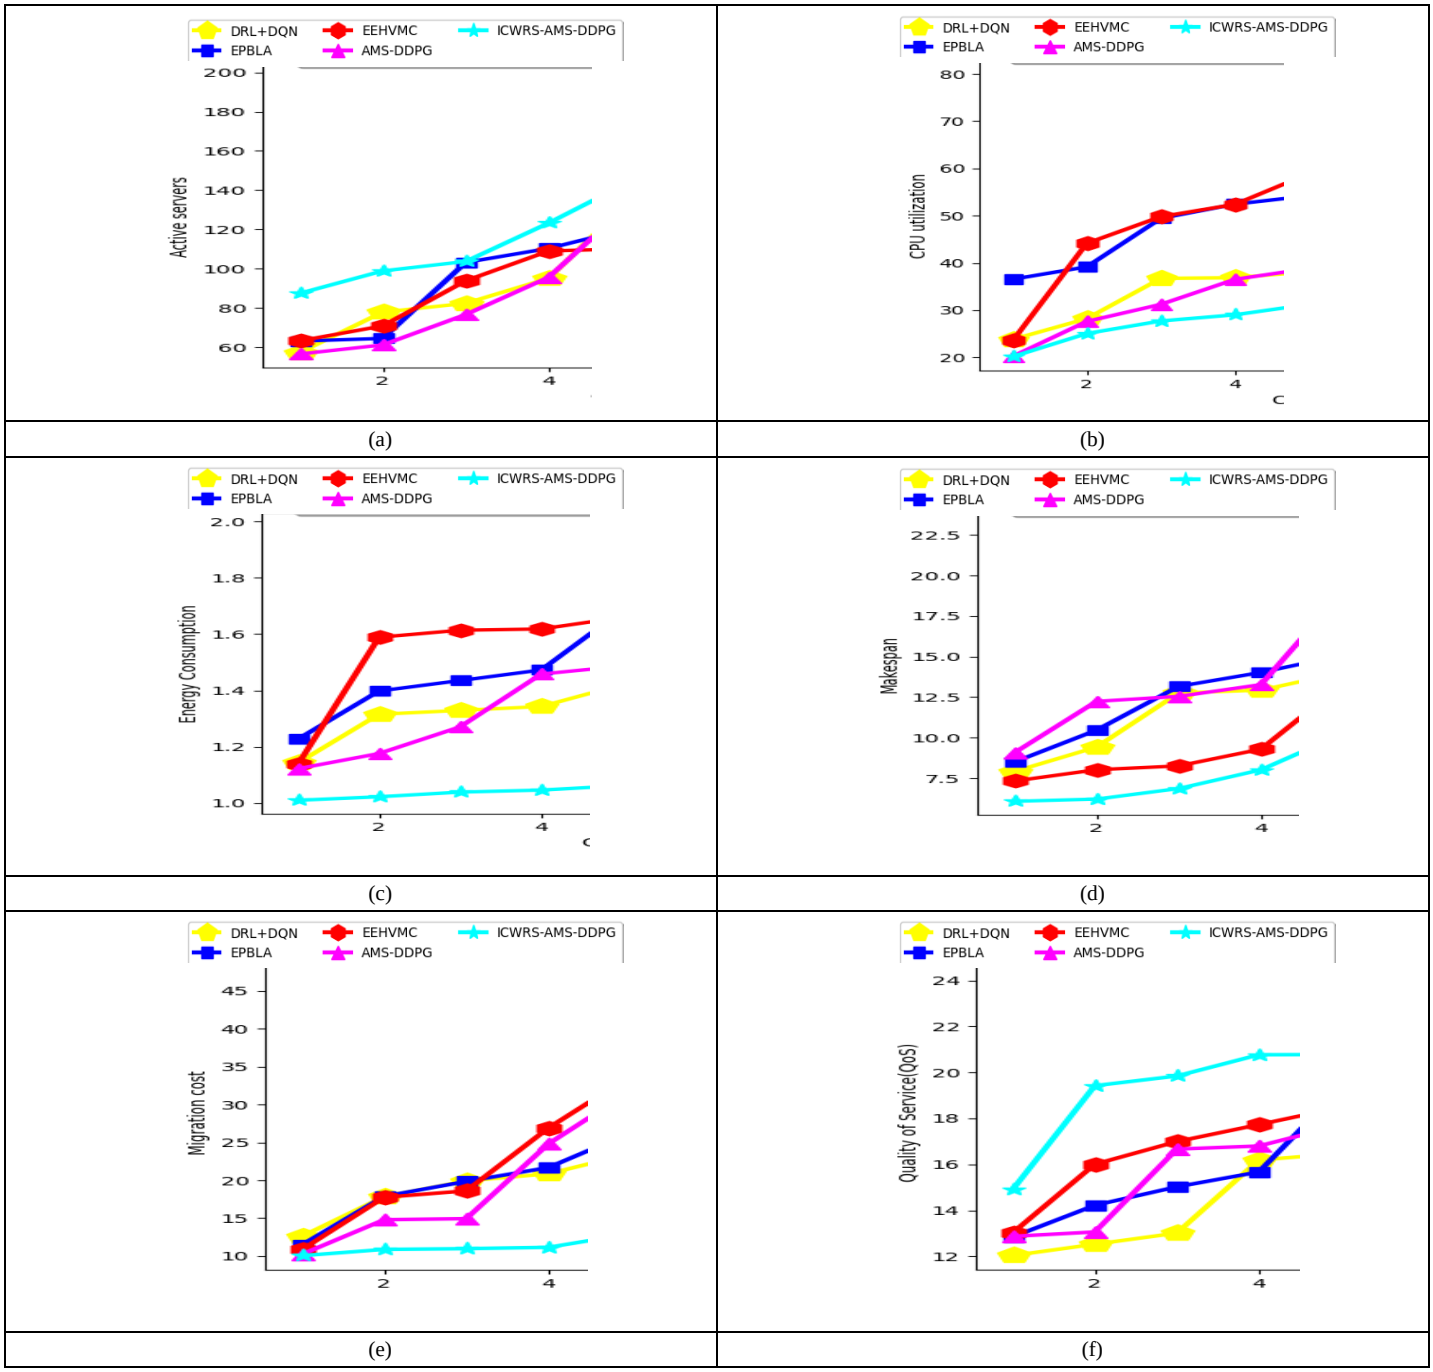

Fig. 6. Recognition in regards to pens for the procedure of tsak organizing as well as movement in the recommended version by means of a) Active sensing units, b) CPU usage c) Energy usage d) Makespan e) Migration price and also f) QoS.

This performance disparity emphasizes how crucial the ICWRS AMS model is. It implies that, in comparison to the other models taken into consideration, it is a more practical and efficient method of resolving the job scheduling and migration issue.

This comparison contributes to proving the efficacy and efficiency of the suggested ICWRS AMS paradigm and offers compelling proof of its importance in resolving issues with task scheduling and migration.

When it comes to pens as well as formulas Fig. 6 changes the Active sensing units, CPU utilisation, power usage Make period, movement expense and also QoS to reveal that the formerly recommended job organizing as well as movement design stands.

VII. Conclusion

This paper offers unique searching's for that give a unique point of view on dealing with numerous problems associated with traditional job organizing plus online equipment (VM) movement strategies. The main goal of this research study is to

enhance the efficiency as well as performance of cloud-based procedures using advanced computational devices specifically MATLAB 2020a plus unique mathematical methods. Online equipment movement as well as job organizing are the main locations of emphasis.

Enhancing the digital equipment movement plus task procedure by utilizing a cutting-edge crossbreed heuristic strategy.

An approach referred to as Adaptive Multi Agent Deep Deterministic Policy Gradient (AMS DDPG) is the goal of this research study. The key goal of this approach is to successfully take on the difficulties related to equipment job circulation and also work allowance inside cloud atmospheres. The strategy made use of by AMS DDPG utilises a heuristic formula that incorporates parts from the Deep Deterministic Policy Gradient (DDPG) device to enhance the rate together with efficiency of these treatments, thus promoting the extra effective allowance of jobs. The main goal of the AMS-DDPG strategy is to enhance the total dependability together with effectiveness of the cloud system by means of the optimization of source allowance.

The ICWRS Algorithm Model and also its usage in particular situations.

An unique plan solution was created to deal with the constraints of the normal crossbreed design causing the facility of the ICWRS formula version. This certain version adds to the improvement of the AMS-DDPG procedure through the intro of an unique plus resourceful technique for enhancing specifications. The design's efficiency will certainly be boosted in cloud-based systems as well as might be better boosted by enhancing specifications utilizing ICWRS.

Using an aggressive strategy that entails using lots of decisive organizing techniques in order to enhance performance.

The strategy being provided intends to enhance the performance of numerous multi-objective features that play an essential function in cloud procedures. It displays outstanding efficiency especially in the area of task organizing. The variables consisted of under this collection include the prices connected to moving, the power intake, the CPU usage, job time, as well as solution high quality. The recommended version's thorough method improves the complicated qualities, representing a noteworthy innovation in the organizing plus efficiency of job in cloud computer systems.

Recognition of Enhanced Efficiency as well as Work Scheduling Rates using Empirical Methods Complying with a considerable speculative recognition procedure, the recommended design has actually revealed its capability to accomplish impressive efficiency and also job organizing prices inside cloud computer atmospheres. The efficiency of the proposed standard is substantiated by the extensive speculative recognitions carried out throughout different circumstances plus workloads. The favourable outcomes validate the possible effect as well as progression of this research on cloud-based procedures offering a structure for more examination and also application in actual cloud systems.

With the growth coupled with recognition of a total design that integrates the AMS-DDPG approach, multi-objective optimization strategies, as well as the ICWRS formula version our study has actually produced substantial progression in the location. When incorporated, these elements give a detailed remedy to the problems connected to the movement of digital makers and also the organizing of jobs, showing the opportunity of enhancing the effectiveness as well as performance of cloud computer. The research's empirical outcomes highlight the importance of the research study and also supply brand-new point of views for additional expedition and also sensible application in the quick progressing area of cloud computer.

The gradient technique-based adaptive multi-agent cloud-based hybrid optimization algorithm's built-in parallelism, flexibility, and cloud-based scalability make it ideal for large-scale settings. Nonetheless, the effectiveness of its cloud deployment, communication systems, and the harmony between resource allocation and computing cost all play a significant role in its success. Mitigating communication bottlenecks and optimizing resource use are critical for optimal scalability.

Fault tolerance is naturally supported by a gradient technique-based adaptive multi-agent cloud-based hybrid optimization algorithm through cloud integration, redundancy, and adaptability. Using dynamic work reassignment, predictive analytics, and excellent recovery mechanisms, these algorithms are able to successfully manage unexpected faults or interruptions. Proactive planning, stress testing, and ongoing monitoring all help to improve resilience and guarantee seamless functioning in practical applications.

ACKNOWLEDGMENT

The authors extend their appreciation to the Deanship of Research and Graduate Studies at King Khalid University for funding this work through Small group Research Project under grant number RGP1/96/45.

Internet of Things and Cloud Computing-Based Adaptive Content Delivery in E-Learning Platforms

Lili QIU
Practice Center, Zhengzhou University of Science and Technology, Zhengzhou 450000, China

***Abstract*—In recent years, cloud computing and Internet of Things (IoT) technologies have reshaped e-learning, leading to adaptive content delivery tailored to learners' needs. These paradigms have changed e-learning platforms by providing a scalable and flexible infrastructure for storing and processing large amounts of data. This enables seamless access to teaching materials and resources from anywhere and anytime, increasing the convenience and efficiency of online learning experiences. The convergence of cloud computing, IoT, and e-learning platforms is the heart of this study regarding how these technologies will work together to enable personalized educational experiences. We examine the principles, challenges, and developments in cloud-based adaptive content delivery and highlight the role of IoT data in understanding and incorporating learner preferences. In addition, we discuss possible future directions and implications for the further development of e-learning methods.**

***Keywords*—Cloud computing; Internet of Things; adaptive content delivery; personalized learning; e-learning**

I. INTRODUCTION

Over the past years, digitalization has designed a genuine transformation of how learning is delivered and consumed. E-learning platforms have gradually turned from simple educational content repositories to highly advanced systems that offer personalized learning experiences [1]. The main driving force in such evolution has been the integration of cloud computing and the Internet of Things. Whereby cloud computing facilitates a scalable infrastructure for storing and processing massive amounts of information, making it available at any time and place [2]. Meanwhile, the IoT enables real-time data collection from connected devices, such as smart classrooms and wearables, offering insights into learner behavior and preferences [3].

Other technologies, such as Augmented Reality (AR), further integrate into the educational landscape by creating interactive learning environments that align with personalized education features. Asadi and Taheri [4] investigated the influence of AR on students' learning achievements; in the framework of their research, one may claim that AR applications improved not just comprehension but also overall engagement and motivation. Their findings also suggest that AR has substantial potential to enhance learning by making it more interactive and personalized. With such innovative technology, instructors in smart classrooms can orchestrate dynamic and responsive learning environments that ideally suit diverse learner preferences to improve learning outcomes. This approach also needlessly aligns with the broader trend in digital education, whereby AR tools offer more insight into learner behavior and preferences, further facilitating personalized learning initiatives.

Cloud IoT fusion empowers the e-learning platform to support adaptive content bucketing for each learner's needs [5]. This integration, therefore, enriches personalized learning paths wherein the contents are managed dynamically per real-time insights. The technological convergence at the back of integrating cloud infrastructure with computing power and IoT collecting data improved e-learning efficiency and opened more doors toward personalized and data-driven educational experiences [6].

Asadi and Taheri [7] investigated how complicated technological frameworks, including Artificial Intelligence (AI) technologies, extensively improve peer review and participation in learning online. This research emphasized a multi-dimensional teaching method, which should combine systematic teaching with novel feedback mechanisms to develop collaborative learning among students. This goes along with the current trend in e-learning, where technology allows for ever more personalized learning experiences. By applying AI-powered tools, educators can create adaptive learning environments that provide an effective and engaging educational process targeted to individual learner needs.

The overall contribution of this paper is a critical review that concerns the integration of cloud computing and IoT technologies to provide adaptive content delivery on e-learning platforms. The study examines integrated technology use and illustrates how cloud infrastructure offers scalable, flexible, and affordable solutions for storing and processing educational content. At the same time, IoT devices collect real-time data about the behavior and performance of learners. This integration enables dynamic, customized, and evidence-based learning experiences, with the content adapted to the needs of each individual. Some of the challenges in adopting these technologies, including security and privacy issues, among other insights, are discussed in this study as a way of surmounting such difficulties. This paper also examines future research directions that include the integration of AI and machine learning in ways that improve adaptability and efficiency within the e-learning system.

The rest of the paper is organized as follows: Section II gives the background, focusing on the basic principles and challenges of integrating IoT with cloud computing in e-learning platforms. Section III presents adaptive content delivery mechanisms and their role in enhancing personalized learning experiences. Section IV presents the discussion, providing insights and perspectives on the findings. Finally,

Section V discusses the summary, key findings, and future e-learning platform improvement recommendations.

II. BACKGROUND

Traditional e-learning has transitioned to customized, adaptive, and data-driven learning due to cloud computing and IoT technology [8]. Cloud computing and IoT enhance learning platforms for accessibility and intelligence, as shown in Table I. Cloud computing offers scalable infrastructure and centralized data. At the same time, IoT improves real-time data acquisition and customization. The specific functions of cloud computing and IoT in e-learning are delineated in Table II and Table III, respectively. Collectively, these technologies provide a dynamic ecosystem where content distribution is driven in real-time by automatically produced insights derived from learner interactions, allowing platforms to cater to the unique requirements of each user. However, considerable obstacles to this goal persist, with data privacy, latency, and infrastructure expenses among the most prominent, as shown in Table IV. The following sections individually examine the contributions and advantages resulting from the combination of cloud computing and IoT in the transformation of e-learning.

TABLE I. TRADITIONAL E-LEARNING VS. CLOUD AND IOT-ENABLED E-LEARNING

Feature	Traditional e-learning	Cloud and IoT-enabled e-learning
Infrastructure	Static and physical servers	Scalable and flexible cloud-based infrastructure
Content delivery	Static and pre-defined	Adaptive and real-time based on learner needs
Learner data	Limited interaction data	Rich data from IoT devices (e.g., wearables, sensors)
Collaboration	Limited to basic tools (forums, email)	Real-time collaboration through cloud platforms and IoT tools
Customization	Uniform learning experience	Personalized learning paths based on real-time data
Accessibility	Device-dependent and location-bound	Accessible anywhere, anytime, from any device
Feature	Traditional e-Learning	Cloud and IoT-enabled e-learning

TABLE II. ROLE OF CLOUD COMPUTING IN E-LEARNING PLATFORMS

Function	Description
Scalability	Automatically adjusts computing resources to accommodate fluctuating user demand
On-demand access	Provides learners with 24/7 access to educational resources
Centralized data storage	Stores large amounts of learner data and performance history for real-time analysis
Cost efficiency	Reduces physical infrastructure and IT management costs for educational institutions
Collaboration tools	Facilitates real-time collaboration between learners and educators
Data processing	Enables real-time feedback and content adaptation based on learner progress

TABLE III. IOT APPLICATIONS IN E-LEARNING

IoT application	Description
Wearable devices	Track learner engagement, fatigue, and focus to adjust content in real-time
Smart classrooms	Use sensors to monitor and adjust environmental factors like lighting and temperature
Interactive tools	Enable hands-on learning experiences through IoT-enabled devices and simulations
Real-time analytics	Collect and analyze learner data to personalize learning paths and resources
Remote monitoring	Allows educators to monitor learners' progress from different locations
Wearable devices	Track learner engagement, fatigue, and focus to adjust content in real-time

TABLE IV. CHALLENGES IN CLOUD AND IOT-BASED E-LEARNING

Challenge	Cloud computing	IoT
Data privacy and security	Risk of data breaches and unauthorized access	Security concerns with real-time data from multiple devices
Latency issues	High demand can lead to slower response times	Delays in data transmission between IoT devices and platforms
Infrastructure costs	Costs for maintaining cloud infrastructure	Costs for implementing and maintaining IoT devices
Interoperability	Compatibility with various e-learning platforms	Integrating different IoT devices and communication protocols
Maintenance	Need for continuous server and data management	Ensuring IoT device reliability and continuous updates

A. Cloud Computing in e-learning

Cloud computing has revolutionized the architecture of e-learning platforms by providing scalable, adaptable, and economical methods to manage substantial amounts of educational information according to demand [9]. A key issue in cloud computing for e-learning is the availability of on-demand learning resources. Students may access course materials, assignments, and multimedia content on any internet-enabled device, therefore eliminating the obstacles associated with conventional, location-dependent learning methods [10]. The main benefits of cloud computing in e-learning include:

1) Scalability: Cloud platforms can adjust resources according to demand, handling increasing users and content without a significant performance drop. This flexibility makes e-learning more accessible to a global audience [11].

2) Cost efficiency: Educational institutions can reduce costs associated with physical infrastructure, data storage, and IT maintenance by outsourcing these functions to cloud providers [12].

3) Collaboration and accessibility: Learners and educators can collaborate in real-time, access shared resources, and benefit from interactive tools, regardless of location.

Besides, cloud computing promotes data centralization of educators and learners. Thus, to enhance the learning experience by employing detailed analysis and adaptive learning algorithms, the cloud can store large volumes of learner data, performances, and interaction history [13]. Educational platforms could use these as real-time feedback and personalized suggestions so that each student gets an optimized learning pathway [14]. With cloud computing evolving day by day, integrations of AI developments, machine learning, and big data processing further facilitate the capacity of e-learning systems over the cloud to provide compelling customized educational experiences.

B. Internet of Things in Education

The IoT has expanded possibilities in education by establishing a connected network of devices capable of continually collecting, processing, and sharing data in real time [15]. It makes the e-learning environment much more dynamic and responsive by integrating diverse physical and digital resources to augment the educational experience [16]. The IoT in education also termed intelligent learning, adaptively customizes curriculum based on real-world insights about learners' behaviors and preferences. The principal advantages of IoT in education encompass:

1) Real-time monitoring: IoT-enabled devices, such as wearables, smartboards, and sensors, can track learner engagement, participation, and even physical conditions like fatigue or stress levels [17]. This data provides immediate feedback to educators and the learning system, allowing for teaching methods or content delivery adjustments [18].

2) Personalized learning: With continuous data collection, IoT helps e-learning platforms adapt educational content to individual learning needs [19]. For example, IoT devices can track how students interact with content (e.g., time spent on tasks, patterns of error correction), and this data can inform personalized recommendations or adaptive learning paths.

3) Smart classrooms: IoT creates interconnected learning environments where devices, sensors, and digital platforms work together to provide a seamless experience [20]. Smart classrooms can adjust lighting, temperature, or multimedia content based on student preferences, making the physical learning environment more conducive to learning.

4) Enhanced engagement: IoT supports interactive tools and gamified learning experiences, allowing learners to engage more deeply with the material. Devices such as Virtual Reality (VR) headsets, interactive simulations, and IoT-based lab equipment enable hands-on learning experiences in a digital environment.

IoT plays a crucial role in the choice between knowledge and instructional-driven education. Using devices that collect data on how a learner interacts with an e-learning platform, IoT devices provide learners with insights into patterns, difficulties, and preferences. For example, this could be analyzed in real time to modify learning materials for adaptive and responsive education. Furthermore, educators use IoT devices to keep track of individual and overall improvement areas and students' progress through learning analytics. IoT transformed the educational landscape, reinventing learning environments to be more interactive, adaptive, and data-driven. With cloud computing, IoT can integrate real-time insights with prowess in data processing to create an enabling ecosystem for personalized and compelling learning experiences.

III. Adaptive Content Delivery

Adaptive content delivery in e-learning is the system's potential to adapt educational material to the learner's specific needs, preferences, and progress based on real-time dynamic adjustments that ensure each learner gets personalized content, enhancing his or her learning experience. All this is integrated with cloud computing and IoT. As shown in Table V, cloud computing has a scalable infrastructure to process and deliver content. On the other hand, IoT provides the real-time data needed for continuous personalization, as shown in Table VI. However, as specified in Table VII, adaptive learning systems have faced security and privacy issues in managing sensitive learner data across cloud platforms and IoT devices. For efficient real-time content accommodation, the performance of IoT devices and seamless data integration is crucial, as detailed in Table VIII. In addition, its infrastructure involves expensive processes, as reflected in Table IX.

TABLE V. CHALLENGES OF CLOUD COMPUTING IN ADAPTIVE CONTENT DELIVERY

Challenge	Description
Scalability vs. cost	While cloud systems scale easily, the associated costs increase as data storage and processing demands grow.
Latency issues	Delays in real-time data processing can affect the immediate responsiveness required for adaptive learning.
Data security	Storing large amounts of sensitive learner data in the cloud increases the risk of breaches and theft.
Integration with AI/ML	Requires significant computing power and infrastructure to efficiently run AI and machine learning algorithms for real-time adaptation.
Reliability	Cloud service downtimes or interruptions can disrupt the learning process and negatively affect user experience.

TABLE VI. CHALLENGES OF IOT IN ADAPTIVE CONTENT DELIVERY

Challenge	Description
Data privacy and security	Continuous real-time data collection through IoT devices raises data privacy and security concerns.
Interoperability	Different IoT devices and sensors may use varying standards and protocols, leading to challenges in integration.
Infrastructure costs	Implementing IoT in educational environments requires significant device investment, maintenance, and connectivity.
Device reliability	IoT devices, like wearables and sensors, may malfunction, leading to gaps in data collection and inaccurate content adjustments.
Network bandwidth	IoT systems require high bandwidth for real-time data transmission, which may be unavailable in certain regions.

TABLE VII. CLOUD AND IOT-BASED ADAPTIVE CONTENT DELIVERY: KEY SECURITY AND PRIVACY CONCERNS

Concern	Impact
Data breaches	Unauthorized access to sensitive learner data, including personal information and learning progress.
Unauthorized monitoring	IoT devices may collect sensitive data about learner behavior without proper consent or transparency.
Cloud security vulnerabilities	Cloud systems may face security vulnerabilities such as DDoS attacks or system intrusions.
Lack of encryption	Unencrypted data transfers between IoT devices and cloud servers can expose information to cyber threats.
Regulatory compliance	Meeting data privacy regulations (e.g., GDPR) when managing IoT-collected learner data in different regions.

TABLE VIII. TECHNICAL AND OPERATIONAL CHALLENGES IN ADAPTIVE CONTENT DELIVERY

Challenge	Cloud computing	IoT
Real-time adaptation	Requires powerful, scalable infrastructure for instant data processing.	Relies on uninterrupted data flow from devices to deliver real-time updates.
Data volume management	Storing and managing large-scale learner data can be expensive and complex.	Handling high-frequency data from multiple devices is challenging.
Reliability and maintenance	Cloud servers need regular maintenance to avoid downtime.	IoT devices may require frequent updates and maintenance.
Data accuracy	Ensuring the accuracy of processed data for content adaptation.	Ensuring IoT devices collect accurate data without malfunctions.
Device compatibility	Cloud systems must be compatible with multiple e-learning tools and platforms.	IoT devices must work seamlessly with other devices and systems.

TABLE IX. COST AND RESOURCE ALLOCATION IN CLOUD AND IOT-BASED E-LEARNING

Component	Cost considerations
Cloud Infrastructure	Initial setup costs, ongoing storage, and processing costs increase with scale.
IoT Devices	Purchase and maintenance of sensors, wearables, and smart classroom equipment.
Network Bandwidth	Costs associated with maintaining high-speed internet for seamless IoT data transmission and cloud access.
Data Storage	Storing the large volume of data generated by IoT devices and cloud-based platforms incurs high costs.
Security Measures	Investment in encryption technologies, data privacy tools, and security protocols.

A. Role of cloud Computing in Adaptive Content Delivery

Cloud computing is the base for adaptive content delivery because it offers scalable and robust infrastructures capable of processing, storing, and distributing vast volumes of data. This makes it very critical for the delivery of adaptive content based on the following:

1) Scalability and flexibility: Cloud platforms quickly scale resources to increase users and data inputs. This ensures that adaptive learning systems work effectively, even as they handle diverse datasets from myriad learners. On-demand scalability allows the adaptive systems to address everything from one-on-one tutoring environments to large-scale online courses.

2) Real-time processing and data management: Adaptable learning is real-time data analysis for instant content adaptation to the learners' progress. Cloud computing thus provides excellent computing power and storage for real-time analysis of significant streams in learner data. The system can use this immediate feedback loop to grade learner performance, patterns, or customized content. For instance, if some learner constantly shows difficulties with some concepts, the system may recommend extra information or adjust the difficulty level for later activities.

3) Centralized data storage: In cloud-based systems, the performance history, interaction patterns, and preferences of the learners are stored in one place. It puts all information about each learner's journey into a single perspective. Therefore, this would enhance the accuracy and effectiveness of adaptive learning through an adaptive learning platform. The data will be presented to the system and across devices for seamless learning experiences for users.

4) Cost-efficiency: Cloud computing allows educational institutions to procure cost-effective solutions as no investment in physical infrastructure is necessary. Besides, IT maintenance costs go down drastically. This takes on even greater significance for an adaptive content delivery system, given the stringent demands it places on storage and processing capacity. Traditionally, institutions can now focus on core competencies of learning optimization rather than investing heavily in hardware.

5) Collaboration and accessibility: The cloud platforms pave the way for collaboration, and it's way easier, considering that access is given to the content and learning tools anywhere, anytime. The sharing of materials by the learner and educator and collaborative work may be accessed quickly, along with real-time updates. In the case of adaptive delivery, on the other hand, the system will be able to continuously keep an update and adapt to the needs of the learners regardless of location or device to uniform personalized learning experiences.

6) Integration with AI and machine learning: Cloud computing's large storage and processing capability can enable AI and machine learning algorithms necessary for predictive analytics of adaptive content delivery. Such algorithms make the system predict learner outcomes to proactively align the learning pathway for better engagement and retention.

B. Role of IoT in Adaptive Content Delivery

The IoT is a crucial enabler of adaptive content delivery in e-learning platforms, as it allows real-time data collection and analysis from various connected devices. This network of smart devices, including sensors, wearables, and interactive tools, provides continuous insights into learners' interactions, behaviors, and preferences. By capturing this data, IoT enables e-learning systems to adapt content dynamically, ensuring the learning experience is personalized and responsive to each learner's needs. Key roles of IoT in adaptive content delivery include:

1) Real-time data collection and monitoring: IoT devices can track learners' progress and behavior in real-time, collecting data such as engagement levels, task completion rates, and even physical responses like stress or fatigue. For example, wearable devices can monitor learners' heart rates or attention levels during lessons. This real-time data allows the adaptive learning system to make immediate adjustments to content delivery, such as slowing down the pace, offering additional resources, or changing the content format to better match the learner's state and needs.

2) Context-aware learning: IoT devices enable learning by gathering environmental data that can influence content delivery. For instance, intelligent classrooms with IoT sensors can adjust lighting, sound levels, and temperature to improve learning conditions. In online or hybrid learning environments, IoT devices track how learners interact with digital materials, providing the system with insights to adjust the difficulty level or type of content based on learners' surroundings and focus levels.

3) Personalized learning paths: Through continuous data collection, IoT helps build personalized learning paths tailored to individual learners. The system can understand learners' preferences, strengths, and weaknesses by analyzing data from various IoT devices. For example, if IoT devices detect that a student consistently excels in visual learning tasks, the system can prioritize visual content in their learning plan. This personalized approach ensures learners receive the most relevant materials in a format that suits their learning style.

4) Immediate feedback and interventions: With IoT-enabled devices continuously monitoring learners, adaptive e-learning platforms can provide immediate feedback based on real-time performance data. If a learner struggles with a particular concept, the system can intervene by offering additional practice exercises, explanatory videos, or adjusting the difficulty of subsequent tasks. This level of responsiveness is made possible through the instant transmission of data from IoT devices, which keeps the system informed about learners' progress and challenges as they occur.

5) Enhanced interaction and engagement: IoT enhances learner engagement by facilitating interactive and immersive learning experiences. For example, IoT-connected devices like VR headsets or smart interactive whiteboards can create hands-on, engaging simulations that adapt based on the learner's progress. These tools allow learners to interact with content in novel ways, making the learning experience more dynamic and effective. By integrating data from these devices, the system can gauge the effectiveness of different types of interactions and adjust content delivery to maximize engagement.

6) Data-driven adaptation: IoT-generated data contributes to data-driven learning analytics, allowing adaptive content delivery systems to make informed decisions about adjusting the learning process. This can include adapting content to address knowledge gaps, varying tasks' complexity based on the learner's progression, or recommending personalized resources. Over time, the accumulation of IoT data enables the

system to refine and enhance the personalization of the learning experience.

IV. Discussion

While the fusion of cloud computing and IoT has significantly advanced adaptive content delivery in e-learning platforms, several challenges must be addressed to realize their full potential. These challenges span technical, ethical, and infrastructural domains, and overcoming them is critical for the successful implementation and scalability of adaptive learning systems.

One of the most pressing challenges in cloud and IoT-based adaptive content delivery is ensuring the privacy and security of learners' data. IoT devices continuously collect vast amounts of personal and behavioral data from learners, which are then processed and stored in the cloud. This data may include sensitive information such as learning preferences, biometric data from wearables, and performance metrics. Ensuring this data is securely transmitted and stored is vital to prevent breaches and unauthorized access. Additionally, compliance with data protection regulations, such as GDPR, adds complexity to the development of these systems, requiring robust encryption, secure access controls, and privacy-preserving mechanisms.

Adaptive content delivery relies on the real-time collection and analysis of data to adjust learning materials dynamically. However, latency, the delay in data transmission between IoT devices and cloud platforms, can hinder the effectiveness of real-time adjustments. High latency can disrupt content delivery for learners in remote or underdeveloped regions with unstable internet connections, making the learning experience less seamless and responsive. Overcoming these limitations requires the optimization of data transmission protocols or implementing edge computing solutions, where data processing occurs closer to the source (the IoT devices), reducing latency.

While cloud computing offers scalability, integrating IoT devices into educational environments can be costly, particularly for institutions with limited budgets. IoT-enabled smart classrooms, wearable devices, and other interactive tools require significant investment in hardware and maintenance. Additionally, scaling adaptive content delivery to accommodate large numbers of learners and IoT devices places further demands on cloud resources, leading to potential cost increases. Striking a balance between infrastructure costs and educational benefits is a challenge, particularly for schools and universities in developing regions.

In adaptive learning environments, data is collected from various IoT devices, each potentially using different communication protocols and formats. Interoperability issues can arise when integrating and processing this diverse data range in cloud platforms. Ensuring that different IoT devices, platforms, and cloud services work seamlessly together requires the development of standardized protocols and data formats. With such standardization, the data collected may be entirely usable, limiting the ability of adaptive systems to deliver personalized content effectively.

Adapting learning content based on real-time data from IoT devices involves sophisticated algorithms that can process a large volume of data, predict learner needs, and recommend appropriate adjustments. Designing and implementing these algorithms is a complex task that requires continuous development and refinement to ensure they accurately reflect learners' progress and preferences. Furthermore, algorithms must account for many factors, such as learning style, emotional state, and cognitive load, to provide effective recommendations. Balancing these factors without overwhelming the learner or causing unnecessary interruptions presents an ongoing challenge.

The use of IoT devices to collect detailed data on learner behavior raises several ethical concerns, particularly around consent and the extent of data collection. Learners may not always be fully aware of the data being collected by IoT devices or how it will be used. Another concern is the potential for bias in content adaptation algorithms, which may reinforce existing educational inequalities. Ensuring that adaptive learning systems are transparent, equitable, and respectful of learners' privacy and autonomy is essential to gaining trust and ensuring ethical use.

The success of IoT-enabled adaptive learning systems depends heavily on the reliability and maintenance of the IoT devices and cloud infrastructure. Any malfunction in IoT devices, such as wearables or sensors, could lead to data collection gaps, affecting the system's ability to deliver personalized content. Similarly, cloud downtime or outages can disrupt the learning process, leading to a poor user experience. Ensuring continuous operation and timely maintenance of IoT devices and cloud services requires skilled personnel and resources.

V. Conclusion

The fusion of cloud computing and the IoT represents a transformative force in the evolution of e-learning platforms, enabling more personalized, adaptive, and efficient content delivery. By leveraging the scalability and flexibility of cloud infrastructure, along with IoT's real-time data collection capabilities, e-learning platforms can now dynamically tailor educational content to meet individual learners' unique needs and preferences. This convergence enhances the learning experience, making it more engaging, responsive, and effective. However, implementing cloud and IoT-based adaptive content delivery successfully presents several challenges. Data privacy and security, latency in real-time processing, infrastructure costs, data interoperability, and ethical concerns must be carefully addressed to ensure these technologies are applied responsibly and effectively. Furthermore, the complexity of content adaptation algorithms and the reliability of the underlying infrastructure remain critical factors for the long-term success of adaptive learning systems.

As educational institutions continue to embrace digital transformation, the future of e-learning lies in further refining these technologies. Integrating advancements such as artificial intelligence and machine learning with cloud and IoT will pave the way for even more sophisticated adaptive systems. These developments will not only enhance the personalization of learning but also help overcome current limitations, ensuring

that education remains accessible, efficient, and equitable for all learners. This study highlighted the significant potential of cloud computing and IoT in reshaping the education landscape. Educators and technologists can create more dynamic, learner-centered environments that offer meaningful, data-driven educational experiences by addressing existing challenges and exploring new technological frontiers.

Design of a Mobile Language Learning App for Students with ADHD Using Augmented Reality

Leonardo Paolo Cesias-Diaz, Jorge Armando Laban-Hijar, Juan Carlos Morales-Arevalo
Faculty of Engineering, Universidad Peruana de Ciencias Aplicadas, Lima, Perú

***Abstract*—Attention Deficit Hyperactivity Disorder, ADHD for short, impedes submission to traditional teaching as it affects cognitive abilities such as executive function skills, memorization, and focus. In this case, how will kids with ADHD learn languages? This paper provides a solution by presenting the capabilities of a mobile language learning tool called AugmentedFocus, which is designed to support children with ADHD through the use of augmented reality. This association has allowed personalized instruction, accompanied by noticeable augmented reality elements so that learners, teachers, and administrators are able to use their mobile phones to comprehend instructional materials. The objective is to evaluate the application's design, architecture, prototype, some testing results, and adjustments made during its implementation, while discussing other features within the context. More significantly, we aim to demonstrate how the mobile application can enhance engagement and retention in language learning among kids with ADHD. Attention Deficit Hyperactivity Disorder obstructs dependency on traditional measures of teaching since it relates to cognitive skills like executory function skills, memory, and focus. In this case, how will kids with ADHD learn languages? This paper addresses the issue by demonstrating the effectiveness of a mobile language learning app, AugmentedFocus that is specifically created for ADHD kids and shows a Technology in education.**

***Keywords*—ADHD; augmented reality; language learning; technology in education; mobile application; design; prototype**

I. Introduction

ADHD is a neurodevelopmental condition that significantly impairs children's ability to concentrate, focus, and retain information thereby posing great challenges within an educational environment [1]. Traditional methods of learning may not be appropriate for an individual with ADHD because of attention and memory problems entailed by such a disorder. Emerging technologies in education, like AR, may introduce new ways to support these students by engaging them in more interesting and interactive learning experiences [2].

Augmented reality is a technology that has appeared in recent years and is being widely used in different areas. In this case, we are looking to adapt this technology to the learning of children with ADHD because they have great difficulty concentrating and this tool allows them to learn in an entertaining and effective way [3]. Because of this we decided to create a mobile application using augmented reality focusing in ADHD students.

The primary goal of this app is to improve attention retention and reduce impulsivity through interactive and engaging educational content [3]. Using a smartphone, students can access a variety of AR-enhanced lessons. Teachers and administrators also benefit from functionalities that simplify content management and tracking student progress.

Although it was not easy to use augmented reality tools due to our inexperience, this was not a reason not to continue with the research and we continued forward until we achieved the objective.

II. Literature Review

Technological progress in the educational sector has brought forth more ways to better learning, especially for people with cognitive challenges. A new method is by using augmented reality, which places digital elements into the real world so that an interesting mixed environment is created; this has been proven by some studies to help keep students' attention, which is very important to people with ADHD [4, 5].

Previous studies have pointed out AR use in creating relatively immersive learning experiences that foster cognitive engagement, especially through immediate feedback [6]. The use of AR in education has been applied to various fields, from science to language learning [7]. Specifically, however, its use as a methodology for teaching language to students with ADHD has not received much attention. This involves an improvement over the existing work by applying AR where it might best benefit such learners, meeting their individual cognitive design requirements.

Research in study [29] was conducted where an interactive laboratory with augmented reality was successfully implemented for engineering, arts and social sciences, and science students. It facilitates practical learning in various disciplines. Within a period of two years and six months, it attracted 7952 student visits and was used in 24 subjects. Despite the obstacles that appeared (lack of augmented reality content and insufficient technical support), the research demonstrated the great interest that students had in the laboratory, where 71.5% were from engineering [29]. Unfortunately, the laboratory was stopped due to the appearance of the COVID-19 pandemic.

III. Methodology

The approach taken in the development of AugmentedFocus was user-centered and iterative, ensuring that the needs of students with ADHD were addressed at every phase. The methodologies followed were Scrum for software development, Flutter for the mobile app design, and ARCore for integrating any augmented reality functionalities [8] [9].

A. Scrum Method

Scrum is an agile methodology framework primarily focused on software development, although it is being attempted to be used in different areas. The objective of this methodology is to facilitate collaboration within a development team and to deliver products constantly, i.e. in an iterative manner. The main agile principles used by Scrum are adaptability, collaboration and continuous delivery [20]. Fig. 1 shows the order of the tasks developed in the Scrum process.

