The key components of this approach focus on the integration of specialized Python libraries that allow the entire data integration flow to be intelligently automated. First, Playwright is used, which in this case plays a fundamental role within RPA scripting by facilitating dynamic interaction with web platforms, executing tasks such as browsing, authentication, and file download in a robust way. Once the data is obtained, Pandas comes into play, the library used for the cleaning, transformation, and validation of the extracted information, allowing for to structure the data in an optimal way for its analysis and subsequent integration. In addition, Oracledb is used to connect to the Oracle database and to load and insert processed data into multiple tables of the management system,

ensuring persistence and consistency of the information. In addition, advanced ML techniques are incorporated to strengthen the quality and reliability of the process: Isolation Forest for the unsupervised detection of anomalies and subtle errors in rows; Autoencoders to identify deviations and unusual changes in the daily reports through deep learning, facilitating the generation of proactive alerts before insertion; and Random Forest for the classification of records into valid or invalid when historical tags are available, optimizing data cleansing. As a final stage of the flow, the validated and persisted data are displayed in enterprise visualization tools, which allow building interactive presentations, monitoring key indicators in real-time, and facilitating strategic decision-making based on reliable and updated information. This combination of tools allows end-to-end automation of a data integration flow, making it scalable, adaptable, and compatible with Machine Learning models to enrich operational intelligence in an automated and continuous way.

This study is structured as follows: Section II reviews related literature. Section III defines core concepts. Section IV details the proposed model architecture. Section V presents the experimental results. Section VI discusses limitations and future work. Finally, Section VII provides the concluding remarks.

II. Related Work

This section reviews previous research and technological developments related to RPA and ML integration techniques. The objective is to establish a theoretical basis for understanding existing solutions, identify current challenges, and highlight the gap that this study seeks to address. Through the analysis of studies in various industries, the convergence between automation and intelligent decision-making is discussed, highlighting the importance of building adaptive and efficient systems in data-driven environments.

In [6], the authors describe how RPA technology has revolutionized services globally, making it possible to replace the human labor force with software robots that incorporate intelligent elements, such as ML, to achieve more advanced and intelligent automation. In an industrial case in Finland, RPA is combined with ML to automate invoice processing in a shared services center, reducing errors, freeing up employees for higher-value tasks, and improving the efficiency and accuracy of the process. The integration of these technologies allows not only the automation of repetitive tasks but also the ability to learn and adapt to changes in data and processes, facilitating more intelligent and flexible automation. The study highlights that this combination can offer a good return on investment. However, this study's weakness is its focus on a single, internal business task (invoicing). It does not address the challenge of validating data extracted from multiple external web platforms, which is the gap this model addresses.

In [7], the authors explain how an RPA has been applied in the financial arena, specifically in predicting stock prices and automating the stock picking process. The research highlights a significant increase in demand for RPA-related jobs, reflecting a growth in the need to automate repetitive tasks in this sector. Price prediction models have been developed using Machine Learning techniques, such as stacked Long Short-Term Memory (LSTM). In addition, RPA's Automation Anywhere tool has been used to automate stock selection based on technical criteria, which helps users generate analysis reports in less time. While this demonstrates a powerful use of ML for prediction, its assumption is that the data is already clean. This approach is insufficient for our research, as this model focuses on validating the quality of internal enterprise data before it can be used for analysis.

In [8], the authors detail how intelligent robotic process automation (IRPA) combines artificial intelligence (AI) and RPA to automate complex unstructured tasks and adapt to changing scenarios. The research developed a process analysis framework for IRPA adoption, identifying key factors through a literature review and a survey of subject matter experts. The framework provides practical guidance for improving supply chain operations in areas such as logistics, purchasing, and inventory management. The strength of this framework is in optimizing unstructured processes. This differs from this work, which addresses the specific challenge of validating structured and semi-structured data extracted from web reports, a gap not covered by this supply chain model.

In [9], the authors state that sustainability in RPA refers to making RPA solutions robust and adaptable to change, enabling their long-term use and preventing them from ceasing to function when process changes occur. The research proposes a universal model for sustainable RPA implementation, consisting of three phases: planning, development and maintenance, and project scaling. In addition, the study highlights that careful planning, including risk assessment, change management and the creation of a center of excellence, is critical to ensure the sustainability of RPA initiatives. Assessing and monitoring aspects related to security, data management and governance are also key aspects to maintain the long-term viability of RPA solutions. While this study provides a valuable framework for the managerial and methodological sustainability of an RPA project, its focus is on governance and planning. It does not propose a specific technical architecture for integrating intelligent validation, which is the primary contribution of this study.

According to the study in [10], in Nordic companies the determinants for the implementation of Robotic Process Automation (RPA) as a digital transformation tool were explored. The technique used was qualitative in approach, using semi-structured interviews with experts from eight organizations in the medical, real estate and accounting sectors. The method combined case study, grounded theory and thematic content analysis. The results showed that the main motivation for adopting RPA was operational improvement through the automation of repetitive tasks, prioritizing labor cost savings. Although benefits such as increased productivity and freeing up time for higher-value tasks were observed, associated risks were also identified, such as technological dependence and vulnerability to system failures. On a quantitative level, the study reports that the return on investment (ROI) in the first year can vary between 30% and 200%, which demonstrates a significant financial impact on the companies analyzed. This research focuses on the business drivers and financial impact of adopting RPA, justifying why an organization would implement automation. However, it does not address the what or how of the implementation itself, specifically regarding the technical

challenge of ensuring data quality. This study fills this gap by presenting a model that embeds ML validation directly into the automation workflow.

III. CONCEPTS

This section presents the main concepts of this work. The objective is to develop a Robotic Process Automation (RPA) script that leverages Machine Learning techniques for enterprise data integration.

A. Robotic Process Automation [11]

It is an automation approach based on software bots that automate business processes by understanding existing procedures.

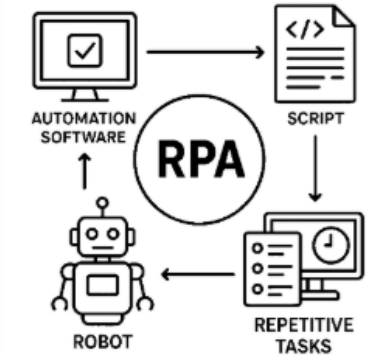

Fig. 1. Main components of this RPA scripting.

In Fig. 1, the main components of RPA, including automation software, scripts, digital robots, and repetitive tasks, and how they interact to optimize business processes is given.

B. Enterprise Data Integration [12]

A set of data extracted from different sources, i.e., raw data. These data require conversions and, after conversion, are stored through various technical processes, providing a single view of the data.

C. Scripting [13]

It is the creation and use of scripts which are programs or sets of instructions written and predefined in code made in some programming language to perform actions on computers in order to speed up the execution of processes and tasks.

D. Python [14]

High-level interpreted programming language created by Guido van Rossum in 1991.

E. Python Libraries [15]

Python libraries are tools that facilitate programming by providing predefined functions for various tasks. In automation and data analysis, Playwright for web browsing and Pandas for structured information processing stand out.

1) Playwright: Test automation framework for web applications, developed by Microsoft. It allows running tests in Chrome, Firefox, Safari, and Edge with a unified API, compatible with JavaScript, Python, and Java. It supports headless mode, network manipulation, and video recording to facilitate test analysis [16].

2) Pandas: Open-source software library designed for data manipulation and analysis in Python programming language [17].

3) Oracledb: It is a widely used database management system known for its robust features and tools for data design, management, and analysis. It supports object-oriented and relational data models, making it versatile for a variety of applications [18].

F. Machine Learning [19]

A subset of artificial intelligence (AI) that enables systems to learn from data and improve their performance over time without being explicitly programmed.

G. Isolation Forest [20]

The Isolation Forest (iForest) algorithm is a popular Machine Learning method for anomaly detection. It is particularly effective due to its low computational complexity and its ability to handle high-dimensional data.

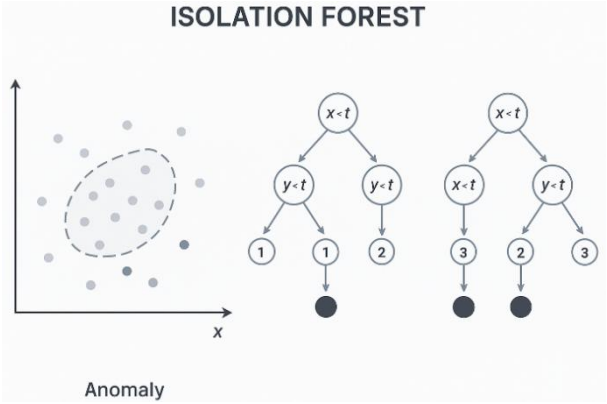

Fig. 2. Isolation forest.

Fig. 2 illustrates how the Isolation Forest algorithm isolates data points using multiple randomly generated trees. Anomalous points are isolated early and appear at shallower depths (dark nodes), whereas normal points require more splits (light nodes). The ensemble of these trees enables the systematic detection of anomalies.

H. Random Forest [21]

Versatile and widely used Machine Learning algorithm that combines multiple decision tree classifiers to improve predictive accuracy and control overfitting. It is especially effective for classification and regression tasks.

As shown in Fig. 3, the original data set is randomly divided into K subsets, and each is trained on an independent decision tree. Each tree makes its own prediction, and all the predictions are then combined by voting (in classification) or by averaging the results (in regression).

I. Autoencoder [22]

Neural network for unsupervised learning, used in dimensionality reduction and data reconstruction. It is composed of an encoder, which compresses the data into a latent space, and a decoder, which reconstructs it from this representation. The architecture of the autoencoder is shown in Fig. 4.

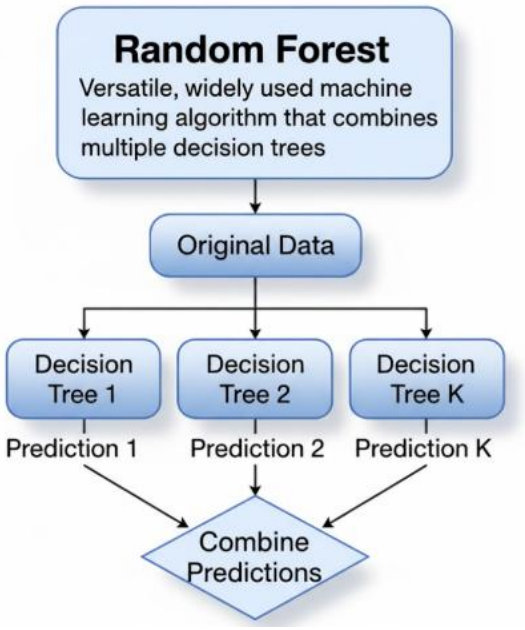

Fig. 3. Random forest.

As seen in Fig. 4, input data (such as daily patterns) is passed through the hidden layer, where the model compresses it into a smaller representation. The output layer then attempts to reconstruct the original data from that compressed representation. If the patterns are normal, the reconstruction will be accurate, but if it is an anomalous pattern, the reconstruction will be incorrect, which helps identify the anomaly.

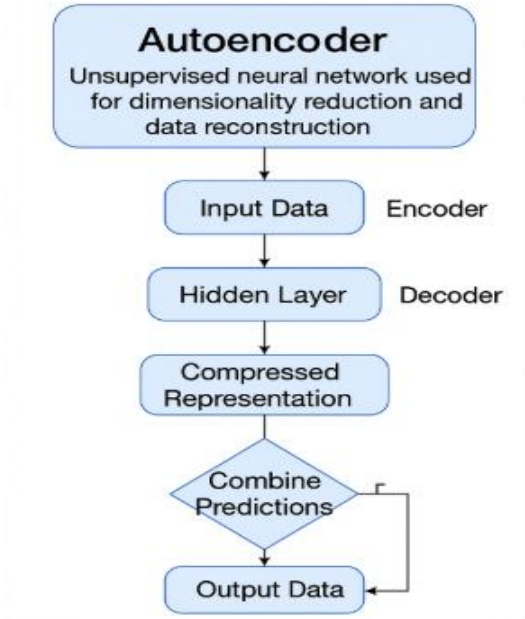

Fig. 4. Auto-encoder.

IV. Model

The proposed RPA model integrates specialized tools to intelligently automate the entire data integration flow. It all starts with the use of Playwright, which allows automated interaction with web platforms, performing tasks such as browsing, authentication, and file downloading in a robust and reliable way. Then, the extracted data is processed by Pandas, a library that allows the cleaning, transformation, and structuring of the information to ensure its quality and consistency. At this stage, a Machine Learning component is incorporated to strengthen data validation: Random Forest classifies records as valid or invalid when historical labels are available, Isolation Forest detects rows with subtle errors through unsupervised detection, and Autoencoders identify unusual deviations between daily reports, generating proactive alerts before proceeding. Once validated, the data is efficiently loaded into a relational database via Oracledb, ensuring its persistence and availability for analytical queries. Finally, the processed and stored information is visualized through data visualization tools, which allow building interactive dashboards for decision making based on reliable, timely, and automated audited data. The complete architecture of this model is shown in Fig. 5.

A. Data Capture and Extraction

In this first stage, Playwright is used, a modern and highly efficient tool that allows simulating human interactions with web browsers in a programmed way, which in this context is adapted to the RPA scripting paradigm to automate dynamic interaction with web platforms, allowing tasks such as navigation between pages, button clicks, credential entry, pop-up web window management, and file downloading. This automation ensures robust, reproducible, and human error-free data collection, laying the foundation for efficient downstream processing.

B. Intelligent Data Processing and Validation

In this stage, the extracted data undergoes a series of transformations using the Pandas library, an essential tool in the Python data analysis ecosystem. Here, cleaning tasks such as null removal, format normalization, field unification, creation of new derived columns, duplicate handling, and structure alignment are performed. However, the key differential of this stage is the incorporation of intelligent validation through Machine Learning algorithms, which allows not only verifying the structure but also detecting semantic or contextual errors in the data.

1) Random forest: Supervised algorithm trained with historical records labeled as valid or invalid, which automatically predicts whether a new record meets the logical integrity criteria or presents errors.

2) Isolation forest: An unsupervised algorithm that detects subtle anomalies in the data without the need for labels. This model analyzes the distribution and isolation of records to identify outliers.

3) Autoencoders: Neural network-based algorithm that detects unusual changes or structural deviations in daily reports compared to previous behavior, generating early warnings when anomalous patterns are identified, such as an atypical volume of data or unusual combinations of fields.

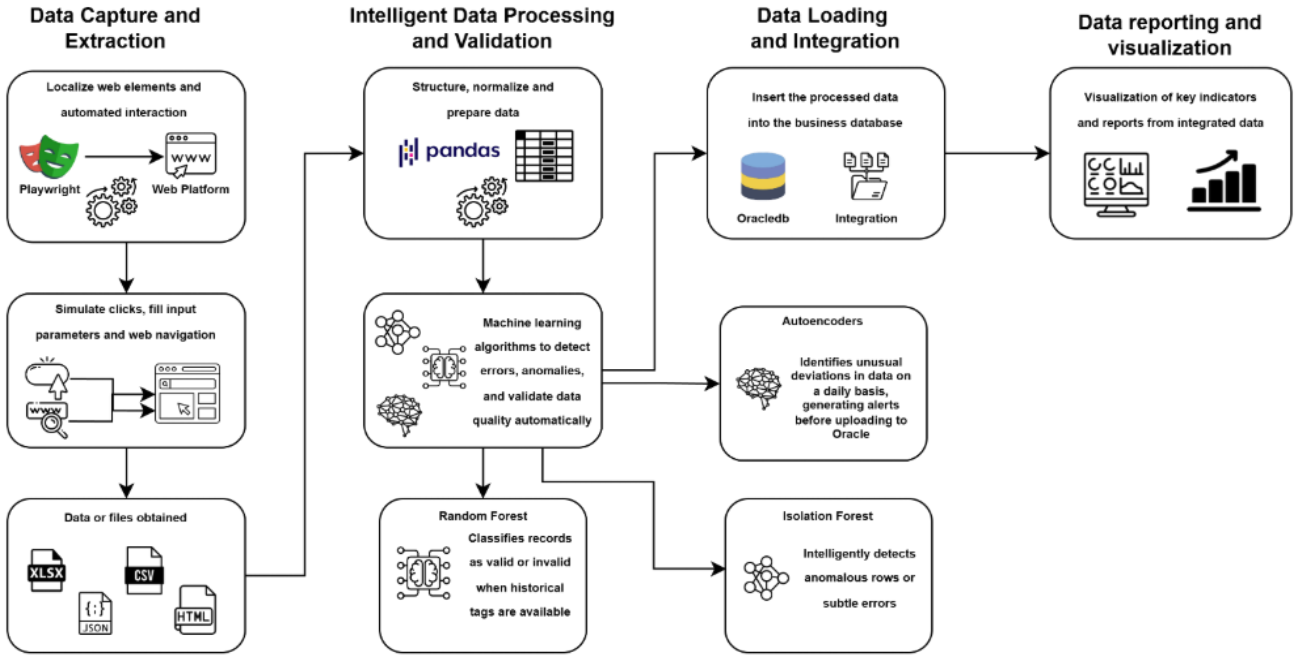

Fig. 5. RPA Scripting model using Machine Learning (ML) algorithms.

C. Data Loading and Integration

At this stage, validated and structured data is prepared for persistence in the corporate storage system. Using the Oracledb client, a secure and efficient connection is established with the Oracle database, where the controlled insertion of the records in the corresponding tables is performed, thus guaranteeing consistency, traceability, and availability of the information for the entire organization.

D. Reporting and Data Visualization

The last stage of the flow focuses on converting the processed data into actionable value. Here, data visualization tools are used (e.g., a Power BI dashboard showing campaign KPIs, anomaly alerts, and performance trends, as shown in Fig. 6) to connect directly to the Oracle database. This stage facilitates strategic analysis by presenting information in a clear, dynamic, and visual way, helping business teams to make decisions based on up-to-date, accurate data previously audited by the automated flow.

Fig. 6. Campaign performance dashboard.

V. Results

To validate the proposed RPA model, its performance was evaluated in two key areas: operational efficiency in reducing execution time compared to manual workflows, and the effectiveness of the integrated Machine Learning algorithms for data validation.

A. Operational Performance Evaluation

First, the baseline reference times for the existing manual processes were established. As detailed in Table I, the manual processing of an average of 8,500 daily records required 3 hours (120 minutes), and the manual loading of 7,400 records required 4 hours (240 minutes).

TABLE I. Daily Operational Benchmark of Manual Flows

Flows	Average daily amount of data records used	Average Manual Execution Times
Data processing	8500 daily records	3 hours
Data loading	7400 daily records	4 hours

Subsequently, the automated workflow was executed for the same tasks. Table II compares the manual versus automated execution times. Data processing was reduced from 120 minutes to 15 minutes, and data loading was reduced from 240 minutes to 40 minutes.

TABLE II. Comparison of Manual and Automated Times

Flow	Estimated time of execution of the manual process	Estimated time of execution of the automated process
Data processing	120 minutes	15 minutes
Data loading	240 minutes	40 minutes

To quantify the efficiency gain, Eq. (1) was used to calculate the percentage of time reduction (RT).

$$RT = \left(1 - \frac{T_{auto}}{T_{manual}}\right) * 100\% \quad (1)$$

where,

$$RT = Time\ reduction$$

$$T_{manual} = Manual\ execution\ time$$

$$T_{auto} = \text{Automated } execution\ time$$

In Eq. (1), the percentage of time reduction achieved by automating an operational process is calculated. It compares the average manual execution time with the automated time. The result indicates how much more efficient the process has become: a high RT value reflects a significant improvement in flow duration, allowing the impact of automation to be quantified in terms of time savings and operational optimization.

Now we apply Eq. (1) to calculate the percentage reduced after applying the automatic solution to both flows in Table I.

- For Data Processing:

$$RT = \left(1 - \frac{15}{120}\right) * 100\%$$

$$RT = 87.5\%$$

The result was that the reduction in time was 87.5%. That is, the 15 minutes represent 12.5% of 120 minutes.

- For Data Loading:

$$RT = \left(1 - \frac{40}{240}\right) * 100\%$$

$$RT = 83.33\%$$

The result showed a reduction in time of 83.33%. This indicates that the execution time has been reduced by that proportion by implementing automation. That is, 40 minutes represent 16.67% of 240 minutes.

B. Intelligent Validation Evaluation

In the second part of the evaluation, the performance of the Machine Learning algorithms (Autoencoder, Isolation Forest, and Random Forest) was measured based on their ability to validate and detect anomalies in the data.

Performance metrics, including Accuracy, Precision, Recall, F1-score, and training time, are presented in Table III.

TABLE III. VALIDATION METRICS FOR AUTOENCODER, ISOLATION FOREST, AND RANDOM FOREST

Algorithm	Accuracy	Precision	Recall	F1-score	Training time (s)
Isolation Forest	0.88	0.87	0.86	0.865	40
Random Forest	0.91	0.9	0.89	0.895	45
Autoencoder	0.92	0.91	0.9	0.905	70

As shown in Table III, the results from Table I were used to compare the performance of three algorithms: Autoencoder, Isolation Forest, and Random Forest. The Autoencoder performed best across all performance metrics (accuracy of 0.92 and F1-score of 0.905), albeit with a longer training time (70 s). The Random Forest showed a good balance between precision (0.90), recall (0.89), and speed (45 s), while the Isolation Forest was the fastest (40 s), but with slightly lower metrics (accuracy of 0.88 and F1-score of 0.865). These results demonstrate that each model exhibits distinct strengths depending on the validation objective.

VI. LIMITATIONS AND FUTURE WORK

This section details the limitations identified during the development of this research, which consequently establish the foundation for future lines of work.

A. Limitations

Although the model demonstrated significant improvements in operational efficiency and data validation accuracy, it is important to acknowledge several limitations:

1) Context-specific data: The model was trained and validated using a specific dataset: daily performance reports of marketing campaigns sent to users of a telecommunications company. The positive results, especially the ML validation metrics in Table III, are tied to this context. The model's applicability and performance in other business domains, such as finance, logistics, or human resources, are not guaranteed and would require separate validation.

2) Requirement for historical data: The model's validation process combines different learning methods. The Random Forest algorithm, which showed strong performance, is a supervised method. This means it requires a history of data already labeled as 'valid' or 'invalid' to be trained. In new implementations where this historical data is not available, the system must depend only on unsupervised methods (Isolation Forest and Autoencoder), which could affect the initial classification accuracy.

3) Error detection nuances: During testing, it was observed that while the Autoencoder was effective at finding structural deviations in daily reports, it sometimes struggled to interpret legitimate seasonal peaks in campaign performance, incorrectly flagging them as anomalies. This indicates a need for future models to better incorporate business seasonality.

4) Maintenance of RPA scripts: The model relies on Playwright for web data extraction. This creates a practical maintenance challenge. The automation scripts depend on web page elements (like CSS IDs) to function. If the source web platforms are updated or change their layout, these scripts can fail and will require manual updates to restore functionality.

B. Future Work

Based on the results obtained and the limitations described, future efforts will focus on improving the model's robustness, adaptability, and traceability:

1) Periodic algorithm retraining: It is recommended to implement a periodic retraining schedule for the Machine Learning algorithms. This is essential to maintain the model's accuracy as data patterns change over time. Updating the

models with recent historical data ensures they remain effective and adaptive.