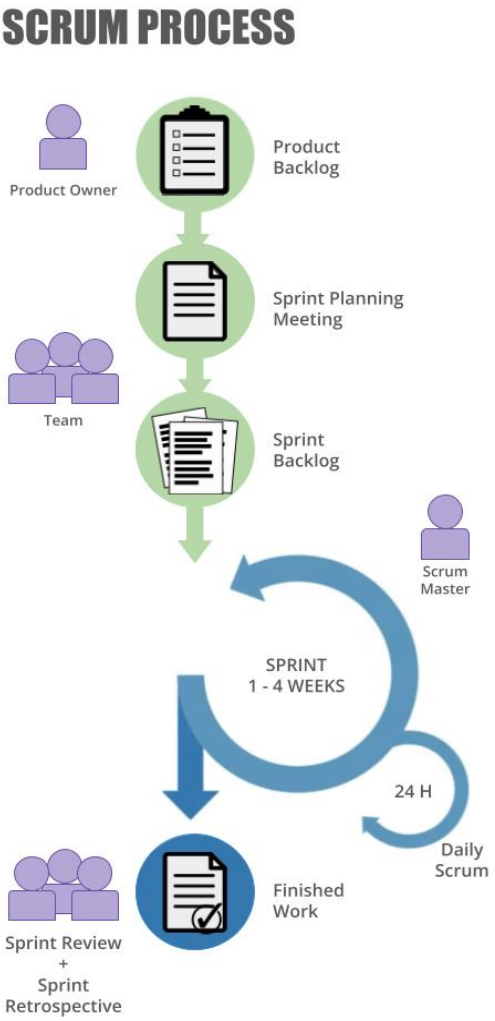

Fig. 1. Scrum process.

The Scrum methodology is composed of four essential components.

1) Small, multidisciplinary teams: Small, multidisciplinary teams that self-organize for the development of each phase and work together to achieve a common goal.

2) Roles

a) Scrum master: The person in charge of supporting the Scrum process, helps solve problems and ensures that the Scrum process is followed.

b) Product owner: This is the representative of the product's stakeholders, helping the team to set the objective to be achieved and prioritize what should be developed.

c) Development team: They are responsible for developing the product and delivering it.

3) Artifacts

a) Product backlog: This is the planned and prioritized list of requirements and tasks to be developed by the Development Team during the development of the product.

b) Sprint backlog: It is the set of tasks chosen for development within a Sprint.

4) Events

a) Sprint: This is the fixed development period in which the chosen set of requirements is implemented.

b) Daily scrum: Short, daily meeting held by the development team to check progress.

c) Sprint planning: Meeting for planning a Sprint.

d) Sprint review: Review meeting of the work accomplished throughout a Sprint.

e) Sprint retrospective: Reflection by the Development Team on a Sprint to find points for improvement.

B. System Design

The AugmentedFocus architecture was designed to support high levels of engagement, ease of use, and scalability. The mobile app was built using Flutter, a robust framework that enables cross-platform compatibility, ensuring that the app can be deployed on both iOS and Android devices [10]. This framework also enables rapid prototyping and testing, which was essential in the iterative design process [11].

Data management and security were priorities from the early stages of development, selecting Firebase as the primary database to store user information, lesson content, and AR assets. Firebase offers cloud-based scalability and strong integration with mobile platforms, making it a suitable choice for this project [12].

The backend API was implemented using Django, a Python framework known for its security and ease-of-use features [13]. Django provided the tools needed to build a secure and responsive application programming interface (API) that connected the mobile frontend to the database and notification system. The API handles user authentication, lesson retrieval, AR asset management, and notifications, which are critical features to ensure a smooth user experience.

C. Augmented Reality Integration

The core functionality of AugmentedFocus lies in its AR-enhanced lessons. We used the ARCore SDK to create immersive and interactive learning environments that integrate 3D objects and animations into language lessons [14]. ARCore was selected due to its compatibility with most smartphones and its ability to render high-quality 3D models in real-time, which is essential for creating engaging content for students with ADHD [15].

AR lessons are designed to incorporate language learning into interactive tasks, such as assembling virtual puzzles, interacting with 3D objects, and completing language-based challenges in a simulated environment. This gamification of learning has been shown to increase motivation and engagement

among students with ADHD, who often struggle to concentrate in traditional learning environments [16].

D. Testing and Evaluation

To ensure that the system met the needs of its users, several rounds of usability testing were conducted with students, teachers, and administrators. Participants were asked to complete specific tasks within the app, such as logging in, accessing lessons, and interacting with AR content. Their feedback was collected and analyzed to identify any usability issues or technical problems that required adjustments [17].

A mixed-methods approach was used to evaluate the application. Quantitative data was collected through system logs and performance metrics, while qualitative feedback was obtained through surveys and interviews with participants. This comprehensive approach allowed us to understand both the technical performance of the system and the user experience aspects [18].

E. Design tools

1) Figma: The use of Figma was essential for the design of the application since this allowed the different prototypes and mock ups to be made in addition to allowing collaborative work with the Development Team because it is a cloud-based technology where several people can edit in real time.

2) Vertabelo: This tool allowed us to create the application's database diagram thanks to the fact that it manages a structure of tables, indexes and relationships between them. This tool was very useful since it is based on cloud technology, which allows the Development Team to work collaboratively.

F. Development tools

1) Flutter: Flutter is an open source development framework created by Google. Firstly, it is well known for its high cross-platform compatibility when developing mobile applications and its simplicity when developing thanks to the Dart language. Secondly, it is a very good work tool because it offers the Hot reload functionalities that allow you to see the changes instantly without restarting the application and Widgets that are reusable components to build the application [10].

2) Dart: It is an open source programming language aimed at developing frontend applications, especially web and mobile. This programming language goes hand in hand with Flutter and is what makes it well known in the creation of multiplatform applications. What stands out most about Dart is the simple syntax it uses because it is very similar to Java, JavaScript and C++, flexible compilation, object-oriented, support for asynchronous functions, automatic memory management and great multiplatform support. Given all of the above, this is why Dart and Flutter are a great match in the frontend development of applications.

3) MySQL: It's relational database manager developed by Oracle. We chose because of his ease of organizing, managing and storing data for application testing.

4) Android studio: An integrated development environment (IDE) for developing Android applications, created by Google. This IDE allows development in languages such as Java, Kotlin, and C++.

5) Firebase: It is a platform based on cloud technology which offers various services such as real-time database, firestore, authentication, storage, hosting, messaging, analytics, crashlytics, predictions and other functionalities based on cloud databases. Firebase was mainly used to host our real-time database and to store and synchronize application data [12].

6) Django: It is a high-level framework that uses the Python programming language, which is characterized by its high development speed, but it does not leave security aside and helps developers avoid common errors in data security. It is also very efficient with both scalability and versatility, allowing developers to adapt their application to the needs of users. Django was chosen due to its ease and speed of development, as well as the great compatibility it has with applications that are related to augmented reality [13].

7) AR Core: It is the SDK developed by Google that focuses on offering a tool to create new interactive and immersive experiences on Android, iOS, Unity and the web. Using interactive objects in the virtual world where it includes motion tracking, depth understanding, environmental understanding, presenters and light estimation. The main use of this tool in the application is to provide augmented reality functionality to generate interactive classes for students with ADHD and thus capture and maintain the attention of students [14].

IV. Development of the Methodology

The Rational Unified Process (RUP) methodology was adopted to guide the development of AugmentedFocus. RUP is a software development process that divides the project lifecycle into four distinct phases: initiation, elaboration, construction, and transition. This methodology was chosen because it offers a structured approach to software development, which is crucial for managing complex projects such as AugmentedFocus [19].

A. Initiation Phase

During the initiation phase, the main focus was on understanding the application requirements, including the specific requirements of students with ADHD. Through collaboration with educators and specialists, key functionalities that AugmentedFocus should include were identified: AR-enhanced lessons, user-friendly navigation, and robust security for student data [20].

Stakeholder meetings were held to align project goals, feasibility, and timelines. An early prototype of the app was also developed to provide a proof of concept for the AR features and mobile interface.

The application requirements were identified through meetings and a prioritized list of applications was created Table I.

These are the functionalities to be developed identified thanks to the meetings with the Product Owner. These user stories also have their own task to be make for every developer during a sprint.

TABLE I. PRODUCT BACKLOG

Code	Title	Value (1/2/3/5/8)
US001	Complete a learning activity with augmented reality	8
US002	Access progress statistics	2
US003	Access additional educational content	5
US004	Record activity progress	1
US005	Set up custom activities with augmented reality	5
US006	Download augmented reality content for offline use	2
US007	Check achievements and progress in activities	2
US008	Log in to the app	1
US009	Interact with objects in augmented reality vocabulary	8
US010	Do vocabulary exercises with augmented reality	5
US011	Explore virtual reality with augmented reality	3
US012	User data security	1
US013	Application accessibility	1

B. Elaboration Phase

This phase includes the system architecture and design. Use cases were defined and a detailed system design was created that described how the various components of the application would interact with each other. The first functional prototype of the application was also developed in this phase, focusing on key features such as user authentication, lesson retrieval, and AR integration [21].

We started with first versions of Fig. 2 logic and Fig. 3 physical diagrams for the app before doing the C4 model diagrams with more specific information.

C. Construction Phase

This phase it's totally focused in the entire application, it was developed in Flutter, we used it to build the front-end of the mobile app, ensuring cross-platform functionality [23]. In parallel, the backend API was built using Django, while Firebase managed data storage and real-time communication between the server and mobile devices [24].

The version control used was github and everything about the application (backend, frontend) is in the repository. We used android studio during the whole development process and using the virtual simulator of android studio to test the application.

D. Transition Phase

This phase focus on deploying the application and ensuring its stability in real-world environments. It includes extensive testing to ensure that the application worked well on different devices and operating systems. In addition, final usability testing was conducted to validate that the user interface was intuitive and accessible for students with ADHD [25].

E. Development

The following images present the system architecture at different levels of the C4 diagram:

The system has three users:

1) *Students with ADHD*
2) *Teachers*
3) *Administrator*

Where these interact with the AugmentedFocus application which is composed of Mobile Application Frontend and Mobile Application Backend, it contains sign-in, security, authenticator controller, AR module, AR controller, lesson controller and notifications functionalities all connected to the database hosted in Firebase, in addition to an external notification system. After that we designed our C4 model diagrams. Firstly Fig. 4 context diagram secondly Fig. 5 container diagram and finally, Fig. 6 component diagram.

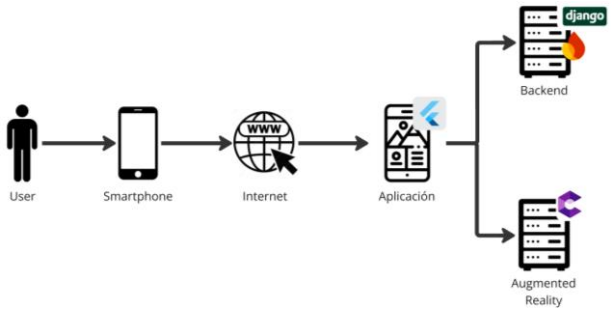

Fig. 2. Logic diagram of AugmentedFocus.

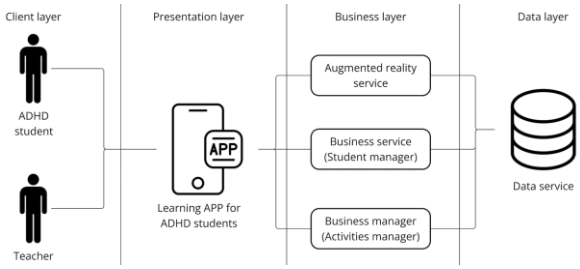

Fig. 3. Physical diagram of AugmentedFocus.

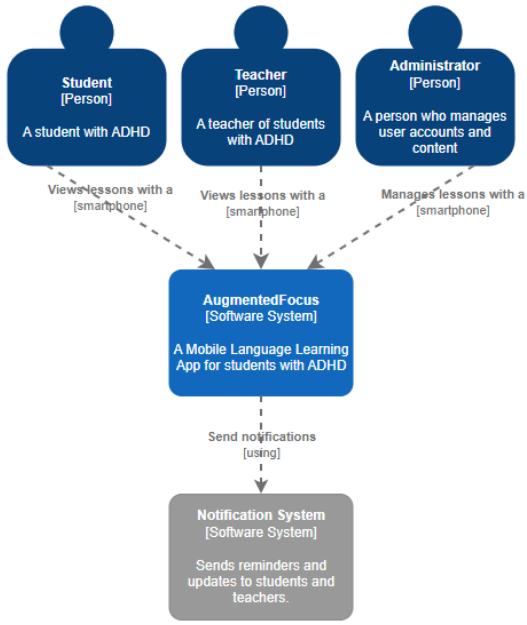

Fig. 4. Context diagram of the AugmentedFocus system.

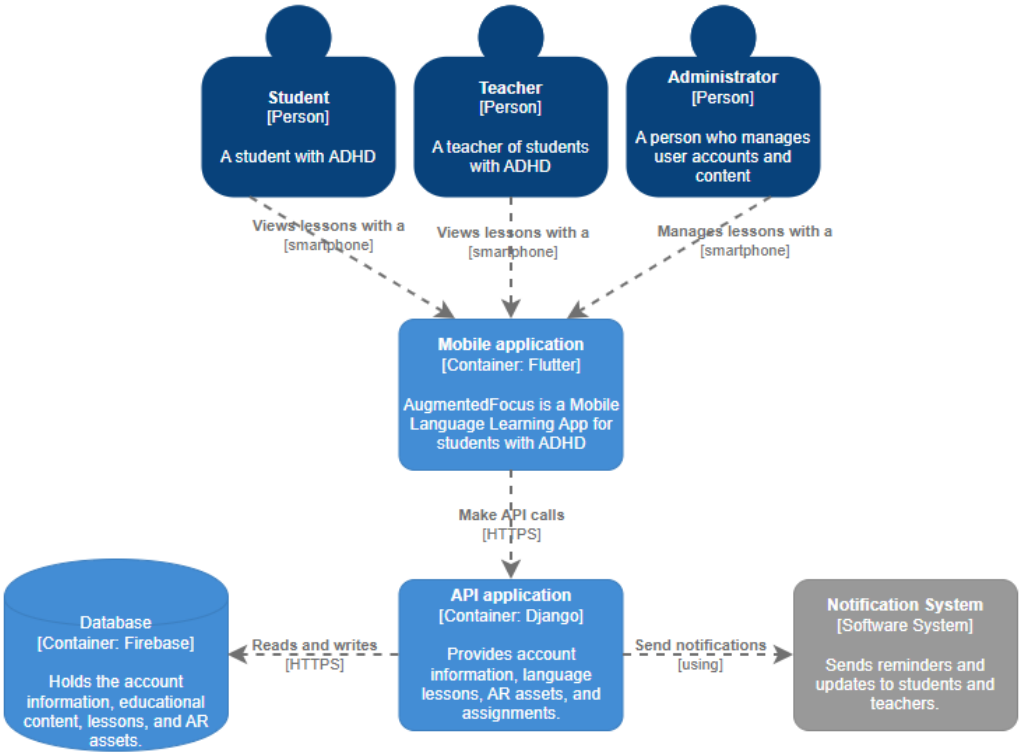

Fig. 5. Container diagram, showing how different systems interact with each other.

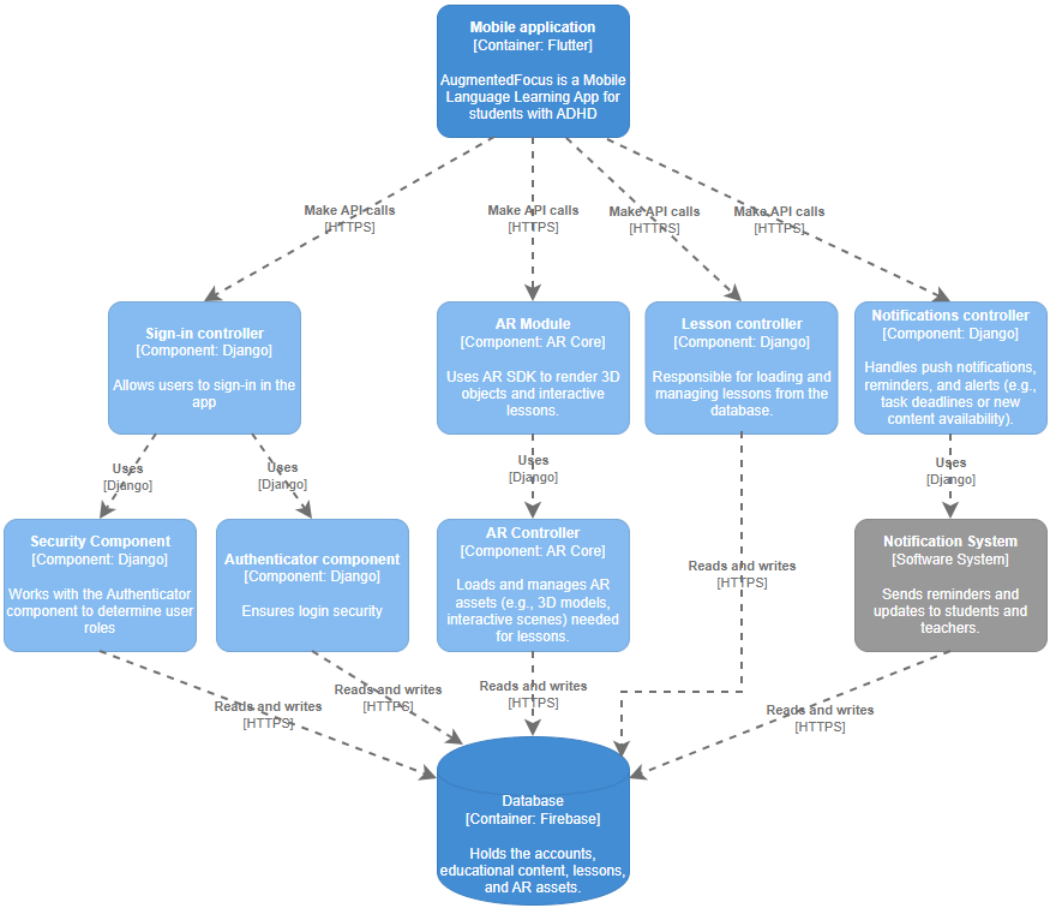

Fig. 6. Component diagram detailing the interactions between the different modules of the system.

After design of the C4 diagrams we decided to start with the mobile application prototypes, since it's an application for kids and teachers we needed to focus on something simple but at the same time useful for our users. Prototypes were designed for the application design which are: Fig. 7 - Welcome Prototype, Fig. 8 - Sign in and Register, Fig. 9 - Upcoming events and Course list, Fig. 10 - Course unit list and Course topic list, Fig. 11 - Grades and Profile, Fig. 12 - Activity and Activity description and Fig. 13. An example of an augmented reality activity. We choose a warm colors and an interface based on a kind of virtual classroom for students because we needed the structure that can be organized due to the activities and different courses that may exist in the school or institute.

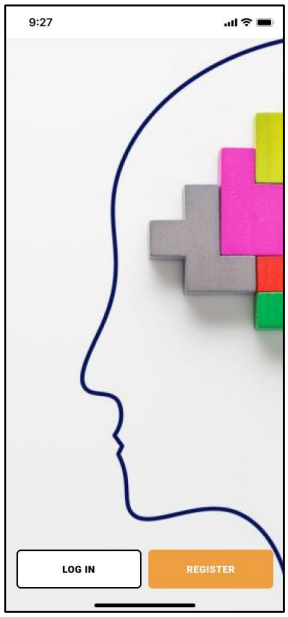

Fig. 7. Welcome prototype.

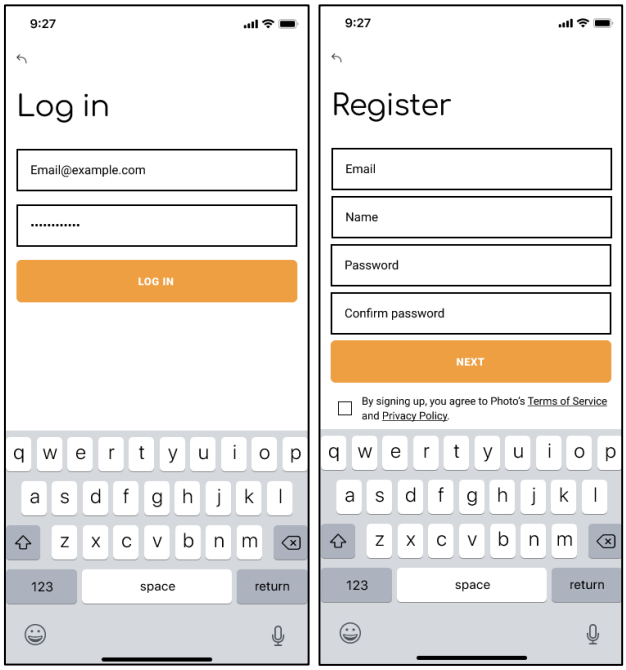

Fig. 8. Sign in and register prototype.

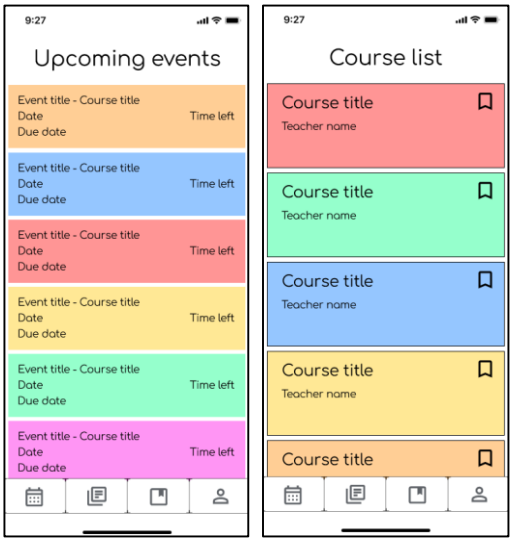

Fig. 9. Prototype upcoming events and course list.

Fig. 10. Prototype of course unit list and course topic list.

Fig. 11. Prototype of grades and profile.

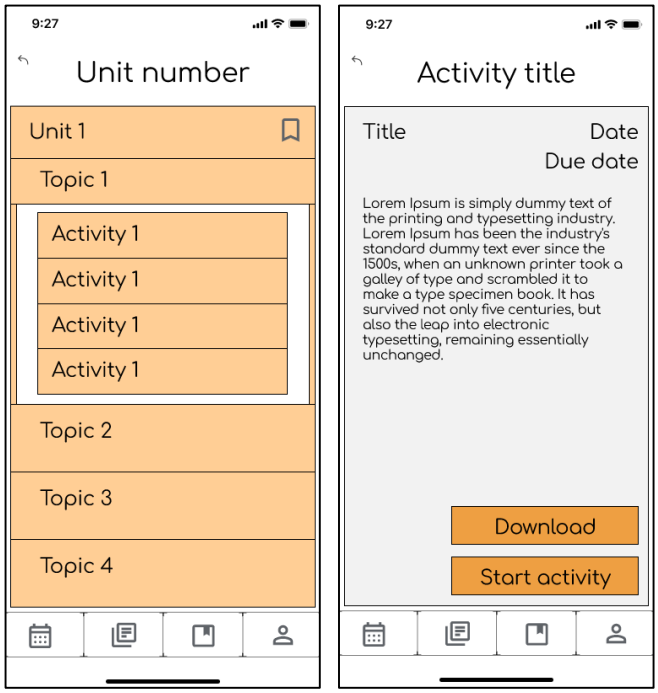

Fig. 12. Prototype of activity and activity description.

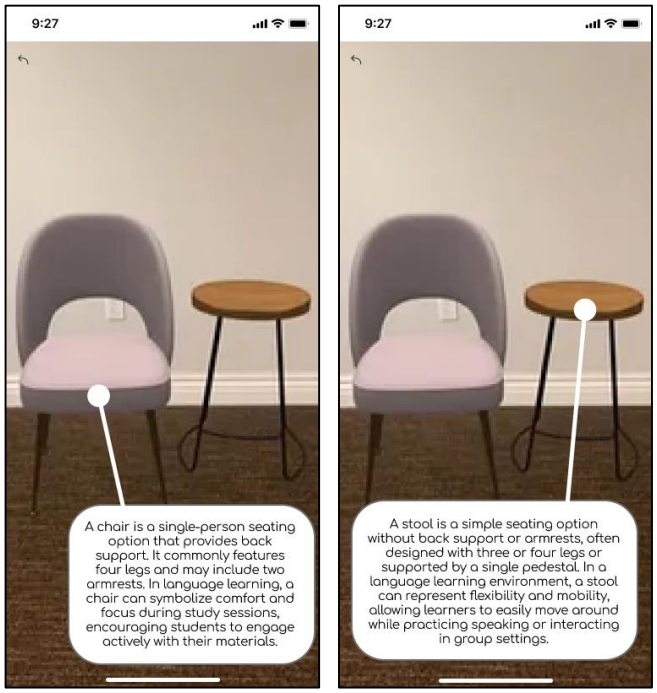

Fig. 13. Prototype of example of augmented reality activity.

V. Application Features

The application offers three very important functionalities to help children with ADHD learn language, including augmented reality activities, a student grade manager, and an augmented reality activity manager.

A. Activities with Augmented Reality

This feature is the main and most important of the application, which gives students the possibility of carrying out language learning activities with augmented reality. This involves interactively combining language classes with 3D models to capture the attention of students with ADHD, which allows capturing and maintaining the attention of these students.

B. Student Manager

Once all students have their account, teachers will be able to monitor information, grades and progress to check their performance within the course and in the same way check whether students are adequately acquiring the knowledge from the classes.

C. Activity Manager with Augmented Reality

The platform provides a manager for augmented reality activities that allows you to enable or disable the different augmented reality activities. This functionality is only enabled for the application administrator.

VI. Results

The tests of usability were done getting a completely well-done performance, the AugmentedFocus app over ten weeks of development. Key performance indicators are lessons activities, lesson completion rates, and feedback on the usability made by the development team. The results were good showing a nice performance and content compared to traditional learning methods. Since we are in the development phase our results are the design and development of the application, which is ready to be tested with real students with ADHD.

VII. Discussion

The results of this study, however, conform to previous studies noting the advantages of augmented reality for students, particular those who are slow learners or have attention problems [26] [27]. The attention deficit that these students may at times present, as a characteristic feature of an educational environment, was mitigated by AR-designed lessons which are interactive and more engaging for students with ADHD [22], [28]. It was evident that this method not only improved students' concentration but also contributed to create a lively and interesting atmosphere which is important in enhancing learning in such age groups. The AR lessons were able to provide experiences that integrate both active visualization and interaction thus making the acquisition of knowledge and skills much easier.

VIII. Conclusion

As AugmentedFocus proves, there can be useful applications of augmented reality in helping students learn with Attention Deficit Hyperactivity Disorder (ADHD), especially in foreign language learning. In the case of this particular app, interactive lessons which also include some gamification elements were included which lead to children having improved focus in their tasks as well as less impulsiveness which is often characteristic of this demographic and is a major obstacle to learning. In this light, the above results indicate that the adoption of new technologies such AR for example, can help change the concept

of how the teachers teach learners with lower cognitive abilities in an even better manner and that is a universal fit approach.

IX. Future Work

Future development of AugmentedFocus will focus on expanding the app to cover a broader range of subjects beyond language learning, such as math, science, and social studies. The approach will broaden the platform's utility, allowing more students to benefit from its interactive features. Additionally, we were thinking about adding adaptive learning algorithms to further personalize lessons based on each student's individual progress and behavior. By tailoring content to users' specific needs, it is hoped to improve learning effectiveness and foster greater motivation. The long-term impact of AugmentedFocus on students' academic performance and emotional well-being will also be evaluated, with the goal of creating a comprehensive educational tool that responds to the unique demands of those with ADHD.

Classification of Painting Style Based on Image Feature Extraction

Yuting Sun
Zhoukou Vocational College of Arts and Sciences, Zhoukou, Henan 466000, China

***Abstract*—The classification of painting style can help viewers find the works they want to appreciate more conveniently, which has a very important role. This paper realized image feature extraction and classification of paintings based on ResNet50. On the basis of ResNet50, squeeze-and-excitation, and convolutional block attention module (CBAM) attention mechanisms were introduced, and different activation functions were selected for improvement. Then, the effect of this method on painting style classification was studied using the Pandora dataset. It was found that ResNet50 obtained the best classification accuracy under a learning rate of 0.0001, a batch size of 32, and 50 iterations. After combining the CBAM attention mechanism, the accuracy rate was 65.64%, which was 6.77% higher than the original ResNet50 and 2.52% higher than ResNet50+SE. Under different activation functions, ResNet50+CBAM (CeLU) had the most excellent performance, with an accuracy rate of 67.13%, and was also superior to the other classification approaches such as Visual Geometry Group (VGG) 16. The findings prove that the proposed approach is applicable to the style classification of painting works and can be applied in practice.**

***Keywords*—Feature extraction; painting; style classification; ResNet50; attention**

I. Introduction

A. Research Background

Under the influence of the continuous development and progress of various technologies, more and more resources are stored in the format of data, which provides a way for people to get the resources they want more conveniently and quickly. Painting, as an art form, has accumulated many excellent works after a long development. An increasing number of approaches have been applied in the research and analysis of paintings as the machine vision technology gradually develops [1]. Painting style refers to the artistic characteristics and expression techniques shown by artists in their works, which can reflect the emotions, personalities, and aesthetics during the creation of artists [2]. The classification of painting styles can help people gain a better understanding of different painting styles, which is an important content in the research of paintings. The traditional style classification of paintings is carried out by professional appreciation experts, which requires experts to have excellent professional knowledge and appreciation ability [3]. However, the manual method requires a lot of workload and has a low efficiency. With the development of machine vision, there is a growing trend of preserving paintings in digital format. As an image classification task, painting style classification can also be realized based on image classification technology.

B. Literature Review

In the current classification of painting works, most methods used to achieve classification based on the extraction and quantification of image color, texture, and other features [4]. Liu [5] decomposed paintings into sparse components and other components based on sparse decomposition and then realized style classification using naive Bayes. It was found through experiments that this method achieved 98.63% accuracy and consumed the shortest classification time. Li et al. [6] extracted the main details and edge information from Dongba paintings for the classification of Naxi Dongba paintings, realized the classification based on a multi-layer graph neural network (GNN), and proved the advantages of this method through experiments on small sample datasets. Bianconi [7] evaluated the effects of color stability and enhancement in paintings and found that neither feature showed significant advantages. Deep learning methods have shown strong capabilities in image feature extraction. Considering the shortcomings of traditional methods in feature extraction, deep learning-based approaches have been increasingly applied in image processing [8]. Liong et al. [9] compared the effectiveness of several deep learning approaches for the automatic classification of Chinese paintings and found that the improved pre-trained neural network achieved 99.66% accuracy when classifying more than 1,000 Chinese paintings belonging to six categories. Qing and Ce [10] proposed a multi-scale convolutional neural network (CNN) framework for classifying painting images, which can integrate global and local information into a single image. They achieved accuracies of 74.12% and 75.88% for the WikiArt dataset and Web Gallery of Art dataset respectively. Zhao et al. [11] constructed an artistic comment graph based on co-occurrence relations and document word relations, enabling through analysis of art comments, they used a graph convolutional network technology to realize the classification of painting types, genres, etc. Extensive experiments verified the performance of this method. Zhong et al. [12] proposed a dual-channel dual-path network for art painting classification. Experiments on two datasets demonstrated that this method achieved good classification accuracy.

C. Research Content

This paper conducted research on the classification of painting styles based on image feature extraction. In Section II, it introduces a method for image feature extraction and classification based on ResNet50, and the improvement to ResNet50 was proposed. In Section III, the designed method was experimentally validated, and the experimental dataset

and results were described, demonstrating the effectiveness of the proposed improvement to ResNet50. Compared with current research, this paper achieved optimization of ResNet50 performance in terms of the attention mechanism and activation function. This article provides a novel and useful method for the classification of painting styles in practice and provides strong support for subsequent painting retrieval and artist identification. Finally, the paper is concluded in Section IV.

II. Image Feature Extraction and Classification Based on ResNet50

A. ResNet50

In the study of image classification, the frequently used method is to extract image features such as color and texture [13] and then classify images based on decision trees, neural networks, and other classifiers. However, compared with ordinary images, paintings contain more details and artistry. Therefore, the traditional image classification methods have poor performance in the classification of painting styles. Deep learning can extract image features through a deep network and realize automatic classification [14]; therefore, feature learning is deeper and more comprehensive. Therefore, this paper chooses the deep learning method to classify painting styles.

ResNet50 is a kind of deep CNN [15]. Generally speaking, as the quantity of layers in the network increases, gradient explosion and disappearance may occur when the feature extraction ability of the network is improved. However, the ResNet series network uses skip connection, that is, in the forward propagation, the input of a layer is directly transmitted to the following layers, so that the feature information of different layers can be transmitted to each other. It has been extensively used in image classification and other scenarios [16]. ResNet50 consists of 49 convolutional layers and one fully connected layer, and Table I presents its structure.

TABLE I. ResNet50 Structure

Layer name	50-Layer
Conv1	7×7, 64, S=2 3×3 maxpool, S=2
Conv2_x	$\begin{bmatrix} 1\times1,64 \\ 3\times3,64 \\ 1\times1,256 \end{bmatrix}\times3$
Conv3_x	$\begin{bmatrix} 1\times1,128 \\ 3\times3,128 \\ 1\times1,512 \end{bmatrix}\times4$
Conv4_x	$\begin{bmatrix} 1\times1,256 \\ 3\times3,256 \\ 1\times1,1024 \end{bmatrix}\times6$
Conv5_x	$\begin{bmatrix} 1\times1,512 \\ 3\times3,512 \\ 1\times1,2048 \end{bmatrix}\times3$
	Mean pool, fully connected layer, Softmax

As shown in Table I, ResNet50 first carries out a convolution and maximum pooling and then carried out feature extraction through four modules with 3, 4, 6, and 3 repetitions. Each block contains three convolutions, and the size of the convolution kernel is 1, 3, and 1, respectively. Finally, the obtained features are passed through mean pooling and the fully connected layer. Softmax outputs classification results.

B. Improvements to ResNet50

In order to enhance ResNet50's focus on the important information related to style distinction in paintings, this paper introduces the attention mechanism to improve the traditional ResNet50. For the modules from Conv2_x to Conv5_x in ResNet50, an attention module is added at the end of each module to improve ResNet50's ability to learn important features. The following two types of attention modules are added.

1) Squeeze-and-excitation (SE) attention mechanism [17]: its principle is to realize the attention of the channel with a high weight by adding a weight to each channel in the feature graph, and there are three main steps.

a) Squeeze: Before squeeze, the importance of each channel is the same. For a $H \times W \times C$ feature graph ($H \times W$ represents the height and width of the feature graph, C is the quantity of channels), the feature value of each channel is computed:

$$z_j = \frac{1}{H\times W}\sum_{i=1}^{H}\sum_{k=1}^{W} X_{ijk} \quad (1)$$

where X_{ijk} refers to the pixel value of the j-th channel in the i-th row and k-th column of the feature map.

b) Excitation: The weight for each channel is learned based on the fully connected neural network. The weight of the j-th channel is written as:

$$s_j = \sigma\big[W_2 f\big(W_1 z_j\big)\big], \quad (2)$$

where W_1 and W_2 are the weights of the two fully connected layers.

c) Scale: The feature graph is weighted based on the channel weight. The weighted feature graph is written as:

$$\tilde{X}_{ijk} = s_j \times X_{ijk}. \quad (3)$$

2) Convolutional block attention module (CBAM) attention mechanism [18]: its principle is to weight both channel and spatial dimensions. The features of the two dimensions are described as follows.

a) Channel attention: The feature descriptions of different dimensions are obtained through pooling operation and then stacked on the channel dimension:

$$M_c(X) = \sigma\big[MLP\big(AvgPool(X)\big) + MLP\big(MaxPool(X)\big)\big], \quad (4)$$

where σ is the Sigmoid activation function and MLP is the fully connected layer.

b) Spatial attention: The feature representations of different dimensions are obtained through pooling operation. After splicing, it passes through a 7×7 convolution layer and then through the Sigmoid function to get the weight coefficient. After multiplying the coefficient with the features,

the final feature map is obtained:

$$M_s(X) = \sigma\left[f^{7\times7}\left(AvgPool(X); MaxPool(X)\right)\right], \quad (5)$$

where $f^{7\times7}$ is a 7×7 convolution kernel

In addition to adding the attention mechanism, the ReLU activation function used in ResNet50 is also improved, and the following activation functions are selected:

- PReLU [19]: $PReLU = max(0, x) + t * min(0, x)$, t takes the default value of 0.25;
- LeakyReLU [20]: $LeakyReLU = \begin{cases} x, x \geq 0 \\ ax, x < 0 \end{cases}$, a takes the default value of 0.01;
- CeLU [21]: $CeLU = max(0, x) + min\left(0, a * \left(exp\left(\frac{x}{a}\right) - 1\right)\right)$, a takes the default value of 1.

III. Experiment and Results

A. Experimental Setup

The experiment was carried out on a Windows 64-bit system, with Inter(R)Core(TM)i5-12500 and 32 G memory. The algorithm was implemented based on the TensorFlow2.4.0 framework. Python programming language was used.

At present, in the investigation of categorizing painting styles, the commonly used datasets include Pandora dataset [22], Wikipaintings dataset [23], etc. As the latter contains more than 80,000 works, it is impossible to achieve adequate training under the limited computing resources. Therefore, only a few images were selected from the Wikipaintings dataset for study. The experimental datasets used are as follows.

1) Pandora dataset: There are a few types of painting styles in it, but they include different styles from 17th ancient Greece to the present. Table II presents different styles and the corresponding number of paintings. During the experiment, an 80% portion was allocated for training purposes while the remaining 20% was designated as the test set.

TABLE II. Distribution of the Pandora Dataset1

Style	Number
Pottery of ancient Greece	350
Movement to destroy religious statues	665
Renaissance	812
Baroque	960
Rococo style	844
Romanticism	874
Realism	307
Impressionism	984
Brutalism	426
Cubism	920
Surrealism	242
Abstract expressionism	340

2) Wikipaintings dataset: It includes more than 80,000 painting works belonging to 25 styles. This paper selected images from ten of these styles for research. The selected styles and corresponding number are shown in Table III. They were also divided into a training set and a test set in a ratio of 8:2.

TABLE III. The Distribution of the Wikipaintings Dataset

Style	Number
Rococo	1,007
Baroque	1,056
Neoclasscism	1,345
Impressionism	1,541
Expressionism	1,112
Early Renaissance	1,512
High Renaissance	1,864
Post-Impressionism	1,825
Surrealism	1,854
Symbolism	1,021

The evaluation of the classification performance was based on the following indicators.

a) Accuracy (A): The proportion of the correctly classified samples to total samples is:

$$A = \frac{n_{TP}+n_{TN}}{n_{TP}+n_{TN}+n_{FP}+n_{FN}},$$

where n_{TP} refers to the true positive sample, n_{TN} refers to the true negative sample, n_{FP} refers to the false positive sample, and n_{FN} refers to the false negative sample.

b) Precision (P): The proportion of positive samples classified as positive is:

$$P = \frac{n_{TP}}{n_{TP}+n_{FP}}.$$

c) Recall rate (R): The proportion of positive samples classified as positive is:

$$R = \frac{n_{TP}}{n_{TP}+n_{FN}}.$$

d) F1 value: The comprehensive evaluation of P and R is:

$$F_1 = \frac{2\times P\times R}{P+R}.$$

B. Analysis of Results

In the follow-up experiment, the parameters of ResNet50 were adjusted to obtain better classification performance. Parameter experiments were performed on the Pandora dataset. First, for the learning rate, the batch size was set at 32, and the total count of iterations was 50. The changes in accuracy under different learning rates are presented in Fig. 1.