2) Enhanced traceability: A crucial next step is to implement systematic logging of key process events, such as data download, validation, insertion, and visualization. This practice not only facilitates audits and post-failure analysis but also supports the continuous improvement of the RPA model.

3) Formal version control: Finally, adopting a formal versioning policy for all models and scripts is highlighted as a priority. Maintaining version control for both the ML algorithms and the data extraction scripts allows for safe modifications and provides a mechanism to revert to a previous stable version if a failure occurs, significantly reducing operational risks.

VII. Conclusion

To begin with, the integration of Robotic Process Automation (RPA) Scripting with Machine Learning (ML) techniques offers a significant advantage over traditional automation approaches, which often lack intelligent validation and risk, propagating poor-quality data. The proposed model significantly enhances efficiency and accuracy by combining automated task execution with a multi-stage validation component using Random Forest, Isolation Forest, and Autoencoders. This layered approach provides a more robust defense against anomalies than research relying on a single algorithm. The system is capable of not only processing data autonomously but also identifying diverse types of errors and ensuring the reliability of the information before it reaches the database. This fusion reduces dependency on manual validation and mitigates data quality risks in dynamic, high-volume environments.

Moreover, the utilization of Pandas as the central tool for data manipulation enables a highly flexible and scalable processing layer. Its powerful functions for data cleansing, transformation, and preparation allow for seamless integration with ML models, ensuring that the input data meets quality standards before predictive or classification tasks are executed.

Finally, adopting an end-to-end automated architecture—from web data extraction to visualization—ensures complete traceability and transparency of the data lifecycle. This comprehensive approach empowers decision-makers with accurate and timely insights, presented through dynamic dashboards and reports. By aligning automation, validation, and visualization, the model offers a robust foundation for intelligent data-driven decisions, thereby establishing a sustainable and forward-looking solution for organizations aiming to scale their data operations efficiently.

How did the Intelligent Search Engine Become Popular Among Chinese Residents Since the Emergence of Deepseek?

Zhixuan Wang[1]*, Yuying Song[2], Hanyu Guo[3]
State Key Laboratory of Media Convergence and Communication, Communication University of China, Beijing 100024, China [1]
School of Journalism, Communication University of China, Beijing 100024, China [2, 3]

***Abstract*—This study, based on the Technology Acceptance Model (TAM) and the Theory of Planned Behavior (TPB), combined with the Stimulus-Organism-Response (SOR) theoretical framework, explores the influencing factors and promotion mechanisms for the popularization of "Deepseek" intelligent search engines in China. Through a questionnaire survey, 343 valid samples were collected, and the structural equation model (SEM) was used for data analysis, verifying 8 out of 10 research hypotheses. Perceived usefulness (PU) and perceived ease of use (PEOU) significantly and positively influence the intention to use, indicating that users' cognition of the functional value and operational convenience of AI search engines is a key driving factor. Subjective norms (SN) directly promote the intention to use but do not indirectly affect it through perceived usefulness, suggesting that the influence of the social environment stems more from irrational paths (such as group atmosphere infection). Perceived behavioral control indirectly enhances the intention to use by improving perceived ease of use and usefulness, highlighting the importance of users' own abilities and device support. Perceived playfulness only indirectly affects the intention to use through perceived usefulness and has no significant effect on ease of use, possibly because the entertainment function increases operational complexity. Technological facilitation has a significant positive impact on both perceived usefulness and ease of use, indicating that the optimization of technical performance (such as interaction efficiency and powerful functions) is the core for enhancing user experience.**

***Keywords*—AI search engine; Deepseek; SOR; Technology Acceptance Model; Theory of Planned Behavior**

I. Introduction

In today's society, where digitalization and mobility are highly integrated, AI search engines, as an intelligent tool of information retrieval, are changing the way people acquire knowledge and information at an unprecedented speed. Their unique features, such as semantic understanding, personalized recommendations, and intelligent interaction, not only enhance the efficiency and accuracy of information retrieval but also provide users with a highly personalized experience. Notably, AI search engines have transcended traditional PC usage scenarios and have achieved widespread adoption through various mobile applications and services, becoming an indispensable tool for information acquisition in daily life and work. As shown in the research by Kaiser et al. [1], generative AI search engines exhibit significantly different user preferences and interaction patterns compared to traditional search engines during practical search tasks, and this technological innovation is reshaping the behavioral paradigm of information retrieval.

However, the users' acceptance behavior towards AI search engines is a complex decision-making process influenced by multiple factors. Relying solely on one single theoretical model to analyze users' acceptance behavior may not fully reveal its underlying influencing mechanisms. Combining the Technology Acceptance Model (TAM) with the Theory of Planned Behavior (TPB) can provide a more comprehensive and in-depth analytical framework for this research. The TAM has theoretical advantages in deconstructing individual technology cognition, while the TPB effectively supplements the explanatory dimensions of social psychological factors [2, 3]. The integration of the two models has become a trend in technology acceptance research in recent years.

The TAM focuses on two key dimensions in the technology acceptance process—perceived usefulness (PU) and perceived ease of use (PEOU). PU reflects users' beliefs about whether the AI search engine can effectively enhance information retrieval efficiency, helping them obtain the information more quickly and accurately. PEOU concerns the ease of operation during the usage process, involving technological designs such as interface friendliness and interaction smoothness. These two factors play an important role in users' initial attitudes and willingness to use [4, 5]. Actually, users' acceptance behavior is often influenced by factors beyond personal cognition, and the single TAM has certain limitations in explaining users' social psychological processes.

TPB explains user behavior from a broader perspective. TPB concerns that behavioral intention is a factor that directly leads to actual behavior, and that behavioral intention is influenced by attitude, subjective norms, and perceived behavioral control. Subjective norms reflect the perceived social or group pressures or expectations, such as the attitudes and behaviors demonstrated by family, friends, colleagues, and professional circles towards using AI search engines. Perceived behavioral control refers to an individual's assessment of their ability to execute the behavior, including aspects such as technical operation skills, relevant knowledge reserves, and resource availability. The introduction of subjective norms and perceived behavioral control can effectively compensate for the traditional Technology Acceptance Model's neglect of social contextual factors [6]. Incorporating TPB into AI search engine

*Corresponding author.

research can more comprehensively reveal the social psychological factors influencing user acceptance behavior, supplementing the TAM's shortcomings in explaining psychological factors such as social norms and self-efficacy [7, 8].

Reviewing previous user studies on intelligent search engines, we find that researchers generally combine the TAM and SOR models for research, but seldom consider the Theory of Planned Behavior. Considering the collectivist cultural atmosphere advocated in Chinese society, Chinese users may use intelligent search engines as "Deepseek" for the reason of following the social trend. The influence of social norms is a factor worth considering when we conduct research on the use of intelligent search engines by Chinese users. Therefore, we have introduced the relevant variables of the Theory of Planned Behavior into the model.

A comprehensive understanding of the internal mechanisms of user acceptance behavior is of crucial strategic significance for developers and promoters of AI search engines. Utilizing a combined theoretical framework of TAM and TPB for research can provide clear and systematic guidance for product optimization and market promotion. This research path not only has theoretical innovation value but also offers actionable, practical guidance for the actual implementation of AI technology.

II. Literature and Hypothesis

In the digital age, the rapid development of artificial intelligence (AI) technology has profoundly changed the way people access information. As one of the important applications of AI technology, the willingness to use AI search engines is influenced by various factors. This study aims to systematically identify the key factors affecting the willingness to use AI search engines by integrating the Technology Acceptance Model (TAM) and the Theory of Planned Behavior (TPB) within the Stimulus-Organism-Response (SOR) theoretical framework.

A. Theoretical Foundation and Research Framework

Define abbreviations and acronyms the first time they are used in the text, even after they have already been defined in the abstract. Abbreviations such as IEEE, SI, ac, and dc do not have to be defined. Abbreviations that incorporate periods should not have spaces: write "C.N.R.S." not "C.N.R.S." Do not use abbreviations in the title unless they are unavoidable (for example, "IEEE" in the title of this study).

1) Core perspective of TAM: TAM, proposed by Davis [9], provides a foundational framework for understanding users' acceptance behaviors towards information technology. This model posits that PU and PEOU are the two core variables determining the extent of user acceptance of a system. Specifically, PU refers to the degree to which a user believes that using a particular system can enhance their work efficiency, while PEOU reflects the extent to which the user perceives the system as easy to use [4]. These two beliefs together form the user's attitude towards using the system, which in turn influences their behavioral intentions and actual usage behavior [10-13].

2) Extended perspective of TPB: TPB, proposed by Ajzen, serves as an extension of the Theory of Reasoned Action and holds significant importance in explaining the mechanism of individual behaviors [6, 14]. TPB posits that behavioral intention is the most direct factor influencing individual behavior, and that behavioral intention itself is a result of the combined effects of attitude, subjective norms, and perceived behavioral control. Subjective Norms (SN) refer to the social pressure perceived by an individual to perform a certain behavior, reflecting the individual's cognition of the expectations of significant others regarding compliance with that behavior. Perceived Behavioral Control (PBC) indicates "the extent to which people perceive they have the ability or control to perform a given behavior", representing the individual's perception of their capability to execute that behavior [15, 16].

3) SOR theoretical framework: The SOR model was proposed by Mehrabian based on the "stimulus-response" framework, where S represents the stimulus, O represents the cognitive organism, and R represents the response made by the subject after receiving the stimulus, following certain internal activities [17-20]. The SOR model is widely applied in fields such as marketing, consumer behavior, and information systems user behavior. It is extensively used to study how individuals perceive environmental stimuli and their behavioral responses, providing a research basis for exploring the mechanisms of individual or group behavior formation. Therefore, it is appropriate to study the willingness of Chinese residents to use AI search engines based on the SOR theoretical framework.

B. Theoretical Integration and the Proposal of Research Hypotheses

Under the SOR theoretical framework, the combination of TAM and TPB provides a more comprehensive theoretical perspective for a deeper understanding of the willingness to use AI search engines [21-23]. This study integrates these two major theories and incorporates emerging variables such as perceived playfulness and technological facilitation, proposing ten research hypotheses aimed at systematically exploring the impact pathways of various factors on the willingness to use AI search engines.

PU and PEOU, as core variables of TAM, have been confirmed in numerous studies to have a critical impact on the willingness to use technology. Davis [9] emphasized that these two key beliefs are the main factors determining users' acceptance of information systems. After Davis' research, the impact of both PU and PEOU was demonstrated [24-26]. Rahman et al. [27] found that PU and PEOU are crucial for fostering a positive attitude towards AI technology when examining students' intentions to use ChatGPT, directly supporting the core tenets of TAM. In specific application scenarios of AI products, these conclusions have been further validated. Ahn and Chen [28] discovered that familiarity with or experience using AI applications positively influences government employees' willingness to use AI, largely achieved

by enhancing users' PEOU. Based on the above research, this study proposes the following hypotheses:

H1: Perceived usefulness has a significant positive impact on the willingness to use AI search engines.

H2: Perceived ease of use has a significant positive impact on the willingness to use AI search engines.

Subjective Norms (SN), as one of the core variables of TPB, reflect the social pressure individuals perceive from significant others. SN can be viewed as "the social pressure perceived to perform a behavior", where behavioral intention is the result of the combined effects of attitude, subjective norms, and perceived behavioral control [29-31]. From this perspective, SN represents the extent to which individuals recognize the expectations of significant others, such as family and friends, to engage in certain behaviors. Ham et al. [32] found that SN are closely related to individuals' perceptions of social pressure from significant others when studying intentions to purchase green food, with the strength of motivation to comply with these views directly affecting behavioral intentions.

In the field of technology acceptance, the role of SN has also been validated. Hansstein & Echegaray [33] found that young adults in urban China who believe that their parents and friends would approve of certain behaviors reported higher behavioral intentions regarding the use of pollution masks. Morris & Liu [34] further pointed out that SN could influence individuals' acceptance of new technologies through psychological effects. Based on the above research evidence, this study proposes the following hypotheses:

H3: Subjective norms have a significant positive impact on the willingness to use AI search engines.

H4: Subjective norms have a significant positive impact on the perceived usefulness of AI search engines.

Perceived Behavioral Control (PBC) in TPB is considered to moderate the effects of attitude and subjective norms on intention. The theoretical origins of the concept of perceived control can be traced back to Rotter's [35] research on internal versus external locus of control, while Bandura's [15] self-efficacy theory further elaborated on the important role of individuals' beliefs in their capabilities in behavioral regulation. Yzer [16] explicitly pointed out that PBC is conceptually similar to self-efficacy, defined as "the recognition of a person's ability to organize and execute a specific type of performance.

In research on AI technology acceptance, the role of perceived behavioral control has also been empirically supported [36-39]. Hong [40] found that PBC affects individuals' willingness to adopt AI technology. Ajzen [14] emphasized that positive attitudes and supportive subjective norms lead to positive behavioral intentions only when individuals believe they have the ability to perform the discussed behavior. Based on these researches, this study proposes the following hypotheses:

H5: Perceived behavioral control has a significant positive impact on the perceived ease of use of AI search engines.

H6: Perceived behavioral control has a significant positive impact on the perceived usefulness of AI search engines.

With the development of technology, Perceived Playfulness (PP) has gradually gained attention as an emerging variable in technology acceptance research [41-43]. Lin et al. [44] found that PP significantly influences users' attitudes in their study of the Nintendo Switch, indicating that the enjoyment derived from participation can enhance PU. This study extends TAM by incorporating variables such as PP, providing a new perspective for understanding user interaction with technology. In the application scenarios of AI tools, the role of PP is also noteworthy. By expanding TAM with variables like PP, related research has further refined the understanding of students' use of AI tools like ChatGPT in educational settings, ultimately finding that PP has a significant positive impact on both PU and PEOU [45]. This integration offers a more nuanced perspective on technology adoption, highlighting the multifaceted nature of user interaction with AI. Based on this, this study proposes the following hypotheses:

H7: Perceived playfulness of AI search engines has a significant positive impact on perceived ease of use.

H8: Perceived playfulness of AI search engines has a significant positive impact on perceived usefulness.

Based on information ecology theory, Technological Facilitation (TF), as an important contextual factor, holds unique theoretical value in technology acceptance research. The concept of "technological facilitation" proposed by Guo & Zhang [46] emphasizes the significant impact of the technological context on users' information needs. They argue that the technological context includes aspects such as system performance, visual effects, ease of use, perceived user risk, and device context, which together constitute the external environment affecting users' technology acceptance behavior. This has been confirmed in subsequent research, indicating that TF reflects the extent to which technological systems provide support and convenience to users. Studies have shown that the technological context positively correlates with users' information needs, and the differentiated personalized services provided by technology are positively correlated with users' perceived benefits of personal information disclosure [47]. This suggests that good TF can promote technology acceptance by enhancing users' PU and ease of use. Based on this, this study proposes the following hypotheses:

H9: Technological facilitation has a significant positive impact on the perceived ease of use of AI search engines.

H10: Technological facilitation has a significant positive impact on the perceived usefulness of AI search engines.

Based on the above theoretical analysis and hypothesis derivation, this study constructs a research model integrating TAM and TPB within the SOR theoretical framework (see Fig. 1). This model takes the willingness to use AI search engines as the dependent variable, with subjective norms, PEOU, and PU as core independent variables, while also examining the impact pathways of perceived behavioral control, perceived playfulness, and technological facilitation. The model clearly illustrates the causal relationships among the variables, providing a comprehensive theoretical framework for understanding the willingness to use AI search engines.

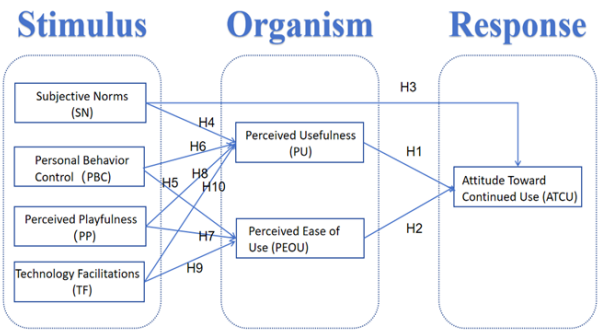

Fig. 1. Research model.

III. Methods

A. Questionnaire Design

Based on the theoretical model developed in this study, seven latent variables were identified. To ensure the reliability and validity of the questionnaire, measurement items were primarily derived from well-established scales and appropriately modified to reflect the characteristics of AI search engine usage intention and behavior. The measurement scales and their associated items for each construct are detailed in Table I.

This study employs a survey questionnaire method to investigate internet users' willingness to use AI search engines. The survey questionnaire consists of two sections. The first section collected demographic information and presented contextual details, including gender, age, educational level, occupation, and average monthly and which AI search engines users have used. The second section measured the latent variables specified in the research model including seven measurement constructs. All items are rated on a Likert 5-point scale. Each variable consists of a set of statements, with response options ranging from "Strongly Agree" to "Strongly Disagree", corresponding to scores of 5 to 1. Since the target population of this study is Chinese residents, the questionnaire was administered in Chinese. Specifically, key constructs (TF, PU, PEOU, and ATCU) adopted Chinese scales developed by domestic scholars.

TABLE I. Measurement Constructs

Construct	Items	Source
Subjective Norms (SN)	SN1: Friends/family often discuss AI search engine.	Lam and Hsu [48] Hsieh et al. [49] Wang et al. [50] Zhao & Liu [51]
	SN2: Friends/family enjoy AI search engine.	
	SN3: Friends/family recommend AI search engine to me.	
	SN4: Friends/family believe I should use AI search engine.	
	SN5: Friends/family support my use of AI search engines.	
Perceived Behavioral Control (PBC)	PBC1: I have the ability to use AI search engines to obtain the information I need.	
	PBC2: My device supports the use of AI search engines for information retrieval.	
	PBC3: If I want to, I can use AI search engines at any time.	
Perceived Playfulness (PP)	PP1: Using AI search engines is enjoyable to me.	Liu & Hsu [52]
	PP2: Using AI search engines stimulates my curiosity.	
	PP3: Using AI search engines makes me happy when I need them.	
Technology Facilitation (TF)	TF1: The features provided by AI search engines make me more willing to interact with them.	Pang et al. [53]
	TF2: The efficiency provided by AI search engines makes me willing to interact with them.	
	TF3: I think the technology behind AI search engines is powerful, and I am willing to use them to solve problems.	
Perceived Usefulness (PU)	PU1: The information retrieved through the AI search engine is helpful to me.	Venkatesh [54] Wang et al. [55] Davis [9] Pang et al. [53]
	PU2: The information retrieved through the AI search engine helps me solve problems.	
	PU3: The information retrieved through the AI search engine contributes to my knowledge acquisition.	
	PU4: The information retrieved through the AI search engine enable me to obtain the information I need.	
Perceived Ease of Use (PEOU)	PEOU1: It is easy to retrieve information using an AI search engine.	Pang et al. [53]
	PEOU2: The information retrieved through AI search engines is easy for me to understand.	
	PEOU3: Accessing and using the information retrieved from AI search engines feels effortless to me.	
Attitude Toward Continued Use (ATCU)	ATT1: I intend to use AI search engines frequently in the future.	Zhang & Zhang [56]
	ATT2: If given the opportunity, I would recommend AI search engines to others.	
	ATT3: Overall, I am willing to continue using AI search engines.	

For the remaining constructs, we adapted established English scales, translated them into Chinese, and administered the questionnaires accordingly.

B. Data Collection and Processing

This study utilized the "Question Star" platform, a professional survey platform in China, for questionnaire design and distribution. Prior to the formal distribution of the questionnaire, the research team conducted a small-scale pilot survey with ten randomly selected participants to test the logical structure and clarity of the questionnaire. Based on the preliminary survey results, necessary modifications and optimizations were made to items that were ambiguous or difficult to understand, ensuring the comprehensibility and measurement validity of the questionnaire content.

During the formal survey phase, the questionnaire was distributed through various social media platforms such as WeChat, Xiaohongshu, and Douban. A snowball sampling method was employed to enhance sample diversity and representativeness, with the aim of covering a broad spectrum of AI search engine users. A total of 501 questionnaires were collected during the survey period. To ensure the validity and analytical rigor of the collected data, rigorous data screening was conducted. Questionnaires from respondents who had not used AI search engines and invalid questionnaires with short response time were excluded, resulting in a final sample of 339 respondents, with a validity rate of 68.5%.

C. Data Analysis

1) Sample characteristics: Descriptive statistics on users' basic information are presented in Table II. The largest age group among the respondents, accounting for 61.0% of the total, was between 18 and 25 years old. This reflects the recent trend that AI applications are predominantly adopted by younger internet users. Approximately 80% of respondents held a bachelor's degree or higher. In terms of frequently used AI search engines, participants showed a clear preference for locally developed Chinese AI search engines, including Tencent Yuanbao, Deepseek, and Doubao. In comparison, platforms developed outside China, such as ChatGPT, were used less frequently. On average, respondents had used 2-3 types of AI search engines.

TABLE II. RESPONDENT PROFILE CHARACTERISTICS

Characteristics	Items	Number	Percentage (%)
Gender	Male	89	25.9
	Female	254	74.1
Age	Under 18	45	13.1
	18-25	217	63.3%
	26-35	15	4.4%
	36-45	29	8.5%
	46 or above	37	10.8%
Education	High school or below	44	12.8%
	Associate degree	15	4.4%
	Bachelor's degree	250	72.9%
	Master's degree or above	34	9.9%
Frequently used AI search engines	Deepseek	277	80.8%
	Doubao	251	73.2%
	Tencent Yuanbao	41	12.0%
	ERNIE Bo	67	19.5%
	Qwen	10	2.9%
	ChatGPT	33	9.6%
	Other	10	2.9%

TABLE III. RESULTS OF THE RELIABILITY AND VALIDITY ANALYSIS

Construct	Item	Factor loading	Cronbach's alpha	Composite reliability (CR)	Average variance extracted (AVE)
Subjective Norms (SN)	SN1	0.832	0.940	0.940	0.758
	SN2	0.847			
	SN3	0.859			
	SN4	0.906			
	SN5	0.907			
Perceived Behavioral Control (PBC)	PBC1	0.883	0.923	0.923	0.799
	PBC2	0.910			
	PBC3	0.889			
Perceived Playfulness (PP)	PP1	0.939	0.927	0.929	0.815
	PP2	0.910			
	PP3	0.857			
Technology Facilitation (TF)	TF1	0.905	0.936	0.933	0.824
	TF2	0.910			
	TF3	0.908			
Perceived Usefulness (PU)	PU1	0.920	0.949	0.948	0.821
	PU2	0.916			
	PU3	0.889			
	PU4	0.889			
Perceived Ease of Use (PEOU)	PEOU 1	0.880	0.924	0.923	0.799
	PEOU 2	0.888			
	PEOU 3	0.914			
Attitude Toward Continued Use (ATCU)	ATCU 1	0.911	0.943	0.942	0.844
	ATCU 2	0.906			
	ATCU 3	0.938			

2) Reliability and validity analysis: This study used SPSS 26.0 to test the reliability and validity of the measurement scale. The overall Cronbach's alpha coefficient is 0.980, well above the commonly accepted threshold of 0.9, indicating that the

scale has good internal consistency and a high level of reliability. As per the data in Table III, all variables achieved Cronbach's alpha coefficients greater than 0.9. The Cronbach's Alpha coefficients and composite reliability (CR) values for each variable are all greater than 0.9, further confirming the good reliability of the measurement scales.

In the confirmatory factor analysis (CFA), the factor loadings for each item were greater than 0.8, indicating the scale has good construct validity. For the vast majority of constructs, the square root of the Average Variance Extracted (AVE) exceeds the correlation coefficients between that construct and others (see Table IV). This shows a clear level of discriminant validity and demonstrates that each construct captures a distinct theoretical dimension and is not confounded with unrelated variables. Although one correlation coefficient slightly exceeds the corresponding AVE, this is considered acceptable according to the research results of Hair et al. [57]. Furthermore, the AVE for each construct is greater than 0.7, indicating strong convergent validity of the scale.

TABLE IV. RESULTS OF THE DISCRIMINANT VALIDITY ANALYSIS

	PP	TF	PBC	SN	PU	PEOU	ATCU
PP	0.903						
TF	0.901	0.908					
PBC	0.767	0.804	0.894				
SN	0.672	0.732	0.738	0.871			
PU	0.872	0.922	0.784	0.676	0.906		
PEOU	0.816	0.887	0.816	0.693	0.832	0.894	
ATCU	0.789	0.847	0.767	0.732	0.846	0.845	0.918

3) Structural model: This study uses AMOS 26.0 software, based on the hypotheses and conceptual model presented earlier, and adopts the maximum likelihood method to conduct structural equation model analysis. The model fitting results are shown in Fig. 2.

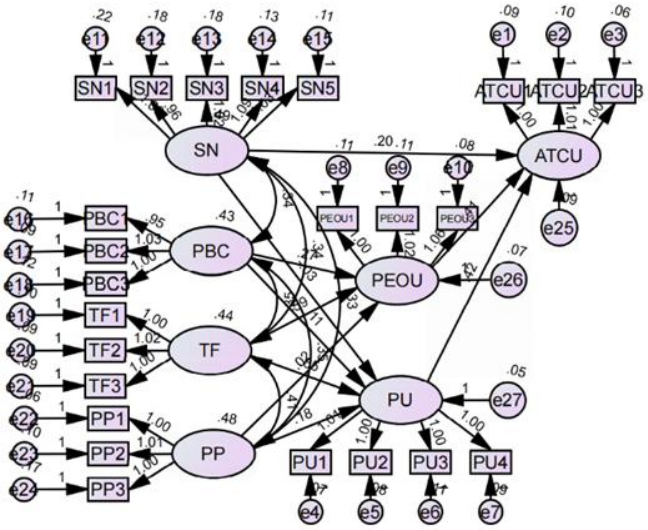

Fig. 2. Structural modeling result.

According to the criteria for good data and model fit provided by Hair et al.'s research [57]. As shown in Table V, all indicators except the GFI value, which is slightly less than 0.9, are above the standard. Considering the complexity of the model in this study, and referring to the research by Yuan and Bentler [58], a GFI slightly less than 0.9 is also acceptable. Therefore, the overall fit of the research model is good.

TABLE V. STRUCTURAL MODEL FIT INDICES

Indices	CMID/DF	GFI	CFI	RMR	RMSE
Value	2.591	0.871	0.962	0.015	0.068
Standard	<3	>0.9	>0.9	<0.08	<0.08

IV. RESULTS

The path standardized coefficients in the structural equation model reflect the significance of the relationship between variables. In this study, the significance is tested by the ratio of the parameter estimate to the standard error (C.R.) and the P value. When the absolute value of C.R. is greater than or equal to 1.96, it can be concluded that there is a significant difference at the significance level of 0.05.

According to the data analysis results of the structural equation model in Table VI, except for H4 and H7, the other eight hypotheses have received varying degrees of support. The influence of subjective norms on the intention to use verifies the theory of planned behavior to a certain extent, indicating that the use, recommendation, and demonstration of AI search engines by people around have an important impact on an individual's intention to use. Especially after Deepseek was launched in China, AI search engines began to be widely popularized, significantly lowering the threshold for using AI search engines. The opinions and attitudes of people around play an important role in an individual's attempt to use new technologies such as intelligent search engines.

From the perspective of the Technology Acceptance Model, perceived ease of use and perceived usefulness remain important influencing factors and paths for the acceptance of new technologies. The results of the hypothesis test show that both perceived ease of use and perceived usefulness have a significant impact on the intention to use intelligent search engines. Moreover, perceived enjoyment, technology facilitation, and perceived behavioral control are also important antecedent variables in the Technology Acceptance Model.

Perceived playfulness has a significant impact on perceived usefulness. From the perspective of technological affordance, the functions provided by intelligent search engines, such as image generation and creative copywriting generation, enhance the enjoyment of using intelligent search engines. Using intelligent search engines has even become a form of entertainment. However, at the same time, the richness and complexity of these enjoyable functions objectively increase the threshold for using intelligent search engines and do not significantly contribute to the improvement of perceived ease of use.

For H4, subjective norm has no significant impact on perceived usefulness. Considering the supported result of H3, the reason might be that people are indeed influenced by those

around them and the environment when using AI search engines, but the mechanism of influence does not operate through a rational path. With the development of the Technology Acceptance Model, researchers have found that the influencing factors of the mechanism are no longer limited to rational and cognitive aspects; emotional and affective factors have also gradually gained attention [59]. Therefore, we believe that the interpersonal environment and social atmosphere do indeed make Chinese residents start to use AI search engines out of subconscious motives such as conformity and imitation, but this external influence does not make them clearly recognize the functions and values of intelligent search engines.

For H7, the interesting functions provided by AI search engines may not significantly enhance the ease of use of AI search engines. This indicates that although AI search engines objectively possess some interesting attributes that can be developed, these interesting attributes, although objectively enhancing users' perception of the functions and values of intelligent search engines, do not significantly improve the convenience of using AI search engines.

TABLE VI. RESULTS OF HYPOTHESIS TESTING

Hypothesis	Path	Estimate	S.E.	C.R.	Test results
H1	PEOU->ACTU	.407	.072	5.672	Supported
H2	PU->ACTU	.424	.067	6.329	Supported
H3	SN->ACTU	.198	.043	4.588	Supported
H4	SN->PU	-.035	.040	-.856	Not supported
H5	PBC->PEOU	.270	.055	4.881	Supported
H6	PBC->PU	.107	.053	2.030	Supported
H7	PP->PEOU	.021	.078	.272	Not supported
H8	PP->PU	.179	.071	2.539	Supported
H9	TF->PEOU	.592	.093	6.381	Supported
H10	TF->PU	.652	.087	7.461	Supported

V. DISCUSSION

Based on the model's measurement results, we propose three strategic recommendations for promoting intelligent search engines represented by Deepseek in China: lowering usage barriers, enhancing entertainment attributes, and emphasizing the influence of social norm factors.

First, lowering the threshold for usage can significantly enhance users' perceived behavioral control. When users feel that they possess sufficient ability to operate AI technology, they tend to exhibit a stronger intention to adopt them. Suryadi et al. [60] argued that improving users' understanding of how AI systems can reduce usage-related anxiety, thereby strengthening their sense of control and willingness to engage with the technology. Our findings further suggest that providing clear tutorials and transparent interface cues can effectively lower perceived complexity and strengthen adoption intentions.

Secondly, enhancing the entertainment attributes of AI systems directly impacts users' behavioral attitudes. Incorporating elements of playfulness and affective interaction can stimulate positive emotional responses and improve overall user experiences. Gaur et al. [61] showed that gamification in AI systems can increase perceived enjoyment and shape users' performance and effort expectancy, thereby strengthening their intention to use the technology. Accordingly, designing AI search interfaces with interactive features, personalized humorous responses, or playful task mechanisms can not only enhance users' enjoyment but also strengthen their positive attitudes toward the system. For example, offering rewarded optional mini-tasks or gamified character settings in the AI interactive interface can make users continue participating.

Finally, social norms play a crucial socio-psychological role in the adoption of AI search technologies. Zhang et al. [62] pointed out that social influence factors can promote group cohesion and enhance users' intention to adopt AI products. Therefore, leveraging social media, expert endorsements, and community interactions associated with the use of AI search engines with socially approved behavior can further enhance users' willingness to use. For example, platforms may highlight expert-recommended search practices or showcase community challenges that reward proficient AI search engine usage, thereby reinforcing the perception that adopting AI search is both normative and desirable.

Regarding research methodology, this study employs structural equation modelling, which effectively measures correlations between latent variables to elucidate the operational mechanisms of various influencing factors. Moreover, this study selects limited variables and cannot cover all potential influencing factors. Also, the structural equation model method does not have causal explanatory power, although it has explored the mechanisms influencing the intention to use. In future research, on the basis of improving the representativeness and typicality of the data, it is necessary to further explore potentially important influencing factors and adopt methods such as experimental methods, instrumental variable methods, and regression discontinuity design to seek causal explanations.

VI. CONCLUSION

Based on the Technology Acceptance Model, this study selects perceived ease of use and perceived usefulness as mediating variables. From the perspective of the Theory of Planned Behavior and technological affordance, subjective norms, perceived behavioral control, perceived playfulness, and technological facilitation are selected as antecedent variables. This study systematically explores the factors influencing the intention to use intelligent search engines and their mechanisms after their wide popularity in China.

The research finds that among Chinese users of intelligent search engines, perceived behavioral control can influence the intention to use through perceived usefulness and perceived ease of use, indicating that users' own ability to use intelligent search engines and objective conditions support are important factors affecting the intention to use. In the promotion of intelligent search engines like Deepseek, it is necessary to cultivate users' relevant knowledge and further lower the usage threshold.

Perceived enjoyment and technological facilitation can significantly influence perceived usefulness. This indicates that the entertainment attributes (such as media content generation, prediction and divination, etc.) and technological improvements (such as multi-round dialogue, natural language, intelligent interaction, etc.) brought by intelligent search engines play an important role in their promotion. Moreover, technological facilitation can significantly influence perceived ease of use, suggesting that, on the whole, the functional expansion of intelligent search engines compared to traditional search engines provides users with a more convenient usage experience.

At the same time, subjective norms can directly influence the intention to use intelligent search engines, indicating that in the popularization process of intelligent search engines in China, group behavior patterns and collective cultural atmosphere have a significant impact on individual usage. Interpersonal relationships and social atmosphere play an important role in the promotion of intelligent search engines.

Software Project Effort Estimation Using Formal Method and Model Checker

Abdulaziz Alhumam
Dept. of Computer Science-College of Computer Science and Information Technology, King Faisal University, Saudi Arabia

***Abstract*—Software project effort estimation is a critical component of software development, as it determines the time and financial resources required to complete a project. Existing estimation techniques—ranging from empirical models and algorithmic methods to heuristic and expert-based approaches—struggle with inconsistent accuracy due to the inherent complexity, subjectivity, and contextual variability across software projects. Although earlier formal methods aimed to reduce confusion by being very precise, they usually don't allow for automated logical analysis or check if the assumptions used for estimation are consistent with one another. To address these limitations, this study introduces a novel formal modeling framework that integrates Z-Specification with the Z3 SMT solver to both formalize and computationally verify effort estimation models. The use of Z notation guarantees the meaning is precise and unambiguous. Furthermore, SMT (Satisfiability Modulo Theories) reasoning adds powerful new abilities that older methods lacked. These new capabilities include automatically finding constraint violations, confirming how parameters depend on one another, and determining feasible estimation ranges under clearly defined conditions. This integration not only reduces ambiguity but also provides a verifiable, machine-checkable basis for evaluating, refining, and comparing diverse effort estimation methods, thereby offering a more robust foundation than traditional or solely formalized models.**

***Keywords*—Software effort estimation; cost estimation; formal methods; SMT Solver; automated verification; Z-specifications**

I. Introduction

One of the crucial concerns for a Software house or company is to deliver the software product to its client or end-users within the agreed-upon timeframe. The software delivered must meet the requirements and satisfy all the quality parameters while remaining within financial budget constraints. Therefore, accurate assessments of the Software Project Effort estimation serve as key factors that may also guide the achievement of important goals. In other words, it is incredibly important to understand and manage the cost through accurate estimation for proper management, improved quality, and enhanced comprehension of the software project. Estimating software costs is an ongoing process that begins at the planning stage and continues throughout the entire duration of a project. Ongoing cost estimation is necessary to ensure that expenditures align with the budget. In the last few decades, many models have been proposed and developed to calculate the software costs. These models are based on various parameters, one of them is based on the use of information from previous projects to assess the current project cost. The other method is to develop essential formulas by analyzing the specific database available. Many of the proposed cost models depend on size measurements, like lines of code (LoC) and Function Points. Precisely determining the size rightly impacts the exactness of cost estimation. However, none of the previously mentioned methods yield an accurate estimation [1].

The widely used Effort estimation models, such as COCOMO and Function Point Analysis, suffer from subjectivity, data-dependency, and a lack of formal verification [2]. Various Formal methods (FM) are proposed, which provide a robust mathematical foundation model and verify system components, and one of the FM is Z [3]. The current study introduces a novel formal framework for software effort estimation that integrates the semantic clarity of Z notation with the automated reasoning capabilities of an SMT solver.

This Z-based formalization ensures semantic clarity, while SMT-backed reasoning introduces capabilities not available in earlier approaches—such as automated detection of constraint violations, verification of parameter dependencies, and exploration of feasible estimation ranges under formally defined conditions. We hypothesize that this rigorous, formally verifiable approach will yield a measurable improvement in estimation accuracy and consistency compared to existing empirical models. We formalized the estimation process, defined its components rigorously, and verified relationships using Z-Schema constructs, then applied the schemas to the Z3 SMT Solver [4] to estimate the software project effort. The results of this validation, presented in Section VII, demonstrate the framework's ability to provide more accurate and transparent estimation ranges.

II. Related Work

In today's software industry, the most important thing for any company is to deliver a project successfully and on time. From a management point of view, predicting efforts is a challenging task. According to the report, 65 to 80 % of projects have delays in their delivery dates. The higher the effort, the higher the cost. Therefore, precise prediction is essential. There are many models for estimating software development effort and costs. COCOMO (Constructive Cost Model) [5] is the most used model. Machine learning methods are more apt for software effort prediction since they can modify more easily. Machine learning can manage the variations better that are used to measure the effort needed to develop software, which depends on many factors — including the size of the problem, the experience of the users or developers, and other comparable inputs.

The effort estimation typically involves input of the project size based on the lines of code (LoC) or Functional points,

complexity levels, risk factors, and historical productivity data. These inputs are often combined using empirical models but are rarely subjected to rigorous formal analysis.

Formal Methods approach is used for writing formal description, analysis, and for the purpose of producing refinements [6]. A formal specification description is abstract, precise and, in a way, comprehensive. Precision drives ambiguities to be questioned and eliminated, the abstraction makes it possible for a human reader to grasp the larger picture, and the completeness ensures that every facet of behavior is described. Second, a thorough analysis can be conducted because of the description's formality. One can ascertain practical characteristics like deadlock-freedom or consistency by examining a single description [7]. Important characteristics like meeting high-level requirements or the accuracy of a suggested design can be ascertained by writing several descriptions from various angles [7]. Formal methods have been studied in the computing community since at least the 1960s, with seminal work by Floyd [9], Hoare [9], and Dijkstra [10] defining techniques for proving programs correct.

One of the model-based notations, which is a strongly typed mathematical specification language, is Z notation, which is not an executable notation that can be interpreted or compiled into running programs. Z-Specification Language provides: Schema-based notation, State and operation modeling, and support for invariants and preconditions. There are special tools for testing Z texts, which are like a mathematical description for software systems, and these tools look for two types of errors. This includes syntax errors like grammatical mistakes, checking if the Z test is written using the correct rules and symbols to be followed for Z notation, and type errors are being used consistently and correctly. These are similar to how a compiler checks the regular computer code before it can run. The characteristic that sets Z apart from other formal notations is the schema, which is used in Z to characterize a system's dynamic and static elements. The Z standard makes it possible to create a clear, verifiable, and traceable model. Z has an ISO standard and is further developed [11].

III. METHODOLOGY

This research study proposes and explores a framework for robust software effort estimation, leveraging an integrated model encompassing key variables, verification schemas, and equation schemas. The framework explicitly defines interdependencies between critical factors such as Effort, Complexity, Productivity, Risk, and Size. It introduces dedicated "Verification Schemas" for validating initial estimations of Effort and Complexity, and "Equation Schemas" that detail the computational relationships for deriving Productivity, Effort, and Complexity. By emphasizing both calculation and explicit validation of estimates, this work aims to enhance the accuracy, reliability, and transparency of software project predictions, addressing the usual challenges in traditional estimation methodologies. Fig. 1 represents a framework for a robust software effort estimation model related to cost, effort, and complexity estimation, for calculating and verifying project metrics, based on initial factor size and risk.

Fig. 2 represents a conceptual model or dependency, which is structured into three main areas: Input Factors, which are size and risk, which directly influences effort and core metrics. The effort calculated from size and risk is a key factor in the equation schemas, the other factors are productivity and complexity. Productivity is influenced by effort which leads to complexity, and which is calculated using formulas derived from effort. Complexity is the final calculated metric, which is influenced by productivity and is the focus of the verification schemas.

A. Variables (Input/State)

This defines the core quantitative and qualitative measures being tracked. These variables serve as inputs to the schemes for Effort: The amount of work needed (e.g., person-hours or person-months), Complexity: A measure of the difficulty of the system, Productivity: The rate at which output is generated (e.g., code per unit of effort), Risk: A measure of potential problems or uncertainties and Size: The magnitude of the system (e.g., lines of code, function points).

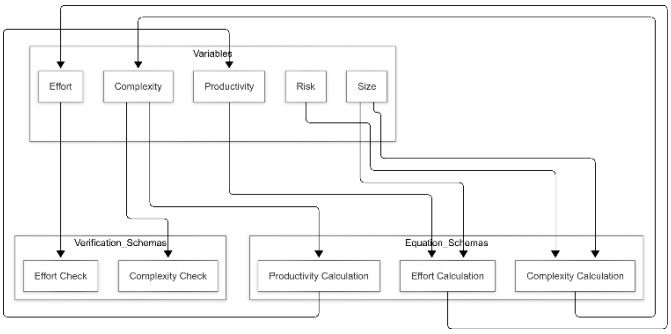

Fig. 1. Framework for robust software effort estimation.

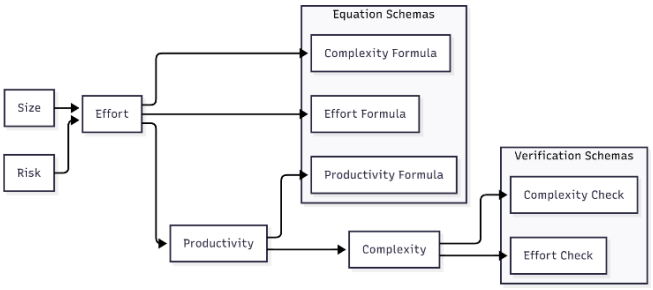

Fig. 2. Conceptual model

B. Verification Schemas

Represents validation or constraint checks on the system's properties. These schemas take variables as input and output as a Boolean value or a report on whether a condition is met. EfforCheck: Depends on effort variable. It checks if the effort falls within an acceptable range or budget and ComplexityCheck: Depend on the complexity variable. Likely checks if the system's complexity is manageable or below a defined threshold. The Verification Schemas checks to validate the calculated metrics: Effort Check: Effort <100 which sets an upper limit or a constraint on the calculated Effort. Complexity1 < Complexity2 suggests a comparative check.

C. Equation Schemas

Represents computations or functions that determine value of one variable based on others. Productivity calculation depends on effort and complexity variables. Effort calculation depends on the size and productivity variables. Complexity

calculation depends on the risk and size variables. Equation Schemas details the mathematical relationships used to calculate the core metrics: `Effort=Size /Productivity`. Effort is inversely proportional to Productivity for a given Size. `Complexity=Size*(1-Risk/10)`. Complexity increases with size but decreases as risk increases. `Productivity=100/Complexity` which defines productivity as inversely proportional to Complexity.

IV. Formal Description

Formal methods are mathematically based techniques and tools for the specification, design, and verification of software and hardware systems. They provide a rigorous framework for describing system properties and behaviors, allowing for precise reasoning and analysis. Fig. 3 given below illustrates a simplified model for calculating the effort required for a project, p, incorporating factors typically considered in project management, and can be interpreted through the lens of formal methods, particularly in the context of system modeling and analysis.

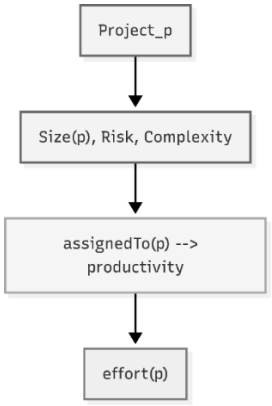

Fig. 3. Sequence of transformations.

The schemas described, which relate Size, Risk, Effort, Productivity, and Complexity through explicit mathematical formulas and constraints, can be formally specified using the Z Notation. The specification below defines the state space of the system and the operations that modify or check the state, based on the provided schemas.

A. Z Specification for Project Metrics Model

1) Basic types: We start by defining the basic sets for the variables in the model. Since all variables represent numerical quantities (size, effort, percentage/ratio), ℕ (natural numbers) and ℝ (real numbers).

```
[ProjectID]
size, Effort, Productivity, Complexity: ℝ
Risk: ℝ
```

2) State schema: The state schema ProjectMetrics defines the variables that constitute the state of the project estimation model.

```
ProjectMetrics
size, Effort, Productivity, Complexity: ℝ
Risk: ℝ
size ≥ 0
0 ≤ risk ≤ 10
effort ≥ 0
productivity ≥ 0
complexity ≥ 0
```

3) Initialization schema: The Init schema sets the initial state of the system, typically with the input variables defined and the calculated metrics initialized to zero or undefined.

```
Init
Δ ProjectMetrics
size’ ∈ ℝ
risk’ ∈ ℝ
effort’ = 0
productivity’= 0
complexity’ = 0
size’ ≥ 0
0 ≤ risk’ ≤ 10
effort’ = 0
productivity’ = 0
complexity’ = 0
```

4) Operation schema: CalculateMetrics: The CalculateMetrics schema represents the core function of the model, applying the "Equation Schemas" to calculate the output metrics based on the current inputs.

```
CalculateMEtrics
Δ ProjectMetrics
risk < 10
complexity’=size x (1-risk/10)
productivty’=100/complexity’
effort’= size/productivity’
size’ = size
risk’ = risk
```

5) Verification Schemas (Constraint Checks): The "Verification Schemas" [8] define checks that must be satisfied. These are modeled as query operations that report success or failure.

a) Effort verification: The CheckEffort checks if the calculated effort is below 100.

```
CheckEffort
Ξ ProjectMetrics
report!: Boolean
```

```
(effort < 100) ⇒ (report!= true)
(effort ≥ 100) ⇒ (report!= false)
```

b) Complexity verification: The CompareComplexity schema checks the constraint $Complexity_1 < Complexity_2$. This requires comparing the current state ($Complexity_1$) to an external value ($Complexity_2$) which is taken as input.

```
CompareComplexity
Ξ ProjectMetrics
Comparison_complexity? : ℝ
report!: Boolean
(complexity < comparision-complexity?) ⇒
(report!= true)
(complexity ≥ comparision-complexity?) ⇒
(report!= false)
```

V. Tools for Automation of Formal Models

Formal methods can help turn a conceptual diagram into a formal model that can be processed by automated tools. There are various tools and approaches that support the automation of Formal models, and these tools help in three ways in specifying the model, which allows users to write the system's properties and behaviors clearly, following rigorous and unambiguous language. These formal methods help in the analysis/verification of the model to check whether it is correct, complete, and satisfies the desired condition, and generate results/code directly from the specification. For effort estimation models, this could mean generating an executable version of the estimation function.