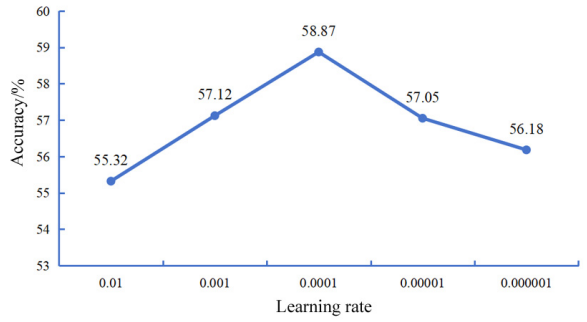

Fig. 1. Changes in accuracy under different learning rates.

In the process of the learning rate decreasing from 0.01 to 0.0001, the accuracy of the improved ResNet50 gradually increased. It reached the highest (58.87%) when learning rate = 0.0001 and then declined. Therefore, the optimal learning rate was 0.0001.

For the batch size, the learning rate was fixed at 0.0001, and the count of iterations was 50. The variation in accuracy under different batch sizes is presented in Fig. 2.

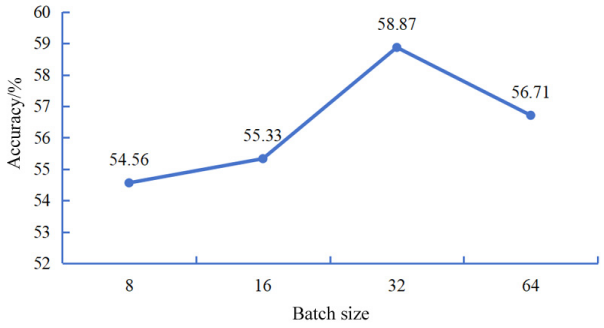

Fig. 2. Changes in accuracy under different batch sizes.

As the batch size increased, the improved ResNet50 also became more accurate. When the batch size was 8, the accuracy was 54.56% at the lowest level, and it was 32, the accuracy was 58.87% at the highest level. Therefore, the optimal batch size was 32.

For the number of iterations, the learning rate was fixed at 0.0001, and the batch size was 32. The changes in accuracy under different iteration numbers are displayed in Fig. 3.

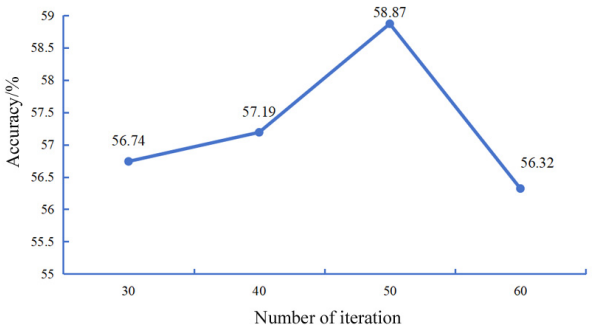

Fig. 3. Changes in accuracy rate under different iterations.

It can be found that when the number of iterations was 60, the accuracy of ResNet50 was the lowest, which was 56.32%; when the count of iterations was 50, the accuracy was the highest (58.87%). Therefore, the optimal number of iterations was 50.

Based on the above results, in the subsequent experiments, the learning rate of ResNet50 was set as 0.0001, the batch size was 32, and the count of iterations was 50. Moreover, ResNet50 was compared with other traditional residual network models. The floating point operations per seconds (FlOPs) and parameters of different algorithms are presented in Table IV.

TABLE IV. COMPARISONS WITH OTHER RESIDUAL NETWORK MODELS

	ResNet18 [24]	ResNet34 [25]	ResNet50	ResNet101 [26]
Accuracy/%	56.46	58.41	58.87	58.89
FLOPs/G	3.67	7.35	8.21	15.54
Parameter/M	11.71	21.83	25.55	44.56

It can be seen that with the increasing depth of the network, the accuracy of ResNet also gradually increased. Among them, ResNet101 achieved the highest accuracy at 58.89%, which indicated a slight improvement of 0.02% compared to ResNet50. However, there was a significant increase in FLOPs and parameter for ResNet101 compared to ResNet50, which not only increased the complexity of the model but also imposed higher requirements on hardware facilities. This was not conducive to practical applications. On the other hand, ResNet50 achieved a good balance between classification performance and complexity, verifying its reliability.

For the improvement of ResNet50, the original ResNet50 was combined with different attention mechanisms. The accuracy for different datasets is presented in Table V.

TABLE V. RESNET50 COMBINING DIFFERENT ATTENTION MECHANISMS

	Pandora dataset	Wikipaintings dataset
ResNet50	58.87	51.37
ResNet50+SE	63.12	56.54
ResNet50+CBAM	65.64	58.79

As shown in Table V, when the Pandora dataset was used, after combining ResNet50 with the SE attention mechanism, the accuracy was 63.12%, which was 4.25% higher than the original ResNet50; when combined with the CBAM attention mechanism, the accuracy was 65.64%, which was 6.77% higher than the original ResNet50 and 2.52% higher than ResNet50+SE. When the Wikipaintings dataset was used, after combining ResNet50 with the SE attention mechanism, the accuracy achieved was 56.54%, which showed an improvement of 5.17% compared to the original ResNet50. When combined with the CBAM attention mechanism, the accuracy obtained was 58.79%, which showed an improvement of 7.42% compared to the original ResNet50 and an improvement of 2.25% compared to ResNet50+SE. These results showed that compared with SE, CBAM

combined with ResNet50 could achieve better performance in the style classification of paintings and had stronger ability to extract image features.

Then, on the basis of ResNet50+CBAM, the improvement of the activation function was compared. The accuracy for different datasets is presented in Table VI.

TABLE VI. RESNET50 COMBINED WITH DIFFERENT ACTIVATION FUNCTIONS2

	Pandora dataset	Wikipaintings dataset
ResNet50+CBAM (ReLU)	65.64	58.79
ResNet50+CBAM (PReLU)	66.32	59.42
ResNet50+CBAM (LeakyReLU)	66.87	59.98
ResNet50+CBAM (CeLU)	67.13	60.37

The ReLU used in the original ResNet50 had the worst performance in classifying painting styles from the Pandora dataset, with an accuracy of only 66.32%. After replacing it with PReLU, the accuracy reached 66.32% (+0.68%). After replacing it with LeakyReLU, the accuracy reached 66.87% (+1.23%). After replacing it with CeLU, the accuracy reached 67.13% (+1.49%). It exhibited the same results for the Wikipaintings dataset. These results showed that CeLU could achieve the best effect in the style classification of paintings in ResNet50+CBAM.

Finally, the ResNet50+CBAM (CeLU) was compared with other methods (Table VII).

TABLE VII. COMPARISON BETWEEN DIFFERENT FEATURE EXTRACTION NETWORKS3

		Accuracy/ %	Precision/ %	Recall rate/ %	F1 value/ %
Pandora dataset	Pyramid local binary pattern (PLBP)+color structure descriptor (CSD)+support vector machine (SVM) [22]	54.70	52.13	50.77	51.44
	MobileNet [27]	54.87	52.31	51.22	51.76
	AlexNet [28]	55.36	53.64	52.11	52.86
	Visual Geometry Group (VGG) 16 [29]	56.52	54.77	55.07	54.92
	VGG 19 [30]	57.12	55.67	55.88	55.77
	InceptionV3 [31]	57.64	56.78	55.97	56.37
	ResNet50	58.87	57.32	56.42	56.87
	ResNet50+CBAM (CeLU)	67.13	65.45	64.59	65.02
Wikipaintings dataset	PLBP+CSD+SVM [22]	47.12	46.77	46.02	46.39
	MobileNet [27]	47.37	47.31	46.54	46.92
	AlexNet [28]	48.05	47.87	46.79	47.32
	VGG 16 [29]	49.35	48.61	47.56	48.08
	VGG 19 [30]	51.07	50.87	48.97	49.90
	InceptionV3 [31]	51.25	51.12	50.33	50.72
	ResNet50	51.37	51.07	50.98	51.02
	ResNet50+CBAM (CeLU)	60.37	59.84	58.49	59.16

It can be found that the traditional method PLBP+CSD+SVM based on feature extraction and classifier had poor performance in painting style classification, with the lowest accuracy of only 54.70% and 47.12%. Specifically, the ResNet50+CBAM (CeLU) exhibited the optimal performance for the two datasets, with F1 values of 65.02% and 59.16%, verifying the reliability of this method in classifying painting styles. Therefore, it can be used in practice to support the classification and retrieval of paintings in real life.

IV. CONCLUSION

This paper studied the classification of painting work styles. A ResNet50-based image feature extraction method was developed to obtain a higher-performance classification algorithm. ResNet50 was improved from aspects of attention mechanism and activation function to achieve image feature extraction and classification. Through experiments on the Pandora dataset, it was found that the classification accuracy achieved by ResNet50+CBAM (CeLU) was 67.13%, which was better than the other deep learning methods. This paper verifies the reliability of the proposed approach; thus, it can be applied in the actual classification of painting styles. The method can be applied in the field of painting work classification and painting information retrieval to promote the informatization and digitization of painting work management.

***Abstract*—Image enhancement is one of the most important areas that is being developed in the field of image processing technology. Image contrast enhancement can significantly improve the perception of the digital image itself. X-ray images are crucial in assisting physicians in the formulation of treatment decisions based on diagnostic information. Contrast enhancement techniques, including Histogram Equalization (HE), Contrast Limited Adaptive Histogram Equalization (CLAHE), and CLAHE with double Gamma Correction (CLAGAMTWO), have been utilized on 30 distinct image datasets. Among the three employed methods, the CLAGAMTWO approach yields the optimal values of SSIM = 0.850 and CNR = 0.773. CLAHE has superior performance with an Entropy value of 7.099. CLAGAMTWO is the superior approach overall, as evidenced by the average metric value, yielding optimal picture quality in visual structure (SSIM), information detail (Entropy), and crisp contrast with little noise (CNR).**

Keywords*—*X-ray; image enhancement; digital image; image processing; grayscale image

I. INTRODUCTION

Image enhancement is one of the most important areas that is being developed in the field of image processing technology. This effectively delivers visual picture enhancement effects and image clarity, both of which are beneficial for subsequent processing and analysis on the computer [1], [2]. Contrast enhancement is critical for improving visual quality in computer vision, pattern recognition, and digital image processing. Low contrast in digital or video images can be produced by a number of causes, including operator inexperience and inadequate imaging equipment. Reduced contrast quality can also be caused by unfavorable environmental variables in the filmed image, such as lack of sunlight or indoor lighting, among others [3]. Articular cartilage and the structures supporting it are vulnerable to deterioration in the degenerative joint condition known as osteoarthritis [4], [5]. X-ray images are crucial in assisting physicians in the formulation of treatment decisions based on diagnostic information [6]. Plain radiology images or X-ray images are one method of determining the condition of the bones. Changes in the skeleton, structure, density, bone deformities, and narrowing of the articular space between adjacent bones can be observed through the use of X-ray images [7], [8], [9]. The low contrast issues in X-ray images of certain intricate components hinder the complete representation of structural information [10]. Consequently, low contrast poses a challenge in discerning elements inside a network area [11]. A possible solution to this problem is to improve the image [12].

Research conducted by study [13] Improve the accuracy of chest X-ray diagnosis by employing DF-GAN (Deep Fusion-Generative Adversarial Networks) data augmentation that is based on text-to-image interaction. The results that were obtained were a sensitivity value of 2.1%, a specificity value of 1.9%, and an area under the curve (AUC) value of 1.4%. Additionally, during training, overfitting was reduced on both sets of data.

Other research concerning the enhancement of chest X-ray images through the use of white balance and CLAHE (Contrast Limited Adaptive Histogram Equalization). The objective of the research is to enhance the precision of pneumonia diagnosis by leveraging the effectiveness of MobileNetV2 and contrast enhancement. It is important to mention that the model achieved the highest accuracy and lowest loss in 50 epoch testing for three-class classification (91.17% accuracy, 35.0% loss) and two-class classification (99.76% accuracy, 7% loss) [14].

Augmented chest X-ray image executed by [15] via deep contrast diffusion learning. The original input image undergoes a multilayer contrast-limited adaptive histogram equalization (CLAHE) method. The low and required contrast are subsequently extracted using CLAHE and transmitted to a residual learning network founded on a convolutional neural network (CNN). The suggested model exhibits a superior

structural similarity index measure (SSIM) compared to alternative techniques.

A class of fractional differential equations can be employed for X-ray picture enhancement [16]. This work determines picture pixel energy utilizing the general k differential equation, which is founded on the K-caputo fractional differential operator (K-CFDO), to enhance visual quality and delineate the problem clearly. The investigation yielded the Brisque, Niqe, and Piqe values for chest X-rays as follows: (Brisque = 23.25, Niqe = 2.8, Piqe = 21.58) and for oral X-rays as follows: (Brisque = 21.12, Niqe = 3.77, Piqe = 23.49).

A strategy for image enhancement involves the utilization of HOG (Histogram Oriented Gradients) [17]. Besides its application in image augmentation, HOG can also be utilized for feature extraction in tuberculosis (TB) chest X-ray pictures. The model applied to chest X-ray images yielded a true positive ratio (sensitivity) of 97.4% and a true negative ratio (specificity) of 97.2%. The results indicate that the model accurately identifies both positive and negative tuberculosis cases.

This study will boost the contrast of X-ray hip images, utilizing the most effective way as a medium for identifying hip osteoarthritis (OA). The acquired X-ray image is in PNG format. Subsequently, the PNG image is transformed into grayscale, followed by an enhancement of the image contrast utilizing Histogram Equalization (HE), Contrast Limited Adaptive Histogram Equalization (CLAHE), and a hybrid approach combining the CLAHE model with two Gamma Corrections. The CLAHE method with two Gamma Corrections will hereafter be designated as CLAGAMTWO. The efficacy of enhancing picture contrast through the three techniques will be assessed utilizing SSIM (Structured Similarity Index Measure), Entropy, and CNR (Contrast-to-Noise Ratio).

II. Literature Review

Currently, digital images are frequently subjected to image contrast enhancement techniques. The perception of the digital image's visual quality can be considerably enhanced through the use of image contrast enhancement [18]. Currently, there are numerous methods of enhancing image contrast, including HE (Histogram Equalization), CLAHE (Contrast Limited Adaptive Histogram Equalization) and Gamma Correction.

A. HE (Histogram Equalization)

An effective histogram encompasses the complete spectrum of values on the gray scale. Histogram equalization is a well-established method for enhancing visual contrast, recognized for its simplicity and effectiveness [19], [20]. The horizontal axis of the histogram denotes the pixel count, while the vertical axis indicates the gray value. The histogram values are derived by quantifying the number of pixels corresponding to each grayscale value present in the image [21]. The fundamental objective of HE is to turn the global histogram equalization into a uniform distribution. Nonetheless, while each image possesses a distinct histogram, following histogram equalization, the pixel values are typically centralized within the midrange of the grayscale, resulting in considerable variations in the average brightness of the image. The typical solution to this issue involves dividing the histogram into two segments and individually equalizing the divided histograms [22].

Conventional histogram equalization can enhance visual contrast by extending the histogram to a specified range. For a given image, the image histogram $H(i)$ for intensity level i is obtained from the number of pixels n_i with intensity level i, which is defined as follows:

$$H(i) = ni \quad for\ i = 0,1,2,\dots(L-1) \tag{1}$$

Where L is the maximum range of gray levels (for 8-bit images it is 256, 0-255) [23]. Based on equation (1), the histogram is divided according to the number of pixels with a certain intensity (the total number of pixels in the image $n = \sum_{i=0}^{L-1} H(i)$) [23], [24]. This result is then used to calculate the probability $p_x(i)$ of pixel i (Eq. (2)) [25], which is then used to calculate the cumulative distribution function (CDF) at [Eq. (3)]. The CDF has a range of values 0-255, as the histogram distribution of the equalization [Eq. (4)] [24].

$$p_x(i) = p(x = i) = n_i/n \tag{2}$$

$$cdf_x(i) = \sum_{j=0}^{i} p_x\,(x = j) \tag{3}$$

$$h(v) = \text{round}\left(\frac{cdf(v) - cdf_{min}}{n - cdf_{min}}\right) \tag{4}$$

B. CLAHE (Contrast Limited Adaptive Histogram Equalization)

Contrast Limited Adaptive Histogram Equalization is a method employed for enhancing contrast in images, particularly in grayscale images [26]. This method's benefit is that it can boost the original image quality, particularly for grayscale photos which medical practitioners regularly apply for high-noise or interference-filled CT or X-ray shots. The CLAHE method concentrates on small segments of the image, referred to as tiles. The contrast of each tile is modified to ensure that the generated histogram for that area matches the specified histogram's shape. Bilinear interpolation links neighboring tiles. This approach is employed to enhance the visual smoothness of the tile combination [27]. The Contrast limited adaptive histogram equalization method can be defined as follows:

$$\beta = \frac{M}{N}\left(1 + \frac{\alpha}{100}(S_{max} - 1)\right) \tag{5}$$

In Eq. (5) it is explained that β represents the limit value, then the variable M represents the area size, N represents the grey-level or grayscale value (256), α represents the clip factor which states the addition of the histogram limit with a value of 1 to 100. S_{max} is the maximum slope permitted.

C. Gamma Correction

Gamma correction [28] is frequently utilized in diverse image processing applications. The process necessitates a fixed parameter, typically represented by the symbol γ, which varies from 0 to 3 to enhance the input image. Gamma correction redistributes the gray levels of the image worldwide based on the set parameter. This solution is effective for underexposed or overexposed photographs, but may not be suitable for images affected by both issues [29]. The classical gamma correction is stated as follows:

$$L = 255\left[\frac{I(x,y)}{255}\right]^{\gamma} \quad (6)$$

In Eq. (6), γ control the degree of image stretching. If $\gamma < 1$, then the overall brightness of the image increases, whereas if $\gamma > 1$, then the image becomes darker than the original image. In this investigation, researchers attempted to apply two Gamma corrections subsequent to the execution of CLAHE on the original image. This was done to enhance image contrast quality.

III. Material and Methods

The PC utilized in this study is a laptop including an Intel Core i7-12700H Processor, NVIDIA GeForce RTX 3070Ti 8GB GDDR6 Graphics with a TGP of 150W, and 16GB of memory configured as 2 x 8GB SO-DIMM DDR5-4800. The programming language employed for computing is Python. X-ray images of the hip joint were acquired from Kariadi Hospital Semarang following the procurement of a research permit with Ethical Clearance No: 535/EC/KEPK/FK-UNDIP/X/2023.

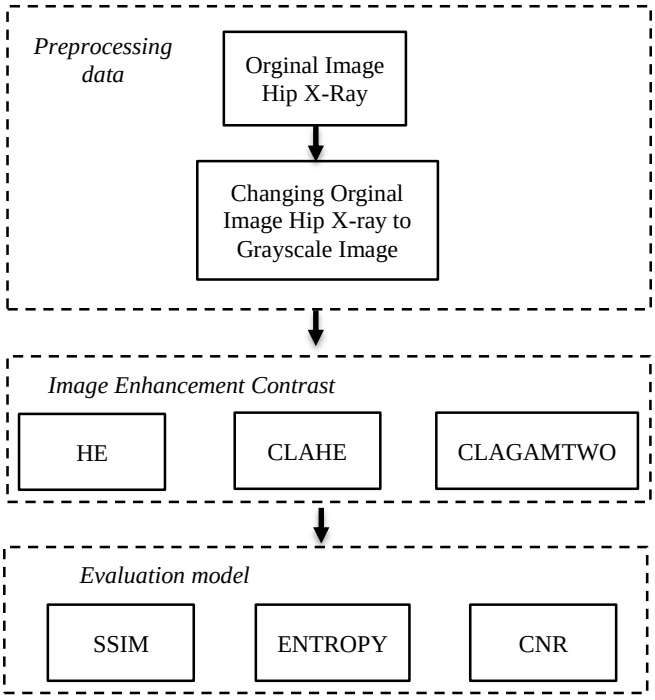

Fig. 1. Research process flow.

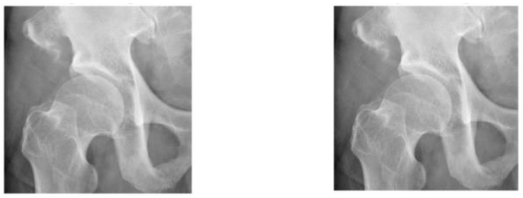
Fig. 1, illustrates the research methodology, which comprises multiple stages, beginning with data preprocessing that involves converting the original hip X-ray image to a grayscale format. Subsequently, the process advanced to the picture enhancement contrast phase employing three distinct techniques: HE (Histogram Equalization), CLAHE (Contrast Limited Adaptive Histogram Equalization), and CLAHE with dual Gamma Corrections (CLAGAMTWO). The final phase involves assessing the outcomes of enhanced picture contrast using the three ways utilizing SSIM (Structured Similarity Index Measure), Entropy, and CNR (Contrast-to-Noise Ratio). A comprehensive explanation will be provided in the subsequent sub-chapter:

A. Preprocessing Data

At this juncture, the original hip X-ray image acquired from the hospital is stored in PNG format [15] with dimensions of 1024 × 1024 pixels. After that the original hip X-ray image will be converted into a gray image so that it can be processed in the next stage. Subsequent to acquiring the hip X-ray image, the next step is to transform it into a grayscale image, as illustrated in Fig. 2. A grayscale image consists of a single color channel representing light intensity on a scale from black (minimum value) to white (maximum value). This procedure is conducted to streamline the data, decrease the information size, and remove color components that are typically unnecessary in medical image analysis.



(a) (b)

Fig. 2. Hip X-ray: (a) Original image and (b) Grayscale image.

B. Image Enhancement Contrast

In Fig. 3, the preprocessed picture will undergo contrast enhancement with HE (Histogram Equalization), CLAHE (Contrast Limited Adaptive Histogram Equalization), and CLAGAMTWO (CLAHE with two Gamma Corrections).

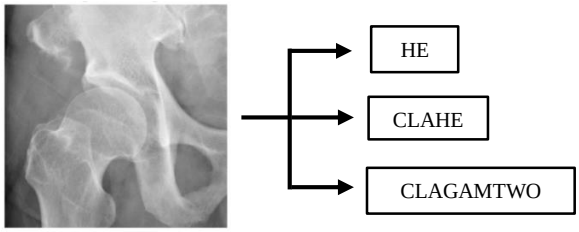


Fig. 3. Contrast enhancement of the original image using HE, CLAHE and CLAGAMTWO.

C. Evaluation Model

The contrast-enhanced image will be assessed using SSIM (Structured Similarity Index Measure), Entropy, and CNR (Contrast-to-Noise Ratio). SSIM [30] is a metric evaluated based on three primary components: brightness, contrast, and structure, as seen in Eq. (7).

$$SSIM\ (x,y) = [l(x,y)]^{\alpha}\ .\ [c(x,y)]^{\beta}\ .\ [s(x,y)]^{\gamma} \quad (7)$$

In Eq. (7), l represents the luminance employed to assess the brightness comparison between two images. c is the contrast utilized to differentiate the spectrum between the most luminous and the most obscure areas of the two photographs. s is the framework employed to analyze the local luminance patterns of the two images in order to identify their similarities and differences. Consequently, α, β and γ are positive constants. The luminance, contrast, and structure of the image can be delineated individually by Eq. (8), Eq. (9), and Eq. (10).

$$l(x,y) = \frac{2\mu_x\mu_y + C_1}{\mu_x^2 + \mu_y^2 + C_1} \quad (8)$$

$$c(x,y) = \frac{2\sigma_x\sigma_y + C_2}{\sigma_x^2 + \sigma_y^2 + C_2} \quad (9)$$

$$s(x,y) = \frac{\sigma_{xy} + C_3}{\sigma_x\,\sigma_y + C_3} \quad (10)$$

Where μ_x and μ_y denote the local means, σ_x and σ_y represent the standard deviations, and σ_{xy} indicates the cross-covariances for images x and y, respectively. When $\alpha = \beta = \gamma = 1$, the index can be simplified utilizing Eq. (8)- Eq. (10), with the outcomes presented in Eq. (11).

$$SSIM(x,y) = \frac{(2\mu_x\mu_y + C_1)\,(2\sigma_x\sigma_y + C_2)}{(\mu_x^2 + \mu_y^2 + C_1)\,(\sigma_x^2 + \sigma_y^2 + C_2)} \quad (11)$$

Entropy quantifies the complexity or diversity of information within an image. A greater entropy number indicates increased complexity and diversity of information inside the image. Entropy is determined by the distribution of pixel intensities in an image and is utilized to evaluate image quality or for pattern detection and segmentation [31]. The subsequent formula pertains to entropy:

$$H = -\sum_{i=1}^{n} p(i) log p(i) \quad (12)$$

In Eq. (12), H represents the entropy. $p(i)$ represents the probability of the occurrence of a pixel intensity i. n represents the quantity of intensity levels in the image.

CNR is a metric utilized to assess the discernibility of the contrast between high and low areas in an image, despite the interference of noise. In image processing, CNR assesses the clarity of a feature or detail in an image, free from interference by noise. A greater CNR signifies that the feature in the image exhibits increased contrast with the background, facilitating visibility [32]. The fundamental equation for CNR is as follows:

$$CNR = \frac{|S1 - S2|}{\sigma} \quad (13)$$

In Eq. (13), $S1\ dan\ S2$ represent the average intensities in two distinct regions, with $S1$ denoting the feature of interest and $S2$ indicating the background area. Meanwhile, σ represents the standard deviation of noise inside the image.

IV. Result and Discussion

In the following section, we will show a comparison of the experimental data obtained from the various methods of picture contrast enhancement that were discussed earlier.

Fig. 4(a1) and 4(a2) depict the original photos alongside their corresponding histograms. Fig. 4(b1) and (b2) illustrate the outcomes of enhancing image contrast using histogram equalization [33]. The histogram's form reveals that the central region of the image exhibits an excessive brightness, while the edges display a pronounced darkness. The histogram illustrates a transformation in shape, initially centralized, now exhibiting an even distribution, with the dark blue hue confined to the right and left margins. Fig. 4(c1) and Fig. 4(c2) illustrate the outcomes of enhancing image contrast through Contrast Limited Adaptive Histogram Equalization [34]. The images exhibit increased contrast, uniformity, and prominence; however, they appear somewhat dark due to the significant enhancement in contrast, as evidenced by the histogram's shape. Fig. 4(d1) and 4(d2) illustrate the outcomes of augmenting picture contrast with CLAGAMTWO. In this part, the researcher employs a method that first applies contrast enhancement through CLAHE, followed by a further enhancement using gamma correction applied twice. The resulting image exhibits commendable contrast, appearing elevated internally and exhibiting a smoother upper surface.

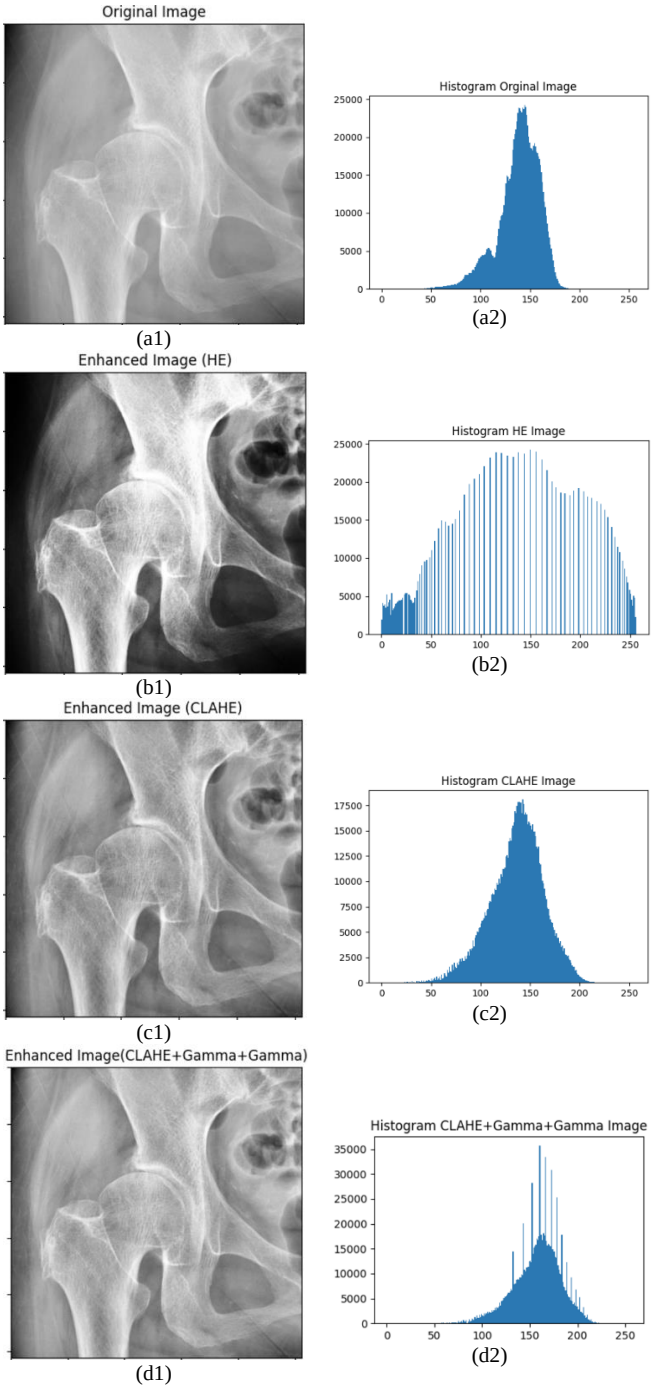

Fig. 4. Image contrast enhancement using HE, CLAHE and CLAGAMTWO.

Image quality evaluation is crucial in digital image processing applications. The researcher performed metric testing using SSIM (Structured Similarity Index Measure), Entropy, and CNR (Contrast-to-Noise Ratio) on several hip

photos presented in Table I, notwithstanding the absence of observed and explained variance in visual quality in certain other photographs.

Table I presents only 10 image values from a total of 30 evaluated. The bold values in the table represent the optimal results achieved through the employed methods. The average SSIM value indicates that the CLAGAMTWO method achieves the highest value at 0.850, followed by CLAHE at 0.826, and HE at 0.644. The CLAGAMTWO method consistently yields image quality that closely resembles the original image, demonstrating its effectiveness in preserving visual structure. CLAHE demonstrates satisfactory performance however, it remains marginally inferior to CLAGAMTWO. In contrast, HE exhibits the lowest SSIM performance, suggesting a diminished capacity to preserve the similarity of image structure.

TABLE I. SSIM, ENTROPY AND CNR VALUES OF 10 SAMPLE IMAGE FROM 30 TESTED DATASETS

Image	Method	Image Quality Assessment		
		SSIM	Entropy	CNR
Image1	HE	0.597	6.238	0.414
	CLAHE	0.885	**6.782**	0.104
	CLAGAMTWO	**0.911**	6.548	**0.944**
Image2	HE	0.664	6.796	0.216
	CLAHE	0.805	**7.221**	0.166
	CLAGAMTWO	**0.845**	7.016	**0.576**
Image3	HE	0.579	6.506	0.569
	CLAHE	0.774	**7.218**	0.264
	CLAGAMTWO	**0.779**	7.045	**0.956**
Image4	HE	0.762	7.032	0.105
	CLAHE	0.834	**7.296**	0.001
	CLAGAMTWO	**0.854**	7.108	**0.607**
Image5	HE	0.609	6.634	0.458
	CLAHE	0.809	**7.222**	0.219
	CLAGAMTWO	**0.855**	6.995	**0.547**
Image6	HE	0.599	6.507	0.623
	CLAHE	0.799	**6.996**	0.319
	CLAGAMTWO	**0.801**	6.822	**1.085**
Image7	HE	0.647	6.542	0.297
	CLAHE	0.849	**6.885**	0.039
	CLAGAMTWO	**0.865**	6.702	**0.909**
Image8	HE	0.663	6.660	0.054
	CLAHE	0.847	**7.132**	0.048
	CLAGAMTWO	**0.875**	6.927	**0.742**
Image9	HE	0.614	6.525	0.254
	CLAHE	0.813	**7.091**	0.170
	CLAGAMTWO	**0.854**	6.881	**0.753**
Image10	HE	0.713	6.738	0.056
	CLAHE	0.848	**7.154**	0.035
	CLAGAMTWO	**0.862**	6.941	**0.613**
Average		**0.850**	**7.009**	**0.773**

For the greatest average entropy value CLAHE (7,099) was obtained, followed by CLAGAMTWO (6,944) and HE (6,617). The CLAHE approach excels in keeping detailed information in the image, demonstrating that CLAHE is more effective in improving the amount of detail. CLAGAMTWO is in second place, displaying pretty high performance in keeping detail, although lower than CLAHE. HE displays the lowest entropy performance, indicating that this method is less able to keep picture detail optimally.

The CLAGAMTWO method once again demonstrates the highest performance in the average CNR measurement, with a value of (0.773), which significantly surpasses CLAHE (0.136) and HE (0.305). CLAGAMTWO is an optimal method for generating high-quality images, as it significantly enhances contrast with minimal noise. The efficacy of CLAHE in enhancing CNR is significantly lower, and HE is also not optimal in this regard, despite being slightly better than CLAHE.

V. CONCLUSION

The CLAGAMTWO method is the most effective method in terms of visual structure (SSIM), information detail (Entropy), and distinct contrast with low noise (CNR) based on the average of the metric values. The CLAHE method is superior in terms of maintaining information detail (Entropy), but it is less effective in terms of increasing CNR when compared to CLAGAMTWO. In contrast to CLAHE and CLAGAMTWO, HE is the method with the lowest performance in all metrics, and as a result, it is not as recommended for enhancing image quality. This demonstrates that the CLAGAMTWO method, as proposed by the researcher, is the most effective method for enhancing the quality of the overall image in terms of visual structure, information detail, and distinct contrast with low noise. The outcomes of this image contrast enhancement will be employed as a diagnostic tool for hip OA in the future. For future work, it may implement a novel deep learning-based methodology, incorporate additional evaluation metrics, and expand the dataset.

Computer-Vision-Based Detection and Monitoring System for Mature Coconut Fruits with a Web Dashboard Visualization Platform

Samfford S. Cabaluna, Maria Fe P. Bahinting, Leah A. Alindayo
Computer Applications Department-College of Computer Studies,
Mindanao State University Iligan Institute of Technology, Iligan City, Northern Mindanao, Philippines

***Abstract*—The Philippines is the second largest producer of coconut products in the world with 347 million trees planted in 3.6 million hectares of land across the country. Traditionally, harvesting coconuts is a labor-intensive process in the Philippines that involves manual climbing and chopping fruits, which carries a high risk of harm or even death. Hence, the number of expert coconut climbers has decreased as a result. In response, current research has concentrated on creating robot harvesters. However, classifying the mature coconut fruit is a major problem in the harvesting process that calls for a great deal of experience, patience, and work. Studies employing Convolutional Neural Networks (CNNs) have shown great accuracy in detecting coconut ripeness, although these efforts have been limited to detection without practical integration with harvesting equipment. Moreover, the present research lacks a comprehensive solution that allows real-time data display and monitoring, such as the maturation stage of coconuts, via a web-based dashboard. This discrepancy emphasizes the requirement for systems that can not only identify the age of coconuts but also work with harvesting technologies and provide intuitive user interfaces for data display and decision-making. In order to fill these gaps, this study presents a computer-vision-based system that monitors and detects coconut fruit maturity, with an emphasis on mature coconuts, by utilizing the YOLOv8 model. With a Mean Average Precision (mAP50) of 99.5%, mAP50-95 of 89.5%, precision of 99.5%, and recall of 99.9%, the system demonstrated great accuracy. A web-based dashboard is also integrated into the system to provide monitoring and visualization of detected coconut fruits, along with notifications for fully ripe fruits.**

***Keywords*—Coconut fruit maturity; coconut maturity detection; computer vision; crop monitoring**

I. Introduction

The Philippines is the world's second-largest exporter of coconuts, with 14.89 million metric tons produced in 2023.

With the pressing issues on risks of manual harvesting which caused a steady decline in coconut harvester population, robot coconut harvesters were developed to address the issue based on the review by Kumar et al. [1]. Furthermore, Cousalya et al. [2] created a mobile operated coconut harvesting machine. These developed harvesters, however, lack a detecting systems that resulted to harvest even the young coconuts. Nevertheless, the studies of Sakthipreasad and Megalingam, Junaedy et al., Titus et al., Wibowo et al., and Divyanth et al. [3], [4], [5], [6], [7], on robotic harvesters that are integrated with vision-based detection but it solely focused on fruit recognition which lead to the harvester inability to specifically locate the matured coconuts.

Determining the ripeness of coconut fruit accurately remains a challenging task which has an impact on product quality and customer satisfaction [8]. Conventional manual techniques take a lot of time and require experience [9], [10], [11], [12], [13], and elements like dim lighting and complicated backgrounds [12], [14] make it hard for computers and humans to recognize coconuts [6], [15], which frequently results in the harvesting of poor or premature coconuts. In response, recent research have been conducted that introduces the concept of coconut maturity detection using several methods. Two studies use the fuzzy logic approach in detecting and classifying coconut fruit maturity [9], [12] which proved to be an effective algorithm where in the study of Megalingam et al. uses the Decision-Making Probability (DMP) model for real-time classification achieving an accuracy of 86.3%, but Mask R-CNN performs better than the other integrated models. Aside from these studies, other researches focused on Convolutional Neural Networks (CNNs) in coconut fruit maturity detection and classification which is commonly implemented having an average accuracy above 90%.

Moreover, Venkatesh et al. [14] implemented the SOLO model, Artificial Neural Network is implemented by Hendrawan et al. [16], Anushya implemented K-Means clustering wherein image features are extracted by Gray-level Co-Occurrence Matrix (GLCM) determining the freshness of the coconut obtaining 97% accuracy [17], Varur et al. [18] researched on coconut development phases classifying into five classes using Xception, ResNet50V2, ResNet152V2, and MobileNetV2, wherein MobileNetv2 produced the best accuracy, Subramanian and Sankar used RestNet-50 and Faster R-CNN wherein ResNet-50 achieved a top-1 accuracy for both premature and mature phases achieving a detection score of 99%, and around 98% top-1 and top-5 accuracies [10], [15], Nguyen et al. also discovered that ResNet101 was the most accurate, using binarized saturation pictures achieving an accuracy of 95% [11], Avudai Nayagam and Devakumar used small VGG net and MobileNet which ensured precise coconut detection when used in real-time on NUC/Jetson Nano boards and climbing robots, however their system's gap focuses on how well those models run on those devices stated [19], and Novelero and Dela Cruz's study (Philippines) used the YOLOv5 model in an on-tree mature coconut fruit detection using UAVs achieving an

This paper is sponsored by the Philippine Department of Science and Technology Engineering Research and Development for Technology.

accuracy of 88.4% which will be of great value in eliminating risks of harvesting coconuts in the future since it can also be useful for coconut crop yield estimation, [20]. In the research of Mandava et al. [13], it is concluded that YOLOv5s is superior in metrics yet needing more datasets.