A. Model Checkers / Theorem Provers

These are core formal tools which are crucial for transforming a formal specification into something that can be analyzed automatically.

1) Z3 (SMT Solver) [4]: A popular and powerful tool named Satisfiability Modulo Theories (SMT) solver developed by Microsoft Research. Using the tool, one can encode relationships as logical formulas used to check for consistency and to find specific values for given certain inputs (Size, Risk, Complexity, Productivity) to calculate the effort.

```
(e.g.,Effort(p)=f(Size(p),
Risk(p),Complexity(p),
Productivity(assignedTo(p),p)))
```

2) Alloy (Relational Model Finder): Alloy is a language and tool for modeling structural properties of software systems [12]. It's excellent for modeling relationships and constraints. Alloy could then analyze these relationships for consistency or discover instances that satisfy certain conditions. While it doesn't directly handle numerical calculations as easily as Z3, it is strong for the qualitative aspects and relationships.

3) PVS (Prototype Verification System) / Isabelle/HOL / Coq (Interactive Theorem Provers) [13-15]: These are more heavyweight tools used for rigorous mathematical proofs.

B. Domain-Specific Modeling Languages (DSMLs) / Low-Code/No-Code Platforms [16].

Though these tools are not strictly used in "formal methods" in the highly rigorous sense of theorem provers, these can bridge the gap between conceptual diagrams and executable models, often with some level of formality.

1) MATLAB/Simulink or LabVIEW [17, 18]: These tools are excellent where one can define functions and simulate scenarios involving mathematical equations and simulations. One can implement Effort(p) function in these environments and then run simulations with varying inputs for Size, Risk, Complexity, and Productivity to see the impact on Effort. They aren't "formal verification" tools, but they allow quantitative modeling and analysis.

2) Business Process Model and Notation (BPMN) [19] Using these tools to model the process of effort estimation. While BPMN isn't a formal method for mathematical models few of the tools allow one to embed executable logic at each step, making the process formally specified and potentially automated. Tools. While primarily for business processes, the "flow" aspect of the diagram could be modeled.

3) General-Purpose Programming Languages: With Formal Libraries Languages, like Python with SymPy, SciPy, or Z3 bindings, one can implement a formal model directly in code.

4) Data Modeling Tools (for structured data and relationships) Tools like erwin Data Modeler [20], PowerDesigner [21], or Sparx Enterprise Architect can create conceptual, logical, and physical data models. While they don't directly "calculate effort", they can formally define the structure of your inputs and outputs. The entities for attributes size, Risk, Complexity, and Team can be defined, which impact the productivity. Using these tools, one can ensure data consistency and define relationships, which is one of the foundational steps for formal models.

VI. Formal Verification using Z3 SMT Solver

To apply the Z3 SMT solver for checking equations related to software project factors like Size, Risk, Complexity, and Productivity, a formal model was created, where the variables were defined and the rules that connect them, and how these variable equations and verification rules were created using Z3 Python API. Define each of the components: *P, Size, Risk, Complexity, assignedTo, Productivity, and Effort, w*hich are proposed specific mathematical forms for these functions (e.g., Size as function points, Risk as a probability of failure, Complexity using cyclomatic complexity). Fig. 3 represents a simple function or a sequence of transformations.

To support formal reasoning, the relationships among the project parameters were encoded as a constraint system amenable to SMT-based verification in Z3. The independent variables Size $\in \mathbb{N}^+$ and Risk $\in \mathbb{Q} \cap [0, 1]$ were instantiated for each case as fixed inputs, while Complexity, Productivity, and Effort were declared as dependent variables with explicit constraint schemas. Complexity was modeled as a monotonically increasing function of both Size and Risk, i.e., $\forall s,r \cdot (s\uparrow \vee r\uparrow) \Rightarrow$ Complexity↑, capturing the empirical effect

that large or high-risk projects induce structural and managerial overhead. Productivity was constrained as a decreasing function of Complexity and Risk, i.e., ∀ c,r · (c↑ ∨ r↑) ⇒ Productivity↓, to reflect degradation of throughput under cognitive load, rework, and verification pressure. Effort was then encoded as an outcome variable derived via an effort-equation schema Effort = f (Size, Productivity), under the assumption that lower productivity under fixed size produces strictly higher effort. The "Project Cases" table enumerates three instantiated assignments (Size,Risk) with their Z3-verified consequences (Complexity, Productivity, Effort) satisfying a l l declared axioms and constraints, thereby exhibiting the expected monotonic progression Size,Risk ⇒

Complexity ⇒ Productivity ⇒ Effort.

A. Project_p (Initial State/Input)

This can be viewed as the initial "system" or "object" under consideration. In formal methods, we would define the set of all projects, perhaps as *P*, where $p \in P$.

Formally, `Project_p` could be represented as an initial state S_0 in a state-transition system, or simply as an input parameter to a function.

B. Size(p), Risk, Complexity (Parameters/Attributes)

These are attributes or properties associated with *Project_p*. In formal methods, these would be formally defined metrics or functions that map a project to a numerical value or a categorical description.

- *Size(p):* $P \rightarrow R^+$ (e.g., lines of code, function points)
- *Risk(p):* $P \rightarrow [0,1]$ (e.g., a probability or a risk score)
- *Complexity(p):* $P \rightarrow R^+$ (e.g., cyclomatic complexity, number of interdependencies)

These could be seen as a tuple of characteristics: *(Size(p), Risk(p), Complexity(p)).* The transition from "*Project_p*" to "*Size(p), Risk, Complexity*" implies an evaluation function or a feature extraction process that characterizes the project.

C. assignedTo(p) → productivity (Function/Relation and Impact Factor)

This is the most critical part from a formal methods perspective, as it introduces a relationship and a derived property.

1) assignedTo(p): This represents the resources (e.g., team members, skill sets) allocated to project p. Formally, this could be a function A:P→R where R is the set of all resource allocations.

2) Productivity: This is an attribute of the assigned resources, or a property derived from the interaction of the assigned resources with the project's characteristics. Productivity could be defined as a function Prod: R×P→R^+. The arrow "→" signifies that assignedTo(p) directly influences productivity. The assignedTo(p) → productivity highlights that this step involves a mapping or a transformation where the characteristics of the assigned team (e.g., their skill levels, experience, team size) influence how efficiently the project attributes (size, risk, complexity) are managed. This could be a complex function incorporating human factors.

D. Effort(p) (Output/Result)

This is the final calculated output of the model.

Effort(p) would be a function that considers the project's characteristics (Size(p), Risk, Complexity) and the derived productivity.

Formally, *Effort(p)=f(Size(p), Risk(p), Complexity(p),*

E. Define Variable

```
from z3 import *

# Define variables as real numbers (can
also be Ints if discrete)
Size = Real('Size')
# Size of the software project (e.g., LOC,
Function Points)
Risk = Real('Risk')
# Risk factor (e.g., scale 0–1 or 0–10)
Complexity = Real('Complexity')
# Complexity of the system (scale 0–10)
Productivity=Real('Productivity')
# Productivity (e.g., LOC/person-month)
```

F. Equation Schemas

These are mathematical models or assumptions defining how variables relate.

1) Effort Estimation Equation

We define effort (E) based on the size and productivity.

```
Effort = Real('Effort')
equation_schema_1 = Effort == Size
                    / Productivity
```

2) Risk-adjusted Complexity Equation

Assume complexity increases with risk:

```
equation_schema_2 = Complexity == Size *
(1 + Risk / 10)
```

3) Productivity Impact by Complexity

Assume productivity decreases as complexity increases:

```
equation_schema_3 = Implies (Complexity > 0,
Productivity == 100 / Complexity)
```

G. Verification Schemas

These are assertions or properties we want to verify using Z3. Verify effort is less than a threshold (say 100 person-months)

```
verification_schema_1 = Effort < 100
```

Verify that increasing risk leads to increased complexity.

```
# Suppose we model two risk levels
Risk1 = Real('Risk1')
Risk2 = Real('Risk2')
Complexity1 = Real('Complexity1')
Complexity2 = Real('Complexity2')
schema_risk1 = Complexity1 == Size * (1 +
```

```
Risk1 / 10)
schema_risk2 = Complexity2 == Size * (1 +
Risk2 / 10)
schema_assumption = And (Risk1 < Risk2)
verification_schema_2 = Implies
(schema_assumption, Complexity1 <
Complexity2)
```

H. Putting it all into Z3 Solver

Constraint Setup for this Data: Below is a minimal Z3 SMT model that encodes the relationships used. This Z3 model computes Complexity, Productivity, and Effort.

```
s = Solver ()
# Add the equation schemas
s.add(equation_schema_1)
s.add(equation_schema_2)
s.add(equation_schema_3)
# Add the verification schema
s.add(verification_schema_1)
# Add additional bounds or assumptions
s.add(Size > 0, Productivity > 0, Risk >= 0,
Risk <= 10)
# Check
satisfiability if
s.check() == sat:
    print ("Verification successful!")
    print(s.model())
else:
    print ("Verification failed or
unsatisfiable.")
```

Fig. 4, Fig. 5, Fig. 6, Fig. 7, and Fig. 8 demonstrate the Z3 (SMT Solver) output when the property of Effort is changed.

```
(.venv) C:\z3_demo>python model.py
SAT result: sat
--- Example satisfying assignment ---
Size = 51
Risk = 490/51
Complexity = 100
Productivity = 1
Effort = 51

(.venv) C:\z3_demo>
```

Fig. 4. Output when the property of Effort <100.

```
(.venv) C:\z3_demo>python model.py
SAT result: sat
--- Example satisfying assignment ---
Size = 17
Risk = 490/51
Complexity = 100/3
Productivity = 3
Effort = 17/3

(.venv) C:\z3_demo>
```

Fig. 5. Output when the property of Effort <10

When the property of Effort is changed to less than 50 "Effort < 50":

```
(.venv) C:\z3_demo>python model.py
SAT result: sat
--- Example satisfying assignment ---
Size = 26
Risk = 120/13
Complexity = 50
Productivity = 2
Effort = 13
```

Fig. 6. Output when the property of Effort <50.

```
(.venv) C:\z3_demo>python model.py
Small & low-risk: sat
SAT result: sat
--- Example satisfying assignment ---
Size = 0
Risk = 0
Complexity = 0
Productivity = 0
Effort = 6

(.venv) C:\z3_demo>
```

Fig. 7. Output when small project <= 15 KLOC with low risk.

```
(.venv) C:\z3_demo>python model.py
Small & high-risk: sat
SAT result: sat
--- Example satisfying assignment ---
Size = 0
Risk = 8
Complexity = 0
Productivity = 0
Effort = 6

(.venv) C:\z3_demo>
```

Fig. 8. Small project <= 15 KLOC with high risk.

VII. Results

Five different project scenarios with varying size and different risk test cases were performed with the exact values to measure the Complexity, Productivity, and Effort for the various computed values that were used for the test cases as shown in Table I.

TABLE I. Various Computed Values

Case	Size	Risk	Complexity	Productivity	Effort
A	20	1	22.0	4.54	4.4
B	40	3	52.0	1.92	20.8
C	60	5	90.0	1.11	54.0
D	80	7	136.0	0.73	108.8
E	100	9	190.0	0.52	190.0

The graphs illustrated in Fig. 9, Fig. 10 and Fig. 11 present a realistic engineering insight, where risk and size amplify complexity, and reduced productivity rapidly inflates total effort. Fig. 9 and Fig. 10 illustrate a critical, non-linear relationship in software projects: as Size and Risk increase complexity across cases increases non-linearly as project size grows and as risk becomes higher as in Case A to Case E. Complexity value more than doubles from Case A to Case B, while the Size only doubles and Risk increases by a small linear step (1 to 3). This means larger and high-risk projects quickly become harder to manage. Complexity amplifies, leading to a sharp drop in Productivity, which ultimately results in a significantly inflated total Effort. Fig. 10 shows a rapid, steep decline in Productivity as the project cases advance. The largest drop occurs early, between Case A and Case B, representing a 57% reduction in productivity.

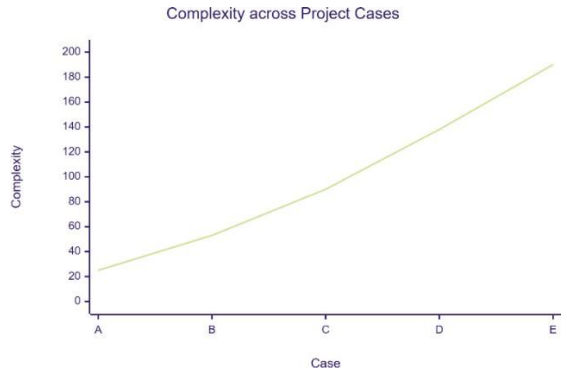

Fig. 9. Complexity across Cases.

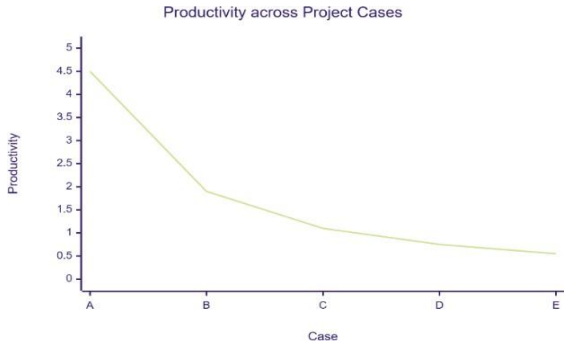

Fig. 10. Productivity across Cases.

Fig. 10 demonstrates the productivity across cases. As complexity increases, productivity drops, which reflects that the real projects' high uncertainty and size reduce the effective delivery rate, and the productivity versus Cases strictly decreases as complexity rises. While Size increases linearly (20, 40, 60, 80, 100), the calculated Effort increases at a highly accelerated rate: Case A to B: Effort increases 4.7 times (4.4 to 20.8). Case D to E: Effort increases by 1.7 times (108.8 to 190.0). The rapid drop in Productivity (due to amplified Complexity) is the primary driver of total project Effort. This phenomenon is a realistic depiction of large, complex, and high-risk projects where the team spends exponentially more time dealing with integration issues, debugging, and coordination (i.e., low productivity) than on core development, resulting in project costs that balloon far beyond the initial linear expectation based on size alone.

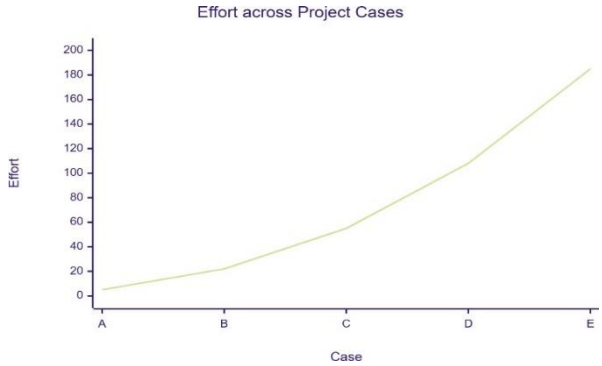

Fig. 11. Effort across Cases.

Fig. 11 demonstrates Effort across cases. Effort increases dramatically when productivity drops and for moderate rises in risk or size have a disproportionate impact on total effort. Effort versus Cases grow sharply as productivity drops.

VIII. Conclusion and Future Work

Software effort estimation has progressed from early heuristic and cost–based models such as COCOMO to more data-driven and logic-based frameworks. This work contributes to that evolution by demonstrating how relationships among Size, Risk, Complexity, Productivity, and Effort can be formalized using Z-notation and verified through an SMT solver such as Z3. Instead of relying on heuristic intuition alone, the encoded schemas enforced logically consistent relationships, ensuring that any computed effort values were entailed by the declared constraints. The illustrative "Project Cases" and the generated graphs confirmed that the expected behavior increases in size and risk propagated to higher complexity, reduced productivity, and elevated total effort. This coherence between historical theory, formal reasoning, and empirical visualization supports the feasibility of combining classical estimation knowledge with modern verification machinery to produce estimations that are interpretable, auditable, and computationally checkable.

In the future, we plan to improve the model by adding more real-world factors such as changing requirements, developer skill levels, number of defects, and outside system dependencies. We also plan to move from fixed (static) values to dynamic ones, so that factors like risk and productivity can change over time as the project progresses instead of staying constant. Hybrid or probabilistic SMT approaches may further enable uncertainty-aware verification and confidence-bounded outputs. Validation with industrial datasets will help assess whether real-world trajectories satisfy or refine the formal schemas. Ultimately, integrating the verified specification into automated tools or dashboards may provide project managers with rigorously justified, real-time decision support, aligning formal verification research with practical software engineering governance.

Cross-Lingual Sentiment Analysis in Low-Resource Languages: A Recent Review on Tasks, Methods and Challenges

Nor Zakiah Lamin[1]*, Azwa Abdul Aziz[2]
Faculty of Computing and Multimedia, Universiti Poly-Tech Malaysia, Cheras, Kuala Lumpur, Malaysia[1]
Faculty of Informatics and Computing, Universiti Sultan Zainal Abidin (UniSZA),
Tembila Campus, 22200 Besut, Terengganu, Malaysia[1, 2]

***Abstract*—Cross-lingual sentiment analysis (CLSA) has become increasingly important in natural language processing and machine learning, enabling the understanding of opinions across diverse linguistic communities, particularly in low-resource languages (LRLs). Despite growing attention, persistent challenges such as limited annotated data, semantic misalignment, and cultural variation in sentiment expression continue to hinder progress. This systematic literature review (SLR) examines recent developments by analyzing the tasks, methods, and challenges reported in CLSA studies focused on LRLs. Following the PRISMA 2020 framework, a comprehensive search was conducted across major databases, including Scopus, IEEE Xplore, SpringerLink, Elsevier, and Google Scholar, covering studies published between 2021 and 2025. After applying inclusion and exclusion criteria, 27 studies were selected for analysis. The findings reveal that while polarity detection remains the dominant sentiment analysis task, emerging directions such as aspect-based sentiment analysis (ABSA), emotion detection, and hate speech recognition are gaining traction. Methodologically, most studies rely on multilingual pre-trained language models (PLMs), supplemented by machine translation, transfer learning, few-shot learning, and hybrid approaches. However, key challenges remain, including the scarcity of high-quality datasets, instability of few-shot performance, difficulties in handling dialectal variation, bias in PLMs, and the lack of standardized evaluation benchmarks. This review concludes by emphasizing the need for more culturally grounded tasks, adaptive hybrid frameworks, and fairness-aware evaluation practices to build robust cross-lingual frameworks and richer linguistic resources for underrepresented languages.**

Keywords*—Cross-lingual sentiment analysis; low-resource language; natural language processing; pre-trained language models; transfer learning; few-shot learning

I. Introduction

The exponential growth of user-generated content across social media platforms, review sites, and online forums has underscored the significance of sentiment analysis in natural language processing (NLP) and machine learning. As a computational approach for identifying and categorizing opinions expressed in text, sentiment analysis plays a pivotal role in gauging public attitudes, tracking brand reputation, and informing decision-making across diverse domains.

While substantial progress has been made in sentiment analysis for resource-rich languages such as English and Chinese, extending these capabilities to a broader set of languages remains a considerable challenge. Many of the world's languages are classified as low-resource, characterized by the lack of large-scale annotated datasets, robust linguistic tools, and standardized benchmarks. This limitation hampers the development of effective sentiment analysis systems for these languages, ultimately leading to their underrepresentation in NLP applications.

Cross-lingual sentiment analysis has emerged as a promising strategy to address this disparity by leveraging knowledge from high-resource languages to improve performance in low-resource settings. Several comprehensive reviews have outlined the evolution of cross-lingual sentiment analysis and its methodological progression from translation-based models to multilingual PLMs. Techniques such as machine translation, multilingual embeddings, and transfer learning have facilitated significant advances in this area. Few-shot and zero-shot learning have recently become popular for addressing limited annotated data. However, challenges persist, particularly in managing dialectal diversity, preserving sentiment polarity across languages, and ensuring the generalizability of proposed models.

Given the growing body of research and the critical need to develop inclusive language technologies, this study conducts a systematic review of cross-lingual sentiment analysis approaches focused on low-resource languages. Specifically, it aims to examine the primary tasks addressed, the methods employed, and the key challenges reported in recent literature. By consolidating these insights, this review seeks to provide a comprehensive understanding of the current landscape and to identify avenues for future research that can advance sentiment analysis in underrepresented language contexts.

II. Basic Terminology

First, it would be useful to define the key terminology related to this research review focus:

*Corresponding author.

A. Sentiment Analysis

The increase in user-generated content on the web has transformed the online platforms into rich repositories of public opinion. People growingly use social media, review sites, and forums to share views on products, services, social issues, trends, and government policies. The surge of textual data reflecting "what people think" has become a critical source of information.

For businesses, the ability to manage in terms of identifying and analyzing these opinions is crucial for understanding customer needs, enhancing satisfaction, and informing market-driven product design. For this reason, sentiment analysis, which involves the computational study of opinions, sentiments, and emotions expressed in text, has emerged as a critical area within natural language processing and data analytics.

B. Cross-Lingual

In the context of natural language processing, cross-lingual approaches refer to methods that enable the transfer of knowledge or models across different languages. These techniques focus on leveraging data-rich languages to improve performance in languages with limited resources. Cross-lingual methods are especially valuable for tasks like sentiment analysis, where labeled data may be abundant in one language but scarce or not available in another languages. By leveraging shared linguistic representations, machine translation, or multilingual embeddings, cross-lingual models seek to generalize sentiment understanding across diverse linguistic contexts.

C. Low-Resource

Low-resource languages are languages that lack extensive computational resources, such as large, annotated datasets, linguistic tools, and benchmark datasets that are readily available for high-resource languages like English or Chinese. This shortage poses significant challenges for developing effective NLP applications, including sentiment analysis. In most cases, these languages also encompass multiple dialects and informal registers, adding further complexity. Therefore, the need for low-resource languages is critical to support more inclusive language technologies and ensure that advances in NLP will benefit a broader spectrum of linguistic communities.

III. Systematic Literature Review

The objective of this review is to systematically examine the recent developments in cross-lingual sentiment analysis within the context of low-resource languages. This study seeks to identify the main tasks addressed, analyze the methods and techniques employed, and highlight the key challenges and research gaps reported in the literature. To achieve this, the review is guided by the following research questions:

Research Question 1 (RQ1):

What are the primary sentiment analysis tasks explored in cross-lingual studies involving low-resource languages?

Research Question 2 (RQ2):

What methods and techniques have been employed to perform cross-lingual sentiment analysis in low-resource language settings?

Research Question 3 (RQ3):

What key challenges and research gaps are identified in existing studies on cross-lingual sentiment analysis for low-resource languages?

A. Search Process

To ensure comprehensive coverage of relevant studies, a structured search was conducted across five major scientific databases, which are Scopus, Elsevier's ScienceDirect, IEEE Xplore, SpringerLink, and Google Scholar, as shown in Fig. 1. These platforms were selected for their extensive indexing of high-quality journals and conference proceedings in natural language processing, machine learning, and computational linguistics.

The search employed combinations of key terms (Table I). The review was limited to publications in English, covering the period from 2021 to 2025, to capture recent advancements in the field. In addition, Google Scholar was used to identify further studies through broader keyword searches and citation tracking, ensuring that potentially relevant grey literature and seminal works were not overlooked. Reference lists of selected articles were also manually screened to identify additional studies relevant to this review.

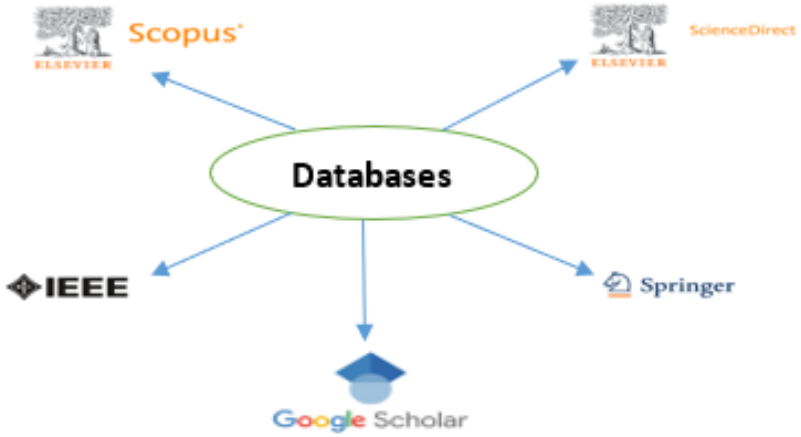

Fig. 1. Database searched.

TABLE I. TABLE OF SEARCH STRING

Database	Search Strings

B. Inclusion and Exclusion Criteria

There is a lot of literature reviews on sentiment analysis. Therefore, to ensure that the search would be manageable and focused, researchers defined some inclusion and exclusion criteria to select the papers for review as follows:

1) Inclusion criteria: Studies published during the period 2021-2025 related to cross-lingual sentiment analysis and studies on tasks, methods, and challenges related to cross-lingual sentiment analysis. The studies focused on low-resource languages instead of high-resource languages. If studies had been published in more than one journal or conference proceedings, researchers chose the most complete version for inclusion. The selection is peer-reviewed articles and written only in English.

2) Exclusion criteria: Studies exclude informal studies (unknown conferences or journals), papers that are irrelevant to the above research questions, non-sentiment analysis in low-resource languages, and papers not written in English.

3) Screening and selection: By using the PRISMA framework, duplicates were removed, and the remaining titles and abstracts were screened to find the relevant papers. Full-text screening was conducted for shortlisted papers. 152 excluded for irrelevance. Therefore, a total of 27 papers were included in the final analysis.

4) Assessment for eligibility: At this stage, 169 full-text articles were assessed for eligibility, and 142 were excluded (not CLSA or not low-resource).

5) Data analysed and included: The 27 papers that were selected for more detailed study are summarized in Table III. This table shows the main information extracted from the selected papers, which are presented in order of the most recent year of publication.

IV. BIBLIOGRAPHY MANAGEMENT AND DOCUMENT RETRIEVAL

Researchers used Mendeley Desktop 2.135.0 to manage all the bibliographic details and citations. The studies that were identified by the above table of search process were scanned by title and abstract according to the inclusion and exclusion criteria. Then, all the papers that were identified as relevant to this research were then downloaded for data extraction and further study.

Table II provides details on the number of research studies that were discovered by the search of the databases in Fig. 1. The search process is illustrated in the form of the PRISMA framework flowchart in Fig. 2. The revised PRISMA 2020 flow diagram (see Fig. 2) details the identification, screening, eligibility, and inclusion process of the 27 selected studies. The search and selection process adhered to the PRISMA 2020 guideline for systematic reviews [28].

TABLE II. NUMBER OF RESEARCH STUDIES IDENTIFIED

Database	Number of papers found		
	Based on key terms (search strings)	Based on title	Based on abstract
Scopus	211	111	95
IEEE Xplore	14	11	11
SpringerLink	63	19	21
ScienceDirect	29	25	9
Google Scholar	406	120	34
Total	723	321	169

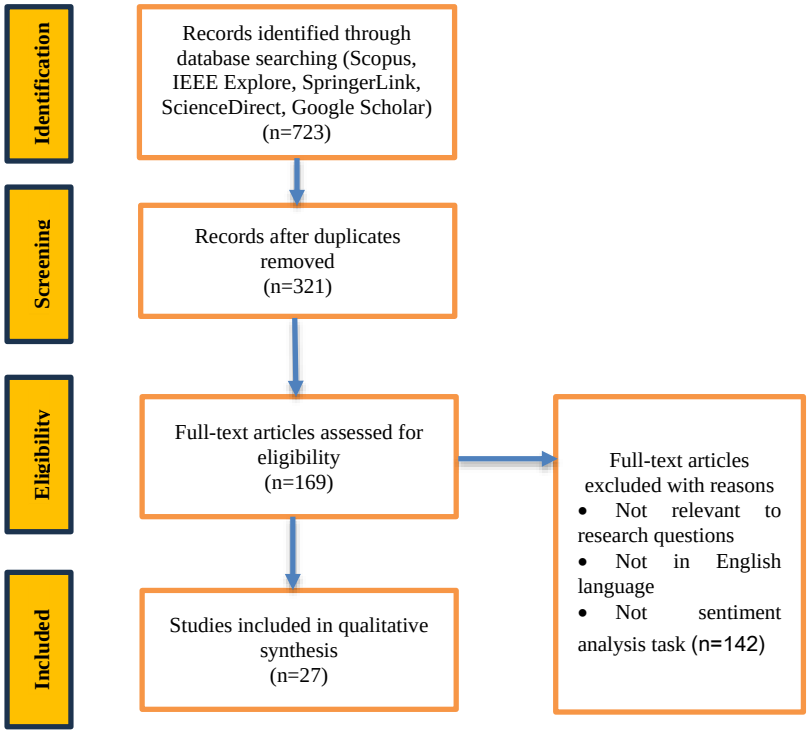

Fig. 2. Revised PRISMA 2020 flow diagram for study selection process.

V. Results and Findings

This systematic literature review analyzed 27 selected studies published between 2021 and 2025 that address sentiment analysis in cross-lingual and low-resource languages contexts. The studies encompass a range of languages, domain such as social media, app reviews, multilingual corpora, and technical approaches. The primary focus is in identifying the sentiment analysis tasks explored (RQ1), the methods and models adopted (RQ2), and the key challenges addressed (RQ3). Each study was assigned a unique identifier and categorized accordingly. Table III shows the number of studies identified.

TABLE III. Number of Research Studies Identified

No	Publication	Tasks / Methods	Key
1	Enhancing cross-lingual hate speech detection through contrastive and adversarial learning [2]	Tasks involved were cross-lingual hate speech detection, zero-shot and few-shot transfer learning and language transfer evaluation.	P1
		Methods used were contrastive learning where the model is trained using contrastive loss to bring semantically similar samples closer in representation space, even across different languages. It also use translation-based augmentation where text from low-resource languages is machine-translated to high resource languages such as English to utilize such annotated datasets. Multilingual Transformer Backbone utilizing XLM-R-RoBERTa as the core model and pretrained on multiple languages. It also used Dual-Encoder Setup for contrastive training and do evaluation benchmarks.	
2	Transformer-Based Abstractive Summarization of Legal Texts in Low-Resource Languages [3]	Abstractive summarization of legal documents in low-resource Indian languages (Hindi, Bengali, Telugu, Tamil, and Marathi) using cross-lingual transfer learning.	P2
		Fine-tuning of mBART and mT5 transformer models pre-trained on multilingual data; use of zero-shot and few-shot learning; translation of low-resource text into English; back-translation to maintain legal semantics.	
3	TFT-TL: Token-Level Filter Training Transfer Learning for Low-Resource Neural Machine Translation [4]	This study used Neural Machine Translation (NMT) for low-resource languages, cross-lingual transfer learning, token-level quality control in knowledge transfer and sequence prediction alignment	P3
		The method involved: ➢ Token-Level Filter Training (TFT): Filters out *unstable token predictions* from the parent model to prevent noise during transfer. ➢ Hierarchical Ranking Loss: A loss function that helps the child model better capture sequence-level dependencies and mimic the parent model's prediction order. ➢ Transfer learning framework using parameter initialization from a high-resource parent model, fine-tuning on low-resource child language and soft label supervision for consistency learning.	
4	Bridging resource gaps in cross-lingual sentiment analysis: adaptive self-	This study involved were cross-Lingual Sentiment Analysis (CLSA) that Transfers sentiment classification models trained in a high-resource source language (e.g., English) to low-resource target languages, Transfer Learning, that utilize pre-trained multilingual models to adapt sentiment knowledge from source to target	P4

	alignment with data augmentation and transfer learning [5]	languages, data augmentation to apply techniques like back-translation and synonym replacement to enhance training data diversity. Finally, performance evaluation conducted to test the model on benchmark multilingual sentiment datasets and comparing it to baseline methods. For the method, Adaptive Transfer Learning Framework is used to do fine-tuning of multilingual transformer models (e.g., mBERT, XLM-R) on labelled source language data. The augmentation techniques used back-translation to generate paraphrases and synonym replacement to create sentence variants while preserving sentiment, The training strategies applied to train the model and do evaluation metrics.	
5	A hybrid model for low-resource language text classification and comparative analysis [6]	This study tasks are on text classification for low-resource language (Malay) that focused on sentiment or review classification using a newly annotated Malay dataset, do comparative evaluation of existing tools on a low-resource dataset to assess performance gaps. There are also, Hybrid Model Development that integrates linguistic rules and transfer learning. Empirical Evaluation were performed using accuracy, F1-score, and statistical testing (paired t-test). The method involved **Tools, Data, Modelling and Evaluation**. ➢ Tools - LangDetect, spaCy, FastText, XLM-RoBERTa, and LLaMA ➢ Data - Dataset of 74,931 user reviews from apps like MyBayar, PDRM, MyJPJ, MySejahtera. A subset of 2,621 reviews was annotated manually with inter-coder reliability (Fleiss' Kappa). ➢ Modeling - Hybrid approach combining rule-based features and transfer learning. ➢ Evaluation - Accuracy: 84% and Statistical significance; $p < 0.05$ using paired t-tests on F1-scores.	P5
6	Sentiment Analysis and Emotion Detection Using Transformer Models in Multilingual Social Media Data [7]	Sentiment Classification – Classify tweets into sentiment categories (positive, neutral, negative). Emotion Detection – Identify emotions such as joy, anger, sadness, and fear from social media content. Use of pretrained transformer models: BERT, RoBERTa, and XLM-R. Application of fine-tuning on two public multilingual datasets containing tweets annotated with sentiment and emotion labels. Comparison with baseline machine learning models (e.g., SVM and LSTM).	P6
7	The Impact of Linguistic Variations on Emotion Detection: A Study of Regionally Specific Synthetic Datasets [8]	The main tasks in this paper are: Emotion Detection, to identify emotional categories (e.g., joy, sadness, anger) from social media texts, evaluation of linguistic variation to assess how regional language variations impact emotion detection performance and synthetic data generation to create regionally specific synthetic datasets for emotion classification tasks. The methods used include: ➢ Synthetic Dataset Construction: A regionally specific emotion dataset was created by generating synthetic variants of tweets from the SemEval 2018 Task 1 dataset. These variants mimic regional dialects and linguistic styles across English-speaking countries. ➢ Transformer-based Models: Multiple pre-trained transformer models (including BERT, RoBERTa, and DeBERTa) were fine-tuned and evaluated on both original and synthetic data. ➢ Cross-Dataset Evaluation: The models were tested on both the original and regionally modified datasets to observe performance changes.	P7
8	Exploring Transfer Learning in a Bidirectional Myanmar-Tedim Chin Machine Translation with the mT5 Transformer [9]	This study did data collection & corpus creation, Text Preprocessing, Model Fine-tuning (Transfer Learning), Bidirectional Machine Translation, and Model Evaluation. It creates dataset which a 10K parallel corpus from the UCSY dataset, covering diverse domains such as, Greetings, Educational stories, Communication, Leisure (e.g., travel, shopping), Resource-related texts (e.g., numbers, time). Then, preprocessing of data was segmented using Syllable-level segmentation and Word-level segmentation. Then, Model is Fine-tuned the mT5 model on both segmentation types and used BLEU score and accuracy to evaluate translation performance.	P8
9	Enhancing Low-Resource Question-Answering Performance Through Word Seeding and Customized Refinement [10]	This study to enhance Low-resource Question Answering (QA) and improve QA performance in low-resource languages (e.g., Hindi) through cross-lingual approaches. The method used Word Seeding (POS-aware noun substitution) to replace English nouns with translated/transliterated Hindi nouns to create bilingual training data, realign answer spans after word substitutions using n-gram similarity and SequenceMatcher. It applied three-stage Transfer Learning: 1. Pretrain on SQuAD 2. Intermediate MLM on Hindi corpus 3. Fine-tune on constructed bilingual QA dataset The models used mBERT and XLM-R (base & large) The evaluation are on MLQA and XQuAD datasets.	P9
10	An Empirical Evaluation of the Zero-Shot, Few-Shot, and Traditional Fine-Tuning Based Pretrained Language Models for Sentiment Analysis in Software Engineering [11]	This study evaluates sentiment classification performance on SE datasets, focusing on developer comments and discussions. It compares zero-shot, few-shot, and traditional fine-tuning methods using PLMs on sentiment classification tasks. It used pre-trained Language Models (PLMs), RoBERTa, BERT, XLNet, GPT-2, BART, T5. As for the learning settings, it applies Zero-Shot Learning, Few-Shot Learning and Traditional Fine-Tuning. For the evaluation, it used five benchmark SE sentiment datasets (e.g., Jira, Stack Overflow). Applied classification accuracy, macro-F1, and weighted-F1 as performance metrics.	P10
11	Motamot: A Dataset for Revealing the Supremacy of Large Language	This study about political sentiment analysis in Bengali language (during election period) and evaluate its performance of various Pretrained Language Models (PLMs) and Large Language Models (LLMs) in sentiment detection. It benchmark political sentiment classification using a newly created dataset.	P11

	Models Over Transformer Models in Bengali Political Sentiment Analysis [1]	It introduced Motamot dataset: 7,058 annotated instances (positive/negative), collected from online newspaper articles in Bangladesh and used certain models: → PLMs: BanglaBERT, Bangla BERT Base, XLM-RoBERTa, mBERT, sahajBERT → LLMs: Gemini 1.5 Pro, GPT 3.5 Turbo It applied zero-shot and few-shot learning techniques and used evaluation metrics for the accuracy comparison across all models.	
12	A comparative study of cross-lingual sentiment analysis [12]	This study focuses on zero-shot Cross-lingual Sentiment Classification where it classifies sentiment in target languages (Czech, French) using models trained only in English (no labelled data in the target language). For the baseline, it develops strong monolingual models for comparison with cross-lingual approaches. It also does experimentation with embedding Techniques to study the impact of embedding normalization, vocabulary size, and in-domain vs. general embeddings for linear transformations. The method us Transformer-Based Models. Linear Transformations + CNN/LSTM to align word embeddings between source and target languages. Then, used Large Language Models (LLMs) (ChatGPT (GPT-3.5 Turbo) and LLaMA 2) in zero-shot prompting settings (no fine-tuning) to achieved competitive or superior performance with higher hardware requirements.	P12
13	Sentiment analysis on a low-resource language dataset using multimodal representation learning and cross-lingual transfer learning [13]	This study analyse sentiment from video data using text, audio, and visual modalities using Multimodal Sentiment Analysis (MSA). It performs MSA on Tamil, a low-resource language with limited annotated data. It curate and annotate a new dataset called MSAT (Multimodal Sentiment Analysis corpus in Tamil), consisting of ~300 utterances with sentiment and emotion labels for the dataset creation. To improve sentiment analysis in Tamil, it used cross-lingual transfer learning to transfer knowledge from English MSA datasets (CMU-MOSI, MOSEI, MELD). It applied SPMMAE (Shared-Private Multimodal AutoEncoder) which is a novel deep learning architecture that extracts unimodal embeddings using Self-Supervised Learning (SSL), learns both shared (common) and private (modality-specific) representations and provides a comprehensive fused representation across modalities. For the Cross-lingual Transfer Learning, the study pretrain the model on large English MSA datasets, fine-tune it on the small Tamil MSAT dataset and demonstrated 11% performance improvement on MSAT through transfer	P13
14	Exploring zero-shot and joint training cross-lingual strategies for aspect-based sentiment analysis based on contextualized multilingual language models [14]	Cross-lingual sentiment classification using multilingual product review datasets (e.g., Amazon reviews in multiple languages). ➤ The model is trained on English data and tested on other languages (zero-shot setting). Multilingual BERT (mBERT) and XLM-R pretrained models Fine-tuning on source (English) data No labeled target language data required (zero-shot cross-lingual approach)	P14
15	Data-Augmentation for Bangla-English Code-Mixed Sentiment Analysis: Enhancing Cross Linguistic Contextual Understanding [15]	Sentiment classification of code-mixed Bangla-English social media posts. ➤ Multi-class classification (positive, negative, neutral) Data augmentation techniques: back-translation, synonym replacement, transliteration Pretrained Transformer models: mBERT and IndicBERT Augmented training to enhance cross-lingual contextual understanding	P15
16	Zero-shot learning based cross-lingual sentiment analysis for Sanskrit text with insufficient labeled data [16]	Sentiment Analysis: The core task is to classify text sentiment (positive, negative, neutral). Cross-lingual Transfer: Apply models trained in one language (source) to another (target) without needing training data in the target language. Zero-shot Learning (ZSL): No labeled examples from the target language are used during training; model infers based on learned representations. Transformer-based Models: Used multilingual transformers like mBERT and XLM-R to generate language-agnostic representations. Fine-tuning on English Data: The model is trained on a labeled English sentiment dataset. Evaluation on Other Languages: Performance is evaluated on unseen target languages (e.g., Chinese, Arabic, Spanish). Cross-lingual Embedding Space: Leverage shared representation space of multilingual models to generalize across languages. Benchmarks Used: XNLI and MLDoc datasets, among others, for evaluation.	P16
17	Sentiment analysis of the Algerian social movement inception [17]	Sentiment analysis of tweets related to the Algerian Hirak social movement Comparative evaluation of models on Algerian Arabic, a low-resource language Classical ML models: Naive Bayes, SVM, Logistic Regression (LR), Decision Tree Feature extraction: Bag of Words (BoW), TF-IDF Pretrained Transformers: AraBERT, DziriBERT, XLM-R (fine-tuned) Evaluation metrics: accuracy, precision, recall, F1-score LR performed best with 68% accuracy	P17
18	How a Deep Contextualized	Cross-lingual sentiment analysis for low-resource languages Improve classification performance and provide explainability in sentiment predictions	P18

	Representation and Attention Mechanism Justifies Explainable Cross-Lingual Sentiment Analysis [18]	-Model architecture: → Pretrained cross-lingual transformer: XLM-RoBERTa for contextualized embeddings → Followed by LSTM (Long Short-Term Memory) for sequence modeling → Integrated attention mechanism to identify key informative words and justify polarity - Comparison with monolingual and cross-lingual baselines	
19	Prompt-based for Low-Resource Tibetan Text Classification [19]	Text classification for Tibetan language in low-resource settings. Address the lack of annotated Tibetan data for NLP tasks (including sentiment analysis and information extraction). This study used prompt-based learning to guide language models to perform classification. It leverages pre-trained language models on a large-scale unsupervised Tibetan corpus and applies few-shot learning to enable effective performance with minimal labelled data. The approach emphasizes generation-based classification, fitting the prompt-learning paradigm.	P19
20	Fake news detection in Dravidian languages using transfer learning with adaptive finetuning [20]	Fake News Detection in low-resource Dravidian languages (Telugu, Tamil, Kannada, Malayalam). This study introduced Dravidian_Fake, the first fake news dataset for Dravidian languages with 26,000 articles. It combined English ISOT dataset and Dravidian_Fake to form a multilingual corpus. Them used transfer learning with pretrained transformer models: ➢ mBERT (Multilingual BERT) ➢ XLM-RoBERTa It also applied adaptive fine-tuning strategy to better adjust models to the multilingual and low-resource scenario. The, used cross-lingual embeddings to transfer semantic knowledge from English to Dravidian languages.	P20
21	Transfer language selection for zero-shot cross-lingual abusive language detection [21]	Zero-shot Cross-Lingual Abusive Language Detection (ALD): Performing ALD in target languages without labeled training data by transferring knowledge from a source language (e.g., English). Transfer Language Selection: Identifying which source language(s) can best support abusive language detection in a given target language under a zero-shot setting. Evaluation Across Languages: Empirically assessing how the choice of source language affects ALD performance in multiple target languages (e.g., Swahili, Urdu, Arabic). This study used model architecture that utilizes the XLM-R (XLM-RoBERTa) multilingual transformer model for performing abusive language detection in a zero-shot setting. For the transfer evaluation strategy, the method involves training the model on one or more source languages and evaluating it directly on target languages without fine-tuning (zero-shot). The transferability metrics explore language similarity, geographical proximity, and cultural traits to assess and explain why certain transfer languages work better. For the experimental design, dataset and evaluation metrics are as follows: Experimental Design: Source languages: English, Arabic, Hindi, Spanish, etc. Target languages: Swahili, Urdu, and Arabic. Dataset: Uses annotated datasets (e.g., HateXplain, OLID, etc.) for source languages and tests performance on target language data. Evaluation Metrics: Primarily uses macro-F1 score and accuracy to evaluate zero-shot performance.	P21
22	Burmese Sentiment Analysis Based on Transfer Learning [22]	Sentiment Analysis of Burmese (Myanmar) texts, which is a low-resource language. Specifically, the task is to classify Burmese texts into sentiment categories (positive, negative, neutral) The study utilizes transfer learning techniques by leveraging pre-trained models such as: ➢ Multilingual BERT (mBERT) ➢ XLM-RoBERTa Fine-tuning is performed using a Burmese sentiment dataset collected and annotated manually. The model performance is compared with traditional machine learning methods like Naive Bayes, SVM, and LSTM-based deep learning models. The best results are achieved using XLM-RoBERTa, demonstrating the effectiveness of cross-lingual transfer in sentiment analysis	P22
23	Deep Persian sentiment analysis: Cross-lingual	Perform sentiment analysis on Persian, a low-resource language, Improve classification accuracy using transfer learning from English data	P23

	training for low-resource languages [23]	Proposed a cross-lingual deep learning framework using English Persian data. It used cross-lingual word embeddings (static & dynamic) and trained on English Amazon reviews, tested on Persian Digikala reviews. It achieved +22% (static) and +9% (dynamic) performance improvement over monolingual methods. Required only a bilingual dictionary for embedding alignment.	
24	Zero-Shot Emotion Detection for Semi-Supervised Sentiment Analysis Using Sentence Transformers and Ensemble Learning [24]	Address sentiment analysis and emotion detection in low-resource settings. This study proposes a framework for semi-supervised sentiment classification. It enables zero-shot emotion classification without labelled data in the target domain. It utilizes Sentence Transformers (e.g., all-MiniLM-L6-v2) to encode sentences into semantic vector representations. The, implement Zero-shot Learning (ZSL) using cosine similarity between sentence embeddings and predefined emotion/sentiment labels. It uses Ensemble Learning to combine outputs from multiple classifiers (SVM, Logistic Regression, Decision Tree). This study introduces pseudo-labelling (semi-supervised learning) where model-predicted labels are iteratively added to the training set to improve classification.	P24
25	Cross-Lingual Knowledge Transferring by Structural Correspondence and Space Transfer [25]	Cross-Lingual Sentiment Analysis (CLSA) → Transferring sentiment knowledge from a label-rich source language (e.g., English) to a low-resource target language (e.g., Chinese) It used ssSCL-ST (Semi-supervised Structural Correspondence Learning with Space Transfer): ➢ Structural Correspondence Learning (SCL): Learns shared feature representations (called pivots) between languages based on co-occurrence in unlabelled data. ➢ Space Transfer: Maps feature spaces between source and target languages to align semantic spaces, allowing knowledge reuse across languages. ➢ Pivot Set Extension: Enhances the quality of shared features across domains. ➢ Semi-supervised Learning: Leverages unlabelled data in the target language to extract useful domain-specific sentiment signals	P25
26	Sentiment Analysis Using XLM-R Transformer and Zero-shot Transfer Learning on Resource-poor Indian Language [26]	Sentiment analysis for resource-poor Indian languages (Hindi); sentence-level classification of tweets and reviews. It used zero-shot cross-lingual transfer using XLM-RoBERTa; trained on English (SemEval 2017 Task 4A) and evaluated on two Hindi datasets (IITP-Movie and IITP-Product); achieves ~60.93% accuracy.	P26
27	A joint learning approach with knowledge injection for zero-shot cross-lingual hate speech detection [27]	Cross-lingual hate speech detection in low-resource languages using zero-shot learning. This study proposed joint-learning architecture using multilingual models (e.g., LASER, MUSE, Multilingual BERT) with injected external knowledge via HurtLex (a multilingual abusive word lexicon). For the testing, it tested on 6 low-resource languages using English as the source and evaluated multiple neural and machine learning models.	P27

A. Sentiment Analysis Tasks

Addressing RQ1, the corpus highlights seven task families, ranging from coarse–grained polarity detection to fine-grained, safety-critical objectives. The unevenness of this distribution carries significant methodological and practical ramifications.