Based on the literature discussed above, the different methods in detecting matured coconut has been successful particularly the utilization of Convolutional Neural Networks (CNN) which incurred a high accuracy rating of above 90% in terms of detecting mature coconut. However, these studies solely focused on maturity detection and was not able to provide a comprehensive solution incorporating real-time display and monitoring of coconut fruits. This emphasizes the necessity for systems that can both identify coconut fruit maturity and integrate it with harvesting technology [20], offering a user-friendly interface for data visualization and informed decision-making.

This paper implements both computer-vision-based detection of coconut fruit maturity using a later model under CNN, the later model, YOLOv8, as it builds upon the success of previous versions and introduces new features and improvements to boost performance and flexibility, applicable as well in different environments with a detailed comparison of its performance metrics to other versions and models [21]. Along with it is an integration with a web dashboard for display and monitoring of scanned coconut fruit maturity data and with a notification system wherein for every detected mature coconut fruit, a notification is sent.

II. Methodology

To design and develop a detection and monitoring system to detect and monitor coconut fruits according to maturity YOLOv8 model was utilized. The researchers as well designed and developed a web dashboard for monitoring the scanned coconut fruits according to maturity. Fig. 1 presents the flow of methods the researchers underwent in coming up with the output of this paper. Having identified the problems as well as motivation to resolve these problems, the researchers then proceeded to the specific objectives consisting of three phases: (Phase 1) the overall design of the system, involving requirements analysis, the design, and the gathering of datasets; (Phase 2) the development of the detection and monitoring systems as well as their integration, involving the processing of the image datasets and their training, and the design and development of the web dashboard for the display of coconut fruit data scanned as well as the integration with the notification system for every mature coconut fruit detected; and (Phase 3) the implementation of the system, involving the testing and evaluation of both detection and monitoring systems.

A. System Requirements Analysis

The following items below serves as guide for the researchers in coming up with the output of this paper. The overall system is limited for experimental purposes:

- Image datasets involve generally both Mature and Premature coconut fruits, wherein Mature coconut fruits include those with both brown and brown-and-green surfaces and Premature coconut fruits include those of young coconut fruits with green surfaces.
- Acquisition of datasets are only limited to close shots angle.
- Web dashboard involves the display of footage of scanned coconut fruits and the display of count data through a line graph chart.
- Count data of coconut fruit maturity are also displayed on the table and can be printed to CSV file.
- The system will send notification mail every time a mature coconut fruit(s) is/are detected.
- The system, limited to experimental use, limits it's testing within the laboratory, not yet real-time.

Fig. 2 shows the architecture of the overall system, involving both detection and monitoring systems based on the listed system requirements analysis above.

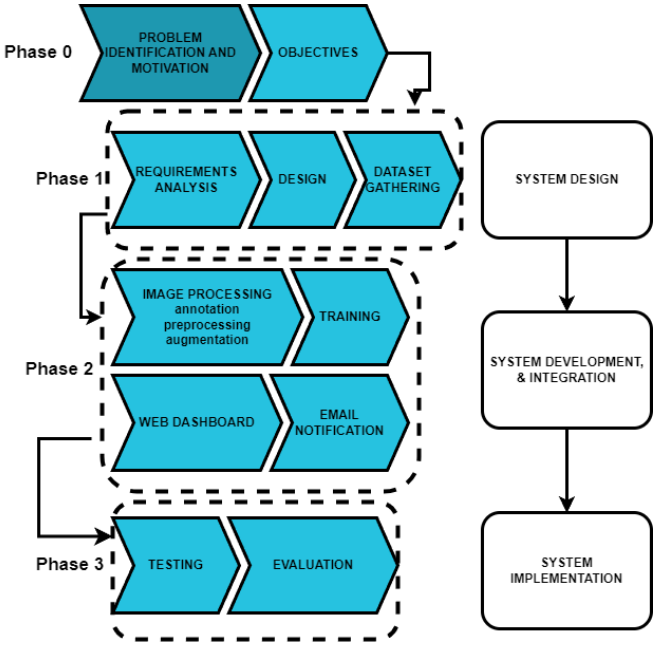

Fig. 1. Methodology flowchart.

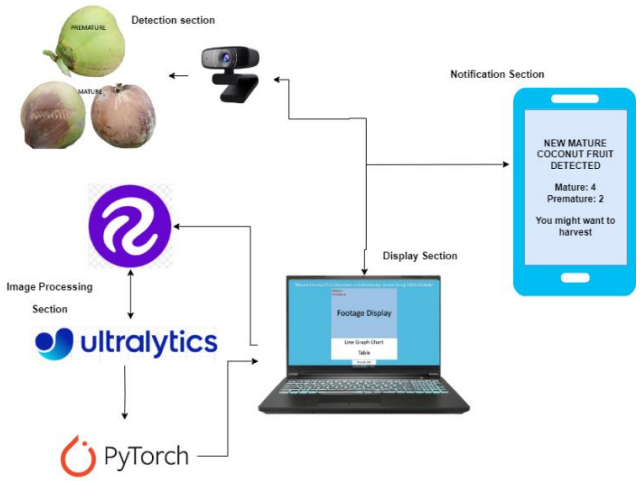

Fig. 2. System architecture.

B. Detection System

This particular section discusses the methods undergone by the researchers in designing and developing the detection system of this paper.

1) Data acquisition: Data were acquired by capturing video footage of harvested coconuts from a farm in Barangay Argayoso, Manticao, Misamis Oriental. Images were extracted at a rate of three per second, resulting in 260 image datasets. These were then uploaded to Roboflow for image processing, including annotation, preprocessing, augmentation, and dataset generation, with two classes: Mature and Premature coconuts (see Fig. 2). Mature coconut fruits include both full brown-colored surface and those with both brown and green surfaces, while the premature coconut fruits include those with green surfaces.

2) Annotation: Following the uploading of images to Roboflow, the platform for annotation was then set up using Smart Polygon (though under the Bounding Box platform) for more precise results. A total of 260 images were annotated, resulting in 409 annotations for the mature class and 403 for the premature class, ensuring a balanced dataset (see Fig. 3).

Fig. 3. Annotation of image datasets.

3) Training of the model: Ultralytics Hub platform was used for the training of the model (see Fig. 4). Google Colab platform was specifically used for the training while the results are automatically uploaded on the Ultralytics dashboard. YOLOv8 model was used for training.

4) Running the trained model: Following the model training is its implementation (see Fig. 5). The researchers have developed a program wherein the scanned coconut fruits according to maturity are counted. Footage is then displayed on the dashboard. Programming of the detection system is done using OpenCV Python.

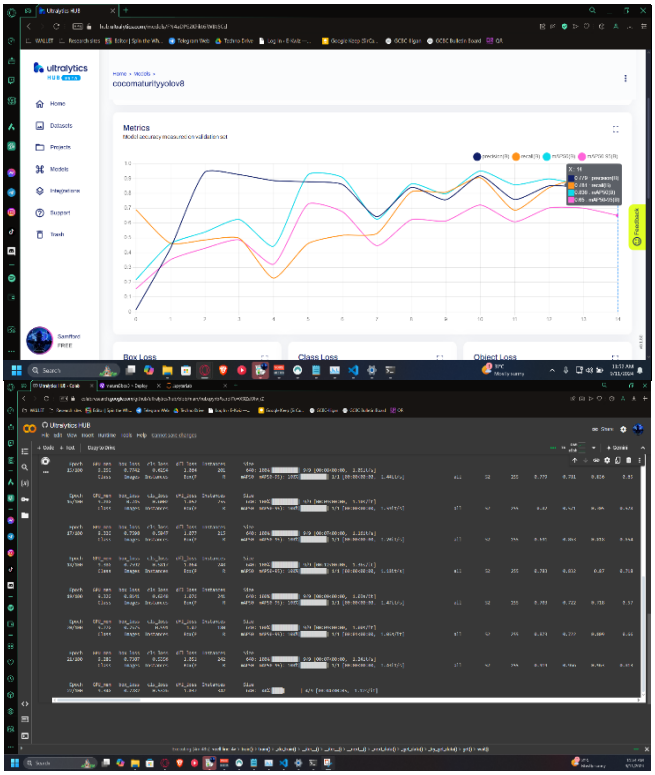

Fig. 4. Training of model.

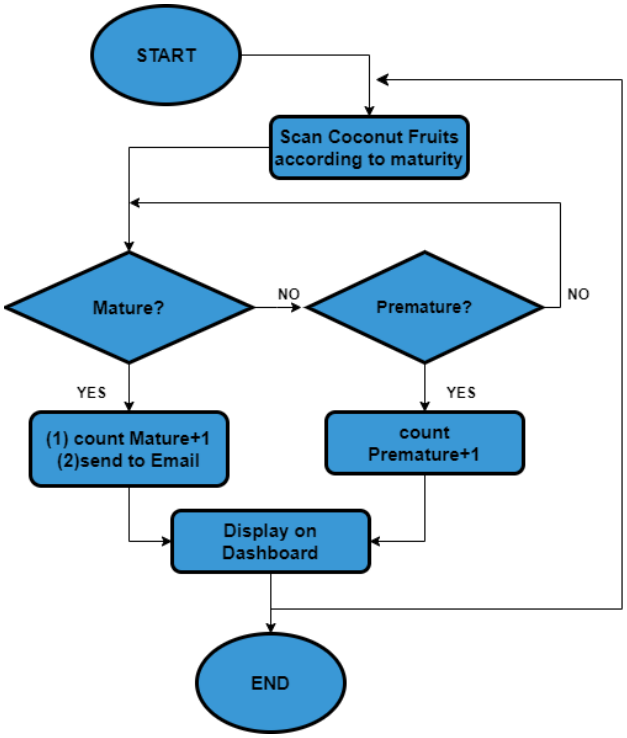

Fig. 5. Detection system flow.

C. Web Dashboard Design

Fig. 6 shows the operational flow of the web dashboard that serves as the display for the overall system. The user will have to go through the homepage where a button will be clicked to enter the dashboard. Once clicked, the user will be led to the main dashboard where the data are displayed.

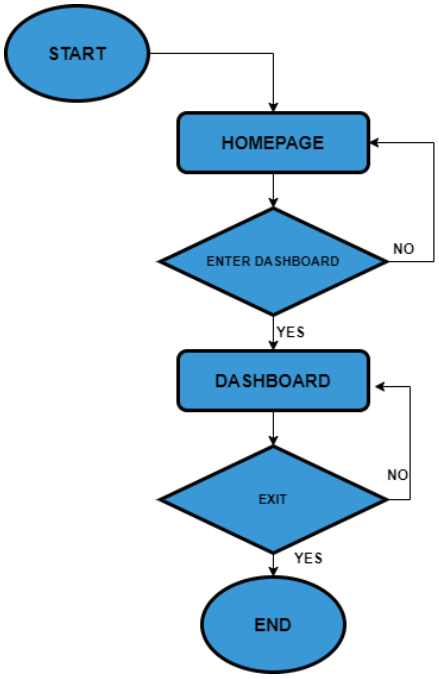

Fig. 6. Web dashboard flow.

D. Integration of Detection System to Web Dashboard and Email

Basic HTML was used in programming the monitoring dashboard with styles for its background image, as well as for the table and charts. The dashboard is then connected to and from the python program in order for the data to be uploaded and displayed on the output of this program. The system is also integrated into the Email for notification purposes.

E. Testing and Evaluation

A sample test run was done for both detection and monitoring systems. As stated earlier, this paper is limited to experimentation, thus the test run was done inside the laboratory.

III. Results

This section presents and discusses the results of this particular paper. Discussion involves the results of training of model as well as the display of data for monitoring.

A. Training Results

After 100 epochs of training, metrics show that the training of the model produced a Mean Average Precision 50 (mAP50) is 99.5% and its mAP50-95 is 89.5%, a 99.5% precision, and 99.9% recall (see Fig. 7) and is gradually increasing.

Fig. 8 presents the results of the training of the model particularly showing the box, class, and object losses.

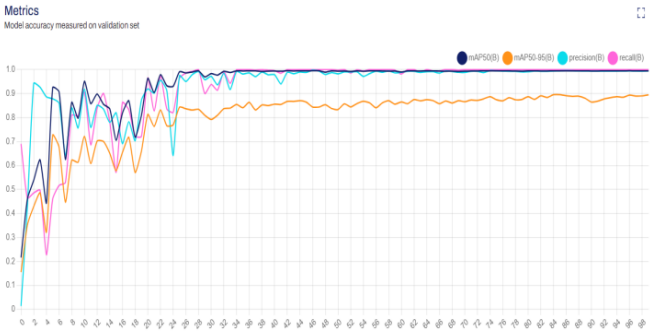

Fig. 7. Training results metrics (mAP, Precision, Recall).

Box Loss shows that at the end of the 100 epochs training, training reaches 46.5% and 53.2% validation. For class loss, training reaches 23.3% while validation reaches 26.8%. Finally, for object loss, training reaches 90.7% and validation reaches at 90.8%.

For the Box Loss, initially, both training and validation loses fluctuate significantly, indicating instability at the start. However, by the end of the graph, both losses converge and stabilize, though the validation loss remains slightly higher than the training loss, indicating that the model generalizes reasonably well but might still benefit from further refinement. This pattern is typical in model training, where validation loss may fluctuate more than training loss due to unseen data.

For the Class Loss, both training and validation losses are initially high, especially around iteration 0, indicating a poor classification performance at the start of training. The training decreases quickly, showing that the model improves its class predictions as training progresses. The validation loss fluctuates significantly, indicating that the model struggles with unseen data early in training. Over time, the validation loss stabilizes, though it remains more variable than the training loss.

Finally, for the Object Loss, both training and validation losses start around 1.2, indicating a relatively high error rate in detecting objects at the beginning of the training. The training loss decreases gradually over time, indicating steady improvement in object detection during training. The curve follows a gentle downward trend, becoming more stable but still showing some fluctuations. The validation loss is initially lower than the training loss and remains relatively stable throughout the training process, hovering around 1.0.

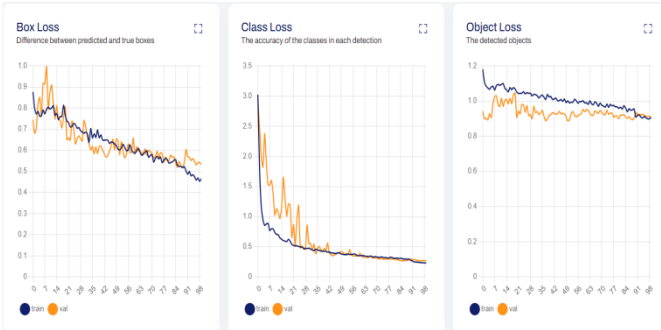

Fig. 8. Training results (Box, Class, Object Losses).

Thus, the model is progressively learning to detect objects better, with both training and validation object losses decreasing and converging. The relatively stable validation loss suggests that the model generalizes well to unseen data in terms of object detection, though there remains room for further improvement as the final loss is still above 0.8. Fig. 9 below presents the confusion matrix based on the results of the training of the model. It particularly presents that 99.5% of actual mature/premature coconuts were correctly detected. 0.5% of predicted mature/premature coconuts were incorrect (wrong predictions). 0.1% of actual mature/premature coconuts were missed (or undetected). Display of detection is presented in Fig. 11.

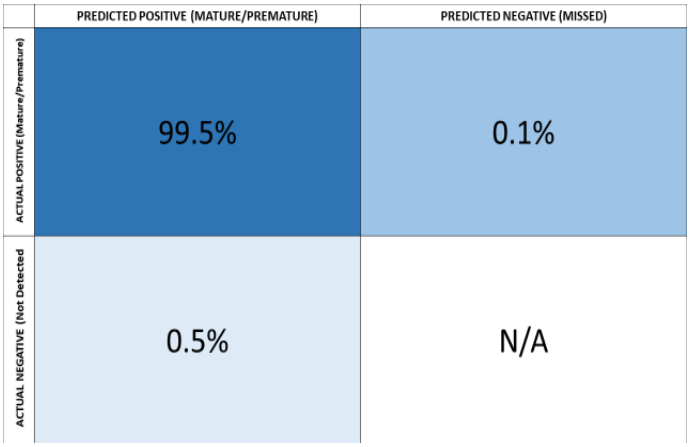

Fig. 9. Confusion matrix.

B. Web Dashboard

This particular section discusses the operation of the web dashboard where the data of scanned coconut fruits based on maturity is displayed. Fig. 10 below presents the homepage of the dashboard, wherein the user has to click the ENTER DASHBOARD button in order to enter the main dashboard.

Fig. 10. Dashboard homepage.

The dashboard consists of the footage of the video of the scanning of coconut fruits. The number of coconut fruits scanned based on maturity is displayed as well on the dashboard. The count data are also visualized on the line graph chart and the table as well. The count data of coconut fruits on the dashboard can also be printed to CSV file.

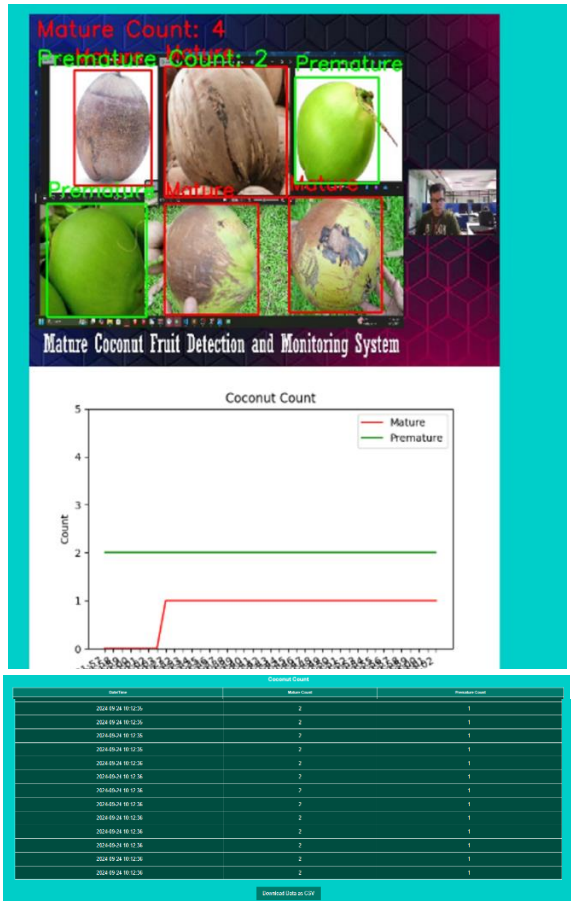

Fig. 11. Monitoring dashboard.

C. Testing and Evaluation of the System

As stated earlier, the overall system was tested and evaluated inside the laboratory since this paper is only limited to experimental level. The overall system was run using an NVIDIA GEFORCE RTX 3060 laptop having a 24GB RAM and 1.5TB internal storage with a 6GB GPU memory. Since the datasets were collected from coconut harvested fruits, therefore, the system can be able to correctly detect the maturity of the coconut fruits when the system's camera is placed very close to the object. Furthermore, with a small amount of datasets wherein mature coconut fruits consists of both brown and brown-and-green surfaces, the system expectedly misclassifies the maturity of coconut fruit. Therefore, more datasets should be added to the training of the model for a more accurate classification of coconut fruits according to maturity.

Fig. 12 below presents the notifications sent to the email for every mature coconut fruit detected. The system will notify through the email every time a new mature coconut fruit is detected.

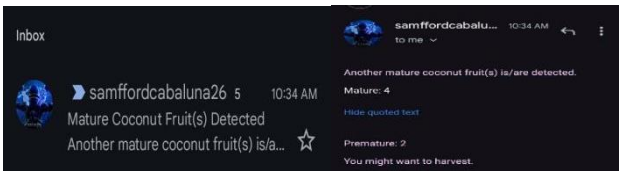

Fig. 12. Email notification.

IV. DISCUSSION

This section discusses in summary the results shown on the previous section, discussing the indications of the figures.

A. Discussion on Training Results

Training results show a gradual increasing in terms of metrics and decreasing in terms of losses, indicating an improving of training results. The overall decrease in both lines for box loss indicates a positive sign of improvement in bounding boxes. The convergence and the stabilizing of losses at a relatively low value for class loss suggests that the model performs well, although it still classifies slightly better on training data than on validation data. Overall, the model's class detection accuracy improves significantly over time, with a more stable training loss, and validation loss eventually converging but with higher variance. There are minor fluctuations for both losses under object loss, but overall, the validation loss shows a stable trend compared to the training loss. Both losses converge toward a similar value below 1.0 by the end of the iterations, suggesting that the model is improving in detecting objects and shows consistent performance on both training and validation datasets. The results shown on the confusion matrix indicate how well-performing the model is in classifying coconut fruit maturity, although there are minor misclassifications, yet the results proved that the model is performing well.

While the model is performing well in classifying coconut fruit maturity, it needs additional image datasets for an even more accurate classification since this paper is limited to close angle shots of the image datasets. Further improvement of such classification requires a consideration of drone shot angles and distances.

B. Discussion on Monitoring System

The monitoring dashboard design prototype displays an outstanding visualization of monitoring the status for coconut fruits in terms of their maturity stages. The notification system through email integrated with it shows that this system can aid in the real-time monitoring of coconut fruits. Since the system is in its experimental stage, this study recommends that for future improvement, the monitoring system will be integrated with an operational mobile app with SMS notification for a more user-friendly monitoring of the app.

V. CONCLUSIONS AND RECOMMENDATION

In conclusion, the researchers have designed and developed, as well as implemented a detection and monitoring system for mature coconut fruits, separating them from premature coconut fruits. The YOLOv8 model proved to be a good model for detection, though more datasets are needed to be added to the training of the model for an even more accurate detection. A web dashboard was also designed and developed, as well as integrated with the detection system, so that the footage of the scanning of coconut fruits are displayed on the dashboard along with the count data, wherein the count data can also be printed to CSV file as well.

Since the model needs more datasets due to some misclassifications occurring in the detection, by way of recommendation, it is highly recommended that there is a certain distance from the camera as well as its lighting resolution to be considered in gathering datasets to prepare the system for deployment with a more accurate detection; on-tree datasets are also highly recommended for training. It is highly recommended as well that the dashboard for display of data will be deployed in a fully operational app. Finally, it is very highly recommended that this system is integrated on a robotic harvester or any automated system by way of modernizing and improving the method of harvesting coconut fruits to aid the harvest of coconut fruits. In addition to increasing coconut harvesting efficiency, this integrated system can help achieve the Sustainable Development Goals (SDGs) of the UN, including Goals 2 (Zero Hunger), 9 (Industry, Innovation, and Infrastructure), and 17 (Partnerships for the Goals).

ACKNOWLEDGMENT

The researchers acknowledge the financial support of the Department of Science and Technology Engineering Research and Development for Technology (DOST ERDT) of the Philippines for this study along with the supervision of the Department of Computer Applications of the College of the Computer Studies of Mindanao State University Iligan Institute of Technology.

Simulation Analysis of Intelligent Control System for Excavators in Large Mining Plants Based on Electronic Control Technology

Lei Sun
School of Intelligent Manufacturing, Shandong Polytechnic, Ji'nan, 250000, China

***Abstract*—With the increasing demand for large-scale mine equipment and the complexity of the operating environment, the intelligent trajectory planning and control of mine systems becomes very important. This paper proposes a proportional-integral-differential (PID) feedback controller combined with adaptive improvement. This controller combines Genetic Algorithm and Particle Swarm Optimization technology to enhance the ability of the excavator's intelligent control system and improve the control accuracy, response speed, and robustness under different working conditions. The results showed that the constructed PID controller improved the average constraint performance by 2.5% through quintic interpolation, and the power consumption was relatively small. The trajectory prediction error of different joints was less than 5% and the displacement and pressure curves of the hydraulic cylinder were stable and symmetrical. The accuracy of the proposed algorithm was 94% and quickly converged to 0.05 after 50 iterations, which was 18.5%, 15.3%, and 17.5% higher than the other three algorithms, respectively. Therefore, the proposed method has high reliability and adaptability in anti-interference ability, trajectory planning progress, and optimization efficiency, and it provides a better solution for intelligent control of the excavator excavation system.**

***Keywords*—Genetic Algorithm; Particle Swarm Optimization; proportional-integral-differential; mining system; intelligent control**

I. Introduction

As global demand for mineral resources continues to rise, the existing production efficiency of the mining industry is unable to meet the current consumption needs. Furthermore, the safety of mining workers and the costs associated with production are also pressing concerns that require immediate attention [1]. Excavators represent the core equipment of large mining plants. However, they currently face significant challenges, including difficulties in dealing with complex mining environments, a lack of flexibility, and a lack of intelligent control [2]. The advancement of Electronic Control Technology (ECT) has provided the possibility for the emergence of Intelligent Control Systems (ICS) for excavators, which can to some extent meet the operational needs of large-scale mining industries. Currently, experts have extensively researched excavator ICS and algorithm optimization [3]. However, the existing excavators have obvious shortcomings in dealing with the changing mine environment, improving operation accuracy, and enhancing intelligent control. To solve these problems, this study proposes an ICS based on ECT to improve the performance of excavators in complex mine environments through advanced control strategies. The innovation of the research lies in the development of a Proportional-Integral-Differential (PID) controller, which combines Genetic Algorithm (GA) and Particle Swarm Optimization (PSO) technology to enhance the adaptability and robustness of the excavator ICS. Through this combined optimization strategy, this method not only improves the control accuracy and response speed but also improves the anti-interference ability of the system in the face of internal and external interference.

This study proposes a PID feedback controller combining GA and PSO technology to improve the ICS performance of large mining excavators. By adopting the PID controller and GA-PSO optimization strategy, the control accuracy and response speed of ICS are improved. Compared with the existing PID control technology, fuzzy control, and GA and PSO when employed in isolation, the improved PID feedback control method combined with GA-PSO has stronger comprehensive performance in search performance and convergence speed and realizes more effective trajectory optimization.

The overall structure of the study includes six sections. Introduction is given in Section I. Section II summarizes the research achievements and shortcomings of ECT in ICS of different countries. The second section studies and designs the simulation model of PID feedback control. Section III tests and analyzes the proposed model. Section IV discusses the experimental results. Discussion is given in Section V and finally, Section VI concluded the paper.

II. Related Works

Significant progress has been made in the application of ECT in excavator ICS [4-5]. Sadiq et al. put forth a PID-Mining Control Systems (MCS) method based on adaptive adjustment, which was designed to address the issue that traditional MCSs are unable to effectively address the influence of nonlinear factors. This method could improve the control performance of load fluctuations. This method has reduced the response time by 13% compared to the PID control technology before improvement [6]. Wellendorf et al. designed a PSO-based PID control parameter optimization method to address the issue of traditional MCS relying on manual experience. It has improved stability by 20% compared to traditional control systems [7]. Kanso et al. proposed an adaptive PID control method based on fuzzy logic to address the limitations of traditional manual experience-based control of mining systems. This method reduced the response time by 14% and improved its robustness

by 34% [8]. Wang Z et al. proposed a PID control technique grounded on Deep Learning (DL) algorithms. The DL and predictive capabilities of this algorithm have improved the accuracy and response speed by 23% and 12%, respectively [9]. Sohail A et al. proposed a mining job scheduling optimization method based on an ant colony algorithm. Compared to traditional control systems, this method has increased mining efficiency by 28% and resource utilization by 10% [10].

The trajectory planning control method based on GA and PSO algorithms has also received widespread attention [11]. Gad et al. proposed a GA-based path optimization scheme for trajectory planning problems in complex environments. This method could obtain the global Optimal Solution (OS) under complex road conditions [12]. Pervaiz et al. developed an approach that simulates the objective function of PSO and updates the position and velocity of particles to obtain the OS, which has a fast convergence performance [13]. Zhang et al. established a trajectory planning control method based on GA-PSO, which expands the search range through crossover and mutation, and locally refines with PSO, significantly improving the accuracy and efficiency of the algorithm [14]. Minh et al. suggested a multi-objective optimization method fused with GA-PSO for nonlinear factors in complex environments. This method utilized the OS and hierarchical selection mechanism to achieve the OS under multi-objective common constraints [15]. Pozna et al. proposed a GA-PSO that combines DL and the feature extraction capability of DL to predict the priority of trajectory points, improving the intelligence level of path planning. This method could be used for path planning in complex environments and ensure the stability and reliability of the results [16].

In summary, existing research has made certain progress in anti-interference and trajectory optimization [17]. However, in more complex large-scale mining environments, the comprehensive control performance of the method still needs improvement, with limitations in response speed, control accuracy, anti-interference ability, and robustness [18-19]. Therefore, this study proposes an ECT-based ICS for large mining plant excavators to enhance their overall performance and control capabilities in complex working conditions. The innovation of the research lies in proposing a PID anti-interference control model based on adaptive improvement, aiming to improve the internal and external anti-interference performance of the algorithm. The trajectory control model combined with the GA-PSO optimization algorithm can improve the optimization of global and local solutions in complex and real-world environments while ensuring the accuracy and efficiency of the solutions. This study provides a better solution for excavator trajectory planning.

III. Methods and Materials

The first section constructs an anti-interference mining system. Firstly, a mechanical arm simulation dynamic model based on improved D-H parameters is established, and forward and inverse dynamics verification is carried out. Finally, a PID controller is introduced to further optimize the control performance of the mining trajectory planning system. The second section introduces the GA-PSO algorithm to optimize the parameters of the PID controller, further enhancing the control performance of the mining system.

A. Construction of PID Feedback Control Simulation Model for Anti-Interference Mining System

The operating environment of large mining plants is complex and harsh. The operation of excavators is inevitably limited by environmental factors, and it is also necessary to deal with self-interference caused by factors such as inertia and vibration during the excavator's movement process [20-21]. To enhance the ability of mining systems to cope with complex environments, it is necessary to construct a PID feedback control simulation model based on mining systems for trajectory planning and control. This study first establishes a geometric simulation model of the Robotic Arm (RA), defining the length, mass, centroid position, and inertia tensor of the joints and linkages of the RA. Subsequently, based on the improved D-H parameters, a coordinate for the linkage of the excavator arm is established, as shown in Fig. 1 [22-23].

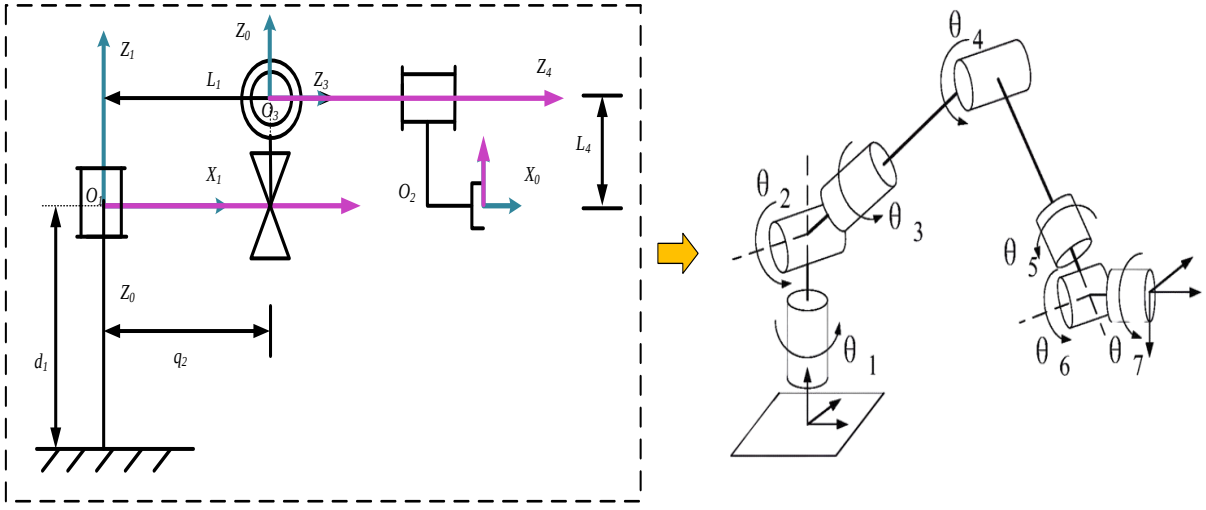

Fig. 1. Structural diagram of the coordinate system of the RA.

Based on the improved D-H parameters, each joint angle and link length of the RA is defined, and a coordinate system is set for each joint to determine the relationship between the joints. A positive dynamics verification is conducted on the constructed geometric simulation model of the RA, thereby obtaining the relationship between the posture and joint angles of the end position of the RA. The homogeneous transformation matrix between the connecting rod and the joint is shown in Eq. (1).

$$ {}_{i}^{i-1}\boldsymbol{T} = \begin{bmatrix} \cos\theta_i & -\sin\theta_i\cos\alpha_i & \sin\theta_i\sin\alpha_i & a_i\cos\theta_i \\ \sin\theta_i & \cos\theta_i\cos\alpha_i & -\cos\theta_i\sin\alpha_i & a_i\sin\theta_i \\ 0 & \sin\alpha_i & \cos\alpha_i & d_i \\ 0 & 0 & 0 & 1 \end{bmatrix} \quad (1) $$

In Eq. (1), ${}_{i}^{i-1}\boldsymbol{T}$ is the transformation relationship between adjacent linkage coordinate systems i and $i-1$. θ_i is the angle of rotation required for the connecting rod connecting two adjacent joints. α_i and d_i are the other angle and displacement length required to connect two adjacent joints. a_i is the horizontal distance between adjacent joints. The transformation matrix effectively describes the directional relationship between each joint and link in the structure of the RA, which can be used to obtain the final posture of the RA and accurately describe the pose of the RA at specific time points during motion. Using MATLAB for inverse dynamics verification, a simulation model is constructed to obtain the motion parameters of the RA. To ensure the accuracy of the excavator during excavation, handling, and movement in complex mining environments, the interpolation method is utilized to simulate the motion process multiple times. The motion parameters of the RA are obtained at each moment and then adjusted to ensure the model's accuracy. To ensure both the economy and stability of the RA control process, a Five Order Interpolation Method (FOIM) is adopted, as shown in Eq. (2).

$$ \theta(t) = A_0 + A_1 t + A_2 t^2 + A_3 t^3 + A_4 t^4 + A_5 t^5 \quad (2) $$

In Eq. (2), $\theta(t)$ is the rotation angle of the RA joint at time t. A_0, A_1, A_2, A_3, A_4, and A_5 are the difference coefficients related to t, representing the positions of each joint of the RA at time t. Through FOIM, more accurate simulation results of the RA are obtained. To further obtain a more optimal robot motion path and determine the objective function, the parameters during the movement of the RA are adjusted to ensure that the path meets the requirements, as given by Eq. (3).

$$ F(x) = \alpha f_1(x) + \beta f_2(x) \quad (3) $$

In Eq. (3), α and β are weighting coefficients. $F(x)$ is the objective function for the optimal path of the RA. $f_1(x)$ is a matrix constraint condition that describes the range of motion space of the RA. $f_2(x)$ is the proportion of the RA in the workspace. Considering the influence of factors such as gravity and inertia during the movement of the RA, this study presents challenges for precise control and efficient operation of the motion. Therefore, the derived joint torque is shown in Eq. (4).

$$ \tau = M(q)q + V(q,q) + G(q) \quad (4) $$

In Eq. (4), τ is the joint torque of the RA. $M(q)$ is the inertia matrix of the RA itself. q, q, and q are the joint gravity, inertia, and centripetal force of the RA, respectively. $G(q)$ is the gravity vector of the RA, which describes the influence of gravity on the joints. $V(q,q)$ is the term for centrifugal force and Coriolis force. In complex mining environments, to completely replace manual labor with excavators, it is necessary to ensure the flexibility of excavator movement. The formula for adaptive adjustment of the RA using an anti-interference tracker is given by Eq. (5).

$$ e_1(t) = x_1(t) - z_1(t) \quad (5) $$

In Eq. (5), $e_1(t)$ represents the velocity prediction error value during the motion of the RA. $x_1(t)$ is a nonlinear interference factor. $z_1(t)$ is the true value of the interference factor. To enhance the control capability of the RA over its own interference factors and increase its joint robustness, this study adopts a PID control strategy for the purpose of planning and controlling the motion trajectory of the RA, as illustrated in Fig. 2.

In Fig. 2, the PID controller uses Lyapunov function to perform error control based on the input joint motion state, and updates its motion state to obtain an anti-interference mechanical arm motion process. By using backstepping adaptation, the limitations of the controller can be effectively addressed. The dynamic equation for noise measurement of the sub states of the RA is shown in Eq. (6).

$$ J\,\theta_L = \frac{1}{n}T_m - B\dot{\theta}_L + T_{dis} \quad (6) $$

In Eq. (6), θ_L and θ_L are angular displacement and velocity. J is the gravity vector of the RA joint. T_m is the joint torque input to the PID controller. B is the adaptive control parameter. T_{dis} is the joint torque output by the PID controller. n is the joint variable of the RA. The parameters in the PID controller can be adaptively adjusted based on the influence of environmental and excavator factors. The calculation of parameter adaptive law is shown in Eq. (15).

$$ \hat{\theta} = \Gamma\varphi p \quad (7) $$

In Eq. (7), $\hat{\theta}$ and Γ are the PID control parameter adaptive law and adaptive matrix of the RA. φ is the error between the predicted and actual values of adjacent joint motion sub states. p is the error value of the motion state of the RA.

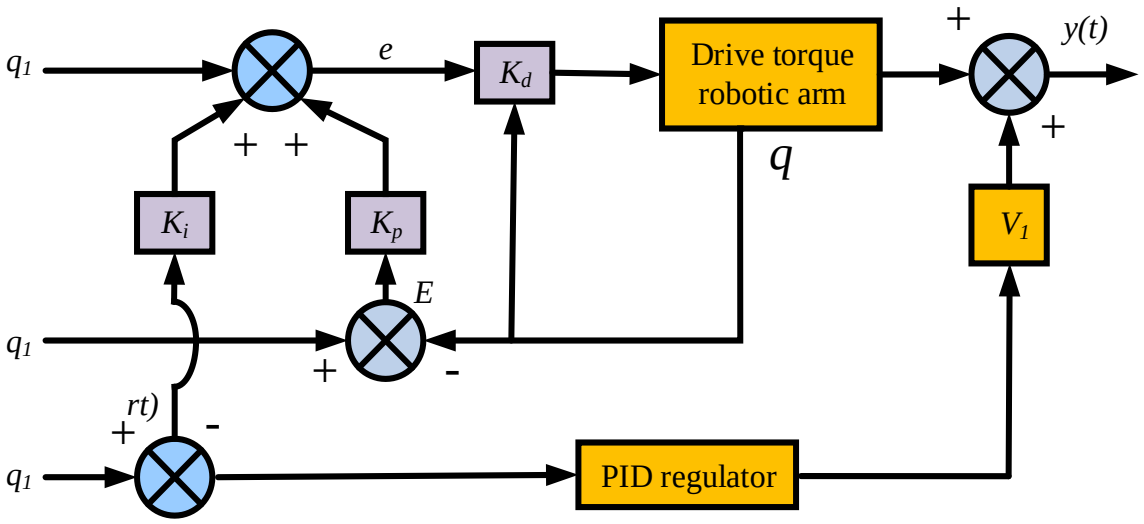

Fig. 2. Schematic diagram of backstepping adaptive control.

B. Construction of Excavator Trajectory Control Model based on GA-PSO

The previous section constructs a mining trajectory planning system based on a PID controller and obtains an anti-interference mechanical arm simulation dynamic model. In the ICS of large mining plants, PID-ECT can achieve excavation trajectory planning and control to enhance the accuracy, efficiency, and flexibility of the excavation process. However, in practical operating environments, due to the complexity of the environment, the feedback control mechanism of PID controllers requires a lot of adjustment time and experience and may encounter problems such as overshoot and oscillation [24-25]. Given these issues, this study proposes a PID control strategy built on GA-PSO to address complex control processes and ensure the accuracy, speed, and robustness of optimal parameter solving. Fig. 3 shows the PID control structure based on the GA-PSO algorithm.

In Fig. 3, GA-PSO searches for the optimal PID parameters to enable the PID controller to provide adjustments for high-frequency and low-frequency signals. GA can search globally by emulating the genetic operations that occur in the natural evolution of organisms. PSO simulates group behavior, and based on the global optimum searched by GA, further performs local fast convergence to obtain more accurate PID parameters. The first step in building GA-PSO is to use GA to randomly generate a set of PID parameters as the initial population, as shown in Eq. (8).

$$u(t) = K_p e(t) + K_i \int e(t)dt + K_d \frac{de(t)}{dt} \tag{8}$$

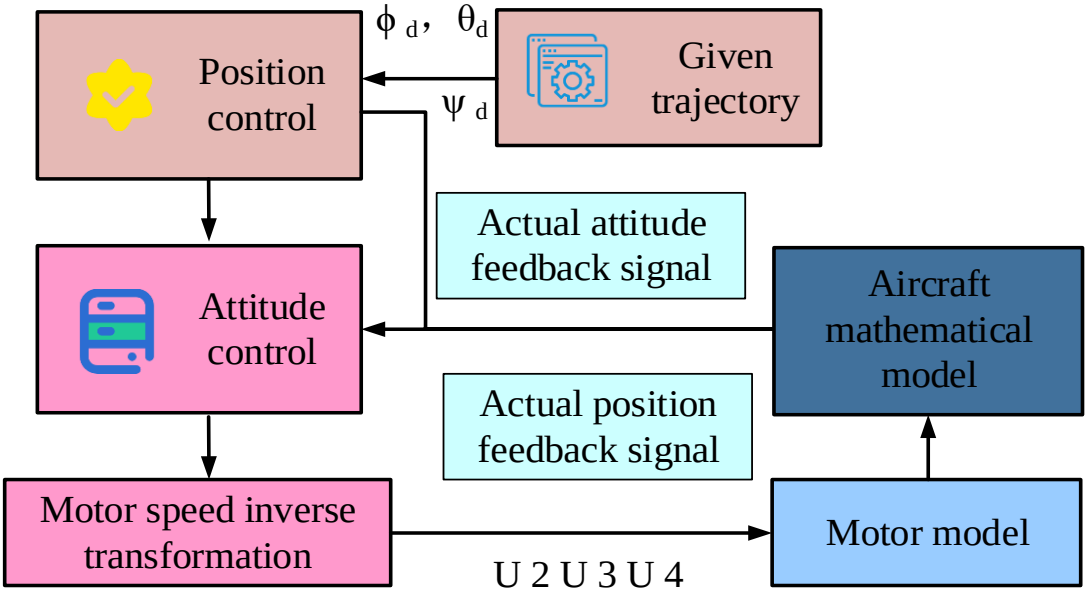

Fig. 3. PID control structure based on GA-PSO.

In Eq. (8), $u(t)$ is the input of the PID parameter vector. $e(t)$ is the error signal of PID control parameters. K_p, K_i, and K_d are the proportional gain, integral gain, and derivative gain of PID control parameters. Each individual input is subjected to fitness calculation, including sum of squared errors, overshoot, and response time, to achieve PID control performance evaluation, as shown in Eq. (9).

$$J = \int_0^T \left(e(t)^2 + \lambda_1 u(t)^2 + \lambda_2 \left(\frac{du(t)}{dt} \right)^2 \right) dt \tag{9}$$

In Eq. (9), J is the fitness function value. T is the total PID control time. λ_1 and λ_2 both represent weight factors. Following each iteration of the population update, an adaptive function is employed to assess the selected PID parameter solutions, thereby identifying the optimal control individual. This creates conditions for the next individual elimination and retention operations to improve the overall quality of the population. Based on the evaluation results of the adaptive function, the expression for selecting probabilities for each individual is given by Eq. (10).

$$P_i = \frac{J_i}{\sum_{j=1}^{N} J_j} \tag{10}$$

In Eq. (10), P_i and J_i are the selection probability and fitness of the current individual i. N means the population size. j is the individual in the population who is currently assigned a probability. To increase the diversity of the population and avoid getting stuck in local optima during algorithm solving, this study randomly selects gene fragments from any two individuals and performs crossover operations to generate new offspring individuals, as shown in Eq. (11).

$$\begin{cases} v^* = (v_1, \cdots, v_{k-1}, v_k, v_{k+1}, \cdots, v_n) \\ u^* = (u_1, \cdots, u_{k-1}, u_k, u_{k+1}, \cdots, u_n) \end{cases} \tag{11}$$

In Eq. (11), $u = (u_1, u_2, \cdots, u_n)$ and $v = (v_1, v_2, \cdots, v_n)$ are the generation of new individuals u^* and $v*$ after chromosome crossing between any two selected parental individuals. k is a random gene fragment cleavage point within the $1 \sim n$ range. Cross operation can increase population diversity, randomly mutate individuals, and further enhance the global nature of the algorithm, avoiding local optima. The random mutation operation performed on individuals is shown in Eq. (12).

$$x_k^* = \begin{cases} x_k + \Delta(t, U_{\max}^k - v_k), random(0,1) = 0 \\ x_k - \Delta(t, v_k - U_{\min}^k), random(0,1) = 1 \end{cases} \tag{12}$$

In Eq. (12), x_k is the individual's randomly selected cutting point for mutation. x_k* is the new mutation point generated after the mutation operation. $random(1,0)$ is a random integer representing the random value of the variance $\Delta(t, y)$. $[U_{\min}^k, U_{\max}^k]$ represents any cutting point within the range. The individual crossover mutation operation process is shown in Fig. 4.

In Fig. 4, by performing cross-mutation on individuals, the PID parameters of individuals can be randomly adjusted to obtain more global parameter solutions. The global advantage of GA has to some extent slowed down the computational speed of the algorithm. To deeply improve the calculation accuracy and velocity of the algorithm, the PSO algorithm is adopted for improvement. PSO is inspired by the foraging process of bird flocks and can accelerate the convergence process by updating particle velocity and position, and increase the accuracy of PID parameters to improve PID control performance. The velocity and location of particles are updated as shown in Eq. (13).

$$\begin{cases} x_i(0) = x_{\min} + rand(0,1) \times (x_{\max} - x_{\min}) \\ v_i(0) = v_{\min} + rand(0,1) \times (v_{\max} - v_{\min}) \end{cases} \tag{13}$$

In Eq. (13), $x_i(0)$ and $v_i(0)$ are the initial positions and velocities of the particles. $x_{\min} / x_{\max}$ and $v_{\min} / v_{\max}$ are the minimum and maximum values of particle position and velocity. PSO achieves further optimization of PID parameters by updating particle velocity and position, and the updated formula is shown in Eq. (14).

$$v_i(t+1) = \omega v_i(t) + c_1 r_1 (p_i - x_i(t)) + c_2 r_2 (g - x_i(t)) \tag{14}$$

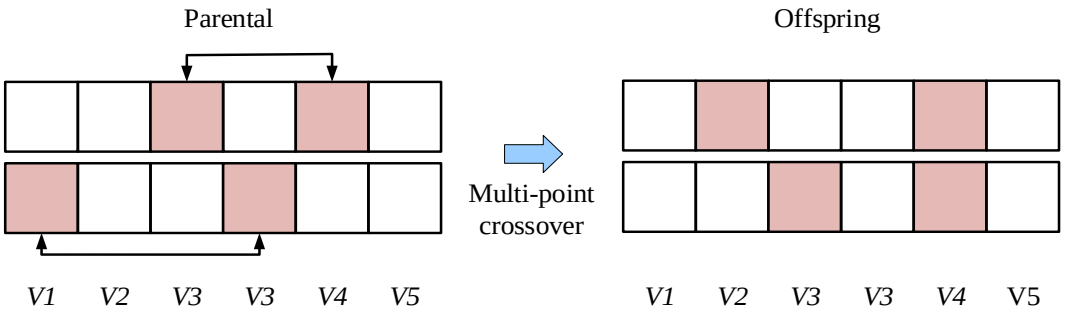

Fig. 4. Execution process of mutation operator.

In Eq. (14), $v_i(t+1)$ is the particle update speed. $v_i(t)$ is the velocity before particle update. ω denotes the inertia weight of particle velocity. c_1 and c_2 both represent learning factors. r_1 and r_2 are velocity weighting factors. p_i and g are velocity updates for particles. $x_i(t)$ is the optimal position for both the individual and the global. The formula for updating the particle's historical position based on its historical location and updated velocity is shown in Eq. (15).

$$x_i(t+1) = x_i(t) + v_i(t+1) \tag{15}$$

In Eq. (15), $x_i(t+1)$ is the current position of the particle after the position update. The schematic diagram of excavator trajectory planning is shown in Fig. 5.

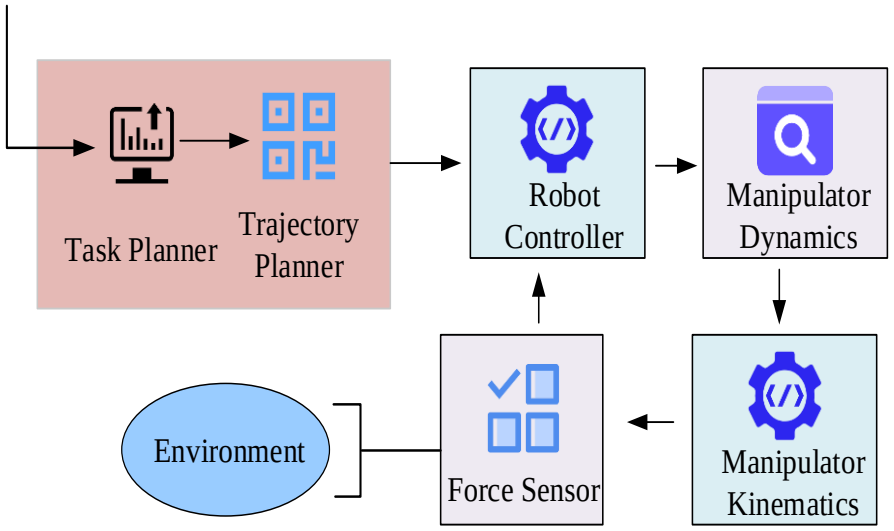

Fig. 5. Schematic diagram of excavator trajectory planning.

In Fig. 5, the process of mining mechanical trajectory planning is the process from task input to control instruction output.

IV. Results

Firstly, the anti-interference simulation model based on PID feedback control is tested to verify its control stability, accuracy, and error value. Next, the application effect of PID-MCS based on GA-PSO optimization is verified. The research method is compared in mining operation control under different working conditions to verify its superiority.

A. Performance Testing of PID Feedback Control for Anti-Interference Mining Trajectory Planning System

To validate the effectiveness of the constructed mining system dynamics simulation model, simulation experiments are conducted on the model. The hardware configuration used for the experimental equipment is Genuine Intel ®CPU 2140 (dual-core) 1.6GHz, 512MB of memory. The experiment is conducted on the MATLAB 7.0 platform. In MATLAB, a 3D simulation model of the linkage coordinates of the RA in the mining system is constructed based on the improved D-H parameters. The simulation experiment is conducted on a scaled-down testing platform to simulate the motion and operation process of the RA in a real environment, creating conditions for the structural and operational analysis of the RA. Table I shows the D-H parameters.

Firstly, the effectiveness of FIOM in controlling the motion of RAs is experimentally verified, using three, five, and nine iterations as comparisons. Each interpolation method is applied to joints 1, 2, and 3 of the RA. The joint motion fluctuation curve over time is used as the evaluation index, as displayed in Fig. 6. In Fig. 6, different numbers of interpolation methods have a good constraint effect on the motion path of the RA, with smooth and continuous curves without significant fluctuations. In Fig. 6 (a), the cubic interpolation method has the worst constraint effect on the motion process of the RA, with significant fluctuations occurring at both the beginning and end of the RA motion. In Fig. 6 (b), FOIM has the best constraint effect with no significant fluctuations, and the curve remains within the range of [-0.25, 0.25]. In Fig. 6 (c) and (d), the seven-degree and nine-degree interpolation methods improved the constraint performance by 2% and 3% respectively based on five degrees, but these two methods have higher energy consumption. This indicates that FOIM can ensure higher constraint performance while also being more energy-efficient.

To further verify the anti-interference ability of the path planning system after adopting the PID controller, the prediction and actual trajectory error of the RA are used as evaluation indicators, as shown in Fig. 7. In the trajectory prediction of four joints using the proposed method, the error is within 5% compared to the true values, and the motion trajectory curves are smooth, continuous, and without significant abrupt changes. In Fig. 7 (a), the application effect in joint 1 is the worst, with a predicted and actual displacement difference of 0.4m. In joint 2 of Fig. 7 (b), the actual and predicted displacement values have the highest overlap, with a difference of less than 0.1m. In Fig. 7 (c) and (d), the error values of joint 3 and joint 4 are at an intermediate level, within 0.3m. The proposed method can overcome the influence of nonlinear factors in the real environment when applied to MCS and has high feasibility and accuracy.

TABLE I. IMPROVED D-H COORDINATE PARAMETERS

Joint	Joint angle/°	Z-axis offset/mm	X-axis offset/mm	Rotation angle around the X-axis	Range of variation
1	-90°~90°	0	59	734	2643mm
2	-34.6°~76.2°	0	3680	0	2677mm
3	0°	136	1734	0	-40°~40°
4	0°	180	1046	0	3000

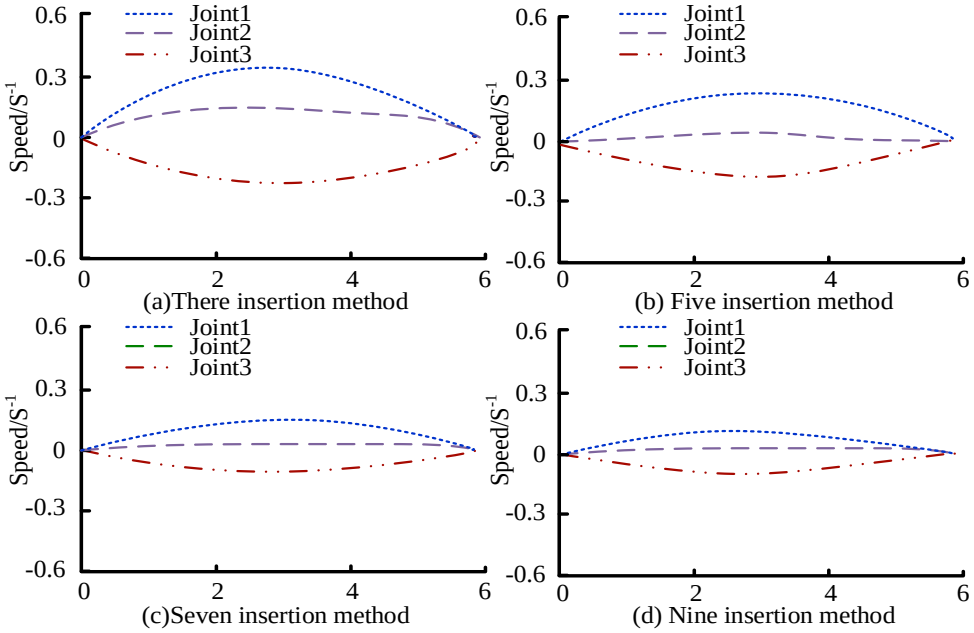

Fig. 6. Comparison of motion speed curves under different interpolation modes.

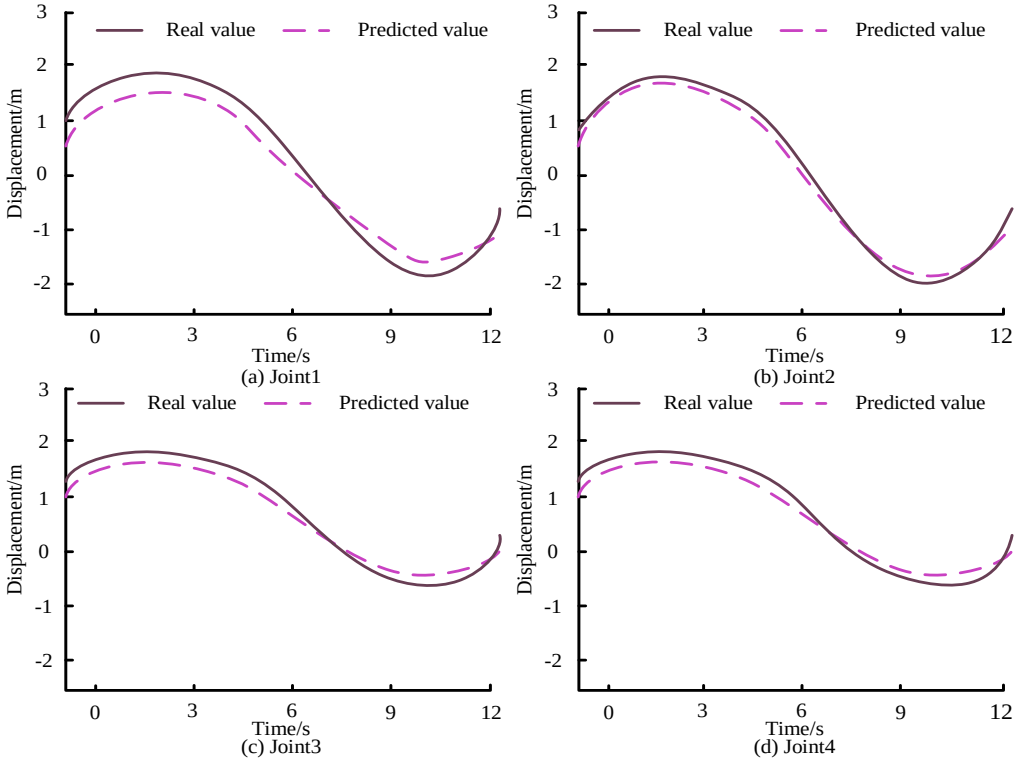

Fig. 7. Performance test under PID control of RA.

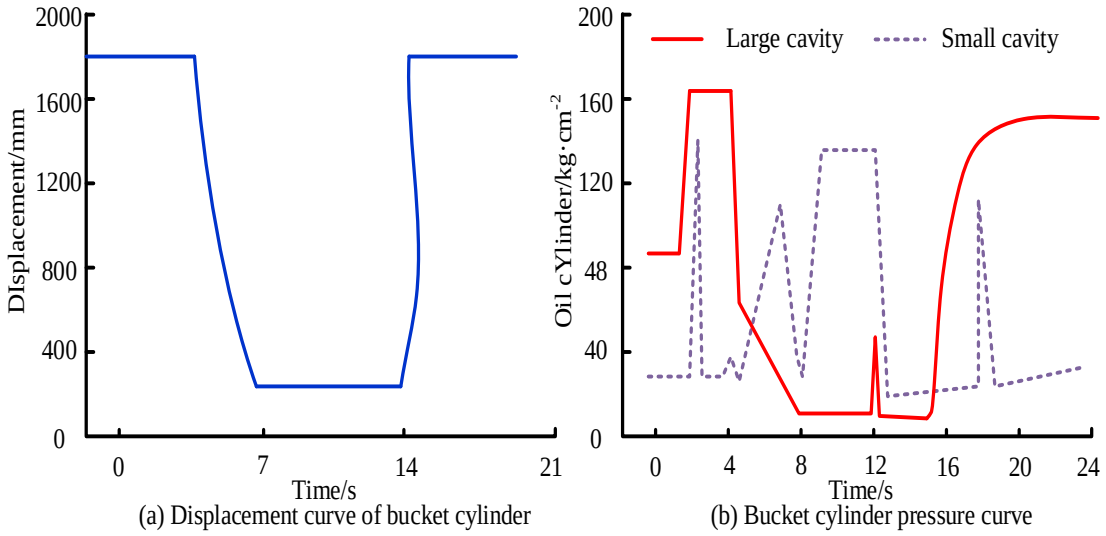
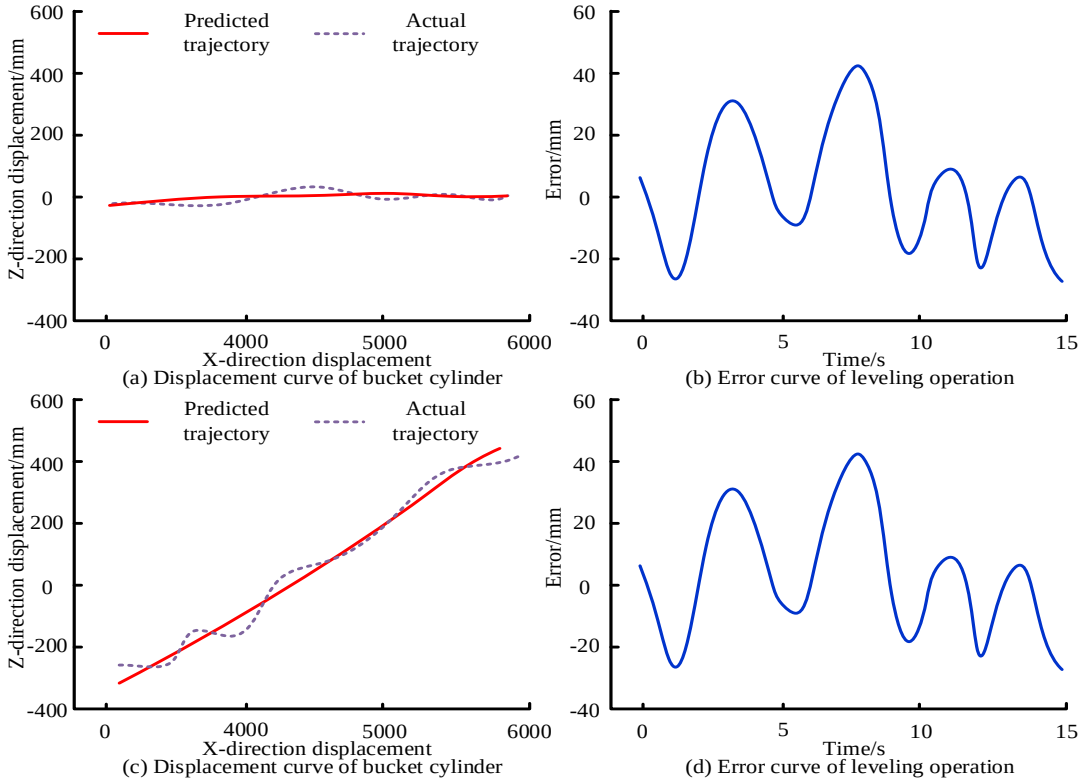
B. Application Verification of PIDMCS based on GA-PSO Optimization

After verifying the performance of the PID-controlled RA simulation model in the previous section, the actual application effect of the PID controller optimized by GA-PSO is analyzed. The displacement and pressure curves of the hydraulic cylinder applied to the practical application scenario of the bucket hydraulic cylinder using the research method are shown in Fig. 8. During the bucket operation, it can move accurately by the pre-set trajectory, and the displacement and pressure curves always show stability. In Fig. 8 (a), the displacement curve of the bucket cylinder encounters obstacles and evades them at 8-11s, and then returns to normal track operation. In Fig. 8 (b), there is consistency in the action of the pressure changes in the large and small chambers of the bucket cylinder at time points 2s, 4s, 8s, 12s, and 18s. The pressure curve exhibits symmetry within the ranges of [2, 4], [4, 8], [8, 12], and [18, 24]. The proposed excavation trajectory control method has good stability and accuracy in controlling the pressure parameters of the hydraulic system and can make the excavator move smoothly according to the predetermined track in practical applications.



(a) Displacement curve of bucket cylinder (b) Bucket cylinder pressure curve

Fig. 8. Displacement and pressure control curve of bucket cylinder.



(a) Displacement curve of bucket cylinder (b) Error curve of leveling operation

(c) Displacement curve of bucket cylinder (d) Error curve of leveling operation

Fig. 9. Trajectory control curves for different work environments.

To further verify the control effect during bucket excavation, the motion trajectory of the bucket during leveling and slope operations is tracked. Fig. 9 shows the error result between the calculated actual value and the predicted value. In Fig. 9 (a) and (b), the trajectory and error curve of the bucket tooth tip indicate that the maximum error in horizontal displacement is 44.21mm. In Fig. 9 (c) and (d), the maximum error of water diagonal displacement during bucket slope operation is 41.41mm. Overall, the motion errors are within a reasonable range, and the motion curve is smooth, continuous, and without significant fluctuations. The proposed method can ensure stable and accurate control effects in two different operating environments, with errors controlled within a reasonable range, and the results have high reliability.

To further verify the practical application effect of GA-PSO in optimizing PID parameters and mining trajectory planning systems, three classic algorithms, Adaptive Genetic Algorithm (AGA), A* Search Algorithm (A*), and Rapidly-exploring Random Tree (RTT), are compared. Fig. 10 shows the results of using the convergence accuracy and rate of the algorithm as performance evaluation indicators. As the number of iterations increases, the convergence accuracy and rate of the proposed algorithm are better than the other three compared algorithms. In Fig. 10 (a), the proposed algorithm converges to 0.05 after 50 iterations, while AGA, A*, and RTT algorithms converge to similar levels after 80, 91, and 110 iterations, respectively. The average convergence rate of the three algorithms is 0.08 lower than the proposed algorithm. In Fig. 10 (b), the proposed algorithm achieves the highest accuracy of 94%, while AGA has the lowest accuracy of only 75%. The accuracy of A * and RTT algorithms is at an intermediate level, which is 15.3% and 17.5% lower than the proposed algorithm. Therefore, the GA-PSO has the best accuracy and efficiency when applied to mining trajectory planning systems.

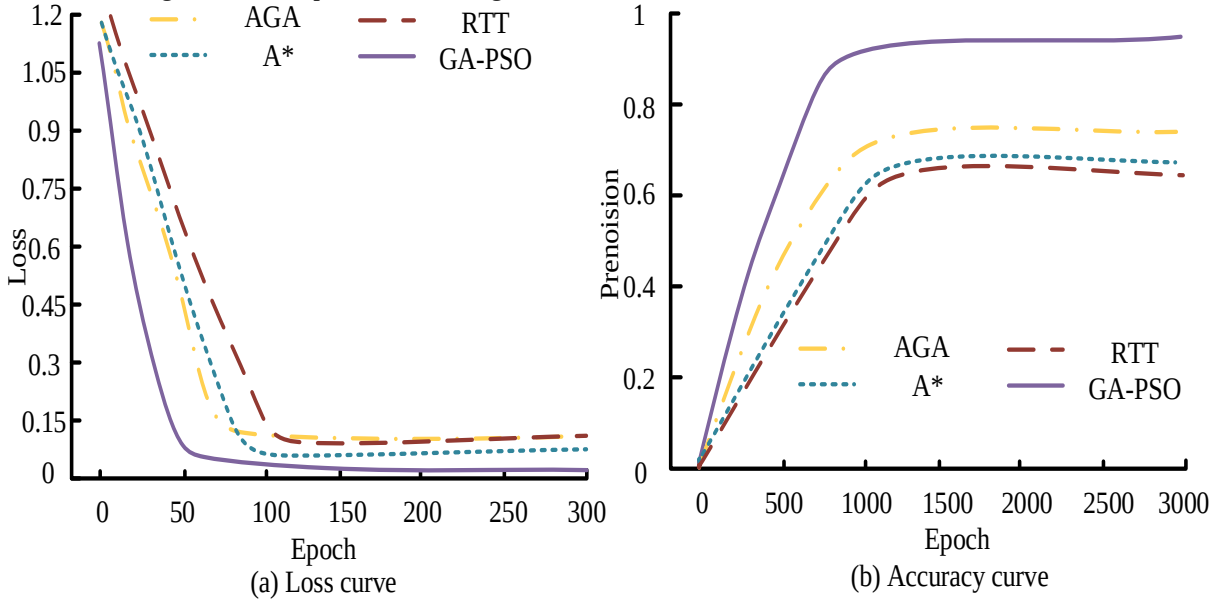


Fig. 10. Comparison of convergence accuracy and efficiency of different algorithms.

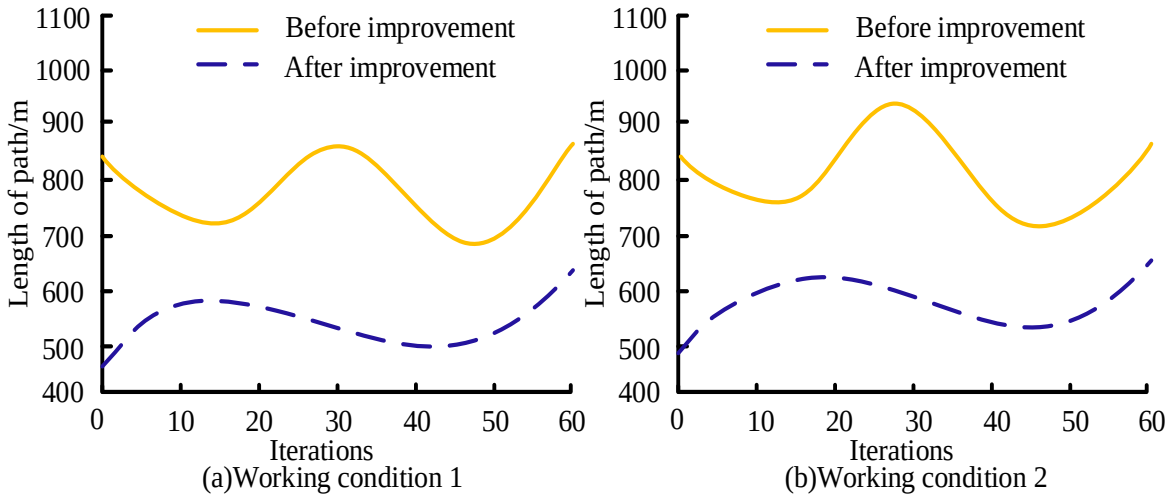

Fig. 11. Comparison of algorithm path planning length before and after improvement.

To test the path planning performance of the research algorithm, it is tested under two different load levels and compared with the improved algorithm using path length as the evaluation index, as exhibited in Fig. 11. Overall, the path length of the improved algorithm is shorter. In condition 1 of Fig. 11 (a), the longest path of the algorithm before improvement is 884m at 30 iterations, which is 46.2% longer than the improved algorithm. In condition 2 of Fig. 11 (b), the improved algorithm has a maximum path of 962m at 60 iterations, a decrease of 43.5% compared to before the improvement. In two different levels of complexity, the error is within 5%, indicating that the improved method has high reliability and accuracy.

V. Discussion

The proposed ECT-based ICS shows obvious performance improvement in the application of large-scale mining excavators by combining the PID controller optimized by GA-PSO technology. The analysis of experimental results demonstrates that the enhanced PID feedback control method exhibits superior comprehensive performance in search performance and convergence speed when compared to traditional PID control technology, fuzzy control, and the use of GA and PSO in isolation. In the aspect of the anti-interference ability, the proposed method effectively improves the robustness of the excavator in the face of internal and external interference through adaptive adjustment of the PID controller. This is reflected in the stability of the displacement and pressure curve of the hydraulic cylinder. The stability and symmetry of the curve show the precise control ability of the system in actual operation [20, 21]. In addition, the trajectory prediction error is controlled within 5%, which further proves the high reliability and adaptability of the system in complex mine environments.

In terms of optimization efficiency, the application of the GA-PSO algorithm significantly improves the accuracy and speed of parameter optimization. A comparative analysis of the algorithms reveals that the proposed algorithm rapidly converges to 0.05 after 50 iterations, with an accuracy of 94%, which is superior to the other three classical algorithms [11-13]. This shows that the GA-PSO algorithm can balance the efficiency of global search and local search more effectively when dealing with complex trajectory planning problems.

VI. Conclusion

Aiming at the intelligent control of large mining equipment in complex mine environments, this paper proposes an ICS based on ECT. Through the PID controller optimized by combining GA and PSO technology, the accuracy, response speed, and robustness of the control system are improved. The experimental results showed that the control system had good stability and accuracy under different working conditions. The trajectory prediction error was controlled within 5%, the displacement and pressure curves of the hydraulic cylinder were stable, and the algorithm converged rapidly after 50 iterations, with an accuracy of 94%. These results proved the effectiveness of the proposed method and provided a practical solution for improving the intelligent control performance of large mining equipment.

Nevertheless, the research is not without limitations. In particular, the comprehensive control performance of the algorithm requires further improvement in a more complex actual mine environment. Future research will concentrate on enhancing the algorithm's adaptability to more effectively address the evolving mine environment. Additionally, more efficient optimization strategies will be investigated to minimize calculation time and enhance control accuracy. In addition, advanced technologies such as DL are considered to be integrated into the control system to further improve the level of intelligent control.

***Abstract*—The complex factors of liver transplant survival and the potential for post-transplant complications are significant challenges for healthcare professionals. This paper aims to identify the ability to use data mining techniques to develop a predictive model for liver transplant failure by identifying the relationship between abnormalities in periodic patients' laboratory results and graft failure. The researchers obtained data from King Faisal Specialist Hospital and Research Centre to address the research problems. First, the classification technique was used to predict cases with a high risk of liver transplant failure. Second, Association Rules were applied to identify associations between abnormalities in patients' laboratory results and transplant failure. Before using data mining algorithms, the patient dataset underwent a cleaning process, which involved removing duplicate entries and uncertain results. The algorithms were applied separately to the data of patients who completed the first year without complications and those who experienced transplant failure. The obtained results were then compared and we observed that abnormal levels in Aspartate Transferase (AST), Red Blood Cell (RBC), Hemoglobin (Hgb), 'Bilirubin Total', and 'Platelet' occurred exclusively in cases that faced liver transplant failure within the first year. Similarly, abnormal levels in 'AST', 'RBC', Alanine Aminotransferase (ALT), and 'Bilirubin Total' were also associated with transplant failure.**

***Keywords*—Graft failure; liver transplant; data mining; predictive model; classification; association rules**

I. Introduction

The growth of technology use in the last decade has led to large amounts of data entering data repositories worldwide. It is unrealistic to extract valuable knowledge manually from this vast, massive data. Therefore, many technologies have been created to assist the user with tools to find useful knowledge and information from this distributed data. Data mining refers to the extraction of valuable knowledge and meaningful information from large databases; it depends on machine learning, statistical methods, and artificial intelligence. The efficacy of data mining has been extensively studied across various domains, including commercial sectors, telecommunications, and healthcare [1].

In the medical industry, sensitive data is produced daily from medical records, patient monitoring, laboratory reports, radiology images, and more. Therefore, data mining applications have shown effectiveness in the healthcare industry. Physicians can use data mining techniques to enhance patients' quality of life by using data to design the best treatment plan, diagnose potential diseases, or predict drug side effects [2].

One medical field recently used in data mining is organ transplantation. Organ transplant refers to replacing a failed organ from a patient with an organ from a Brain deceased donor or living donor. This operation gives the patient with end-stage organ failure the chance to have a normal life [3]. Liver transplantation (LT) is the ultimate medical intervention for patients with advanced liver disease. However, there are main challenges that reduce the benefits of liver transplants, the shortage of grafts available for transplant, the increase in the patients on the waiting list, and the probability of graft failure after the surgery. Patients are subjected to strict monitoring of their vital functions and extensive analysis during past and post-transplant to predict any signs of liver failure. In addition, transplant patients undergo high doses of immunosuppressants, especially within the first year post-transplant, to reduce the possibility of liver failure. However, many factors affect graft survival, making the early prediction process complex [4].

According to these challenges, physicians find it difficult to predict patients with a high risk of graft failure and improve the chance of saving the graft and the patient's life [5]. Therefore, several scores and models have been evaluated to predict contributing factors to achieve a successful post-LT outcome. It is important to note that most of these models were introduced several years ago, applied to different populations, and focused on different kinds of organ transplants; Kidney, Lung, or Heart. In this research, the focus is to study a model to predict patients with a high risk of liver failure post-liver transplant (LT).

II. Literature Review

A. Data Mining in Predicted Failure Transplant Organ

Many prior studies built different models based on data mining methodologies to predict graft survival. These studies covered kidneys, lungs, liver, and Stem Cell transplantation. Some researchers have developed a new predictive model, and others compared different data mining algorithms to improve the accuracy of predictions.

Atallah et al. [5] used hyper-classifiers to predict kidney transplant outcomes. They proposed a method to predict kidneys before transplants dependent on three stages, the preparation stage, feature selection stage, and then prediction stages. In the first stage, they proposed preparing the data which consisted of

data cleaning and removal of all instances that have missing data. In the feature selection stage, only relevant features are extracted to improve the accuracy of the model. The last stage is conducting the predicting phase using the KNN algorithm. They found the highest accuracy by using this method, they achieved 81.5% accuracy.

Also, Oztekin et al. [11] proposed a feature selection methodology based on a genetic algorithm (GA) to achieve a high classification accuracy to predict the quality of life after a lung transplant. The GA-selection algorithm was applied along with kNN, ANN, and SVM as classification models. The result shows that SVM had the highest accuracy in predicting quality of life following lung transplantation.

In other studies, the predictor of the risk of Kidney transplant failure has been investigated in different cohorts. Naqvi et al. [16] conducted machine classification algorithms to develop prediction models for the risk of graft failure using support vector machines (SVM), AdaBoost, RF, ANN, and logistic regression over patients' data in three cohorts. The result of accuracy shows that SVM and AdaBoost have the highest rate over the cohorts.

To compare the accuracy of a different model, [10] compared nine algorithms using 10-fold stratified cross-validation, which were: logistic regression, linear discriminant analysis, quadratic discriminant analysis, support vector machines (using linear, radial basis function, and polynomial kernels), decision tree, random forest and stochastic. In the same idea, [10] [9] compared six algorithms: Naïve Bayes (NB), alternating decision trees (ADT), and logistic regression (LR) which produce models with interpretable structures, whereas multilayer perceptron (MLP), random forest (RF) and AdaBoost attempt to detect for the one which will give the highest accuracy.

On the other hand, [13] compared between three data mining (DM) methods to predict Kidney Transplant Survival. The models are the C&R Tree Model, Neural Network Model, and C5.0 Model. The accuracy of the C5.0 Model was the highest. It was 91.5% within the first year of transplant.

Also, [15] studied the cases of failure and success of LT by studying factors related to the patient and the donor and comparing the accuracy of the classification before and after the feature Selection. By comparing the accuracy results when applied Neural Network and Random Forests before FS: 0.734 and 0.787 and after FS: 0.835 and 0.818.

All previous studies have highlighted the use of classification in predicted transplantation outcomes; on the other hand, [14] used the association rules to predict important factors for who did and did not have kidney failure five years post-kidney transplant for live and deceased donor recipients. He identified factors common in both patients (live and deceased donor recipients) and factors important only in deceased donors. Also, he identified the factors associated with graft Failure. These factors match with what is usually observed in patients in the clinic. Table I summarizes the Application and Techniques Used in Organ Translation Studies.

B. Liver Transplant in the Kingdom of Saudi Arabia

Organ transplant has been one of the medical revolutions in the last two decades [6]. It gave patients with end-stage organ failure a chance to live a normal life by removing the organ from one person "the donor" and transplanting it to the recipient who has organ failure. The most common organs that are transplanted include the heart, kidneys, lungs, and liver. As a result of the high burden of liver disease in the country, there is a high demand for liver transplantation. The estimated LT is around 75 patients per million.