1) Text classification or polarity detection: A large share of studies (P1, P2, P8, P9, P11, P13, P14, P15) focus on document or sentence level polarity. This prevalence is understandable where polarity tasks are easy to formulate and compare, and they remain useful as baseline capability checks. However, the heavy reliance on polarity implicitly rewards simplified sentiment theories, often missing stance, irony, intensifiers/negation, and code-switching phenomena that are common in low-resource language discourse.

2) Aspect-Based Sentiment Analysis (ABSA): ABSA appears in (P5, P10, P19, P22), targeting feature-level opinion in the example of service versus price. Cross-lingual ABSA in low-resource languages is data definition constrained, where aspect taxonomies are often imported from English and may not map to local discourse. An example of culturally specific service norms or product attributes. This can misrepresent label spaces and decrease transfer performance even the model's capacity is adequate. Therefore, the suggestion is to use community-informed aspect induction (unsupervised or semi-supervised discovery of aspects from in-language corpora), followed by lightweight alignment to any global schema. The evaluation can be done with partial-credit measures, example in hierarchical aspects to prevent artificial penalties on culturally grounded aspect definitions.

3) Emotion detection: Emotion detection in studies (P6, P16, P20) probes beyond polarity, for example, anger and joy. Progress is slowed by annotation scarcity and cultural variation in emotion expression (metaphor, honorifics, and emojis). Porting Western emotion inventories can mislabel affect in low-resource languages. Suggestion is to adopt culturally grounded annotation protocols and combine psychological lexicons + PLM features. It may use few-shot adjudication with bilingual experts to calibrate labels before scaling.

4) Cross-lingual transfer (XLT): Studies in P3, P4, P7, P12 and P18 adapt models from a source (typically English) to a target low-resource language. XLT often yields higher pairwise accuracy but requires per-pair tuning and incurs cost when many targets exist. As a suggestion, do incorporate target-aware adapters or vocabulary augmentation for report transfer efficiency (accuracy gain per labeled/compute unit).

5) Multilingual Sentiment Classification: MSC in studies (P17, P21, P24) trains a single model across many languages. It scales coverage but risks representation interference when typologically distant languages share parameters. It is recommended to adopt adaptive multilingual training which cluster languages by typology/script/morphology, pre-adapt per

cluster, then soft-share layers across clusters. Report per-cluster gains/losses to make interference visible.

6) Few-shot or zero-shot learning: Few or zero-shot methods studies in P23, P25 and P26 reduce dependence on labels. Gains are fragile yet sensitive to prompt wording, verbalizers, and the representativeness of very small support sets. Overclaiming of generalization from one prompt template is common. Therefore, it is suggested that prompt diversity protocols be enforced in multiple paraphrases or verbalizers and report variance across seeds or prompts. Consider its consistency of regularization or meta-learning for stability.

7) Hate speech or abusive content: One study which is P27 targets toxicity detection. This task is ethically high-stakes and linguistically nuanced, such as slurs, reclaimed terms, sarcasm, and code-switching. Importing English toxicity lexicons risks false positives and cultural harm. Therefore, the suggestion is to combine a curated community of lexicons with reclaiming flags plus contextual PLM signals and audit false positive rates on minority dialects.

In summary, the evidence for RQ1 indicates that the field is task diversifying, but cross-lingual sentiment analysis for low-resource languages remains over-indexed on polarity. To avoid distorted progress signals, future work should elevate fine-grained tasks with culturally valid label spaces and robustness of the first evaluation.

B. Methods and Techniques in Cross-Lingual Sentiment Analysis

Addressing RQ2, the findings reveal that methods extend beyond PLM-centric transfer to include translation-based pipelines, contrastive or self-supervised learning, and hybrid strategies that combine neural architectures with linguistic resources, where each offering different trade-offs in scalability and robustness. The strongest studies compose these elements rather than betting on a single paradigm.

1) Pre-Trained Multilingual Language Models (PLMs): PLMs such as mBERT, XLM-R, and MT5 that are used in (P1, P3, P4, P7, P12, P18, P23, P25) serve as the most common baseline for cross-lingual sentiment analysis. These models are trained on massive multilingual corpora and can transfer knowledge across languages without requiring paralled data, making them highly appealing for low-resource settings. They provide quick performance gains by leveraging shared representations between high-resource languages and low-resource languages. However, PLMs also show significant limitations where their performance does not equally benefit high-resource languages that dominate pretraining data. As the benefits degrade sharply for low-resource languages, specifically in those with rich morphology, code switching, or non-Latin scripts. This imbalance raises concerns about fairness and inclusivity. Similar conclusions were drawn in recent works highlighting the critical role of pre-trained language models and their adaptability across linguistic boundaries [29], [30]. To address these limitations, researchers propose bias-aware fine-tuning, which introduces adapter layers for parameter-efficient specialization per language cluster and applying morphology-aware tokenization to reduce subword fragmentation and preserve sentiment-bearing morphemes. These strategies could make PLMs more equitable and effective for underrepresented languages.

2) Few or zero-shot learning: These learning methods in studies (P23, P25) aim to minimize dependence on any annotated datasets by transferring sentiment knowledge across languages with little or no labelled data in the target language. In few-shot settings, the model is provided with only a few labelled examples, while zero-shot learning transfers directly without any labelled target data, that is often relying on prompts or shared representations. These approaches offer label efficiency, making it highly attractive for low-resource languages where annotation is scarce. However, the findings show that performance is highly variable, depending on prompt wording, random seeds, or the representativeness of the small labelled set. This instability makes few-shot and zero-shot methods unreliable for consistent deployment in sensitive domains. To address this, researchers recommend reporting confidence intervals across multiple prompt templates rather than relying on single run results that employ agreement-based exemplar selection to reduce topic bias in few-shot settings and incorporating consistency losses across paraphrases to stabilize output. These improvements would strengthen the reliability of low label transfer methods in cross-lingual sentiment analysis.

3) Translation-based pipelines: Translation-based pipelines, employed in studies (P2, P9, P15), provide a practical workaround for low-resource languages by leveraging resources from high-resource languages. The process typically involves translating text written in a low-resource language (LRL) into a high-resource language (HRL) such as English, and then applying a sentiment classifier trained on the HRL (e.g., an English sentiment model). This approach is attractive because it allows researchers to bypass the lack of annotated datasets in LRLs by "borrowing" established tools and datasets from HRLs. However, this method is prone to translation noise, where idioms, sarcasm, negations, or culturally specific expressions are mistranslated, leading to distorted sentiment predictions. Translation systems may also encode systematic bias against informal registers, dialectal variants, or slang common in social media, further reducing reliability. To improve robustness, researchers suggest training with noise-augmented machine translation (MT) outputs, such as back-translations or synthetic error injection, adding quality-estimation filtering to remove unreliable translations, and calibrating classification thresholds by domain to account for translation-induced variability. While practical, translation pipelines should therefore be treated as interim solutions rather than definitive methods for sustainable CLSA in low-resource settings.

4) Contrastive or self-supervised alignment: Studies such as P18 and P27 adopt contrastive learning and self-supervised approaches to improve cross-lingual alignment without relying on parallel corpora, which are often unavailable in low-resource languages. These methods train models to bring semantically

similar pairs closer together and push dissimilar ones apart in the embedding space, thereby creating shared cross-lingual representations. While this reduces dependence on expensive parallel datasets, the effectiveness of these methods depends heavily on the availability of large volumes of unlabeled in-language text, which is typically scarce in LRLs. To mitigate this limitation, researchers suggest combining contrastive loss with weak lexicon anchors, such as small bilingual lexicons or cognate lists, and leveraging distant supervision signals from social media, such as emojis or reaction labels, to reduce data demands and improve robustness.

5) Hybrid approaches (rules + neural) robustness and interpretability: Hybrid approaches, as explored in P14 and P20, integrate rule-based features with pre-trained language models to improve robustness in sentiment analysis for low-resource languages. These systems are particularly effective in handling linguistic phenomena such as negation, intensifiers, and morphological variations (e.g., prefixes and affixes) that often confuse purely neural models. Although hybrids are sometimes dismissed as outdated, they remain valuable in LRL contexts, where PLMs frequently struggle with dialectal drift and morphological complexity. The main drawbacks are the engineering effort required to develop and maintain language-specific rules and the limited portability across languages. Suggested design patterns include using rules as weak supervision signals to generate high-precision training data, adopting noise-aware objectives to handle imperfect labels, applying constrained decoding to avoid polarity flips near negators, and performing morphology normalization before tokenization to reduce misclassification.

6) Linguistic resource engineering: Studies in P6, P16, and P22 highlight the continued importance of linguistic resources such as sentiment lexicons, pivot-based alignment, and corpus construction in supporting sentiment analysis for low-resource languages. These resources, often considered "traditional", remain high-leverage tools when PLMs underperform, as they provide interpretable anchors for sentiment recognition. However, a key limitation is coverage drift, as lexicons quickly become outdated due to the rapid evolution of language, especially in social media contexts. To address this, researchers recommend semi-automating lexicon expansion through distributional similarity or retrofitting techniques, supported by human-in-the-loop validation to ensure quality. Furthermore, documenting update cadence and monitoring out-of-vocabulary sentiment drift over time are necessary to maintain the reliability and relevance of these resources.

7) Fine-tuning strategies: Fine-tuning strategies, examined in studies such as P1, P11, P13, and P17, adapt pre-trained multilingual models to sentiment tasks through end-to-end optimization. While full fine-tuning often achieves strong results in high-resource and medium-resource settings, its effectiveness in true low-resource languages is limited. With very little annotated data, full fine-tuning risks catastrophic forgetting of cross-lingual generalization and is computationally demanding, making it less accessible for researchers with limited resources. A more sustainable alternative is parameter-efficient adaptation methods, such as adapters, low-rank adaptation (LoRA), or prefix-tuning, which require fewer parameters and are less computationally intensive. Researchers also recommend performing ablation studies to identify which layers benefit most from adaptation and reporting computational budgets alongside accuracy scores to promote reproducibility, equity, and fair comparison across studies.

Overall, the synthesis of findings for RQ2 suggests that no universal winner for all the methods. The most credible pipelines are composite, matching technique to language typology, script, morphology, and domain, where they report robustness, cost, and portability, and not just peak scores.

C. Challenges and Research Gaps in Cross-Lingual Sentiment Analysis

Addressing RQ3, this review identifies seven recurring obstacles in cross-lingual sentiment analysis (CLSA) for low-resource languages (LRLs). Importantly, many of these barriers are structural as well as technical, reflecting deeper issues of fairness, inclusivity, and sustainability in the field.

1) Annotated data scarcity: A recurring challenge across multiple studies (P1, P3, P5, P14, P20, P22) is the limited availability of annotated datasets in low-resource languages. This scarcity severely constrains the development and evaluation of supervised models and encourages over-reliance on translation or synthetic data generation, which are often imperfect substitutes. Without high-quality annotated resources, model performance cannot be reliably compared, and advances risk being skewed toward well-resourced languages. To address this, researchers highlight the importance of community-driven dataset creation, underpinned by fair compensation and participatory governance. Complementary strategies, such as active learning to maximize annotator efficiency or simplifying task designs through pairwise preference judgments rather than fixed multi-class labels, can further reduce annotation costs while maintaining data quality.

2) Semantic misalignment across languages: Studies such as P4, P7, and P18 report difficulties with semantic misalignment, where shared embedding spaces fail to capture culturally specific sentiment cues. This is particularly problematic for languages with rich morphology or those that rely heavily on honorifics, pragmatic markers, or cultural idioms to express sentiment. In cross-lingual evaluations, aligning syntactic and semantic representations remains one of the most pressing issues in current research [31]. As a result, models trained on generic multilingual embeddings often misinterpret or dilute language-specific sentiment signals. Research is therefore needed to develop context- and morphology-aware representations, introduce language-cluster adapters to better capture typological variation, and incorporate contrastive alignment methods anchored by small bilingual lexicons to preserve semantic nuance across languages.

3) Translation noise in pipeline methods: Translation-based approaches, used in studies P2 and P9, often suffer from translation noise, where idioms, sarcasm, or polarity shifters are mistranslated, leading to distorted sentiment predictions. Such noise contaminates the downstream classification process, as models are forced to learn from inaccurate or incomplete representations. This problem is particularly acute in informal or domain-specific registers such as social media. To mitigate these risks, research has suggested noise-aware training, where models are trained with intentionally corrupted translations to increase robustness; quality-estimation filtering to remove unreliable translations; and domain-specific machine translation tuning, which prioritizes sentiment-sensitive phenomena during training.

4) Domain and dialect mismatch: Another significant gap arises from domain and dialect mismatch, reported in studies such as P10, P19, and P22. Models trained on generic domains (e.g., product reviews) often perform poorly when transferred to specialized domains like healthcare or law, where sentiment expressions differ significantly. Similarly, dialectal variation within languages remains underserved, with models frequently failing to adapt to non-standard forms or code-switching. Addressing this requires domain adaptation techniques such as adapter modules or feature alignment, as well as dialect-sensitive evaluation splits to ensure fair testing. In addition, code-switch stress tests should be integrated into benchmarks to better reflect the realities of multilingual online communication.

5) Bias in PLMs and unfair performance distribution: Bias embedded within pre-trained multilingual models is another critical challenge, as highlighted in (P23, P26). PLMs tend to disproportionately benefit high-resource languages, while low-resource ones face significantly higher error rates. This unequal distribution of performance amplifies digital inequity, leaving already underrepresented communities further behind. To address this, researchers recommend systematic bias audits, which assess per-language and per-dialect performance disparities, alongside re-weighting strategies during fine-tuning to rebalance training. Furthermore, fairness metrics should be reported alongside accuracy, ensuring that performance is evaluated not only in aggregate but also across linguistic subgroups.

6) Few-shot performance instability: While few-shot and zero-shot learning promise inclusivity for languages without annotated data, studies (P25, P26) consistently report performance instability. Results fluctuate depending on prompt design, choice of verbalizers, or random seeds, making them unreliable in production or high-stakes contexts. This instability undermines confidence in few-shot learning as a dependable solution for CLSA in LRLs. Suggested remedies include adopting prompt sets instead of single prompts, systematically reporting variance across runs, introducing consistency regularization to stabilize predictions across paraphrased inputs, and exploring meta-learning approaches to improve generalization from small support sets.

7) Evaluation inconsistency and weak comparability: Finally, a persistent obstacle identified in studies such as P6, P12 and P24 is the lack of standardized evaluation benchmarks. The use of heterogeneous datasets, task formulations, and metrics makes it difficult to compare results across studies, weakening claims of "state-of-the-art" performance. This inconsistency fragments the field and slows cumulative progress. To resolve this, the community should prioritize the development of shared multilingual evaluation suites covering both high- and low-resource languages, incorporate robustness benchmarks for negation, sarcasm, and code-switching, and mandate cost/compute reporting to contextualize performance claims. Future studies could also draw from ongoing advances in multilingual hate speech detection and emotion-based sentiment tasks to ensure fairer evaluation across diverse language contexts [32].

Across all challenges, three cross-cutting practices are recommended to elevate CLSA research from reporting scores to producing scientific evidence. First, papers should include robustness and fairness audits to demonstrate reliability across languages and domains. Second, cost–benefit disclosures (e.g., annotation hours, compute budgets) should accompany accuracy reports to ensure equitable comparisons. Third, error taxonomies should be included to highlight common failure modes such as negation, intensifiers, irony, dialect variation, or code-switching. Overall, the analysis of RQ3 indicates that progress in CLSA for LRLs depends less on any single algorithmic innovation and more on achieving method–task fit, culturally valid label spaces, and transparent reporting practices. By addressing structural as well as technical barriers, the field can move toward more equitable and robust sentiment analysis systems that reflect the linguistic diversity of global communities.

VI. Discussion

This systematic review of 27 studies on cross-lingual sentiment analysis (CLSA) for low-resource languages (LRLs) reveals a field that is advancing in technical scope yet uneven in inclusivity and robustness. Synthesizing across the three research questions (RQ1 to RQ3), three thematic insights emerge: task diversification, methodological trade-offs, and persistent structural barriers.

A. Diversification of Sentiment Tasks (RQ1)

In addressing RQ1, the findings show that while polarity detection continues to dominate, there is a gradual shift toward fine-grained and socially relevant tasks, such as aspect-based sentiment analysis (ABSA), emotion detection, and hate speech recognition. This diversification signals maturity, as researchers recognize that polarity alone cannot capture the richness of human affect or the complexity of multilingual discourse.

However, the evidence also suggests that this diversification is uneven and shallow. ABSA and emotion detection remain marginal in CLSA studies, largely because of annotation challenges and cultural divergence in sentiment expression. For example, most ABSA implementations borrow English-based aspect taxonomies, which may not align with domain-specific discourse in LRLs, while emotion detection often relies on

Western-centric psychological categories. These practices risk semantic distortion, producing models that are technically functional but culturally misaligned. Recent studies continue to highlight the challenges of extending CLSA frameworks to low-resource languages, where semantic alignment and transfer learning remain key strategies for improving sentiment transfer across language pairs [33].

Thus, CLSA research must move beyond convenience-driven task choices toward context-driven task design. Future work should incorporate culturally grounded annotation schemes, involve community participation in defining aspects and emotion categories, and focus on safety-critical tasks like hate speech detection, where the stakes are highest for marginalized communities.

B. Methodological Diversity and Trade-Offs (RQ2)

In relation to RQ2, the reviewed studies demonstrate a wide methodological spectrum: pre-trained multilingual models (PLMs), few-shot and zero-shot learning, translation-based pipelines, contrastive/self-supervised methods, hybrid approaches, and linguistic resource engineering.

Each approach offers distinct strengths and weaknesses. PLMs provide scalability and strong baselines but disproportionately benefit HRLs due to biased pre-training data. Translation pipelines remain practical but introduce translation noise, which distorts sentiment signals in idiomatic or informal language. Few- and zero-shot approaches promise inclusivity but suffer from instability, with results swinging according to prompt design or dataset composition. Few-shot learning techniques have gained momentum as an effective solution for data-scarce settings by optimizing inter-sample relationships and improving class separation [34]. Hybrids and linguistic resources appear "old-fashioned", yet they deliver robustness and interpretability in morphologically complex or dialectally diverse languages, precisely the settings where PLMs struggle.

The key insight is that there is no universal solution. Instead, the most promising direction lies in composite or adaptive frameworks, where methods are tailored to the typology, morphology, and domain of each language. For example, PLMs can provide general cross-lingual representations, while rule-based components enforce negation handling, and lexicons anchor culturally specific sentiment cues. Studies that experimented with such combinations (e.g., P14, P20, P22) highlight the value of methodological hybridity, yet systematic evaluations of these trade-offs are still rare.

Going forward, CLSA research should explicitly report trade-offs—not only accuracy but also robustness under domain/dialect shift, annotation cost, computational budget, and fairness outcomes. Without such transparency, the field risks celebrating narrow performance gains while ignoring broader inclusivity and sustainability concerns.

C. Structural Challenges and Research Gaps (RQ3)

With respect to RQ3, the most striking finding is that progress in CLSA for LRLs is constrained less by algorithmic capacity than by structural limitations. Data scarcity remains the single greatest bottleneck, forcing reliance on synthetic augmentation or translation proxies. While useful stopgaps, these substitutes cannot fully replicate the richness of authentic, in-language annotations. Semantic misalignment persists as a fundamental challenge, with PLMs failing to capture culturally embedded sentiment cues in typologically distant languages. Translation noise undermines the reliability of pipeline methods, especially in informal or idiomatic domains. Domain and dialect mismatch continues to degrade model robustness, revealing that general-purpose CLSA systems lack adaptability. Bias in PLMs introduces unfairness, privileging HRLs at the expense of underrepresented languages, while few-shot instability limits the practical reliability of low-label methods. Hybrid cross-lingual approaches have shown promise in handling dialectal variations by combining multilingual representations with localized embeddings [35]. Finally, evaluation inconsistency fragments the field, making results across studies incomparable and slowing cumulative progress. These gaps underline that CLSA for LRLs is not only a technical challenge but also a socio-structural one, tied to questions of fairness, inclusivity, and cultural validity.

D. Broader Implications and Future Directions

Three implications for the future of cross-lingual sentiment analysis (CLSA) research emerge: Firstly, task relevance matters, where research agendas must expand beyond polarity detection to emphasize fine-grained and socially impactful tasks such as ABSA, emotion detection, and abusive language detection. These tasks are harder to annotate but yield greater societal value. Secondly, adaptivity is essential. Rather than pursuing "one-size-fits-all" methods, researchers should embrace hybrid and adaptive pipelines, combining PLMs with rule-based cues, lexicons, and contrastive learning, depending on the linguistic and domain context. Finally, fairness and inclusivity must be central. Without deliberate attention to dataset creation, bias mitigation, and evaluation standardization, CLSA risks reinforcing digital inequality. Low-resource language communities will continue to lag unless they are directly involved in defining sentiment tasks, building resources, and validating models.

In summary, the synthesis across RQ1 to RQ3 reveals that cross-lingual sentiment analysis (CLSA) for low-resource languages (LRLs) is progressing, but in fragmented and uneven ways. The technical toolkit is expanding—PLMs, few-shot learning, and contrastive methods all offer promise—but structural barriers persist. True progress will come not from chasing higher accuracy on polarity benchmarks, but from building inclusive, adaptive, and culturally grounded cross-lingual sentiment analysis CLSA systems that reflect the realities of the languages and communities they aim to serve.

Taken together, the answers to RQ1 to RQ3 reveal that CLSA research for low-resource languages is marked by imbalances in task focus, tensions in methodological design, and persistent structural barriers. These findings highlight that technical progress alone will not guarantee equitable outcomes. Instead, the field must reorient toward questions of relevance (task selection), reliability (methodological robustness), and responsibility (fairness and inclusivity). Building on this synthesis, the next section outlines the broader implications of these findings and proposes future directions that can guide a more inclusive and sustainable research agenda.

E. Synthesis Framework for Cross-Lingual Sentiment Analysis (CLSA) in Low-Resource Languages

To consolidate the findings of this review, this subsection introduces a Synthesis Framework for Cross-Lingual Sentiment Analysis (CLSA) in low-resource languages (see Fig. 3). The framework reconceptualizes the challenges identified across the reviewed studies—not as limitations, but as *drivers of research innovation*. Specifically, three fundamental challenges which are data scarcity**,** domain mismatch**,** and cultural bias**,** emerge as key factors shaping how CLSA methods and tasks evolve. Moreover, dialectic preference bias persists even in large-scale PLMs, raising concerns about fairness and representational balance across dialects [37].

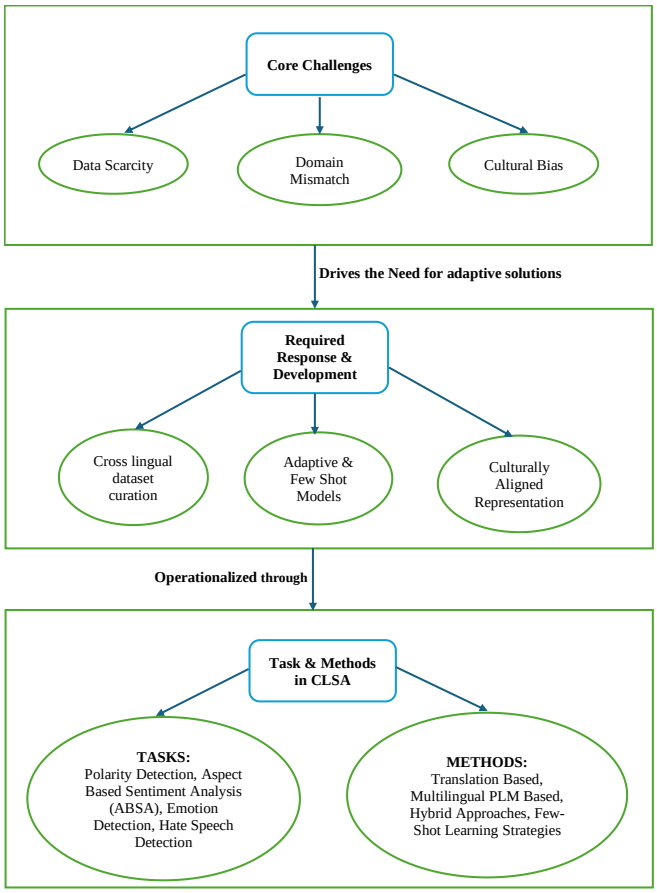

Fig. 3. Synthesis framework linking core challenges, development needs, CLSA tasks and methods in low-resource languages.

As illustrated in Fig. 3, these challenges generate distinct research and development needs, including cross-lingual dataset curation to address the lack of annotated resources, adaptive and few-shot learning techniques to enable knowledge transfer under limited supervision, and culturally aligned semantic representations to mitigate linguistic and contextual bias. Each of these needs directly influences the design of current and future CLSA tasks and methodological approaches.

The lower layer of the framework connects these needs with the practical implementation space—encompassing core CLSA tasks (polarity detection, aspect-based sentiment analysis (ABSA), emotion detection, and hate speech identification) and methodological strategies (translation-based, multilingual PLM-based, hybrid, and few-shot learning approaches). This linkage demonstrates how theoretical constraints are translated into actionable design choices. For instance, data scarcity stimulates the development of few-shot learning models, while cultural bias drives hybrid and knowledge-injected approaches that integrate linguistic and contextual knowledge. The importance of community-driven dataset development is evident in recent work on low-resource languages such as Bhojpuri, Maithili, and Magahi, which demonstrates how localized corpus design strengthens model generalization [38].

In summary, the proposed framework synthesizes empirical evidence from the reviewed literature into a structured, three-layer model that explains why certain CLSA methods emerge and how they align with the evolving research landscape. Rather than presenting CLSA as a static taxonomy of techniques, this synthesis reframes it as a dynamic, challenge-driven ecosystem, in which methodological innovation continuously responds to the constraints of low-resource linguistic environments.

The framework illustrates how major challenges such as data scarcity, domain mismatch, and cultural bias drive the need for adaptive solutions, leading to the development of new research responses and methodological innovations in cross-lingual sentiment analysis.

TABLE IV. COMPARATIVE SUMMARY OF TASKS, METHODS, AND CHALLENGES IN CROSS-LINGUAL SENTIMENT ANALYSIS (CLSA) FOR LOW-RESOURCE LANGUAGES

Task Type	Dominant Methods	Key Challenges	Research Gap / Opportunity
Polarity Detection	Translation + PLM	Translation noise, imbalance	Domain-adaptation across dialects
Aspect-Based SA (ABSA)	Hybrid + Few-Shot Learning	Aspect misalignment	Need culturally grounded aspect extraction
Emotion Detection	PLM + Contrastive	Semantic bias	Lack of local emotion lexicons
Hate Speech	PLM + Knowledge Injection	Bias & toxicity lexicon gaps	Fairness and bias auditing frameworks

As summarized in Table IV, the comparative overview highlights how each task category aligns with dominant methods, key challenges, and potential research opportunities within CLSA for low-resource languages. These patterns are consistent with prior large-scale reviews on cross-lingual sentiment analysis that documented similar task-method trends and evaluation issues [36].

VII. IMPLICATIONS AND FUTURE DIRECTIONS

The findings of this review carry theoretical, methodological, and practical implications for advancing cross-lingual sentiment analysis (CLSA) in low-resource languages (LRLs). The synthesis of RQ1 to RQ3 highlights that the field is at a crossroads, while technical capacity has expanded through pre-trained multilingual models (PLMs) and few-shot learning, progress remains constrained by imbalanced task focus, uneven methodological robustness, and structural barriers to inclusivity.

A. Theoretical Implications

From a theoretical perspective, the review underscores that CLSA research has been overly anchored in polarity detection,

reinforcing a narrow view of sentiment as binary or ternary classification. These risks oversimplifying human affect and ignoring culturally specific sentiment categories. A theoretical implication is the need to reconceptualize sentiment in multicultural, multilingual contexts. Instead of importing Western-centric taxonomies, future work should build frameworks that emerge from local discourse—for example, through community-driven aspect induction or culturally validated emotion ontologies. This would strengthen the linguistic and psychological validity of CLSA tasks in LRLs.

B. Methodological Implications

Methodologically, the findings imply that no single technique is sufficient for CLSA. PLMs provide scalability but are biased toward high-resource languages. Translation pipelines are pragmatic but prone to semantic drift. Few- and zero-shot learning are inclusive but unstable. Hybrids and linguistic resources offer robustness but demand manual effort.

The implication is clear, adaptive, composite frameworks should be the methodological standard, not the exception. Future CLSA studies should report trade-offs explicitly, including robustness under domain and dialect shift (not just peak accuracy), cost–benefit ratios (annotation hours, compute budgets vs. performance gains), and fairness metrics (performance gaps between HRLs and LRLs). Such transparency will enable the field to move beyond fragmented "accuracy chasing" and toward scientific accumulation and practical reliability.

C. Practical Implications

Practically, this review reveals that the current trajectory risks widening the digital divide between high- and low-resource languages. Without deliberate intervention, CLSA advances will disproportionately benefit languages already well-represented in pre-training corpora. This has real-world consequences: LRL communities may remain excluded from tools for opinion mining, public health monitoring, or content moderation.

To counter this, future CLSA must be inclusive by design. This means establishing community-driven dataset creation initiatives with fair compensation and participatory governance, designing culturally sensitive benchmarks that capture local discourse phenomena such as code-switching, dialectal variation, and culture-specific sentiment markers, and building bias-aware evaluation frameworks that surface disparities across language families, domains, and social groups. These steps would ensure that CLSA contributes not only to academic progress but also to equitable digital participation.

D. Future Research Directions

Based on the synthesis, several concrete research directions emerge. Firstly, task diversification. Researchers need to move beyond polarity detection toward ABSA, emotion detection, and abusive language detection in cross-lingual and low-resource settings. Prioritize tasks with high societal impact (e.g., detecting harmful speech, understanding public health discourse). Secondly, culturally grounded task design. Researchers may develop annotation schemes and sentiment categories that reflect local cultural contexts rather than importing English-based taxonomies. Thirdly, adaptive hybrid frameworks. Future research may combine PLMs with linguistic rules, lexicons, and contrastive/self-supervised objectives to improve robustness in morphologically rich or dialectally diverse low-resource languages (LRLs). Fourthly, fairness-aware model development where researchers can integrate bias detection, fairness metrics, and bias mitigation as core evaluation components, ensuring that CLSA does not exacerbate inequalities between high resource languages (HRLs) and low-resource languages (LRLs). Next, standardized multilingual benchmarks. Establish shared, community-maintained evaluation suites that cover HRLs and LRLs, include robustness tests (negation, sarcasm, code-switching), and track performance parity across language families. Finally, apply transparent reporting practices. Encourage CLSA publications to disclose not only accuracy metrics but also annotation cost, computational budget, variance across seeds/prompts, and error taxonomies. This would promote replicability and responsible claims of state-of-the-art performance.

In conclusion, the implications of this review are clear to state that CLSA for LRLs is not just a technical challenge but a socio-technical enterprise, where fairness, inclusivity, and cultural grounding are as important as model performance. Future research must adopt adaptive, hybrid, and community-driven approaches to ensure that sentiment analysis truly serves the linguistic diversity of the world. By embracing this agenda, the field can shift from incremental performance gains toward building equitable, culturally resonant, and globally relevant sentiment analysis systems.

VIII. CONCLUSION

This review has systematically examined recent advances in cross-lingual sentiment analysis (CLSA) for low-resource languages, focusing on the interrelations between sentiment tasks, methodological approaches, and the challenges that shape them. The findings reveal that despite substantial progress in multilingual pre-trained models and translation-based pipelines, CLSA still faces persistent issues related to data scarcity, domain mismatch, and cultural bias.

To address these gaps, the study proposed a Synthesis Framework for CLSA (Fig. 3), which integrates the connections between core challenges, emerging research needs, and corresponding methodological responses. This framework illustrates how each limitation serves as a catalyst for innovation—driving the development of adaptive and few-shot learning models, cross-lingual dataset curation, and culturally aligned representation strategies. By interpreting challenges as enablers of progress, the framework transforms CLSA from a descriptive research field into a dynamic, challenge-driven ecosystem**.**

In summary, the review highlights that future CLSA research should move toward adaptive, ethically informed, and context-aware models that not only achieve cross-lingual transferability but also preserve the cultural and linguistic diversity of low-resource communities. The proposed synthesis framework can serve as a conceptual guide for these future directions, promoting more inclusive, robust, and equitable sentiment analysis across languages and dialects.

Advances in Natural Language Processing for Radiology: State-of-the-Art Techniques, Applications, and Open Challenges

Kotha Chandrakala[1], Dr. Shahin Fatima[2]
Research scholar, Department of Computer Science and Engineering,
Koneru Lakshmaiah Education Foundation, Hyderabad-500075, Telangana, India[1]
Assistant Professor, Department of Computer Science and Engineering,
Koneru Lakshmaiah Education Foundation, Hyderabad-500075, Telangana, India[2]

***Abstract*—Radiology reports encode critical clinical observations from medical imaging in an unstructured textual form that is central to modern clinical diagnosis and decision support. In this context, natural language processing (NLP) has emerged as a key clinical NLP technology for automatically extracting, classifying, and interpreting information from radiology reports. This study presents a structured review of more than sixty recent contributions on NLP for radiology, covering approaches that range from traditional rule-based pipelines to contemporary deep learning and transformer-based models. We examine how deep learning architectures, including BERT, GPT-4, multimodal transformers, and vision–language alignment networks, are applied to core tasks such as disease classification, tumor response assessment, cancer phenotype extraction, radiology report generation, cohort identification, quality assurance, and longitudinal patient follow-up. Particular attention is given to knowledge graph integration, multimodal cross-attention, and zero-shot learning strategies that adapt large language models to radiology-specific workflows. We also analyze key barriers to clinical adoption, including limited annotated data, domain generalization gaps across institutions, ethical and fairness concerns, and the need for transparent model explainability. Based on this synthesis, the review outlines future research directions for building interpretable, multimodal, and clinically robust NLP solutions that integrate technological, clinical, and operational perspectives to advance radiology report analysis and medical imaging–driven care.**

Keywords*—Natural language processing; radiology reports; deep learning; transformers, medical imaging; report generation; clinical NLP

I. Introduction

The integration of artificial intelligence (AI) into clinical workflows has reshaped healthcare delivery, particularly in medical imaging and diagnostic interpretation. Among the various AI techniques, natural language processing (NLP) has become a key approach for extracting clinically meaningful information from unstructured text, especially radiology reports. These reports are rich in contextual and diagnostic detail but are often ambiguous and stylistically heterogeneous, which limits their direct use in automated systems. NLP helps bridge the gap between free-text documentation and structured representations that can support robust clinical decision-making.

Radiology reports play a central role in clinical decision-making by translating complex imaging findings into concise narrative summaries. The number of imaging examinations and the corresponding volume of textual interpretations continue to increase, making it challenging for clinicians to assimilate all available information efficiently. NLP-based systems assist with tasks such as automated diagnosis [1], identification of additional or incidental findings [4], tumor response classification [9], and assessment of disease progression [14]. These tools can reduce cognitive workload, improve consistency, and support timely decision-making. Over time, radiology NLP has evolved from rule-based approaches to advanced deep learning and transformer-based models such as BERT and, more recently, GPT-4.

Recent developments in deep learning and multimodal architectures have further expanded the possibilities for NLP in radiology. Models that align image and text representations, integrate radiologists' eye-gaze patterns, or employ cross-modal transformers offer improved performance and interpretability compared with earlier pipelines [25], [56], [29]. Hybrid systems that combine convolutional neural networks (CNNs), long short-term memory (LSTM) networks, and semantic evaluators have also shown strong results in radiology report generation and related downstream applications [22].

Despite these advances, several challenges hinder widespread clinical deployment. Model performance often deteriorates when applied to institutions other than the ones in which they were developed, due to differences in report style, structure, and terminology. The scarcity of large, high-quality annotated datasets limits the ability to train and validate models across diverse patient populations and imaging modalities. Concerns about data privacy, algorithmic bias, and lack of transparency remain, especially for deep learning–based systems used in high-stakes diagnostic settings. Domain-specific language models pre-trained on biomedical corpora (e.g., BioBERT, PubMedBERT) alleviate some of these issues, but the overall landscape remains fragmented and rapidly evolving [31].

This review concentrates on recent advances in NLP for radiology, encompassing a broad spectrum of techniques, applications, and clinical scenarios. It draws primarily on more

than 60 plus peer-reviewed studies published between 2020 and 2025 in venues such as IEEE Access, IEEE Transactions, and leading medical informatics journals. By mapping NLP methods to concrete radiology applications—including diagnostic automation, report generation, quality assurance, cohort identification, and clinical decision support—the review aims to provide a clear picture of current capabilities, limitations, and emerging directions [33].

The contributions of this work are threefold. First, it offers an updated synthesis of radiology-focused NLP methods, spanning rule-based systems, classical machine learning, deep learning, transformer models, and multimodal vision–language architectures. Second, it introduces a structured taxonomy that links technical approaches to clinical use cases such as disease classification, tumor response assessment, and longitudinal patient tracking. Third, it highlights cross-cutting challenges in data quality, domain generalization, explainability, and ethical deployment, and distills practical implications for developing clinically robust and trustworthy NLP solutions in radiology.

Unlike earlier reviews that primarily focus on individual application areas (e.g., breast cancer, de-identification, or report generation), this study provides a unified taxonomy that links techniques (rule-based, deep learning, transformers, foundation models) to end-to-end radiology workflows, including quality assurance, cohort identification, and longitudinal tracking. It also synthesizes very recent work (2020–2025) on multimodal vision–language models, synthetic data, and privacy-preserving training, which are not comprehensively covered in prior surveys.

The remainder of this study is organized as follows: Section II reviews NLP techniques applied to radiology reports, from foundational rule-based pipelines to modern deep learning and transformer-based models. Section III summarizes major application areas and representative use cases of radiology NLP. Section IV discusses technical approaches and methodological aspects, including data pre-processing, feature representation, model architectures, training strategies, and evaluation metrics. Section V provides a discussion of clinical translation, challenges, and limitations. Section VI outlines emerging trends and future research directions. Finally, Section VII concludes the study by synthesizing key insights and reflecting on the implications for future radiology-focused clinical NLP research and practice.

II. Background and Related Work: NLP Techniques in Radiology

A. Rule-Based and Statistical Methods

The initial NLP systems employed in the field of radiology made use of rule-based frameworks, which benefited from handcrafted lexical rules for extracting structured information from narrative reports. The clarity and ability to interpret these methods make them good candidates for clinical audits and quality control tasks [9], [13]. However, their problems with static ontologies and sensitivity to linguistic diversity limited scalability and generalizability. Techniques such as n-grams and TF-IDF were useful in document classification and term weighting, but only correlated according to the study [7].

B. Classical Machine Learning Approaches

With the help of machine learning (ML) models like support vector machines (SVMs), decision trees, and logistic regression, tagging of diseases associated with radiology reports resulted in semi-automated cohorts [6], [14]. A central role is played by feature engineering with bag-of-words, syntactic dependencies, and domain-specific lexicons. Machine learning (ML) models had greater adaptability than rule-based systems, but these models often relied on shallow representations of language and were not interpretable (see [8]).

C. Deep Learning and Hybrid Architectures

The introduction of deep neural networks, such as CNNs and RNNs, helped build richer contextual representations in radiologic natural language processing (NLP). CNN models worked well for spatial semantics performance, while LSTM architectures were effective for temporal dependency modelling of sequential clinical narratives [17], [22]. The combination of CNN-LSTM or attention-based RNN for various tasks, such as CT reporting in emergencies and response classification tasks [22], [26]. The clinical explainability challenge requires large annotated corpora despite the improved performance of the models [23].

D. Transformers and Foundation Models

Transformer architectural designs, such as BERT, BioBERT, and Clinical BERT, changed the paradigm of radiology NLP. Models pre-trained on large biomedical corpora can learn bidirectional contextual semantics better [21], [54]. Fine-tuned variants have been used successfully for tumor response classification [9], cancer report prioritization [10], and impression summarization [30]. In recent times, large language models LLMs like GPT-4 and ChatGPT have been used for radiology reporting, and they offer promise for zero-shot and few-shot, cross-institutional generalization, and adaptation [36], [60]. However, there are ongoing risks of hallucination, fairness, and clinical safety issues.

TABLE I. Summary of NLP Use Cases in Radiology

Application Area	Techniques Used	Representative Studies	Clinical Benefit
Disease Classification	Rule-based NLP, Transformers	[2], [6], [9], [10]	Faster triage, improved coding accuracy
Tumor Response & Phenotyping	BERT, LSTM, Attention Networks	[1], [3], [5], [14]	Personalized treatment planning
Report Generation	Multimodal Transformers, Reinforcement Learning	[20], [21], [25], [28], [37]	Streamlined documentation, reduced workload
Cohort Identification	Rule-based NLP, Knowledge Graphs	[4], [7], [14], [15]	Efficient trial recruitment, population health
Quality Assurance	Ontology Matching, NLP Audits	[12], [13], [16]	Standardized reports, error detection
Longitudinal Tracking	State-space Models, Cross-modal RNNs	[17], [34], [35], [40]	Time-based outcome prediction

The main NLP use cases in radiology identified in the reviewed literature—including disease classification, tumor response assessment, report generation, cohort identification, quality assurance, and longitudinal tracking—are summarized in Table I, and a comparative overview of rule-based, classical machine learning, deep learning, and transformer-based methods is provided in Table II.

TABLE II. COMPARATIVE SUMMARY

Technique	Strengths	Weaknesses	Representative Studies
Rule-based	Transparent, interpretable	Poor scalability, rigid syntax	[9], [13]
ML Models	Adaptable, efficient	Requires manual features	[6], [14]
Deep Learning	Captures complex context	Data-hungry, opaque	[22], [26], [23]
Transformers	Generalizable, state-of-the-art	Computationally intensive, ethical concerns	[21], [30], [54], [60]

Fig. 1 illustrates a generic NLP pipeline for radiology reports, from raw text input to downstream clinical tasks.

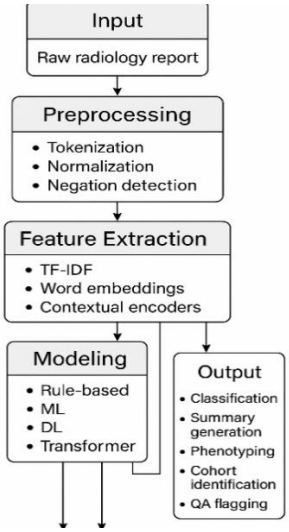

Fig. 1. NLP pipeline for radiology reports.

III. RESULTS AND APPLICATIONS OF NLP IN RADIOLOGY

Natural language processing (NLP) has emerged as a powerful tool to convert unstructured radiology narratives into structured ones. As radiology report volumes are exploding, the NLP-based solutions enable scalable, precise analysis for different diagnostic, operational, and research use cases. This section discusses important uses of NLP in radiology from various literature sources, as well as future perspectives.

A. Automated Disease Classification

One of the primary applications of NLP in radiology is the automatic classification of diseases from narrative reports. The techniques that have been used for the classification of pulmonary embolism, abdominal aortic aneurysms, and metastatic lesions are rule-based as well as machine-learning-based. Gaviria-Valencia et al. created a near-real-time NLP model to detect abdominal aortic aneurysms, which achieved a good recall and precision in clinical deployment scenarios [2]. Likewise, Laurent et al. employed a rule-based NLP pipeline within oncology workflows to classify tumor response outcomes in a timely manner [9].