As the growth of organ transplant activities all over the world, the Kingdom of Saudi Arabia (KSA) picked up the pace in this field. In 1985, the Saudi Center for Organ Transplantation (SCOT) was established as a government center to monitor organ transplantation activities in KSA. Indeed, the first organ transplant in KSA was a kidney transplant from a living donor in 1979 [12], while the first LT was in 1991 [7]. Nowadays, there are over 20 organ transplant programs throughout the KSA, and four of them are LT centers. In Riyadh, there are three centers and the last one is in Dammam. Over 2000 LTs have been performed over the four centers, 50% of these surgeries performed at King Faisal Specialist Hospital and Research Center (KFSH&RC) in Riyadh. For each LT center, there is a waiting list based on the Model for End-Stage Liver Disease (MELD) scores.

III. Methodology

To answer the research questions, we applied two Data Mining methodologies. First, we applied several common classification algorithms to predict failure cases. Second, we conducted Association rules to identify the relationships among patients' data.

The main steps were followed:

- Data collection.
- Data preprocessing.
- Predicting Liver Failure: a. Classification. b. Association Rules, As shown in Fig. 1:

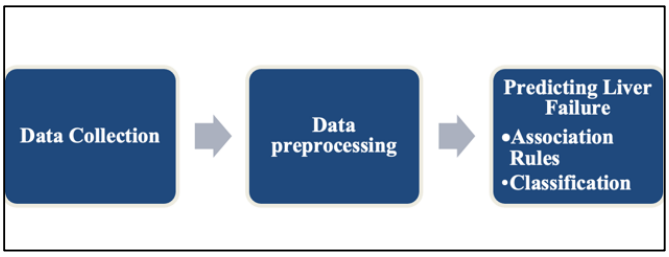

Fig. 1. Main steps of the data mining process.

A. Data Collection

The data used in this study was obtained from KFSH&RC and presented in a CSV format. The dataset included lab results of 1118 patients who underwent LT between 2002 and 2018, totaling 772339 rows and fourteen columns. Each row represented a specific lab result for one patient on a particular date. Eighty-one different labs were taken; it is important to note that the frequency of lab repetition varied depending on the patients at other times, and not all labs were taken for every patient. Moreover, there were duplicate data, missing data, and laboratories without any results, Table II summarizes the dataset:

TABLE II. Summary of Patients' Dataset

Data Set Size	Number of Attributes	Unique Establishment IDs
772339	14	1118

The dataset contains six columns with different dates for each lab:

- ORIG_ORDER_DT_TM
- DRAWN_DT_TM
- RECEIVED_DT_TM
- CURRENT_START_DT_T
- LAST_UPADTE
- RESULT_PERFORM_DT_TM

By referring to the specialist doctor about the importance of these columns, it was found that the most critical column among them is: RECEIVED_DT_TM

All unimportant columns were excluded from the table, and retained only the following ones**:**

- RESULT_PERFORM_DT_TM
- MRN
- BIRTH_DT_TM
- CATALOG
- LAB_TEXT_NAME
- RESULT

Descriptions of the attributes are presented in Tables III:

Table II: Dataset attributes description

TABLE III. Dataset Attributes Description

#	*Attribute name*	*Type*	*Description*
1	RESULT_PERFORM _DT_TM	Datetime	Date of receipt of the patient's analysis request
2	MRN	int64	Unique ID for each patient
3	BIRTH_DT_TM	Datetime	The birth date of each patient
4	CATALOG	object	The categories for each laboratory test
5	LAB_TEXT_NAME	object	The name of laboratory test
6	RESULT	int64	Represent the result of the laboratory test

Another CSV file was obtained reviewing cases completed a year without complications and unsuccessful cases from 2001 to 2019. The number of patients in this file is 1140 cases: 1031 success cases, 121 failure cases, and 26 cases without information. Fig. 2 shows the increase in liver transplant cases during the previous years at the KFSH&RC:

B. Data Preparation

Usually, the raw data contains noise, missing, or duplicated data that can affect the quality of data mining results, so the data preparation phase is a crucial step. The researchers follow steps that are suitable for their methodologies according to the type and size of the data and the data mining technique used [18]. This phase is also important for better understanding and realizing data. It consists of data cleaning, data labeling, and addressing class imbalances.

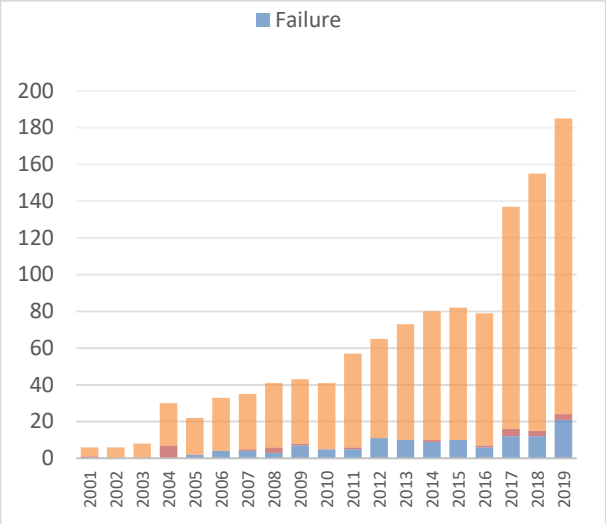

Fig. 2. The liver transplant cases during the previous years at the KFSH&RC.

1) Data Cleaning: The data obtained is vast, and complex, with many Null cells and duplicate data. Also, all rows were excluded for pediatric patients who were younger than 15.

Data cleaning involved removing:

- All rows with missing values.
- All rows if the "Result" column contains "Indeterminate", "Hemolyzed", "See the comment" or "Equivocal".
- All rows if received date more than one year before the transplant.
- All duplicated rows.

2) Data labeling: The laboratory results vary in distributed values; any difference from the normal range is considered abnormal, so a "Class" column has been added, which shows the status of the laboratory results if the result is within the normal range or abnormal.

Data Labeling involved modified:

- "Result" value if "Result" = "positive" to 1 , and Negative to 0,
- Determined the normal range for each laboratory test, if the result is within the normal range the class will be = 0, otherwise if the result is above or below the class will be Abnormal = 1.

Table IV represents the normal ranges of each laboratory.

TABLE IV. LABORATORY RESULTS IN NORMAL RANGES

LAB_TEXT_NAME	Normal Range
AFP	0 -10
Albumin	34 - 54
Alk Phos	44 - 54
ALT	19 - 25
ANA Screen	Negative
AST	8 -33
Bilirubin Total	0 -21
CA 125	0 - 35
CA 19-9	0- 37
Ca Level	8.6 – 10.3
Ceruloplasmin	14 – 40
Cl	96- 106
CMV IgG	1 - 21
CMV IgM	Negative
CO2	20 - 29
Creat	61.9 – 114.9
e-GFR	60 - 90
Ferritin	11 - 336
Globulin	20 - 39
Hct	0.3 - 0.5
Hgb	138 - 172
Hgb g per dL	14 - 18
IgA	0.8 - 3
Iron	10 - 30
Iron Saturation	0.15 – 0.55
K	3.5 – 5.3
MCH	27 - 33
MCHC	33.4 - 35.5
MCV	80 - 95
Mg	0.85 – 1.1
MPV	8.9 - 11.8
Na	135 - 145
NRBC Auto	0 - 0.3
Platelet	150 - 450
PO4	2.3 – 4.7
Pro-Brain Natriuretic Peptide	100 - 400
Protein Total	60 - 83
Quantiferon-TB	Negative
RBC	4.2 - 5.4
RDW	12.2 - 16.1
Sm Muscle Ab	Negative
TIBC	42.96 – 80.55
Total Cell Count (NRBC)	0 - 100
Toxoplas IgG	0 - 44
Toxoplas IgM	Negative
UIBC	21 - 84
Urea	5 - 20
WBC	4.5 - 11

3) Addressing class imbalance: The data set has two categories, failure transplant cases and success transplant cases. There was a significant class imbalance whereby the failure transplant had a significantly lower number of instances compared with the success transplant. To solve this issue, the Minority Oversampling Technique (SMOTE) was used.

4) Reorganized dataset: In the dataset, each row represented a specific laboratory result for one patient at a particular date. To prepare the dataset, the dataset was reorganized. Each row represents all laboratory results for one patient at a specific date.

5) Feature selection: The feature selection stage is predicated upon the principle of diminishing the pool of features to only encompass the most valuable features, thereby augmenting the model result. Researchers employ various techniques to eliminate irrelevant features, to enhance the efficiency and accuracy of the model.

In studies [5], [19], and [16] removed all unnecessary features, and all patient identifications (such as transplant ID, donor ID, and patient ID). Moreover, the study in [20] removed all unnecessary attributes, and kept only 27 relevant attributes from the dataset containing 389 attributes. Also, they removed the data of pediatric patients [21]. Identify the critical features used in statistical tests of the association between each feature and output variable. They exclude only three variables from the model. The study in [11] used Genetic Algorithms to minimize the number of features. They also excluded the feature with a large number of missing values. The dataset encompasses a total of 81 laboratory tests, with the exclusion of laboratories that conducted tests for only 10% of the patients or laboratories that showed normal results in the majority of patients. Consequently, 33 laboratory tests remained in the dataset.

C. Predicting Liver Failure Use DM Algorithm

We have followed two DM approaches to answer the research questions, using classification to predict the failure cases, and to investigate the labs that have highly impacted on liver failure we used the Association rules method.

1) Classification: Classification is a predictive supervised learning technique that classifies the data into predefined classes. It is one of the most widely used DM techniques in medical research [9]. It aims to predict target classes; it could be a binary or multilevel approach. In binary classification, there are two classes to predict, such as patients with "positive "or "negative" diagnoses. On the other hand, in multilevel classification, there are more than two predicted classes.

In this research, we have applied five algorithms: Random Forest – KNN – GaussianNB – SVC – ANN.

2) Association rules: Association Rules Mining (ARM) also known as "Market basket analysis" is an unsupervised learning method used with transactional databases [8]. [17] introduce Association Rules as generating associations or/and correlations among frequent items in large transactional databases.

Let transactional database $\mathcal{T}$ contain a set of items, $\mathcal{I} = i_1, i_2 \dots, i_m$ as binary attributes, each transaction t represented as set of items $i_k \subset \mathcal{I}$ where i_k=1 ,the advance of ASM is to seek for the term: $\mathcal{X} \rightarrow \mathcal{Y}$ where $X, Y \subset \mathcal{I}$ and $X \cap Y = \emptyset$. Apriori algorithm is a well-researched ARM algorithm. The concept of the Apriori Algorithm is using a breath-first strategy to eliminate unnecessary rules that are unsatisfied with minimum support (mins up) and minimum confidence. To implement Apriori Algorithm, 2 steps are performed:

First step: Find all possible candidates C from each itemset in the database, where a large k-itemset is generated from k-1-itemset with satisfied minsup.

Second step: generate all rules from these candidates' itemsets.

Minimum support formula is:

$$Support = \frac{feq(X,Y)}{number\ of\ t}$$

The formula for association rules algorithm set of features,

$$confidence(X|Y) = \frac{feq(XY)}{feq(X)}$$

D. Model Evaluation

The evaluation stage of the algorithms employed holds paramount significance in the data mining process, as it demonstrates the viability of the technique utilized. Various mechanisms are employed to conduct evaluation techniques based on their respective types.

1) Classification evaluation: In the evaluation of classifications, researchers employ a variety of techniques. In our current study, we have utilized the Confusion Matrix method to assess the effectiveness and accuracy of these classifications. The confusion matrix is widely recognized as the most commonly used tool for measuring classification effectiveness [22]. This method proves particularly valuable in quantifying important measurements such as Recall, Precision, and Accuracy.

To find these measurements, the Confusion Matrix technology depends on comparing the prediction results and the real values as shown in Table V:

TABLE V. CONFUSION MATRIX

		Actual Value	
		Positive (1)	***Negative (0)***
Predictive Value	**Positive (1)**	**True Positive**	**False Positive**
	Negative (0)	**False Negative**	**True Negative**

To elucidate the concept of four fields; "True Positive, False Negative, False Positive, and True Negative" in the context of our research, it is important to note that we are dealing with two classes for which we aim to construct a predictive model:

True Positive (TP): The prediction of the state is positive, and the actual outcome is positive.

True Negative (TN): The prediction of the state is Negative, and the actual outcome is Negative.

False Positive (FP): The prediction of the state is positive, and the actual outcome is Negative.

False Negative (FN): The prediction of the state is Negative, and the actual outcome is positive.

To find the values of Recall, Precision, and Accuracy from Confusion Matrix:

$$\text{Recall} = \frac{TP}{TP+FN}$$

$$\text{Precision} = \frac{TP}{TP+FP}$$

Accuracy = how many correct predictions from both classes; Positive and Negative.

2) Association rules evaluation: Association Rules Evaluation is a crucial aspect of data analysis that aims to uncover meaningful relationships and patterns within datasets. This research delves into the intricacies of association rule mining, a popular technique employed in one key aspect of our research that involves measuring the strength of association rules through metrics such as support, confidence, and lift. These metrics allow us to quantify the level of dependency between items or variables in a rule. Additionally, we explore various evaluation measures like conviction and leverage to gain a comprehensive understanding of the associations discovered.

The minimum support formula is:

$$Support = \frac{feq(X,Y)}{number\ of\ t}$$

The formula for association rules algorithm set of features,

$$confidence(X|Y) = \frac{feq(XY)}{feq(X)}$$

E. Tools and Software

The research is based on classification techniques and the hardware used is a MacBook Pro (14-inch, 2021) with M1 pro 3.22 GHz processor 8 Cores, and the memory is 16 GB 2133 MHz LPDDR5. The research used Python software, specifically on a Jupyter Notebook. Python was chosen because it has a large support community and various libraries that provide extensive functionality. One such library used in this research is scikit-learn, which supports different classification methods and is widely accessible. Also, panda's library ‹was used extensively by taking advantage of the functions that supported the preparation phase of the data.

IV. Results

The complexity of the data is quite intricate, as no patient has undergone more than 13 tests in a single day. After eliminating the laboratories that were only utilized for 10% of patients, we were left with 31 labs, which is a huge amount to handle. To address our research inquiries, we employed two data mining approaches. These techniques will examine the outcomes achieved through the classification technique, followed by an assessment of the results obtained using association rules.

A. Association Rules

The dataset provided encompasses all laboratory tests conducted for each patient on specific dates. The data within the table lacks a systematic arrangement. To address this, we have employed the association rule mining technique to uncover relationships between abnormal results. By comparing the outcomes generated from a dataset comprising both failure cases and alive cases, we aim to identify significant associations. Association rule mining holds great significance in transactional datasets as it enables the discovery of intricate relationships among different data elements. Consequently, its application in analyzing patient laboratory results proves highly convenient.

In order to implement Association Rules, the initial phase entailed categorizing each laboratory result with a corresponding class. The class denoted as "Normal" was encoded as 0, which will be traversed by the algorithm. Conversely, the class labeled as "Abnormal" was encoded as 1, which will be interpreted by the algorithm.

Moving on to step two, the dataset consisted of 2366 rows. Out of these, 372 rows were dedicated to failure cases (FC) and 1994 rows to success cases (SC). However, there was an imbalance in the final dataset. To address this issue, the SMOTE algorithm was applied. This resulted in an expanded dataset with a total of 3988 rows. This expansion ensured that both FC and SC had an equal representation of 1994 rows each. For step three, the association rule technique was employed on both the FC and SC datasets using identical parameters. The minimum support was set at 0.4, while the minimum confidence threshold was set at 1. The researcher applied the Apriori algorithm to analyze the data and obtained interesting results. Specifically, the researcher discovered that a total of 1848 rules were generated in instances of success, while 1968 rules were generated in cases of failure. To further investigate these findings, the researcher compared the results and found that most of the rules appeared in both cases of failure and success. Additionally, the support and confidence values for these rules were very close. The analysis revealed that certain rolls, namely AST, RBC, Hgb, 'Bilirubin Total', and 'Platelet', were higher in cases that experienced liver transplant failure within the first year. Furthermore, height was also found to be associated with AST, RBC, ALT, and 'Bilirubin Total', as indicated in Table VI.

TABLE VI. Unique Results Shown with FC

Rules	***support***	***confidence***
'AST' ^ 'RBC' ^ 'Hgb'^ 'Bilirubin Total'^ 'Platelet'	0.46	0.95
'AST' ^ 'RBC' ^ ' ALT'^ 'Bilirubin Total'	0.40	0.91

It was deemed necessary to seek the expertise of a specialist doctor at KFSH&RC for their evaluation. The esteemed specialist doctor duly reviewed the findings and concurred that this discovery holds a significant interest.

B. Classification

The study aimed to investigate the efficacy of using DM in identifying the most vulnerable cases of LTF based on periodic laboratory results. To achieve this objective, a comprehensive analysis was conducted using a commonly employed algorithm. The primary focus was to assess the potential of DM in accurately pinpointing individuals at high risk for LTF, solely relying on their lab test outcomes.

After preprocessing and organizing the data, we proceeded to apply various algorithms including Random Forest, K-Nearest Neighbors (KNN), Gaussian Naive Bayes (NB), Support Vector Classifier (SVC), and MLPClassifier on the dataset. The outcomes revealed that Random Forest exhibited the highest accuracy among all algorithms. It achieved an accuracy rate of 85 percent. Following closely behind, KNN demonstrated a respectable accuracy of 81 percent, while MLP Classifier achieved an accuracy of 78 percent. On the other hand, SVC and Genesis NB yielded lower accuracies with rates of 60 percent and 54 percent respectively. Table VII shows the Performance Evaluation for all five algorithms.

TABLE VII. PERFORMANCE EVALUATION FOR CLASSIFICATIONS

Classifier	Precision	Recall	Precision	Recall	Accuracy
	Success Case		Failure Case		
Random Forest	86	84	84	86	85
KNN	83	80	79	82	81
GaussianNB	80	73	77	83	78
SVC	62	53	58	66	60
ANN	60	35	52	75	54

The results were presented to a specialist doctor who agreed with the reality of some of the results.

V. CONCLUSION

Data mining technologies hold significant promise in healthcare, especially in predicting medical outcomes and identifying risks. This study, in collaboration with the Organ Transplant Center of Excellence and the Center of Genomic Medicine at KFSH&RC, demonstrates the predictive power of data mining in liver transplant outcomes. Using patient data from 2002 to 2018, two data mining techniques, classification, and association rules, were applied. Among five algorithms tested, Random Forest proved most effective, achieving an 85% accuracy rate in predicting liver transplant failure. The association rules technique, using a support value of 0.4 and a confidence value of 1, identified elevated levels of 'AST', 'RBC', 'Hgb', 'Bilirubin Total', and 'Platelet' as significant indicators of transplant failure. These findings were validated by the hospital's Adult Transplant Hepatology consultants, who stressed the need for further research incorporating larger sample sizes and additional variables such as age, gender, body mass, and liver failure causes. Expanding this study to other organs and hospitals across Saudi Arabia could enhance predictive accuracy and clinical utility.

The influence of data mining technologies is particularly evident in contemporary technological revolutions within the realms of marketing, industry, finance, and education. However, in the domain of health research, investigations are still centered on exploring the potential benefits of data technologies to aid physicians in predicting diverse diseases and detecting potential hazards to patients' lives at an early stage, thereby presenting a significant challenge to medical practitioners. According to the results obtained, depending on patients' laboratory data only to predict the failure of liver transplant is not enough, so further research is recommended to add a larger sample size of patients including age, gender, body mass, and the cause of liver failure to increase the accuracy of the system and obtain high credible results. The study can also be applied to study failure in transplanting other organs and expand research to all hospitals and centers within Saudi Arabia.

Synthesizing Realistic Knee MRI Images: A VAE-GAN Approach for Enhanced Medical Data Augmentation

Revathi S A[1], B Sathish Babu[2]
Dept. of Computer Science, RV College of Engineering, Bangalore, India[1]
Dept. of AI&ML, RV College of Engineering, Bangalore, India[2]

***Abstract*—This study presents a novel approach for synthesizing knee MRI images by combining Variational Autoencoders (VAEs) and Generative Adversarial Networks (GANs). By leveraging the strengths of VAEs for efficient latent space representation and GANs for their advanced image generation capabilities, we introduce a VAE-GAN hybrid model tailored specifically for medical imaging applications. This technique not only improves the realism of synthesized knee MRI images but also enriches training datasets, ultimately improving the outcome of machine learning models. We demonstrate significant improvements in synthetic image quality through a carefully designed architecture, which includes custom loss functions that strike a balance between reconstruction accuracy and generative quality. These improvements are validated using quantitative metrics, achieving a Mean Squared Error (MSE) of 0.0914 and a Fréchet Inception Distance (FID) of 1.4873. This work lays the groundwork for novel research guidelines in biomedical image study, providing a scalable solution to overcome dataset limitations while maintaining privacy standards, and pavement of reliable diagnostic tools.**

Keywords*—Custom loss function; decoder; discriminator; GAN; latent space; VAE

I. Introduction

Deep learning has renovated medical imaging, improving diagnostic accuracy, treatment preparation, and patient monitoring. Despite its potential, the field faces significant challenges, particularly in musculoskeletal imaging, where limited access to diverse, high-quality datasets impedes progress. This is exacerbated by privacy concerns and the cost-intensive nature of data collection and annotation. To address these barriers, this study proposes a novel VAE-GAN framework for synthesizing realistic and diverse knee MRI images. By integrating the latent space representation capabilities of Variational Autoencoders (VAEs) with the generative strength of Generative Adversarial Networks (GANs), the proposed method aims to overcome the shortcomings of existing augmentation techniques while maintaining clinical relevance.

The VAE-GAN framework balances the diversity of VAEs with the sharpness and realism provided by GANs. Specifically, the VAE's latent space ensures continuity, making it suitable for generating diverse samples, while the GAN component enhances image fidelity, addressing the critical need for high-quality training datasets in medical imaging. This synergy enables the generation of realistic knee MRI images that reflect the variations needed for machine learning model training.

However, existing generative methods present restrictions that make them less suitable for this task:

1) Standalone GANs are prone to mode collapse, which restricts the variety of generated images and reduces their applicability in representing diverse medical conditions.

2) VAEs often produce blurry outputs due to their reliance on reconstruction loss functions, which prioritize structural accuracy over fine details.

3) Other generative models, such as Diffusion Models, require significantly more computational resources, making them unrealistic for medical imaging applications with restricted data.

By addressing these limitations, the proposed VAE-GAN framework emerges as an effective solution to the problem of data scarcity in knee MRI imaging, paving the way for better augmentation techniques that enhance the performance of diagnostic tools.

The limited availability of high-quality, diverse, and privacy-compliant medical imaging datasets significantly hampers the progress of robust and generalizable deep learning techniques for diagnostic applications. Existing methods for data augmentation and synthesis often fail to achieve the required balance of realism, diversity, and fidelity, limiting their effectiveness in medical imaging contexts.

The research explores how a hybrid generative model can effectively synthesize realistic and diverse knee MRI images to address the problem of data scarcity in medical imaging. It investigates the optimal architectural and loss function designs needed to stabilize image quality with reconstruction accuracy in the synthesized data. Furthermore, the study examines how the proposed VAE-GAN framework compares to existing generative methods in terms of quality metrics and clinical applicability.

The objectives of this research are to implement a VAE-GAN-based framework capable of producing realistic and diverse knee MRI images and to design a custom loss function that integrates reconstruction loss, KL divergence, and adversarial loss to achieve high-fidelity image generation. Additionally, the study aims to validate the model's performance

using quantitative metrics such as Mean Squared Error (MSE) and Fréchet Inception Distance (FID), as well as through qualitative assessments of the synthetic images' visual quality.

Magnetic Resonance Imaging (MRI), a critical tool for assessing musculoskeletal disorders, especially knee-related conditions, is a domain where deep learning can substantially enhance diagnostic accuracy and patient outcomes. However, the accomplishment of deep learning techniques in biomedical imaging is heavily dependent on the accessibility and image resolution of the datasets used. High-quality medical image data is often scarce and challenging to obtain due to patient privacy concerns. Furthermore, the processes of data collection and annotation are both costly and time-consuming, frequently resulting in datasets that lack the necessary diversity and volume to train robust and generalizable machine learning models. In knee MRI data, specific challenges include variations in pathology presentation and imaging protocols, complicating the training process further [1].

To address these challenges, the proposed VAE-GAN (Variational Autoencoder-Generative Adversarial Network) framework combines the robust data encoding capabilities of VAEs with the powerful image generation capabilities of GANs. VAEs excel at compressing data into a latent space, enabling the generation of new data instances, but sometimes produce outputs that lack the sharpness and detail characteristic of high-quality MRI scans [2]. Conversely, GANs generate sharp, high-definition images through adversarial training but face challenges such as training instability and mode collapse—a condition where the variety of produced images is insufficient [3]. By integrating these models, the VAE-GAN framework achieves a balance between realistic detail and diversity in synthetic knee MRI images.

The introduction should also include a section listing the reasons for choosing the proposed VAE-GAN method, detailing why it is particularly appropriate for addressing the challenges outlined in the study. Additionally, it would be advantageous to point out which limitations of existing methods make them less suitable for this problem. Including such a rationale would provide greater clarity on the motivations behind the selected approach.

This paper explores the architecture and functionality of the VAE-GAN model, focusing on its application for synthesizing knee MRI images. A detailed examination of the encoder, decoder/generator, and discriminator is provided, along with the custom loss function that optimizes image reconstruction accuracy and resolution. Experimental results validate the model's effectiveness in creating authentic and diverse synthetic knee MRI images, demonstrating its potential to enrich medical imaging datasets and enhance the performance of machine learning models used in medical diagnostics.

Additionally, this study carefully addresses the ethical concerns associated with deploying generative methods for data augmentation in healthcare. The input images used for model training were thoroughly anonymized, and all procedures adhered strictly to ethical standards, ensuring patient confidentiality at every stage.

A. Paper Structure

The remainder of the paper is organized as follows: Section II reviews related work in biomedical imaging and generative modeling. Section III presents the methodology, including the proposed VAE-GAN architecture and training procedures. Section IV discusses the experimental setup, results, and evaluation. Section V highlights limitations, ethical considerations, and future work. Finally, Section VI concludes the study and summarizes its contributions to the field.

II. Literature Review

Bio Medical imaging plays a crucial part in current healthcare by facilitating the diagnosis and management of various health conditions. However, challenges such as limited data availability and concerns over patient privacy hinder the development of robust machine-learning techniques for image analysis. Variational Autoencoders (VAEs) and Generative Adversarial Networks (GANs) have emerged as powerful generative models, offering solutions to these challenges. This section explores the implementation of VAE-GAN models in medical imaging, highlighting their methods, effectiveness, and potential drawbacks.

VAEs and GANs are distinct but complementary approaches in generative modelling. VAEs consist of an encoder-decoder structure, where the encoder compresses medical images into a latent space, retaining essential features. The decoder reconstructs the image from this compressed representation, with a tailored loss function ensuring that the output closely matches the original and that the latent space accurately reflects key medical attributes [13]. Conversely, GANs use a generator-discriminator framework. The generator generates images that captures those in the training set, whereas the discriminator evaluates their authenticity. This adversarial interaction drives the generator to create realistic images [3].

The synergy of VAE-GAN techniques lies in their capability to combine VAE's efficient latent space encoding with GAN's image refinement capabilities. The VAE encodes medical images into a meaningful latent space, and the GAN uses this encoding to generate realistic images, preserving essential characteristics while enhancing overall quality. VAE-GAN models have shown remarkable versatility, particularly in data augmentation. They can produce synthetic images that are almost indistinguishable from real ones, expanding the range of training datasets and improving machine learning models' performance in tasks namely image segmentation and classification. These models also excel in denoising, removing extraneous noise while preserving critical structures, making them perfect for applications like tumor detection and disease progression monitoring [3]. Additionally, VAE-GANs can generate disease-specific images, offering valuable resources for medical training and refining diagnostic systems.

Despite their potential, VAE-GAN models have some drawbacks. Their complex architecture requires substantial computational resources and careful hyperparameter tuning for optimal performance. One common issue is mode collapse, where the variety of generated images diminishes, limiting the model's applicability across diverse medical scenarios [3]. The latent space's interpretability in VAEs remains a challenge,

potentially obscuring insights into how model decisions are made [4]. Additionally, biases in training datasets can propagate through VAE-GAN models, leading to biased outputs and skewed diagnostic results [5]. While VAE-GAN models represent significant developments in medical image processing, addressing these limitations is critical for their ethical and practical application in healthcare settings.

Recent advancements in generative models, particularly GANs and Diffusion Models (DMs), have expanded the scope of medical image synthesis. GANs have demonstrated proficiency in creating realistic images, but they face tests such as training unpredictability and mode breakdown [6, 7]. Conversely, VAEs produce a larger variety of outputs and are fewer prone to mode collapse, though the images they generate sometimes lack sharpness due to smoothing tendencies in their loss functions [8]. Diffusion Models (DMs) offer a promising solution by producing original and diverse outputs, though their adoption in clinical settings is hindered by high computational demands and extended processing times [9, 10]. This review explores the evolving landscape of these technologies, aiming to balance quality, speed, and diversity in medical image synthesis [11].

GANs have become essential in advancing realistic image synthesis, particularly for enhancing medical imaging datasets. While GANs are adept at producing images that thoroughly resemble actual medical data, they can still suffer from mode collapse, leading to a limited variety of generated images. To address this, more advanced versions of GANs, such as Wasserstein GAN (WGAN) [12] and Conditional GAN (CGAN) [13], have been developed, significantly improving image quality and offering greater control over image generation. Deep generative models are revolutionizing biomedical imaging by improving diagnostic and treatment processes. VAEs are praised for their straightforward training and ability to capture complex data distributions. This ability makes them irreplaceable in medical imaging, where a rich representation of data is crucial. However, the occasional blurriness of VAE-generated images has led to the advancement of hybrid models like VAE-GANs, which combine the encoding power of VAEs with the image refinement abilities of GANs, resulting in clearer and more diverse outputs [18].

Diffusion Models (DMs) represent a breakthrough in generative modelling, excelling in capturing detailed, high-dimensional data distributions typically found in medical images. Their ability to replicate intricate features suggests they may outperform VAEs and GANs in relationships with realism and quality [19]. However, the high computational demands and lengthy processing times required by DMs limit their practicality, especially in real-time applications. Innovations such as Progressive Distillation [20] and the Fast Diffusion Probabilistic Model (FastDPM) [21] aim to optimize the sampling process while maintaining high-quality outputs. The Denoising Diffusion Implicit Model (DDIM) [22] balances speed with output fidelity, underscoring the importance of refining generative models.

This review categorizes deep generative models into three main types: GANs, VAEs, and DMs. GANs have made a significant impact on medical image augmentation, with iterations such as Wasserstein GAN (WGAN) [14] and Deep Convolutional GAN (DCGAN) [16] proving essential in generating realistic 2D MRI sequences. Studies by Han et al. [23] validate WGAN's superior performance in producing images that are indistinguishable from original medical scans. Likewise, Progressive Growing of GANs (PGGAN) [17], when merged with traditional data augmentation methods, has directed to improved classification algorithm performance. Conditional GANs [15] have been especially effective in generating targeted, realistic synthetic images, as demonstrated by Frid-Adar et al. [24] and Guibas et al. [25].

VAEs also show a critical role in diversifying medical imaging datasets. Research by Zhuang et al. [26] highlights Conditional VAEs (CVAEs) and Conditional WGANs' capability to produce high-quality brain images, enhancing classification model accuracy. The outline of Independently Conditional VAE (ICVAE) by Pesteie et al. [28] marks a noteworthy development in VAE technology, improving classification and segmentation tasks through increased diversity. Recent studies recognize the probability of Diffusion Models in generating high-resolution 3D MRI images. Research by Pinaya et al. [27] emphasizes DMs' superiority in producing authentic MRI samples. Moreover, the brain SPADE model introduced by Fernandez et al. [29] integrates DMs with VAE-GANs to create labeled MRI images, crucial for training segmentation models. Furthermore, explorations by Lyu and Wang [30] into DMs' image translation capabilities show that they can convert MRI to CT scans with greater accuracy than outdated methods, demonstrating the significant impact of these models on medical imaging.

In conclusion, deep generative methods, namely GANs, VAEs, and DMs, are transforming medical imaging. These methods are pivotal in tackling issues like data scarcity and augmenting datasets for improved diagnostic accuracy. Their ability to synthesize high-quality images, translate between imaging modalities, and enhance training datasets underscores their potential to advance diagnostic practices and medical research. Future developments promise to further expand their efficacy, making them invaluable tools in healthcare.

III. METHODOLOGY

The methodology deployed for constructing and training a VAE-GAN model for synthesizing knee MRI images is composed of several intricate stages, from initial data preprocessing to the sophisticated dynamics of model training. This model capitalizes on the compressive data encoding capabilities of Variational Autoencoders (VAEs) and the image generation prowess of Generative Adversarial Networks (GANs). Herein, we elucidate the encoder's latent space utilization for image synthesis, the beta hyperparameter's role in the VAE loss function, the chosen architecture's pertinence to knee MRI imaging, the enhanced model diagrams for augmented clarity, and the tailoring of the custom loss function to medical imaging.

The VAE-GAN framework was selected because it combines the strengths of two advanced generative models. VAEs excel at compressing data into a continuous latent space, ensuring diversity in synthesized outputs, while GANs are well-known for generating sharp and realistic images through

adversarial training. By integrating these models, the VAE-GAN framework addresses limitations of standalone methods:

1) VAEs sometimes produce blurry outputs due to their reconstruction-focused loss functions.

2) GANs are prone to training instability and mode collapse, reducing output diversity.

This hybrid approach effectively balances the sharpness and realism of GAN-generated images with the structural fidelity and diversity provided by VAEs, making it particularly suitable for the complex requirements of knee MRI image synthesis. Fig. 1 shows model architecture flowchart.

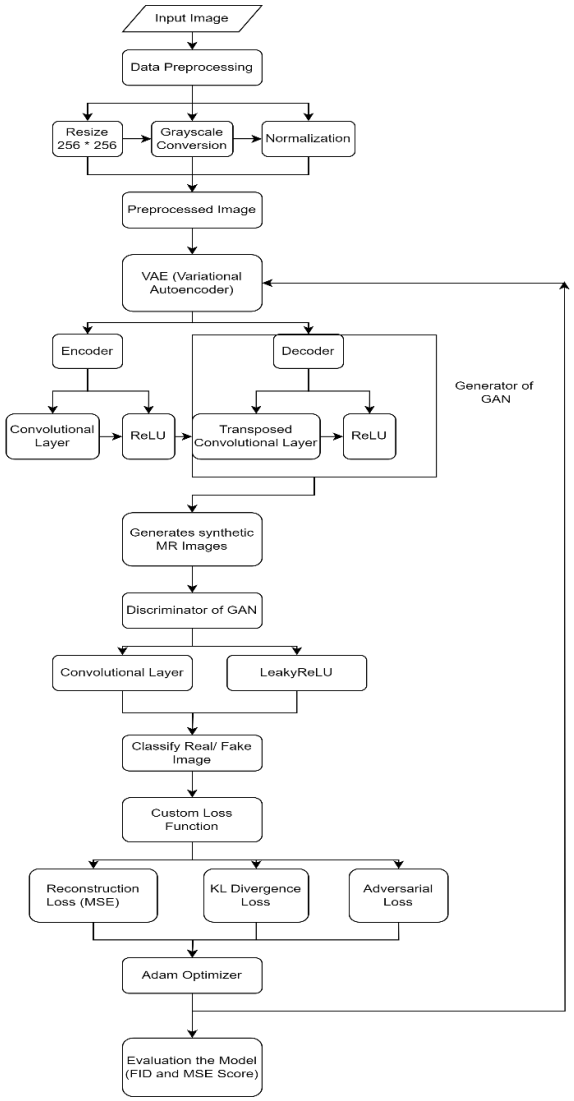

Fig. 1. Detailed model architecture flowchart.

A. Data Collection and Sample Selection

The dataset used in this training was sourced from the Osteoarthritis Initiative (OAI), an openly accessible repository of knee MRI data. The images were selected based on the following criteria:

1) Availability of high-resolution knee MRIs.

2) Representation of four severity levels of osteoarthritis: normal, mild, moderate, and severe.

3) Ensuring diversity across patient demographics, imaging protocols, and pathology presentations.

From the OAI dataset, 150 knee MRI images were selected, including: 10 normal images, 50 mild images, 65 moderate images, 34 severe images.

Efforts were made to ensure that the dataset represented a wide spectrum of knee osteoarthritis conditions, thus enhancing the generalizability of the model.

B. Data Preprocessing

1) Initial data input: The dataset consists of 150 knee MRI images, each resized to 256x256 pixels. These images correspond to four distinct severity levels of knee osteoarthritis (OA): normal, mild, moderate, and severe. This provides an adequate range for capturing pathological variations across OA stages.

a) Grayscale conversion: Knee MRIs were initially in color, but for this task, the images were converted into grayscale to simplify the data. Grayscale imaging emphasizes intensity values, which are critical in medical imaging to capture structural details. This conversion reduces the number of channels from 3 to 1, making computations more efficient without losing the essential information.

b) Normalization: Min-max normalization was applied to scale pixel values to a [0, 1] range. This normalization aids in stabilizing numerical computation during model training by ensuring consistent data scales, which speeds up convergence and reduces training instability.

c) Resizing images: Each image was resized to a fixed 256x256 resolution using bicubic interpolation. This method preserves image quality while ensuring uniformity in input data dimensions, which is necessary for training convolutional neural networks (CNNs) and other deep models (see Fig. 2).

Fig. 2. Input MRI images of knee OA.

C. Encoder and Decoder Model

After these steps, the data is cleaned, standardized, and ready for input into the VAE-GAN model, providing an optimal starting point for further processing and generation.

1) Variational Autoencoder (VAE): The encoder compresses the input MRI images into a latent space representation. It comprises of a sequence of convolutional layers followed by ReLU activations. Key architectural choices include:

a) Convolutional layers: Four convolutional layers are used, with increasing filter sizes (32, 64, 128, and 256) at each layer, designed to progressively capture image features from basic edges to complex patterns.

b) Filter size: The kernel sizes used were 3x3 for the initial layers, transitioning to 2x2 in deeper layers to down sample spatial dimensions efficiently.

c) ReLU activation: Applied after each convolutional layer to introduce non-linearity, enabling the model to learn more complex representations.

d) Batch normalization: Introduced after each convolutional block to stabilize and accelerate training, preventing vanishing/exploding gradient problems.

e) Latent space representation: The final dense layer of the encoder outputs two variables, mean (μ) and variance (σ^2), representing the latent distribution. The dimensionality of the latent space was set to 128 dimensions, balancing between representational capacity and computational efficiency.

2) VAE Decoder / GAN Generator: The decoder (also serving as the GAN generator) reconstructs images from the latent space representation:

a) Transposed convolutional layers: Four layers of transposed convolutions are applied to up sample the image back to its original size (256x256). This "unpooling" mechanism helps restore the resolution lost during encoding.

b) Activation functions: ReLU activation is applied throughout, except in the final layer, where a sigmoid activation is used to ensure pixel values remain between [0,1].

c) Batch normalization: Continues to be applied in the decoder to avoid overfitting and stabilize the gradient flow.

3) Generative Adversarial Network (GAN) discriminator: The discriminator serves to distinguish between actual and synthetic MRI images. It follows a convolutional neural network (CNN) architecture:

a) Convolutional layers: Five convolutional layers, each using LeakyReLU activation, which allows a small gradient flow when inputs are negative, addressing the vanishing gradient problem typical in GAN training.

b) Dropout: A dropout layer is introduced with a rate of 0.3 to prevent overfitting, particularly crucial when training with relatively small medical datasets.

c) Sigmoid activation: The output layer uses sigmoid activation for binary classification (real vs. synthetic).

D. Custom Loss Function

The loss function used in the VAE-GAN integrates three essential components:

1) Reconstruction loss: This is the mean squared error (MSE) between the actual and reconstructed images. It guarantees that the VAE's decoder produces images that closely match the input MRI scans.

2) KL Divergence loss: This term penalizes the deviation between the latent distribution q(z|x) and the prior distribution p(z), ensuring that the latent space aligns with a standard normal distribution.

3) Adversarial loss: Derived from the GAN framework, this loss encourages the generator to produce realistic images that can "fool" the discriminator. It is calculated as −log(D(G(z))), where G(z) is the produced image and DDD is the discriminator output.

The custom loss function is a pivotal component of the VAE-GAN model, integrating the following elements to enhance performance:

$$\text{Reconstruction Loss: } L_{recon} = \|x - \hat{x}\|^2 \quad (1)$$

$$\text{KL Divergence Loss: } L_{KL} = D_{KL}(q(z|x) \,||\, p(z)) \quad (2)$$

$$\text{Adversarial Loss: } L_{adv} = -log(D(G(z))) \quad (3)$$

The total loss function is a weighted sum of these components:

$$L_{VAE-GAN} = L_{recon} + \beta L_{KL} + L_{adv} \quad (4)$$

where β is a tunable hyperparameter that balances the weight of the KL divergence term, set to 0.1 in this study. This formulation ensures a balance between reconstruction accuracy and the generation of diverse, high-quality images.

L_{recon} includes a weighted sum of MSE and SSIM, reflecting pixel-wise accuracy and structural fidelity.

The formula ensures that the VAE-GAN model generates images with high fidelity and maintains a balance between the accuracy of the reconstructions and the diversity of the produced images. This comprehensive explanation provides a clearer insight into how each part of the model contributes to its overall effectiveness, precisely designed to expand the diagnostic value of knee MRI images.

E. Training Procedure

1) Optimizer: Adam optimizer was used together for the generator and discriminator, chosen for its adaptive learning rate capabilities, which is critical for stabilizing the GAN training process. The learning rate was set at 0.0002, and the β1\beta_1β1 hyperparameter was set to 0.5 to ensure a smooth training trajectory.

2) Batch Size: A batch size of 32 was used, optimized for the size of the dataset and the available computational resources.

3) Epochs: Training was conducted for four full epochs due to the size of the dataset. Future work may focus on increasing

the dataset size and extending the number of epochs to improve model generalization.

F. Training Procedure

Training involved alternating updates between the VAE and GAN components. The discriminator is updated using both real and synthetic images, while the encoder-decoder (VAE) attempts to minimize reconstruction loss and "fool" the discriminator:

1) Dual-update mechanism: For each batch, the discriminator is updated to differentiate real from fake images, followed by updates to the encoder-decoder to generate realistic images.

2) Callbacks: Early stopping and learning rate reduction on plateau were employed to optimize the training method and prevent overfitting.

IV. Results

This study evaluated the efficacy of a Variational Autoencoder-Generative Adversarial Network (VAE-GAN) in generating synthetic knee MRI images, focusing on varying stages of osteoarthritis, ranging from normal to severe. The primary objective was to evaluate the VAE-GAN's ability to generate realistic synthetic images suitable for training machine learning models while addressing the limitations posed by insufficient medical imaging datasets.

Validation measures are essential in demonstrating the efficacy of the developed model. Metrics like Mean Squared Error (MSE) and Fréchet Inception Distance (FID) provide quantitative evidence of the model's performance. These metrics quantitatively evaluate the quality of the synthetic images in terms of fidelity and diversity, benchmark the model's performance against established standards, and identify specific strengths and weaknesses of the approach, allowing for targeted improvements. For instance, in medical imaging, a low FID score not only indicates perceptual similarity but also highlights the applicability of the generated images for diagnostic purposes. Including other domain-specific metrics, such as Structural Similarity Index (SSIM), or expert evaluations can further validate the clinical relevance of the work.

The model achieved an MSE score of 0.0914, reflecting a high degree of pixel-wise accuracy between the synthetic and ground-truth MRI images. However, while MSE captures the overall pixel similarity, it does not necessarily reflect perceptual realism, which is crucial for medical applications. This is where the FID score of 1.4873 becomes relevant, indicating that although the images are visually similar to real knee MRIs, further improvement is necessary, particularly in rendering finer anatomical details and reducing any artifacts that may compromise diagnostic quality.

A. Comparison to Existing Methods

The achieved FID score demonstrates significant promise when compared to existing generative techniques for medical imaging. Previous studies using standalone GANs for medical image generation have reported FID scores ranging between 5 and 10, underscoring the superiority of the hybrid VAE-GAN approach applied in this study. This improved performance likely stems from the combined strengths of VAEs, which effectively capture the latent structure of complex medical data, and GANs, which enhance the sharpness and overall quality of the produced images.

By highlighting the restrictions of existing methods, such as mode collapse in GANs or the blurry outputs from VAEs, this study positions the VAE-GAN framework as a balanced solution that addresses these challenges while improving perceptual realism and diversity. Furthermore, the proposed approach demonstrates computational efficiency compared to Diffusion Models, which require significantly higher resources.

B. Impact of Dataset Size

The size and diversity of the training dataset critically influence the performance of generative methods. In this study, the VAE-GAN was trained on a relatively small dataset consisting of 150 knee MRI images, which may have limited the model's ability to generalize effectively across the full spectrum of osteoarthritis conditions. Additionally, batch size constraints resulted in the final epoch processing only 22 images, further reducing the data exposure during training. Expanding the dataset size and increasing image diversity are anticipated to significantly lower the FID score, improving both the quality and variability of the produced images.

C. Visual Quality of Synthetic Images

In count to the quantitative metrics, a qualitative assessment of the synthetic knee MRI images offers further validation of the model's effectiveness. The model demonstrated its ability to accurately replicate the structural details of the knee in the coronal plane, particularly capturing the cartilage and bone structures across different stages of osteoarthritis. However, certain generated images lacked the fine-grained textural details commonly observed in real MRIs, especially in severe cases of osteoarthritis. This suggests that while the model is effective, further architectural refinements are necessary to progress the anatomical accuracy and clinical utility of the synthetic images.

D. Interpretation of Results in Medical Imaging Context

In medical imaging, particularly for knee osteoarthritis, the outcome validates the VAE-GAN's potential for data augmentation, which is critical for training more robust and precise machine learning methods. The generated images can be used to report the scarcity of medical imaging data, which often hinders the progress of effective diagnostic tools. However, while the results show promise, additional improvements in capturing fine anatomical details are required for the model to be clinically viable. Ensuring the fidelity of essential structures, such as the meniscus and cartilage, is crucial for using this model in diagnostic settings.

E. Limitations and Next Steps

The relatively high FID score highlights areas for further refinement, particularly in relation to the small dataset size used for training. Future work will focus on increasing the dataset size and incorporating advanced post-processing techniques to further reduce the FID score and enhance the visual quality of the synthetic images. Additionally, incorporating domain-specific metrics namely the Structural Similarity Index (SSIM) and seeking expert evaluations from radiologists will provide a

more comprehensive assessment of the model's clinical applicability and guarantee that the produced images meet the standards necessary for real-world medical diagnostics.

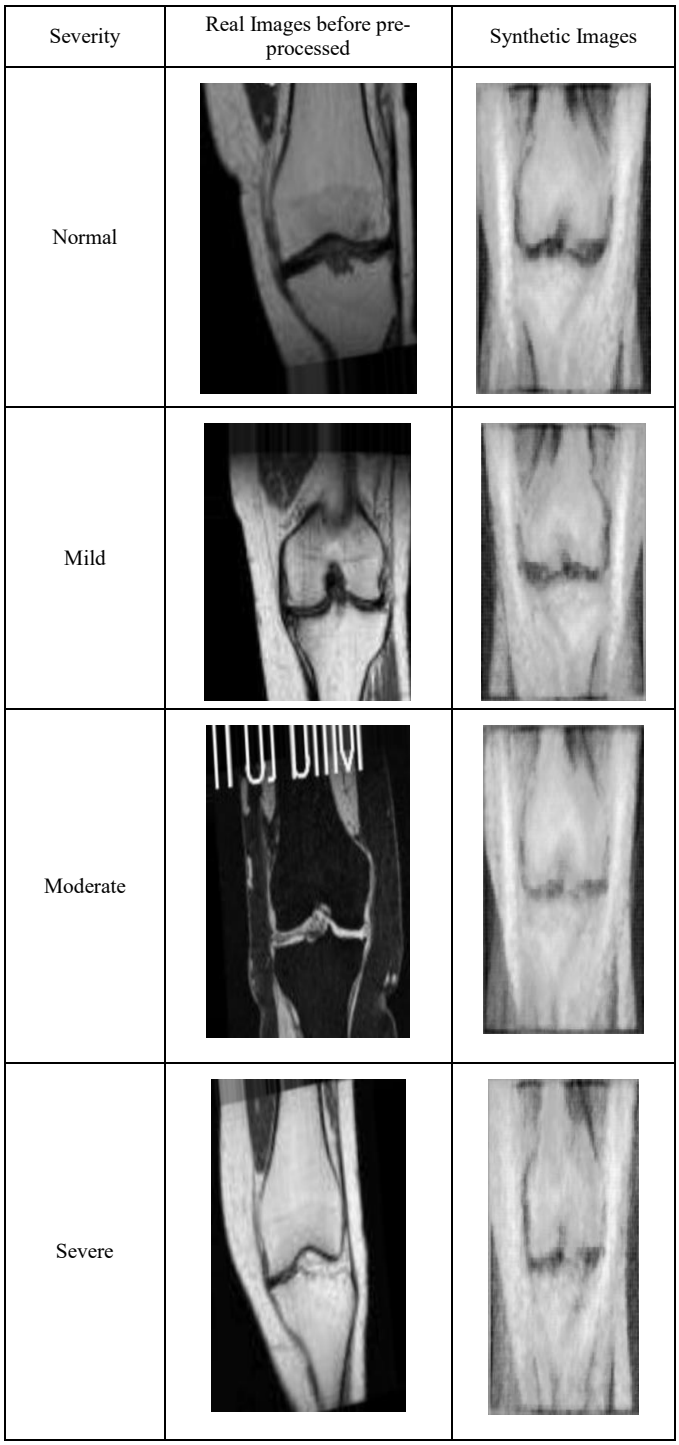

Fig. 3. Illustrates the examples of the synthetic knee OA images produced by the VAE-GAN Model, highlighting its capacity to replicate a wide spectrum of knee OA severities.

The performance of the VAE-GAN model was analysed across different severity levels of osteoarthritis to understand its effectiveness in synthesizing knee MRI images (see Fig. 3). For normal cases, the model achieved an MSE of 0.087 and an FID of 1.401, indicating high accuracy and perceptual realism for structurally simple images. As the severity increased to mild cases, the MSE slightly rose to 0.092, with a corresponding FID of 1.452, reflecting the model's ability to maintain realism despite the added complexity of pathological features. In moderate cases, the MSE increased further to 0.096, and the FID reached 1.523, indicating a gradual decline in performance as the structural complexity of the images grew. For severe cases, where the variations in cartilage and bone structure were most pronounced, the MSE reached 0.101, and the FID increased to 1.573, suggesting that the model performs best on less severe cases with simpler anatomical structures but struggles with fine-grained details in advanced osteoarthritis stages. Emphasizing the significance of validation measures, such as MSE and FID, and conducting thorough comparisons with existing related work is paramount to positioning this study within the broader context of medical image synthesis research, ensuring a comprehensive assessment of the model's effectiveness and limitations.

V. Conclusion

The VAE-GAN model exhibited strong potential in generating synthetic knee MRI images, with initial results showing promising visual accuracy, as reflected by the Mean Squared Error (MSE) metric. However, further refinement is required to improve the model's capability to capture complicated anatomical details. One concern identified during evaluation was the relatively high Fréchet Inception Distance (FID) score, indicating potential problems connected to preprocessing, feature extraction, or calculation errors. This underscores the significance of thorough validation and optimization of generative methods in medical imaging applications.

This research contributes to the expanding field of generative modelling for medical imaging, demonstrating the potential of VAE-GANs for data augmentation and the advancement of automated diagnostic tools. Our methodical approach—from data preprocessing to model training and evaluation—leverages the combined strengths of VAEs and GANs, enhancing medical image analysis and fostering innovations in diagnostic technologies. Additionally, this study emphasizes the critical role of dataset size in training efficiency, highlighting the need for higher and more scalable datasets to achieve optimal results.

Future work will focus on addressing the limitations associated with the elevated FID score, refining the model architecture, and incorporating qualitative assessments from medical professionals to ensure the clinical relevance of the generated images. Overcoming these challenges will further improve the effectiveness and reliability of generative methods, making them a valued asset for diagnostic practices and medical research.

***Abstract*—Efficient robot navigation in operational environments requires precise tracking of the path from the starting point to the destination, typically generated using pre-stored map data. However, obstacles in the environment can complicate this process, making reliable obstacle avoidance critical for successful navigation. This paper introduces innovative techniques for robotic navigation and obstacle avoidance, specifically designed to assist visually impaired individuals. To mitigate the limitations and inaccuracies inherent in sensor data, we employ sensor fusion algorithms that integrate inputs from infrared, ultrasonic, vision, and tactile sensors. Additionally, visual landmarks are incorporated as reference points to improve internal odometry correction and enhance mapping accuracy. We believe that our approach not only increases the reliability of navigation but also enhances the robot's ability to operate effectively in diverse and challenging conditions.**

***Keywords*—Robot; obstacle; avoidance; visually impaired; sensors**

I. Introduction

Certain types of robots, such as tracking and follower robots, can operate effectively without relying on maps. However, map-based mobile robots, which utilize pre-existing environmental data, are often employed for more complex tasks. The primary purpose of mapping is to store and generate path-related data, which can then be used with various planning techniques to facilitate navigation between specific locations. This integration is essential for mobile robot localization and path-learning algorithms [1].

Mobile robots typically use two types of maps: topological and geometric. Topological maps require minimal memory and computational complexity, relying more on map data than sensor data for path generation. These maps are computationally efficient and support the use of search algorithms. This paper uses a topological map to evaluate the role of mapping in robot navigation. However, map-based paths can be affected by environmental obstacles, making it necessary to establish a fundamental path between two nodes rather than relying solely on an exact route. Detecting and avoiding obstacles during navigation is essential, and the avoidance path is sensor-based. As a result, a well-designed robot navigation system combines both map-based and sensor-based approaches [1] [2] [3].

Various sensors are used in mobile robot navigation to measure specific environmental variables such as range, object dimensions, and landmarks. This paper discusses the operation, features, errors, and limitations of commonly used navigation sensors while introducing modern techniques for accurately measuring navigation variables to improve system performance. Additionally, the interface between blind users and the guidance system is a crucial consideration, as traditional communication methods, such as displays and buttons, are not feasible for visually impaired individuals. Voice interaction is proposed as the most effective communication protocol. To facilitate this, a phonetic integrated circuit approach is implemented for the human-robot interface [3].

II. Related Work

Efficient robot navigation, especially for assisting visually impaired individuals, has been a focal point of research in recent years. A significant aspect of this research involves sensor fusion, which improves the accuracy and reliability of robot navigation by combining data from various sensor types.

Sensor fusion algorithms have been widely used to improve robot localization and obstacle avoidance by integrating data from multiple sensors such as ultrasonic, infrared, vision, and tactile sensors. Doherty and McGinnity [4] present various sensor fusion techniques that enhance mobile robot navigation and control, demonstrating that combining data from different sources can improve system performance, particularly in dynamic environments. Bansal and Thakur [5] discuss robust sensor fusion algorithms that improve localization accuracy in mobile robots, focusing on dynamic sensor data handling in real-time situations. These techniques are highly relevant to overcoming the limitations of individual sensors in environments with unpredictable obstacles.

Effective obstacle avoidance is crucial for autonomous navigation in complex environments. Cai and Liu [6] explore various obstacle avoidance strategies, emphasizing real-time decision-making to dynamically adjust the robot's path. Zhang and Wang [7] present a dynamic obstacle avoidance system for autonomous robots using sensor fusion, where obstacles are detected, and the robot adjusts its trajectory accordingly. These studies provide insights into how obstacle detection and avoidance can be integrated with a robot's navigational strategies to ensure safe and efficient movement, especially in environments with moving or unexpected obstacles.

Robotic assistance for visually impaired individuals has gained increasing attention in recent years, focusing on the development of navigation systems that offer greater autonomy and independence. Chien and Lin [8] provide an overview of assistive robotics technologies designed for the blind, detailing

the challenges and solutions associated with robot navigation in dynamic and unfamiliar environments. Vig and Zupan [9] review mobile robotic systems for the visually impaired, examining various navigation aids such as ultrasonic sensors and voice feedback systems, highlighting their potential to significantly improve the mobility of individuals with visual disabilities. These studies emphasize the importance of developing reliable and user-friendly assistive systems that can help visually impaired individuals navigate their surroundings more independently.

In systems designed to aid the visually impaired, voice interaction becomes a critical interface for communication between the user and the robot. Meyer and Sharma [10] explore the development of speech-based interfaces for mobile robots, which provide intuitive and hands-free communication. They highlight the challenges of designing robust voice recognition systems that can operate in various acoustic environments. Singh and Gupta [11] further expand on speech recognition for assistive robotics, focusing on the development and challenges of integrating speech recognition systems to create effective real-time communication between users and robots. This work underscores the necessity of voice-based interfaces for creating an intuitive and inclusive user experience for blind individuals.

Effective mapping strategies, particularly the use of topological and geometric maps, are central to the navigation and localization of mobile robots. Renaud and Dufour [12] compare topological and geometric maps, discussing their respective advantages and limitations in robot navigation. Topological maps, which are often simpler and more memory-efficient, are well-suited for mobile robot navigation, especially in dynamic environments. Ali and Shah [13] review path planning algorithms and mapping techniques for autonomous robots, with a focus on their application in real-world navigation tasks. The combination of map-based and sensor-based navigation methods, as proposed in this paper, reflects the growing interest in integrating both mapping strategies to ensure reliable and efficient movement in complex environments.

III. Mobile Robot Navigation

A. Path Search

Path search procedures utilize map data to execute specific algorithms aimed at identifying the optimal path between nodes, with the map stored in the robot's memory. A sophisticated search algorithm, based on artificial intelligence techniques, was implemented to generate a path that combines a sequence of nodes and their interconnections. As shown in Fig. 1, node A represents the source, node D serves as the goal, and r1, r2, and r3 denote the topological relationships among the intermediate nodes [14].

To improve path efficiency, an optimal search algorithm can be applied. The choice of algorithm depends on the desired path characteristics and the capabilities of the implemented method. Accordingly, this robot integrates both sensor-based paths and direct map-based paths. The applied search algorithm focuses solely on determining the path between two nodes, with additional optimization performed to estimate the most efficient route. Furthermore, the selected path is refined using a microcontroller by implementing the "First Depth Search" algorithm. The topology underscores that the path consists of nodes and their interconnections, as illustrated in Fig. 1.

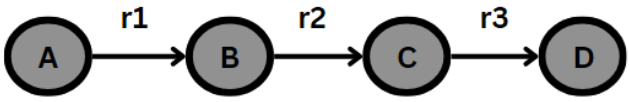

Fig. 1. Sample path between nodes in topological mapping.

B. Navigation Sensors

The robot integrates a variety of sensors to detect and measure environmental variables critical for navigation. Navigation sensors generally fall into two main categories: obstacle measurement sensors and landmark detection sensors. Theoretically, the same sensor can perform both functions depending on the variable being analyzed and the processing applied.

The most commonly used and effective sensors in mobile robots include infrared range sensors, laser range finders and scanners, ultrasonic sensors, vision sensors, GPS, and tactile sensors, among others [1].

In the robotic system proposed in this paper, tactile sensors are combined with infrared and ultrasonic sensors for obstacle detection, avoidance, and localization. Ultrasonic sensors, in particular, measure the distance between the robot and objects using two configurations. The first configuration employs triangulation, where distance is determined geometrically. In this method, the sensor emits ultrasonic waves and detects their reflections from the object at a specific angle (see Fig. 2). The distance is then calculated using reflection equations.

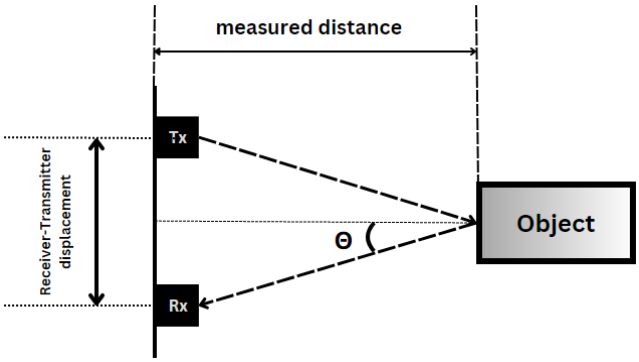

Fig. 2. Measuring distance via triangulation.

Θ: is the reflected angle.

The other implemented method is the measurement of time-of-flight. The echo of emitted ultrasound waves is detected to calculate the time between emitting the wave, Tx and receiving its echo, Rx, and then the range between the sensor and the object is calculated using Eq. (1), where: d is the measured distance, t is the time of flight, and T is the surrounding temperature.

$$d = (1 + x)^n = \frac{t}{2}[0.6T + 331.6] \quad (1)$$

A vision system is employed to identify various objects in the surrounding environment. By applying different image

processing techniques, the extracted features assist in robot navigation. The processor's capability and the interface's efficiency in processing image data with acceptable speed and accuracy are critical criteria [3] [15].

In this paper, an image-based assessment of robot positioning is utilized to avoid obstacles, while localization errors are corrected through internal odometry error correction using pattern recognition. Pattern recognition is applied to images containing specific landmarks, where a landmark is a label or an image featuring a number or text that represents a specific node on the map.

The vision system consists of a simple webcam, along with an image processing unit (IPU) based on a specific microprocessor, which is programmed in MATLAB using the Image Processing Toolbox and Real-Time Embedded Target Coder for the microprocessor. The IPU has two outputs: the object detection output, which is sent to the sensor fusion unit, and the landmark detection output, which is sent directly to the CPU.

IV. The Architecture of the Blind Guidance Robot

The primary objective of our proposed robotic system is to significantly improve the guidance process for individuals with visual disabilities, providing them with a safer and more independent means of navigation. As shown in Fig. 3, the robot features a modular design, allowing for easy customization and maintenance. The CPU module serves as the core management and synchronization unit, built with advanced microcontrollers that enable real-time processing and decision-making.

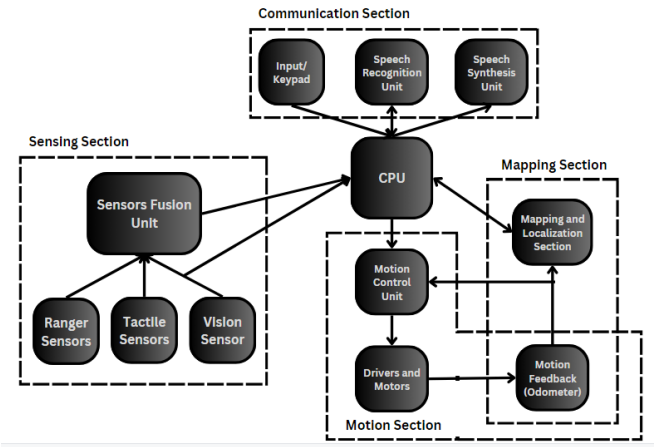

Fig. 3. System architecture of the blind guidance robot.

Detailed specifications of the topology and odometry unit are presented in Fig. 4, highlighting the system's ability to effectively map its environment and track its position. This robotic system is designed with an intelligent methodology, equipping it with learning capabilities that allow it to adapt to its surroundings. It employs various sensors to collect data, enabling a comprehensive understanding of the environment and ensuring safe navigation.

The robot's main function is to learn a map of its surroundings and navigate from one specific point to another with precision. By integrating obstacle detection and avoidance mechanisms, the robot can effectively navigate around obstacles, ensuring a smooth and reliable experience for users. Ultimately, this system aims to empower individuals with visual disabilities, fostering independence and confidence in their ability to navigate complex environments.

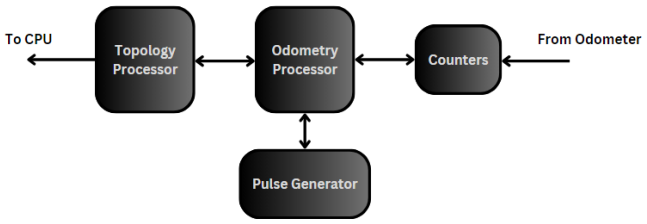

Fig. 4. Design of mapping and localization unit.

V. Design Implementation

A. Navigation Sensors

Generally, navigation sensors face a variety of drawbacks due to measurement errors and inherent limitations, which can significantly affect their performance in real-world applications. The resulting imprecision is both predictable and measurable, depending on the operational characteristics and design of each sensor. For example, ultrasonic range finders, as shown in Fig. 5, are known for their poor angular resolution. This limitation makes them ineffective at detecting oblique or smooth surfaces, posing considerable challenges in environments where such surfaces are common. Consequently, obstacles that do not reflect sound waves directly may go undetected, leading to potential navigation errors [16].

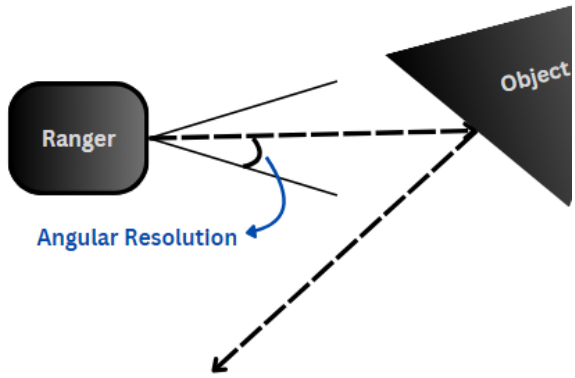

Fig. 5. Sound waves reflection on oblique surface.

In contrast, infrared range sensors have their own set of limitations. They are particularly susceptible to interference from bright light, which can lead to inaccurate readings. Furthermore, these sensors struggle with measuring distances to reflective surfaces, such as liquids and glass, resulting in additional complications during navigation. Their angular resolution is also suboptimal, meaning they may misjudge the proximity of objects, thus impairing the robot's ability to navigate effectively in complex environments [16].

Vision sensors, while capable of providing rich data about the surroundings, also face significant challenges. They typically offer lower precision in distance measurements compared to other sensor types and require substantial processing power to analyze visual input effectively. This high

computational demand can limit their real-time application in mobile robotics, as the robot may need to prioritize speed and responsiveness over detailed analysis.

These limitations highlight the need for careful sensor selection and the implementation of advanced algorithms to mitigate measurement errors and improve overall navigation reliability. In many cases, combining multiple sensor types can leverage their complementary strengths, leading to more accurate environmental perception. Additionally, ongoing research and development in sensor technology aim to address these challenges, enhancing the precision and adaptability of navigation systems across various applications.

All of these limitations are effectively addressed through the implementation of sensor fusion techniques, which involve using multiple sensors to measure the same environmental variable. For example, combining ultrasonic range finders with infrared sensors helps mitigate challenges related to detecting oblique surfaces and glass, which are often problematic for individual sensor types. By integrating the strengths of different sensors, the robot gains a more comprehensive understanding of its surroundings, thereby enhancing navigational accuracy and safety.

Traditionally, sensor data fusion is carried out using conventional computational methods. However, these approaches generally require high processing precision and can become computationally intensive, making them less suitable for real-time applications in mobile robotics. This challenge is particularly critical when rapid decision-making is essential for safe navigation in dynamic environments [2].

In this paper, we employ fuzzy logic computing techniques to facilitate rule-based data fusion, eliminating the need for a detailed analytical model of the sensors used. The input sensors' membership functions, as shown in Fig. 6, illustrate how various sensor readings are integrated and interpreted within the fuzzy logic framework. By using fuzzy logic, we can better manage the inherent uncertainties and imprecisions in sensor data, enabling more nuanced decision-making processes.

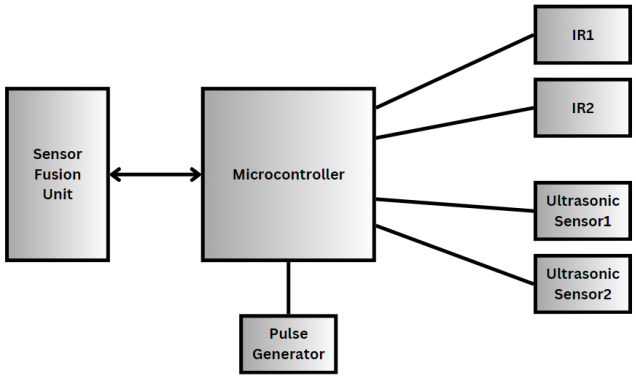

Fig. 6. Structural design of rangers control and conditioning unit.

The fuzzy computing sensor fusion unit is designed using a microprocessor, a powerful yet compact solution for processing sensor data. This unit continuously reads the outputs from all navigation sensors, processes the data in real time, and generates decisions regarding obstacle detection and avoidance. After analyzing the sensor inputs, the unit sends critical information to the CPU, which coordinates the robot's navigation strategies.

This innovative approach not only increases the reliability of navigation but also enhances the robot's ability to operate effectively in diverse and challenging conditions. The integration of fuzzy logic allows the system to adapt to varying levels of sensor reliability and environmental complexity, improving overall operational efficiency. By enabling the robot to make informed decisions quickly, we aim to create a more robust and reliable navigation system that ultimately enhances the user experience for individuals with visual disabilities. This methodology demonstrates the potential of advanced computational techniques to revolutionize mobile robotics, paving the way for smarter, more autonomous systems.

B. Map Learning

This paper proposes a lead-through programming method for robot map learning, in which a programmer manually guides the robot through various environments while the robot autonomously collects environmental data using its sensors, supplemented by user input. This interactive approach not only facilitates efficient data collection but also enhances the accuracy of the mapping process, ensuring that the robot can effectively understand and navigate its surroundings [14].

At its core, the topological map is constructed as a collection of relational paths, represented as straight lines. Each branch of the map consists of a straight-line path that maintains a specific angle relative to a defined frame of reference. Consequently, the robot's learning process focuses on accurately measuring the distance between two nodes and the angles that relate to this reference frame. This geometric representation is crucial for the robot's ability to navigate complex environments, as it provides a simplified yet effective way to understand spatial relationships.

As the learning process begins, the odometry unit actively measures and models all relevant map data, constructing the corresponding map branches in real time. This dynamic modeling ensures that the robot captures the nuances of its environment, including variations in terrain and the presence of obstacles. The data collected during this phase forms the foundation for building a reliable map that the robot can reference during subsequent navigation tasks.

Moreover, the programmer plays a critical role in the mapping process by entering the number of nodes at each landmark location. This input is essential for establishing key reference points within the topological framework, allowing the robot to create a network of interconnected paths. By defining these landmarks, the programmer enhances the robot's ability to identify and navigate to specific destinations within the environment, improving its overall usability.

At the conclusion of this comprehensive process, a well-defined topological map is successfully created, enabling the robot to navigate its environment with a heightened understanding and improved efficiency. The lead-through programming method not only streamlines the map-building process but also fosters an intuitive collaboration between the human programmer and the robotic system. This synergy results

in a robust navigation solution tailored to the specific needs of the environment being mapped.

Furthermore, this innovative approach has practical applications beyond traditional robotics, particularly in assisting individuals with visual disabilities. By empowering users to engage directly in the mapping process, we promote inclusivity and ensure that the robot can adapt to unique environments that are meaningful to its users. Ultimately, this lead-through programming methodology represents a significant advancement in robotic learning and navigation techniques, paving the way for smarter, more autonomous systems capable of operating effectively in a variety of real-world scenarios.

C. Motion Control Unit (MCU)

The drive motors of the robotic system are controlled by the microcontroller unit (MCU), which manages various aspects of motor performance, including speed, direction, reversing, and dynamic stopping. This comprehensive control is essential for achieving smooth motion and precise position control, enabling the robot to navigate its environment effectively.

When the CPU commands a specific straight path, along with its length and angle, the motion control unit calculates the required parameters for the motors. This involves determining the appropriate speed and timing for each motor to ensure that the robot follows the designated path accurately. The closed-loop control system continuously monitors the motors' performance in real time, making adjustments as necessary to maintain the intended trajectory.

This closed-loop feedback mechanism is crucial for handling dynamic conditions, such as changes in terrain or unexpected obstacles. By constantly comparing the robot's actual position and movement against the desired path, the MCU fine-tunes motor commands to ensure adherence to the planned trajectory. This capability not only enhances navigation accuracy but also contributes to the overall stability and reliability of the robotic system.

Additionally, the system allows for responsive maneuvering, enabling the robot to execute tasks such as reversing or performing dynamic stops without losing momentum or control. This level of sophistication in motor control is vital for applications requiring high precision, such as assisting individuals with visual disabilities, where the robot must navigate complex environments safely and effectively.

Overall, the integration of the MCU with the drive motors creates a robust and adaptive motion control system that supports the robot's ability to operate smoothly in a variety of settings, facilitating a more intuitive and effective navigation experience.

D. Human Robot Communication

Since our primary objective is to design a blind guidance robot, the interaction between the user and the robot relies exclusively on oral communication. This approach is essential to ensure that individuals with visual disabilities can effectively engage with the robotic system. The robot receives commands from the blind user through an advanced speech recognition system, capable of accurately interpreting vocal instructions in real time [3].

Once the robot processes the user's commands, it provides feedback through a built-in speaker, conveying information in a clear and accessible manner. This two-way communication not only facilitates command execution but also keeps the user informed about the robot's actions and surroundings, enhancing their sense of control and awareness [14].

The implementation of this oral communication system is designed to be intuitive, allowing users to issue commands naturally without requiring specialized training. By using voice as the primary interface, the robot fosters a more inclusive interaction model, empowering blind users to navigate their environments confidently.

Additionally, the speech recognition system can be enhanced with adaptive learning capabilities, enabling it to improve accuracy over time based on the user's specific speech patterns and preferences. This personalization further strengthens the user experience, ensuring that the robot can respond effectively to individual needs. Overall, this oral communication framework plays a critical role in the functionality of the blind guidance robot, making it a valuable tool for enhancing mobility and independence for individuals with visual impairments [3] [2][14].

E. Speech Synthesis Module

This paper implements a sophisticated speech synthesis system based on a phonetic chip capable of producing a wide range of sounds. The phonetic system is carefully controlled and trained by initially receiving specific phrase data through a computer interface. Once programmed, the system operates as a stand-alone unit, with a microcontroller facilitating seamless communication between the phonetic system and the CPU to send the necessary phrase programs to the speakers [17].

When the phonetic integrated circuit (IC) receives a program containing the phonetic structure of a designated phrase—transmitted via a serial control protocol—it processes this data and generates the corresponding sound associated with that phrase. This approach ensures that the robot can effectively convey information and respond to user commands in a clear and intelligible manner [17].

To enhance the audio output quality, sound tuning is performed using a double-stage low-pass filter, which helps eliminate unwanted high-frequency noise and ensures that the produced sounds are smooth and natural. This filtering process is crucial for optimizing the user experience, as clear audio communication is essential for effective interaction between the blind user and the robotic system.

By leveraging this phonetic synthesis approach, the robot can provide verbal feedback, enhancing situational awareness for the user and allowing for more interactive navigation. The flexibility of the system enables it to be programmed with a variety of phrases tailored to assist users in different scenarios, significantly improving the robot's functionality as a guidance tool. Overall, this speech synthesis system represents a vital component of the robot's user interface, fostering an engaging and responsive communication experience for individuals with visual disabilities. Fig. 7 shows the block diagram of our speech synthesis unit.

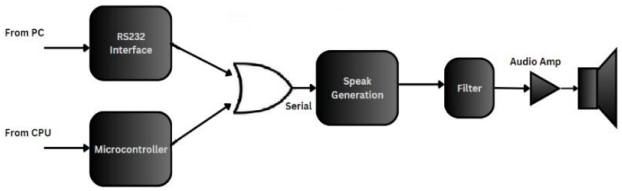

Fig. 7. Block diagram of the speech synthesis unit.

F. Speech Recognition Module

The speech recognition module is designed to recognize up to 40 distinct words, each with a maximum duration of 0.96 seconds. Notably, this module supports a speaker-independent speech recognition system, enabling it to effectively interpret commands from various users without requiring extensive training. Each trained word is assigned an index ranging from one to forty, facilitating easy identification and processing.

In recognition mode, when a word is successfully identified, its corresponding index number is output by the system and transmitted to the CPU as the recognition result. This seamless communication allows the robot to take appropriate actions based on user commands. A comprehensive overview of the speech recognition approach and the underlying algorithms will be presented in a forthcoming paper, providing further insights into the technical intricacies involved [18][19].

The speech recognition unit operates in two distinct modes: training mode and running mode. In training mode, the unit captures the user's spoken word and associates it with a specific index number between one and forty. It then saves the unique voice pattern along with its assigned number in the SRAM, ensuring that the system can recognize the word in future interactions [18].

Once training is complete, the system transitions to running mode, where it continuously listens for spoken input. During this phase, the module remains vigilant and ready to recognize speech at any time. If a recognized word is detected, its corresponding number is sent to the CPU, prompting the robot to execute the designated action. This dual-mode functionality enhances the flexibility and responsiveness of the system, allowing for efficient communication and interaction with the user.

Overall, the implementation of this speech recognition module is a critical component of the blind guidance robot, significantly improving its ability to understand and respond to user commands in real-time. The speech recognition unit is shown in Fig. 8.

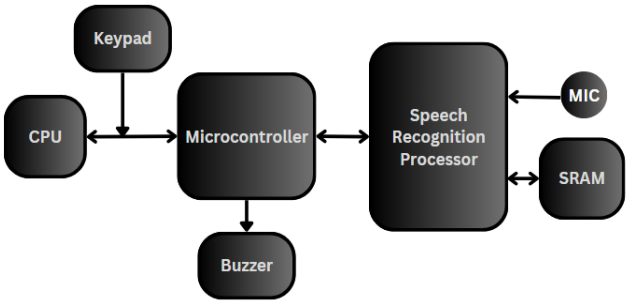

Fig. 8. Block diagram of the speech recognition unit.

VI. Results

This paper applies the described robot design in an indoor environment, where a comprehensive map is constructed. When commands are issued to the robot, it begins movement from a specified source point to a designated destination. Fig. 9 illustrates the test results, demonstrating the effectiveness of the robot's navigation system.

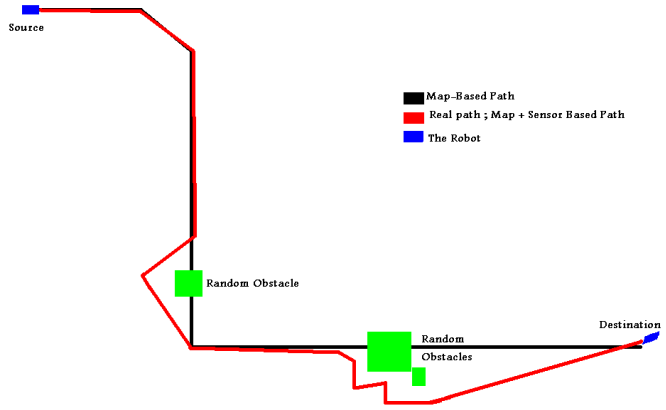

Fig. 9. Indoor environment test results.

In the figure, the black line represents the map-based path generated through the topological mapping process, reflecting the pre-defined routes established during the learning phase. In contrast, the red line illustrates the actual path taken by the robot, which is a dynamic combination of both map-based and sensor-based navigation strategies.

The sensor-based path begins with the detection of obstacles, represented in green on the diagram. Upon encountering an obstacle, the robot employs its obstacle avoidance algorithms to navigate around it effectively. Once the obstacle is bypassed, the robot reorients itself and returns to the next node as indicated in the topological map, ensuring continuity in its route.

This integration of both mapping and sensor data enables the robot to adapt in real-time to changing conditions in the environment, enhancing its navigational accuracy and reliability. By successfully blending map-based navigation with responsive obstacle avoidance, the system demonstrates its ability to operate effectively in complex indoor settings, paving the way for practical applications in assisting individuals with visual impairments. The results underscore the potential of this robotic design to facilitate independent movement and enhance user confidence in navigating unfamiliar spaces.

VII. Conclusion and Future Work

In conclusion, this paper presents a comprehensive approach to designing an autonomous blind guidance robot that effectively integrates advanced navigation, speech recognition, and user interaction technologies. By employing a lead-through programming method for map learning, the robot can autonomously navigate complex indoor environments, adapting to dynamic conditions through a combination of map-based and sensor-based paths. The implementation of a robust speech synthesis and recognition system facilitates intuitive communication between the robot and its users, ensuring that

individuals with visual impairments can interact seamlessly with the technology.

The results demonstrate the effectiveness of the robot's navigation capabilities, highlighting its ability to detect and avoid obstacles while maintaining a clear route based on a topological map. This integration of various systems not only enhances the robot's operational efficiency but also significantly improves the user's experience, promoting independence and confidence in navigating unfamiliar spaces.

Future work will focus on further refining the speech recognition algorithms and expanding the robot's capabilities to handle more complex environments. Overall, this research contributes to the ongoing development of assistive technologies aimed at empowering individuals with visual disabilities, paving the way for more inclusive and accessible robotic solutions.

ACKNOWLEDGMENT

This research did not receive any specific grant from funding agencies in the public, commercial, or not-for-profit sectors. The authors would like to thank the editor and anonymous reviewers for their comments that help improve the quality of this work.

Face Anti-Spoofing Using Chainlets and Deep Learning

Sarah Abdulaziz Alrethea, Adil Ahmad
Information Technology Department, King Abdulaziz University, Jeddah, Saudi Arabia

***Abstract*—Now-a-days, biometric technology is widely employed for many security purposes. Facial recognition is one of the biometric technologies that is increasingly utilized because it is convenient and contactless. However, the facial recognition system has become the most targeted by unauthorized users to get access to the system. Most facial recognition systems are vulnerable to face spoofing attacks. With the widespread use of the internet and social media, it has become easy to get videos or pictures of people's faces. The imposter can use these documents to deceive facial authentication systems, which affects the system's security and privacy. Face spoofing occurs when an unauthorized user attempts to gain access to a facial recognition system using presentation attack instruments (PAIs) such as photos, videos, or 3D masks of the authorized users. Therefore, the need for an effective face anti-spoofing (FAS) system is increased. That motivated us to develop a face anti-spoofing model that accurately detects presentation attacks. In our work, we developed a model that integrates handcrafted features based on Chainlets (as motion-based descriptor) and the convolutional neural network (CNN) to provide a more robust feature vector and enhance accuracy performance. Chainlets can be computed from deep contour-based edge detection using Histograms of Freeman Chain Codes, which provides a richer and rotation-invariant description of edge orientation that can be used to extract Chainlets features. We used a benchmark dataset, the Replay-Attack database. The result shows that the Chainlets-based face anti-spoofing method overcome the state-of-art methods and provide higher accuracy.**

***Keywords*—Presentation attacks; Chainlets; contour; handcrafted features; chain code; CNN; face anti-spoofing**

I. Introduction

In recent years, there has been an increasing interest in human recognition using biometric systems. Facial recognition systems are among the most popular biometric systems on the market because of their ease of use, high performance, and high level of security compared to iris and fingerprint recognition [1]. It is widely used in real-world applications, such as online payment and e-commerce security, smartphone-based authentication, secure access control, and others [2]. However, because of the widespread use of face recognition technologies, they have increasingly been the focus of Presentation Attacks (PAs). These attacks can be categorized into two types: (1) Impersonation attacks are an unauthorized user attempt to spoof someone else's identity, and (2) Obfuscation attacks are a user attempt to avoid being recognized by the system [3]. Face spoofing is when an unauthorized user tries to gain access to the facial recognition system by using one of the Presentation Attack Instruments (PAIs) like a photo (Print attack), a digital video (Replay attack), or wearing a mask (3D mask attack) of the authorized user [4] [5]. The most popular PAs are photo and video because they are easy to obtain and inexpensive compared to 3D mask attacks.

Face anti-spoofing (FAS) methods can be categorized into four main types: liveness, texture, 3D geometric, and multiple cues-based. 1- Liveness-based methods utilize motion in video frames to distinguish between real and spoofed faces. 2-Texture-based methods analyze the micro-texture of the object in front of the camera. 3- Three-dimensional geometric methods rely on the 3D structure of the user's face. 4- Multiple cues-based methods combine various techniques, such as integrating texture features with motion features [6].

In prior works, most face anti-spoofing methods based either on traditional methods, which use machine learning or deep learning. The first-mentioned is by extracting the handcrafted features and training the classifier to differentiate between fake and real faces [7]. It provides good performance in some situations; however, the researcher should have prior knowledge to design the features. Also, it cannot guarantee that the technique will function well in an unknown environment. The methods based on deep learning are more robust and concentrate on designing the model's structure, and are better able to handle a wide range of frequency responses. In general, deep learning models tend to outperform shallow ones [8]. The Convolutional Neural Network (CNN) architecture was proven that it is very effective for face anti-spoofing and superior to the other algorithms in terms of feature extraction [7]. However, optimizing the parameters would need a large number of training samples, which is not feasible for the existing face anti-spoofing databases [8].

In our proposed strategy, we use both handcrafted features and deep learning to obtain more robust features and produce a face anti-spoofing model with high accuracy [8]. Although there are many attack types with different scenarios, until now, there is no outstanding technique for face anti-spoofing systems. There is little attention paid to the development of a fusion strategy that incorporates various liveness features with multiple visual cues. Integrating liveness features from multiple cues will improve the detection accuracy of the face anti-spoofing system [9]. Deep learning models, particularly Convolutional Neural Networks (CNNs), have shown encouraging outcomes in numerous visual recognition tasks, leading researchers to use them in face anti-spoofing [2].

Integrating of handcrafted features and deep features has been used in face anti spoofing with promising results. The paper [10] integrates the handcrafted features with deep learning. It proposes an approach to enhance motion cues for face anti-spoofing using a CNN-LSTM architecture. This

architecture combines Convolutional Neural Networks (CNNs) for spatial feature extraction and Long Short-Term Memory (LSTM) networks for capturing temporal dynamics across video frames. While Eulerian Motion Magnification is used to enhance subtle motion cues, it also degrades image quality. This can sometimes impact overall feature extraction negatively. Also, the temporal features are sensitive to low-quality frames affected by blur or noise, reducing effectiveness.

Consideration of the cues of motion across video frames requires taking into account the changes in objects, such as the face for each frame in terms of orientation and shape boundaries, which play a major role in detecting fundamental changes in impersonation. The paper in [11] introduces Chainlets, a novel object detection and recognition descriptor in computer vision. Chainlets build upon edge-based representations, improving upon existing methods like Histograms of Oriented Gradients (HOG) by incorporating edge connectedness and ordered orientation changes. This enhancement enables Chainlets to handle challenges like orientation invariance. While Chainlets were used for ear recognition and pedestrian detection and achieved competitive results with simple classifiers SVM, this motivated us to use Chainlets with Deep learning in the face anti-spoofing field to differentiate the fake and real faces. More specifically, in our work, we developed a model that integrates Handcrafted features based on Chainlets[11] (as motion-based-descriptor) and deep learning (CNN network) to enhance the performance in terms of accuracy.

The contributions of this paper are:

1) Utilizing a novel, generalized feature descriptor, Chainlets, for face anti-spoofing.

2) Built a model that integrates handcrafted features with CNN to get more robust features to improve the accuracy.

3) The experimental results demonstrate that Chainlets deliver better performance in face anti-spoofing than other algorithms.

This paper is organized as follows: Section II presents the literature review, Section III presents the methodology, Section IV discusses the experiments, and Section V presents the conclusions.

II. Related Work

Nowadays, Face anti-spoofing FAS is important for all facial recognition systems to discriminate between real and fake faces. Most FAS methods are based on either traditional methods or deep learning. The following sections briefly review the relevant works performed in face spoofing detection based on traditional and CNN based FAS techniques [7].

A. Traditional FAS Methods

Traditional FAS methods involve extracting handcrafted features and training classifiers to differentiate between fake and real faces [7]. Consequently, all existing Traditional FAS methods can be categorized into face anti-spoofing methods depending on motion information, texture information, 3D geometric, or multiple information. The methods based on handcrafted features provides good performance in some situations; however, the researcher should have prior knowledge to design the features. Also, it cannot guarantee that the technique will function well in an unknown environment [8].

1) Motion cue-based methods: The motion-based methods endeavor to detect liveness based on movement, for example, mouth movement or eye blinking or others. This method effectively detects photo attacks however provides poor performance in detecting video attacks [6].

The study in [12] proposed a method for Counter-Measures which is based on the correlation of foreground and background movement. This technique detects motion correlation between the scene's background and the user's face to indicate spoofing attack existence depending on optical flow (OF) to estimate direction. Additionally, histograms, normalization, comparison, and OFC quantization are employed to analyze frames for correlation. In the results and conclusion, this study presents a photo-attack dataset, which includes spoofing attacks under various conditions, and successfully detects photo attacks using motion correlation, achieving a 1.5% Half Total Error Rate (HTER).

These previous studies [13] [14] aim to propose methods for detecting liveness. The study in [13] presented an algorithm to evaluate liveness in face image sequences, with the goal of adding liveness awareness in a non-intrusive manner. This system is based on new Optical Flow (OF) and employs local Gabor decomposition and SVM experts. The system operates in real-time, with an input of three frames and an output of a liveness score; if the value of the score is 0, that means no liveness (fake face), and if it is 1, that means the maximum liveness (real face). The study's method depends on integrating the detection of face and the estimation of Optical Flow (OP) in order to indicate the liveness score. This integration is a combination between Optical Flow of Lines (OFL) by means of 1D Gaussians employment including derivatives and implementation of model based on a logpolar grid Gabor and SVM features. The XM2VTS database has been used for evaluation. The results show the success and robustness in detecting the liveness. Furthermore, the rate of error was about 0.5%. However, this method is not effective against video replay attacks.

The objectives related to this study [11] fall under presenting a new approach for detecting pedestrian and recognizing ear, proposing utilize of Chainlets as a new object descriptor. In computer vision applications, Hand-crafted models have shown encouraging results for pedestrian recognition. Based on these findings, human identification and other applications have adopted the Histogram of Oriented Gradients (HOG) features. Unlike traditional methods like Histograms of Oriented Gradients (HOG), which fail to model edge connectedness, Chainlets use Histograms of Chain Codes to enhance object descriptiveness and provide orientation invariance. Chainlets, which we refer to as normalized histograms of chain codes, are used as new descriptors for detection/recognition in the suggested unique method. In addition, experiments demonstrate that Chainlets perform better than HOG-based algorithms and also deep networks in particular cases. Speaking of methodology, this study's method using an ordered oriented data which is computed from deep contour based on edge detection; Chainlets. Chainlets produce strong results for pedestrian

detection, boosting performance in comparison to previous hand-crafted descriptors and setting a new standard for biometric ear recognition. However, the current state of the art uses a quicker R-CNN and an improved classifier to enhance deep features for pedestrian identification. Even greater performance may be achieved by combining these improved classifiers with Chainlets. Aside from pedestrian detection and recognition, we feel that Chainlets have a lot of potential for usage in other areas such as face anti-spoofing.

This paper in [15] also utilized Chainlets, introducing an algorithm for ear recognition called the Chainlet-Based Ear Recognition method, which incorporates multi-banding image processing and support vector machine (SVM) classification. The approach involves splitting an ear image into multiple bands based on pixel intensity and using the Canny edge detection algorithm to extract edges in each band. These edge maps are combined into a single binary edge map representing the ear's contours. It achieved high accuracy with optimal band counts on two benchmark datasets: IITD II and USTB I.

2) Texture cue-based methods: The methods based on texture took use of the fact that a genuine face has a distinct illumination pattern and texture than the 3D mask, paper, or LCD surface utilized to perform the presentation attack [16]. It aims to explore the micro-texture of the object in front of the camera [6]. Texture feature-based methods utilize two kinds of features: static or dynamic. The Static texture cues extract spatial texture features from a single image. In comparison, the dynamic texture cues extract spatiotemporal texture features from video sequences [6]. In this method, the computational complexity is low, and the implementation is easy; however, with the recent and high-resolution cameras and high-quality pictures, the texture information is not enough, and we need to combine it with other information [17].

These previous studies [18] [19] aim to propose methods based-on color texture analysis. This paper [18] proposed a novel face anti-spoofing approach based on analysis of color texture. This study focus on using chrominance information in order to discriminate fake faces from real ones, while other studies have focused on evaluating the luminance of the face pictures. Related to methodology and experiments, the information relative to joint color texture, which comes from the luminance and the chrominance channels, has been analyzed based on a color local binary pattern descriptor. Furthermore, the histograms of feature have been extracted separately from each picture band. For the classification, they utilized a SVM with RBF Kernel. In the result, the investigation of the useful color space among HSV, RGB, and YCbCr spaces has been indicated. The performed experiments on CASIA and Replay-Attack databases have delivered excellent results taking into account a very promising results related to capabilities of generalization.

This paper in [20] proposed a new approach to detecting spoofing attacks based on texture analysis regarding characterization of printing artifacts, image quality assessment, and differences in light reflection. In addition, this study aims to present a new model by evaluating facial image textures in order to distinguish between live face and face in a printed image. This study considers the NUAA Photograph Imposter Database. The evaluation of the facial images' texture has been done by multi-scale local binary pattern (LBP). Speaking of methodology, the live objects must appear fixed as much as possible by minimizing the blinking motion of the eye and other movements. For the classification, they utilized a SVM with RBF Kernel (LibSVM). The results, this approach is robust and fast in calculations and demands no cooperation from the user, where the accuracy achieves 98.0%.

3) 3D Geometric cue-based methods: The 3D geometric-based methods use the depth information of the face to differentiate between a 2D face (photo or video attack) and a 3D face (real face). This method effectively detects photo and video attacks; however, it is not adequate to detect 3D mask attacks and is also costly because it needs additional hardware [17].

This paper in [21] proposed a new approach for detecting face liveness in order to eliminate spoofing attacks based on recovering sparse 3D facial structures. The methodology involves capturing faces in videos or photo sequences from at least three viewpoints, detecting facial landmarks, and selecting key frames. After that, the recovering operation of the sparse 3D facial structure can be done based on the chosen key frames. Eventually, a training process for the Support Vector Machine (SVM) is performed in order to differentiate the real faces from the fake ones. They evaluate the proposed method using three datasets, CASIA, NUAA, and Idiap databases. In the results of experiments, the proposed method has achieved ideal performance in detecting liveness where the accuracy achieved 100% for Face Liveness Detection. It outperforms the state-of-the-art methods in differentiating the genuine, planar, and warped image faces. The disadvantages of this method are that it provides good performance just for detecting photo attacks, not others. Also, it needs various viewpoints where one image is not enough. In addition, if the number of key frames is not enough, it can affect the performance.

This paper in [22] proposed a multispectral approach for FAS with not only (VIS) spectra imaging but also with the near infrared (NIR) one in order to execute VIS–NIR image consistency for spoofing detection purposes. Related to methodology and tools, correlation analysis has been employed in order to achieve a more compatible anti-spoofing method. The overall system consisted mainly of: (i) trained correlation confidence map to have a robust system, (ii) VIS–NIR correlation model, (iii) illumination robust feature extraction, and (iv) final classifier to perform detection. First, to avoid unbalanced illumination terms, input has been preprocessed by histogram equalization and face to eye position normalization, then region features. In addition, the information of correlation is calculated based on features of NIR and VIS photo patches. The proposed method has achieved an effective performance in handling spoofing attacks with different illumination, and also intra and cross dataset testing protocols on the three datasets (Ms-spoof, self-collected and PolyU-HSFD) based on extracting complementary features on VIS and NIR photos. The ACER (%) is 1.76 in the self-collected dataset, and 0.241 in Ms-spoof dataset.

4) Multiple cues-based methods: The multiple cues-based methods consider combining multiple cues such as motion information with texture information. This method detects varied kinds of face presentation attacks [6]. The methods based on multiple cues are superior in accuracy; however, it needs high Computations [17].

This paper in [23] proposed a liveness detection system that integrates motion and texture cues, exploiting scene context and eye blinks in a real-time system to non-intrusively resist spoofing attacks. The proposed method utilized the conditional random field model for eye blinks and LBP to compare the scene context to the reference images. Two databases were created for evaluating the system: a photo-imposter video database and a live face video database. The experimental results verified the system's reasonable ability to counter spoofing attacks and its robustness against camera shifts as well as its achievement of 99.5% accuracy. However, this method is unsuitable for real-life applications as the camera must remain fixed in the same position.

This paper in [9] proposed a multi-cues integration framework for face anti-spoofing utilizing a hierarchical neural network in order to enhance the ability of generalization. The proposed method is meant to fuse image quality cues and related motion in order to detect liveness. They extract image quality features using shearlet (SBIQF) and motion features using optical flow. In addition, they fuse features from multi cues using bottleneck representations that can effectively integrate various features of liveness. They evaluate the method using three databases: Replay-Attack, CASIA-FASD, and 3D-MAD datasets. Effective performance was achieved, with Equal Error Rates (EERs) of 0% in the Replay-Attack and 3D-MAD databases and 5.83% in the CASIA-FASD database.

B. CNN-Based FAS Methods

This section discusses strategies that exclusively employ deep learning techniques or combine shallow machine learning and deep learning techniques based on their performance, strengths, and weaknesses.

This paper in [24] proposed a study utilizing CNNs to learn features with high discriminative ability, with the aim of enhancing FAS effectiveness. The OpenCV detector was employed for face detection, followed by the refinement of bounding boxes around facial landmarks to encompass the majority of facial regions. Images were resized to 128 × 128 pixels, and the Caffe toolbox was used for CNN training with a learning rate of 0.001, decay of 0.001, and momentum of 0.9. For classification, SVM with RBF kernel was employed. The proposed method was evaluated using Replay-Attack and CASIA datasets, achieving significant improvements over previous methods, with a 5% reduction in HTERs. However, the proposed method exhibited unsatisfactory performance in inter-test scenarios.

This paper in [10] proposed an FAS method based on a joint CNN-LSTM network, considering motion cues across video frames. This study extracted high discriminative properties and features from video frames using conventional CNN. The combination of these extracted features with Long Short-Term Memory (LSTM) was employed to capture temporal dynamics within video sequences. Additionally, Eulerian motion magnification was utilized to enhance facial expressions, while the attention mechanism in LSTM ensured the model focused on dynamic frames. The Adam optimizer was used for training the network with a learning rate of 0.00001. The proposed method was evaluated using Replay-Attack and MSU-MFSD datasets, achieving improved performance in generalization ability and fine-grained motion detection, with an HTER of 3.53% and an ACC of 96.47% in the Replay-Attack dataset. However, the experimental results indicated that dynamic variations in temporal features are beneficial for enhancing generalization ability.

This paper in [25] proposed an FAS method using CNN alongside a handcrafted technique (LBP-TOP) for feature extraction and classifier training. This method eliminates the need for detection, refinement, or enlargement steps. A cascading process for the LBP-TOP technique with CNN was performed to extract spatiotemporal features and obtain discriminative clues between genuine access and impersonation attacks. The proposed method was evaluated using the Replay-Attack and CASIA datasets, demonstrating significant potential for employing LBP-TOP with CNN for anti-spoofing purposes. An EER of 3.22% and HTER of 4.70% was achieved in the Replay-Attack dataset. Experimental results indicated competitive performance compared to previous methods.

This paper in [8] proposed a face anti-spoofing method regarding the deep local binary pattern. This study depends on extracting the handcrafted features from the convolutional responses related to tuned finely CNN model. First, the CNN has been finely tuned using a trained model of VGG-face. After that, the features of LBP are computed from the convolutional responses and combined in unique vectors of feature. These vectors are used by a SVM classifier in order to detect spoof faces. Related to samples, two databases are considered CASIA-FA and Replay-Attack. In the results, the investigation of the useful color space among HSV, RGB, and YCbCr spaces has been indicated. The experiments have delivered excellent results taking into account very promising results related to capabilities of generalization. The EER (%) is 0.1, and HTER (%) is 0.9 in Replay-Attack dataset. The EER (%) is 2.3 in CASIA-FA dataset.

This paper in [26] proposed a new approach for detecting face spoofing by extracting local features, specifically LBPs and simplified Weber local descriptors (SWLDs). The integration of Weber local descriptors (WLD) and LBP features ensures preservation of the local intensity information and edge orientations. The methodology involved two streams: an LBP-based CNN and a SWLD-based CNN. Initially, face regions were localized using Viola-Jones face detection. Subsequently, LBP and SWLD features were extracted by dividing the image into smaller parts. The features were encoded using CNN. Eventually, a non-linear SVM classifier with a radial basis function kernel was employed to determine whether a face was live or fake. The proposed method was evaluated using the Replay-Attack and CASIA datasets and achieved competitive results, with an EER and HTER of 2.62% and 2.14%, respectively, in the CASIA dataset and 0.53% and 0.69%, respectively, in the Replay-Attack dataset. This method's minimal complexity makes it suitable for real-time applications.

This paper in [27] proposed a new novel architecture consisting of a two-stream Frequent-Spatial-Temporal-Net for face anti-spoofing, which mainly combines the advantages of temporal, frequent, and spatial information. In addition, this study aims to achieve a multi-frame spectrum photo for the discriminative deep neural-network in order to distinguish between fake and live video. This study presents first the substantial properties related to the model. Then, elaborating the proposed network architecture is employed beside a strategy of learning in the pipeline. The implementation in MXNet and adoption of 4 blocks ResNet-v1b-18 for spatial part is used. While 0.3 rate of learning, 0.0001 weight decay, and 0.03 rate of Freq-Temp-Net stream learning are adopted. They evaluate the proposed method using three datasets: CASIA-SURF, OULU-NPU, and SiW datasets. Experimental results show a promising enhancement considering the proposed method besides the improved demonstrated ability of generalization compared with previous and existing approaches where the ACER (%) is 0.016 in CASIA-SURF, 1.1 in OULU, and 0.67 in SiW.

III. METHODOLOGY

To fulfill this study's objectives, we proposed designing a face anti-spoofing model capable of discriminating between real and fake faces with high accuracy. In Fig. 1, the proposed algorithm consists of five main stages: image pre-processing, Edge Detection, finding contours, extracting chainlets Features, and CNN model. The Chainlets were chosen as a motion-based descriptor due to their proven effectiveness in pedestrian detection and biometric ear recognition [11].

Chainlets is a concept that suggests that each object edge in an image can be represented as a histogram of chain codes, with each chain code representing the direction of connected edge segments. The label shifts between two absolute chain code-based Chainlets histograms can be used to determine the approximate rotation. Absolute chain code is dependent on the image's edge orientation, which results in different codes for rotated versions of objects. The frequency of occurrence of each of the eight directions, which depicts the shape of the object, is calculated by a chain code histogram. The picture sequence's Chainlets are first computed and concatenated with the sequence's first image, which can characterize motion direction and orientation.

A. Image Preprocessing

Before extracting Chainlets, the image needs to be preprocessed. Fig. 2 shows the stages of image processing. First, the image will converted to grayscale, and then GaussianBlur will be applied to reduce noise from an image. cv2.GaussianBlur(img, (5,5), 0).

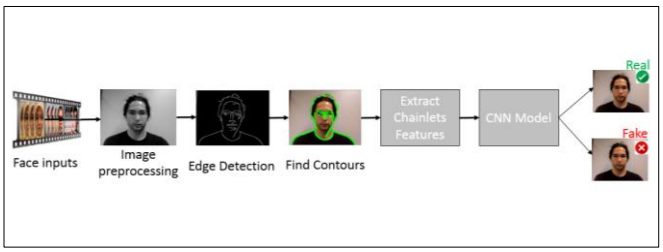

Fig. 1. The proposed algorithm.

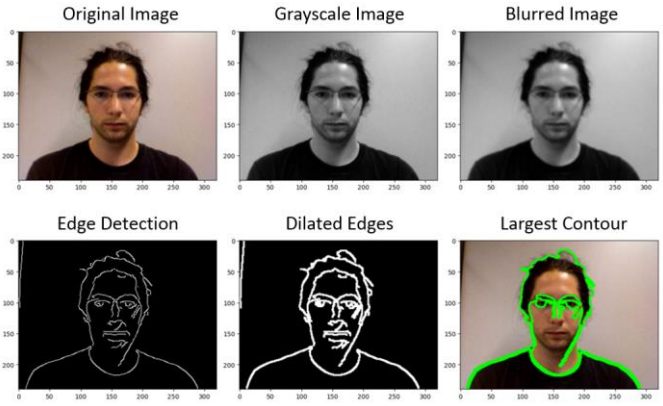

Fig. 2. Stages of image processing.

B. Edge Detection

The Canny edge detection algorithm [28] is a classic method that has proven its effectiveness over the years and remains widely utilized. Its approach is grounded in three main goals: (i) minimizing error rates, (ii) accurately locating edge points, and (iii) producing thin edges. We used canny edge detection with threshold values minVal and maxVal.

cv2.Canny(img, 50, 150)

Then the detected edges are dilated using a 3 x 3 kernel to close any gaps in the edges.

C. Finding Contours

Contours can be viewed as a plot or curve that links all the consistent points—typically found along the edges of a digital image—that exhibit similar colors or intensities. These connected points are associated with one another. Contours serve as useful tools for various applications, including structural analysis, object segmentation, object recognition, and others [29]. We used the find contours function from OpenCV and it has three parameters: the input image, contour retrieval mode, and contour approximation method.

cv2.findContours(img, cv2.RETR_EXTERNAL, cv2.CHAIN_APPROX_SIMPLE)

D. Extracting Chainlet Features

The representation of an image plays a crucial role in image processing and facial recognition. A key feature of an image is conveyed through the shapes created by the edges of an object. Histograms of Oriented Gradients HOG capture some of this information; however, it fails to account for important spatial relationships concerning the edges of an object. Specifically, HOG does not consider the connectedness of the edges, and the sequence and arrangement of orientation changes are not reflected in the histogram. The reason for using Chainlets as motion-based descriptor is that a face's appearance and shape can be effectively represented by the density of relative chain codes, which encode rotation-invariant edge detection. While this idea is related to HOG, it utilizes longer, connected edges, offering a more comprehensive and rotation-invariant representation of edge orientation [11].

We extract handcrafted features using the Chainlets which are built on the concept of Freeman chain codes [30] by making

them rotation-independent and more localized, thus mitigating the negative impacts of partial occlusions. It is characterized by local edge orientations that are aggregated into a global histogram sequence representing the entire image.

Chain code [31] is a method for documenting a sequence of edge points along a contour, indicating the direction of each edge in the sequence. These directions are categorized into eight distinct orientations. The notation progresses clockwise around the contour, starting from the first edge. Each subsequent edge's direction is represented by one of the eight chain codes. The direction associated with the 8-neighbor of an edge is illustrated in Fig. 3.

A chain code histogram measures how often each of the eight directions occurs, indicating the shape of the face. Fig. 4 illustrates the steps of extracting Chainlets features. Firstly, divide the binary image into cells, then compute the chain code for each one, compute chain code histogram and normalized, the all blocks' collection represents the Chainlets features. Finally, the extracted chainlets features are passed to the CNN model.

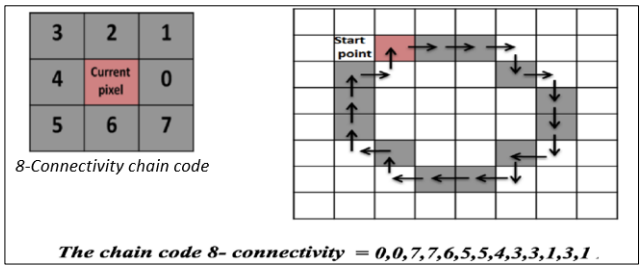

Fig. 3. Example of extracting chain code (clockwise).

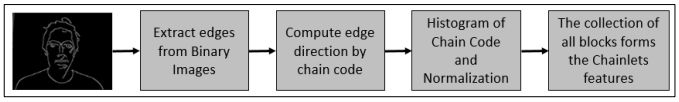

Fig. 4. Extracting chainlets features.

E. CNN Model

We build a CNN model for learning features. Our CNN model consists of three convolutional layers and 3 dense layers. The response normalization layers are applied to the outputs of the three Conv layers. Max pooling layers are utilized to generate the output for the three convolutional layers. Moreover, the 4th, 5th, and 6th layers are Dense layers. Further, we add the Dense layer with sigmoid activation to produce the binary output. We use Adam optimizer with a learning rate of 0.001. When compiling the model we use Binary Cross Entropy as the loss function to train the model for binary output, 1 is spoof face and 0 is real face.

IV. Experimental Results

We used a benchmark dataset, which is Replay-Attack. The Replay-Attack dataset contains 1,300 videos from 50 subjects, including real and fake face-spoofing attacks. For every subject, four genuine and eight fake sequences are obtained under various lighting terms with two support conditions (Fixed and Hand-held). Fig. 5 Shows example images from the Replay-Attack database. The images in the top row are genuine, while those in the bottom row are fake.

Fig. 5. Example of images from the Replay-Attack database.

The training set contains 93679 frames, the testing set 23395 frames, and the validation data size is 21055 frames. We evaluated the proposed model's performance to prove its effectiveness using the following metrics: Half Total Error Rate (HTER), Equal Error Rate (EER), and accuracy. The experimental results clearly demonstrate that the proposed Chainlets-based face anti-spoofing technique significantly surpasses state-of-the-art methods. This performance can be justified by the fact that integrating Chainlets as handcrafted features with deep learning will extract valuable features and produce a high-performance face anti-spoofing technique. Table I and Fig. 7 show that the proposed technique achieves the best performance compared with other state-of-art methods. Our model achieves high accuracy at 99.85%, the HTER is 0.15%, and the EER is 0.15%. Fig. 6 presents the training and validation accuracy and loss for the proposed algorithm.

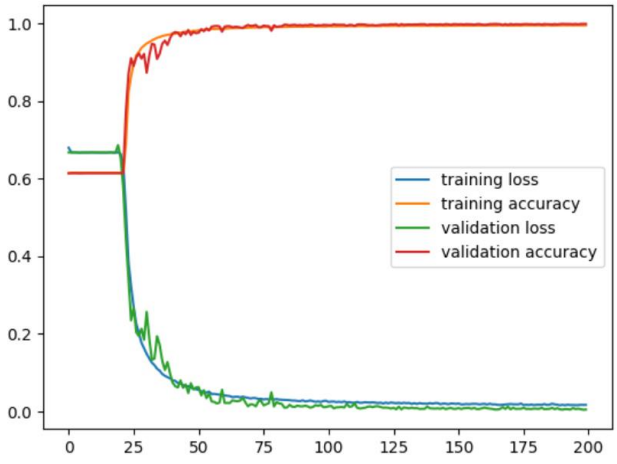

Fig. 6. Training and validation accuracy / loss curves.

TABLE I. Evaluation of Model's Performance Against State-of-the-art Methods

Approach	Replay-Attack Dataset		
	EER(%)	*HTER(%)*	*Accuracy(%)*
CNN + LBP-TOP [25]	3.22	4.70	-
DeepLBP + CNN + SVM [8]	0.1	0.9	-
CNN with LBP and WLD + SVM [26]	0.53	0.69	-
CNN-LSTM [10]	-	3.53	96.47
Chainlets + CNN (Our method)	**0.157**	**0.153**	**99.85**

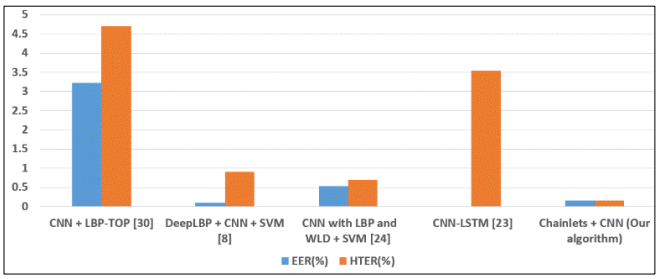

Fig. 7. The EER and HTER for the Replay-Attack dataset.

V. CONCLUSION

Given the current widespread use of the internet and social media, it is easy to obtain videos or pictures of individuals' faces, making most facial recognition systems vulnerable to spoofing attacks. An imposter can use such readily available materials to deceive facial authentication systems, thereby compromising their security and privacy. There are many attack types with different scenarios, so until now, there is no outstanding technique for face anti-spoofing. In our proposed algorithm, we depend on both handcrafted features (Chainlets) and deep learning (CNN) to obtain more robust features and high accuracy in the face anti-spoofing system. Thorough experiments were conducted on the Replay-Attack dataset to assess the effectiveness of the proposed Chainlets-based face anti-spoofing method. Our approach achieved perfect discrimination between real faces and spoof faces. The EER is 0.157%, the HTER is 0.153%, and the accuracy is 99.85%, which is better than the state-of-the-art methods. However, this work does not address the detection of 3D mask attacks. This aspect will be considered in future work.

***Abstract*—The exponential growth in video content has created a critical need for efficient video summarization techniques to enable faster and more accurate information retrieval. Video summarization has excellent potential to simplify the analysis of large video databases in various application areas ranging from surveillance, education, entertainment, and research. DSTC-Sum, a novel supervised video summarization model, is proposed based on Depthwise Separable Temporal Convolutional (DSTC). Leveraging the superior representational efficiency of DSTCN, the model addresses computational challenges and training inefficiencies encountered in traditional recurrent architectures such as Recurrent Neural Networks (RNNs) and Long Short-Term Memory (LSTMs). Additionally, this approach reduces computational overhead and memory usage. DSTC-Sum achieved state-of-the-art performance on two commonly used benchmark datasets, TVSum and SumMe, and outperformed all previous methods with F-scores by 1.8% and 3.33%, respectively. To validate the model's generality and robustness, the model was further tested on the YouTube and Open Video Project (OVP) datasets. The proposed model did slightly better on these datasets than several popular techniques, with F scores of 60.3 and 58.5, respectively. Finally, these findings confirm that this model captures long-term temporal dependencies and produces high-quality video summaries across all types of videos.**

***Keywords*—Video summarization; depthwise separable temporal convolutional; video processing; deep learning**

I. INTRODUCTION

In recent years, the proliferation of video capture devices and their declining costs have led to an unprecedented increase in video data volume. There are many kinds of visual data, but the video is one of the most significant. It is impossible to expect people to be able to see these videos and extract relevant information from them due to the vast amount of data included inside them. According to the Cisco Visual Networking Index report [1], it will take a human more than 5 million years to watch all the movies published on the Internet each month by 2022. Because of this, developing computer vision systems that effectively browse vast amounts of video data is becoming an increasingly important goal. Video summarizing has emerged as a potential technique that may assist viewers in dealing with the massive amount of data in the video.

When given an original video as input, video summarizing produces a more condensed version that still contains all the essential information from the original. Video summarizing has numerous potential applications (for example, indexing, browsing, and surveillance) [2, 3]. Summary videos may also be helpful for various downstream video analysis activities. For instance, running other analytic algorithms on shorter videos, such as action recognition, can be done more quickly.

Recent methodologies [4-6] address video summarization as a sequence labeling challenge, focusing on identifying and extracting key video segments efficiently. The Recurrent Neural Networks (RNNs) with Long Short-Term Memory (LSTM) have been modified as an RNN variant to address this issue [7]. The LSTM model has a one-to-one correspondence between each time step and video frame. The LSTM model generates an output binary value at each time step, which indicates whether this frame was chosen for inclusion in the summary video. The LSTM methodology has the advantage of recording the long-range structural connections between frames. However, some limitations are embedded into these LSTM-based models. In LSTM, the computation typically proceeds from left to right. It indicates that the model can only perform one frame at a time, with each frame having to wait until the processing of the frame has been completed before it can begin. Even if there is bi-directional LSTM (Bi-LSTM) [8], the computation still has the same issue when using Bi-LSTM in either manner. Because of the sequential nature of the LSTM computation, it is impossible to readily parallelize it to make the most of the GPU resources. As temporal classifiers, sequence-based architectures such as RNN and LSTM are computationally costly, memory-heavy, and challenging to train. Temporal Convolutional Networks (TCNs) [9, 10] have recently demonstrated promising performance in video summarizing tasks.

In this work, to solve the abovementioned challenges, the DSTC-Sum model was designed based on the Depthwise Separable Temporal Convolutional Network (DSTCN), which efficiently extracts long-term temporal dependencies and local features. Unlike RNN-based models, which are computationally inefficient, sequential in nature, and reliant on domain-specific annotations, TCNs allow the addition of new layers while being computationally less expensive, quicker to train, and lightweight [11]. This makes traditional methods like RNNs and LSTMs unsuitable for large-scale datasets and

longer videos. The DSTC-Sum model leverages Depthwise Separable Convolutions (DSC) to improve feature representation while requiring low computation and memory [12]. Its scalable and dataset-agnostic design ensures efficient extraction of temporal dependencies and enhances generalizability across diverse video datasets. The benefits of DSTCN include the use of large kernels to capture long-range relationships while limiting the number of overall parameters, resulting in compact models. Additionally, large adjacent kernels effectively extract both global and local temporal features. By enabling simultaneous analysis of all video frames through GPU parallelization, DSTC-Sum addresses the challenges of computational inefficiency, scalability, and poor temporal modeling, achieving superior performance compared to current video summarization techniques.

We conducted comprehensive evaluations on two benchmark datasets, TVSum and SumMe. In the standard-supervised setting, the DSTC-Sum model achieved an F-score of 48.7%, which increased to 52.8% with data augmentation. On the TVSum dataset, the model attained an F-score of 61.2% in the standard setting, improving to 62.9% with augmentation. These results demonstrate the superior performance of the DSTC-Sum model compared to state-of-the-art techniques, with notable improvements of 1.8% and 3.33% on the two datasets, respectively. This highlights the model's enhanced ability to accurately predict the importance of video segments and generate high-quality summaries. The DSTC-Sum model's effective capture of temporal dependencies and key factors sets it apart, underscoring its potential for broader video summarization applications. To further evaluate the model's generalizability and robustness, we extended our experiments to two additional datasets: YouTube and the OVP. The model demonstrated superior performance on these datasets, achieving F-scores of 60.3% and 58.5%, respectively, outperforming several state-of-the-art techniques. These results underscore the model's effectiveness in capturing long-term temporal dependencies and generating high-quality summaries across various video genres.