BERT and other transformer-based models improved the classification accuracy of transformer models. Ayanouz et al. showed that the transformer-based NLP is better than traditional methods for prioritizing oncological radiology reports for review [10]. Moreover, Ong et al. introduced a neural NLP system that effectively identified disease responses from free-text radiology reports, with good agreement with a manual expert assessment [6].

B. Tumor Response and Cancer Phenotyping

NLP is used in oncology to help extract phenotypic information as well as track tumors. Fink et al. used deep learning for evaluating oncologic outcomes from structured radiology narratives, providing a scalable framework for retrospective outcome studies [1]. Maghsoudi and colleagues proposed a transformer-based NLP model for cancer-associated thrombosis. The model might facilitate real-time phenotype surveillance of hematologic malignancies [5].

According to the review, most of the breast cancer-related NLP applications aim to extract information related to tumour characteristics, receptor status, and treatment response using imaging studies [3]. In addition, predictive oncology is aided by the use of NLP pipelines to create digital twins of metastatic progression using longitudinal radiology report data [14] [18].

C. Radiology Report Generation

Development of a report is one of the most active areas of research in the field of NLP, where a report-generating system creates a coherent report from the relevant information. Recent models use vision-language mechanisms, reinforcement learning, and attention methods. The visual-textual cross-modal interaction network designed by Zhang et al. allows contextual alignment of image features with generated text, improving the fluency and relevance of reports greatly. Likewise, Yi et al. proposed a hybrid reward-based learning model that improves the quality of language outputs while preserving diagnostic specificity [28] [39].

Various strategies have emerged for report synthesis, such as multi-phase supervision, hierarchical classification, and gaze-guided alignment. GPT-4-based transformer encoding models were used by Olivato et al. [21], which result in strong language understanding capabilities, improving adherence to medical conventions and report completeness.

D. Cohort Identification and Surveillance

Natural language processing helps find groups of patients easily for clinical trials and more. According to Sekler et al., NLP has immense potential in identifying secondary findings buried in text (PET/CT reports) and largely ignored in oncological cohort's manual review [4]. According to Donnelly et al. [7], Natural language processing (NLP) could enable automated audits of electronic medical records to assist with disease surveillance, if potentially scaled out across hospital systems [19].

Batch et al. further investigated NLP-driven cohort extraction through metastasis detection pipelines that combined

structured sequences of radiology reports, which aid in building cancer digital twins [14].

In addition, Paul et al. showed that cohort curation was ethically compliant when de-identification models were built on radiology reports while preserving data utility [15].

E. Quality Assurance and Clinical Auditing

It is important to have quality and uniformity in radiological documentation for diagnosis and accreditation. Fei et al. developed a framework that uses NLP to monitor the quality of reports of pulmonary nodules. It highlighted variations in the vocabulary used and the completeness of reports. Kale et al. used knowledge graph techniques to detect inconsistencies in radiologist dictation to standardize reports and facilitate retrieval [12].

These NLP tools can be used for internal auditing within the institution. They also allow benchmarking against national or institutional reporting. According to Yu et al., NLP and machine learning models must undergo external validations before they may be used or integrated into a clinical quality system [16].

F. Longitudinal Analysis and Outcome Prediction

In addition to static analysis, NLP facilitates the long-term monitoring of disease progression and treatment response. Chuang et al. introduced a machine learning framework that organized CT liver tumor reports over time, making treatment response tracking easier and interpretable [17]. Zhang et al. used state-space modeling to create radiology reports sequentially to ensure temporal, spatial, and temporal dependencies [35].

Gao et al. applied multi-modal representation learning to predict the response to neoadjuvant therapy in breast cancer from its radiology text. Here, insights from NLP are aligned with therapeutic planning [40]. Likewise, Song et al. proposed a temporal residual network that includes time-sensitive report features to enhance prediction accuracy in radiologic sequences [34].

The datasets examined in this review draw on both large, publicly available chest X-ray collections and institution-specific oncology cohorts. Widely used resources such as MIMIC-CXR, CheXpert, and OpenI offer substantial volumes of radiology images and accompanying reports for model development, while in-house hospital and oncology datasets typically provide CT, MRI, and PET/CT reports with more detailed phenotypic and tumor response information. Table III outlines the main public and private datasets included in the surveyed studies, along with their imaging modalities and annotation characteristics.

TABLE III. PUBLIC/PRIVATE DATASETS FOR RADIOLOGY NLP

Dataset Name	Type	Modality	Annotation Type
MIMIC-CXR	Public	X-ray	Findings
CheXpert	Public	X-ray	Labels
OpenI	Public	X-ray	Reports
Private Hospital A	Private	CT, MRI	Phenotypes
Private Oncology Group B	Private	PET, CT	Tumor Response

IV. RESEARCH METHODOLOGY AND TECHNICAL APPROACHES

In radiology, natural language processing (NLP) draws on a wide range of technical strategies, including both traditional machine learning and modern deep learning. Each family of methods varies in its ability to represent clinical language, cope with variation in reporting styles, and remain robust across different healthcare institutions. In practice, radiology NLP workflows can be viewed as passing through five main stages: data preprocessing, linguistic analysis, feature construction, model training, and performance evaluation.

A. Data Preprocessing and Normalization

This study highlights the basics of NLP, specifically the first step in carrying out NLP on Medical text. Radiology reports often include abbreviations, negations, terms of anatomy, and ungrammatical forms. The text can be segmented properly using tokenization, sentence segmentation, and part-of-speech tagging. Techniques such as negation detection (NegEx and its variants) are specifically important in the medical domain to determine present or absent findings [13], [59].

Mapping synonyms to medical ontologies, such as SNOMED-CT or RadLex, also belongs to Normalization. According to some studies, Information extraction (IE) is used to convert free text phrases to structured representations for downstream machine learning systems.

B. Feature Engineering and Representation

Standard approaches use handcrafted features like term frequency-inverse document frequency (TF-IDF), bag-of-words, and n-gram statistics [7]. Early implementations were effective, but weaker in semantics, and failed to capture the connection between entities. The move towards distributed representations – word embeddings (Word2Vec, GloVe) and contextual embeddings (ELMo, BERT) – enhances the expressivity of the input features [21], [54].

In radiology contexts, embeddings adapted to domains like clinical BERT or Blue BERT trained on biomedical corpus have shown much improvement in performance on classification and generation tasks [17], [24]. The availability of models that project image and text features into shared cross-modal embeddings has made it easier to compare and align human and automated annotations. [25], [26], [56].

Table IV groups the models used in the reviewed studies into major categories and counts how many works fall into each category.

TABLE IV. CATEGORIZATION OF NLP MODELS USED IN STUDIES

Model Category	Example Algorithms	No. of Studies
Rule-based	Regex, Ontologies	6
Classical ML	SVM, RF	4
Deep Learning	CNN, RNN	10
Transformers	BERT, GPT	20
Multimodal	ViT-BERT, CLIP	8

C. Modeling Architectures

The architecture selection often depends on the task. Conventional methods for classification include support vector machines (SVM), random forests (RF), and logistic regression [6], [14]. Use of deep learning models on unstructured inputs has seen an increase in popularity over traditional methods.

Recurrent neural networks (RNNs) and their gated variants [e.g., recurrent neural networks, long short-term memory (LSTM), gated recurrent unit (GRU)] are commonly used to model the sequence of radiology text. CNN-LSTM hybrids have been utilized for the interpretation of emergency CT reports [22], while attention-based RNNs enhance focus on clinically salient terms [26]. The most researched models in recent literature are transformers like BERT, RoBERTa, and GPT-based models due to their contextual understanding and transfer learning capabilities [10], [21], [30].

Multimodal models incorporate both visual and textual data. Architecture involving eye-gaze guided networks [25], hierarchical attention transformers [21], and semantic fusion [56] facilitates cross-modal alignment of radiology images and reports.

Fig. 2 depicts the main technical components and data flow within radiology NLP architectures.

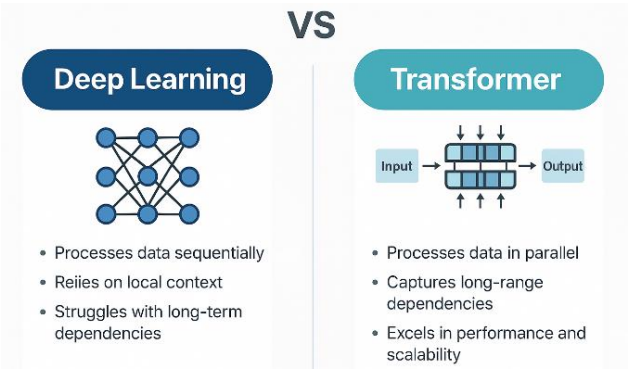

Fig. 2. Radiology NLP architectures: Technical components and data flow.

D. Model Training and Optimization

Training models of NLP in radiology faces challenges of class imbalance, noisy annotations, and limited labeled datasets. To mitigate these, researchers adopt techniques such as.

- Data augmentation refers to paraphrasing, back-translation, and synonym replacement.
- Transfer Learning: Fine-tuning pretrained models like BioGPT and GPT-4 on clinical corpora [36], [21].
- Semi-supervised Learning uses pseudo-labels or weak supervision on big, unlabeled datasets.
- Reinforcement learning was used for report generation (to enhance the quality of generated reports) with task-specific reward functions [28], [37].

Optimization methods may range from simple gradient descent to complex pieces such as AdamW, and regularization (dropout, weight decay) may be applied to prevent overfitting.

E. Evaluation Metrics and Benchmarking

Assessment of radiology NLP models requires both quantitative and qualitative evaluation. For tasks involving classification and extraction, standard metrics are precision, recall, F1-score, and AUC-ROC [2], [9], [11]. In the context of report generation, the BLEU, ROUGE, and METEOR scores are used to measure the linguistic similarity of reports with ground-truth text [20], [59].

There may be clinical relevance that these metrics miss. So, expert-in-the-loop validation, qualitative scoring by radiologists, and utility-based evaluation (e.g., diagnostic usefulness) are gaining more and more interest [16], [23], [24].

Table V outlines the key stages in typical radiology NLP pipelines, along with representative techniques and example studies.

TABLE V. KEY TECHNICAL STAGES IN RADIOLOGY NLP PIPELINES

Stage	Key Techniques	Challenges Addressed	Representative Works
Preprocessing	Tokenization, NegEx, Lexical mapping	Noise reduction, ambiguity handling	[13], [59], [62]
Feature Representation	TF-IDF, Word2Vec, BERT, Cross-modal embeddings	Semantic encoding, domain adaptation	[7], [21], [25], [56]
Modeling	SVM, CNN-LSTM, BERT, GPT-4, Hierarchical Transformers	Accuracy, context-awareness, scalability	[6], [22], [30], [54], [60]
Training	Fine-tuning, Reinforcement Learning, Semi-supervised	Data scarcity, generalization	[27], [28], [36], [61]
Evaluation	F1, AUC, BLEU, Human scoring	Performance, clinical relevance	[9], [16], [23], [59]

V. DISCUSSION: CLINICAL TRANSLATION, CHALLENGES, AND LIMITATIONS

In this section, we examine how radiology-focused NLP systems are being incorporated into clinical practice and highlight the main barriers reported in the literature. The discussion centers on data quality and variability, domain adaptation and robustness, interpretability and clinician trust, ethical and regulatory issues, and the practical challenges of embedding these tools into everyday radiology workflows.

Radiology and natural language processing (NLP) have advanced considerably, but scaling their use in routine clinical practice still faces major obstacles. The restrictions include technical, infrastructural, ethical, and regulatory. To move research-grade models into healthcare, we need to know these challenges.

A. Data Quality and Heterogeneity

Variations in radiology reports exist between institutions, modalities, and radiologists. It is difficult to develop generalized NLP models because the reporting styles, terminologies, and report structures vary. Further, many public

datasets are small or insufficiently diverse to enable transfer across institutions [16], [24], [59]. There is a lack of annotated datasets for fine-grained tasks, which include tracking tumor response and rare disease classification [5], [6].

Also, clinical documentation contains a lot of abbreviations, misspellings, and vague phrases. These problems cause a decline in performance of the rule-based and traditional machine learning models, which require robust pre-processing and normalization pipelines [13], [62].

To illustrate how datasets and methods align in practice, Table VI highlights representative combinations of application areas, datasets, and NLP techniques.

TABLE VI. KEY APPLICATIONS, DATASETS, AND METHODS

Application Area	Dataset Used	NLP Techniques
Disease Classification	MIMIC	Rule-based, ML
Tumour Monitoring	Private Oncology B	LSTM, BERT
Report Generation	CheXpert	GPT-4, RLHF
Cohort ID	OpenI	Keyword Search, Graph NLP
QA & Audits	Institutional Reports	BERT + Ontology

B. Domain Adaptation and Model Generalization

Pretrained language models (e.g., BERT, GPT) show good performance on benchmark datasets, but often underperform when deployed in new hospital systems, due to domain shift [24], [60],[63]. Phase post-training methods can be applied to fine-tune Clinical BERT, since their flexible design is suitable for diverse tasks.

Although powerful, transformer-based models are data-hungry and overfit to institutional-specific data [36]. Also, it is still a challenge for globally-operable NLP systems to generalize across languages, cultures and regions.

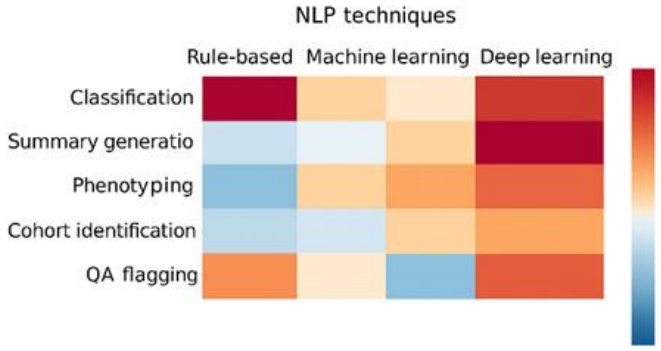

Fig. 3. Application-wise NLP techniques heatmap.

As illustrated in Fig. 3, the heatmap contrasts how frequently different NLP techniques are applied across major radiology tasks such as report generation, information extraction, and decision support. This visualization helps highlight which approaches are currently dominant in specific applications and where there is still scope for methodological exploration [52].

C. Explainability and Clinical Trust

The clinical use of NLP tools based on deep learning may face challenges not easy to overcome. Clinicians often demand explanations for automated decisions, especially in high-stakes settings like oncology or emergency [23]. Although rule-based methods are transparent, they do not scale. The adoption of transformer models in clinical workflows has been limited, despite the emergence of attention visualization, saliency mapping, and explainable AI (XAI) frameworks [27], [28].

Guidelines From U.S. And Other Countries. Essentially, the “provenance” and “autonomy” standards set by the FDA or EU MDR also require traceability and human oversight, which are not yet fully established in most deep learning NLP pipelines.

D. Ethical, Legal, and Privacy Concerns

NLP systems that work on radiology reports must abide by strict privacy regulations such as HIPAA in the U.S. or GDPR in Europe. Even though automated de-identification tools have been improved, there remains a risk for re-identification, especially when text is paired with imaging metadata. If certain demographics or disease types are underrepresented in the training data, resulting models may encode bias and deliver uneven performance across patient groups [59].

Improperly constrained large language models (LLMs) can hallucinate clinically inaccurate content, which raises serious safety concerns [30, 36]. Models are fine-tuned on specific data.

E. Integration into Clinical Workflows

Integrating NLP models into radiology information systems (RIS) or electronic health records (EHR) poses various and unique challenges. Legacy systems compatibility, real-time processing, and usability are some of the issues. According to Laurent et al. [9] and Sekler et al. [4], tight integration is important for adoption success. The models should also be efficient in delivering output while not affecting model workload and reporting workflows.

Automation only works well when there is a match in user interface, design, and time of decision [7], [23].

Taken together, these issues show that technological improvements by themselves are not enough. For radiology NLP tools to be used reliably in everyday care, they need rigorous external evaluation, clear governance frameworks, and joint design with radiologists, other clinicians, and hospital IT teams. The next section extends this discussion by describing emerging trends and research directions that seek to overcome these challenges.

VI. EMERGING TRENDS AND FUTURE DIRECTIONS

As Natural Language Processing is rapidly evolving, various changing trends are modifying its role in Radiology. These advances in multimodal foundation models, explainable AI, and the generation of synthetic data will tackle current shortcomings and spur off-the-shelf clinical use. This section mentions the future directions from the recent literature.

A. Multimodal and Vision-Language Models

One major change is the creation of vision-language models that combine imaging features into their textual data sets. With the help of these architectures, the interpretation of diagnostic images and their descriptions can occur simultaneously, thereby aiding in consistent reports and appropriate characterization of disease. Recent works like Med3DVLM [43] [45], Eye-Gaze Guided Alignment Networks [25], and crossmodal causal representation learning [29] illustrate this trend [44].

Techniques for pretraining vision and language models, specifically contrastive learning and attention mechanisms, are intended to achieve multi-modal generalization (e.g., X-ray, CT, MRI) and clinical adaptability (e.g., [25], [42], [56]).

Recent foundation-model efforts in chest imaging and cross-modal alignment further illustrate this trajectory [44], [45], [49], [50].

Table VII summarizes common evaluation metrics used in the reviewed studies and typical performance ranges reported for each.

TABLE VII. EVALUATION METRICS AND REPORTED PERFORMANCE

Metric	Used In	Typical Score Range
Accuracy	Classification	0.85-0.95
Precision	Detection	0.80-0.93
Recall	Detection	0.75-0.92
F1 Score	Overall	0.78-0.94
BLEU	Text Gen	20-35
ROUGE	Summarization	40-55

B. Generative Language Models and Radiology Report Synthesis

The emergence of GPT-4, BioGPT, and similar large generative models permits the development of fluent, clinically relevant report generation. Models fine-tuned on specific domain data can generate summaries, impressions, and full reports from both structured and unstructured inputs [21], [30], [36]. According to Zhang et al. [20] and Yi et al. [28], generating text through guided reinforcement learning and using a hybrid reward function can help maintain the factuality of generated text.

Additionally, ChatRadio-Valuer [36] and DDaTR [34] examine longitudinal context modeling to provide a consistent narrative across follow-up images, which is essential in oncology and chronic disease.

Several new radiology report generators refine longitudinal coherence and task-specific optimization across diverse datasets [34], [39], [51]–[53].

C. Explainable and Transparent NLP Models

The need for interpretability remains a clinical trust and regulatory concern. The new methods embed explanatory features within the model output. For instance, the observation-state-aware report generator [38] and the reward-based attentive mechanism [28] mark clinician-relevant tokens or phrases, providing insight into the decisions. Other works use knowledge-enhanced graph representations [12], [40] to track inferences and enable auditability [41].

As these methods become more developed, they can be incorporated into PACS viewers or RIS dashboards to provide radiologists with real-time, interpretable aids.

D. Self-Supervised and Few-Shot Learning Paradigms

Data annotation in medical NLP is resource-intensive. Self-supervised learning (SSL), implemented through masked language modeling or contrastive pretraining on unlabeled radiology corpora, and is increasingly used in this domain [24], [26]. The implementation of S3-Net [26] and zero-shot grounding technologies [46] [47] demonstrates how SSL allows for flexible reuse of models across tasks with minimal supervision.

Training foundation models on medical imaging data opens up a vast number of possible tasks. Artemova et al. showed that it is possible to do few-shot and prompt-based learning in the context of radiology [42]. For example, Lu et al. [48] demonstrated the feasibility of prompt-based learning for medical visual question answering using the BLIP language–vision model. This can make large foundational models accessible to resource-poor hospitals facing rare disease scenarios [45].

E. Integration with Real-Time Clinical Decision Support

Future NLP systems will be integrated and used in the clinical workflow in real-time. Some types of clinical decision support services are point-of-care decision support, triage alerts, and automated billing code assignment. For example, automatically identifying the priority of reports and flagging incidental findings can impact patient safety and throughput.

Technologies such as iterative feedback loops with radiologists [30] and systems built into emergency settings [22] are already demonstrating potential improvements in efficiency without increasing cognitive burden.

F. Synthetic Data Generation and Privacy-Preserving Models

The creation of synthetic data with the help of text generators and image augmentation can counter the issues associated with privacy and the shortage of data. Models such as LHR-RFL [28] and GAN-based simulators facilitate controlled variation of training samples that mitigate overfitting and enhance robustness.

In addition, federated learning frameworks and privacy-aware architectures (e.g., differential privacy and secure multi-party computation) are being investigated for cross-institutional model training without centralizing patient data [15], [32].

Fig. 4 outlines the evolving NLP landscape in radiology, mapping emerging trends such as large language models, multimodal integration, and real-time clinical decision support. It highlights how these advances are expected to reshape reporting workflows, reduce clinician burden, and enable more personalized, data-driven imaging care in the near future.

Privacy-preserving training and federated learning are being actively explored to address data sharing constraints [15], [32], [55], [57], [58].

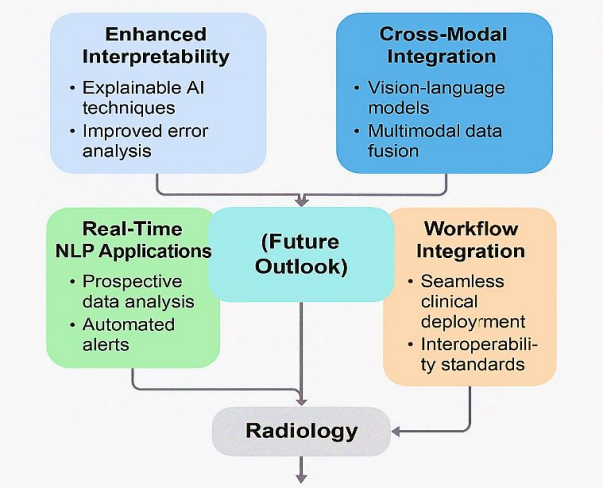

Fig. 4. Future outlook: NLP landscape in radiology.

VII. Conclusion

Over the past decade, natural language processing has become a central component of research at the interface of radiology, medical imaging, and clinical informatics. The studies reviewed in this study show that NLP can meaningfully support clinical workflows by automating parts of disease classification, tumor response assessment, radiology report generation, cohort identification, quality assurance, and longitudinal tracking of patient outcomes. When combined with electronic medical records and modern machine learning, radiology NLP systems have the potential to reduce manual effort, improve consistency, and surface clinically relevant information that might otherwise remain buried in free-text reports.

At the same time, multiple barriers continue to limit routine clinical deployment. Performance often drops when models are applied to data from new institutions or imaging protocols, reflecting differences in report style, vocabulary, and documentation practices. The scarcity of large, carefully annotated datasets constrains both model development and robust external validation. Concerns about data privacy, fairness, and the opacity of complex deep learning and transformer-based models add further friction, particularly in high-stakes diagnostic settings. Addressing these issues requires not only better algorithms but also clearer standards, transparent evaluation, and close collaboration between radiologists, data scientists, and hospital IT teams.

Looking ahead, several technical and methodological trends are likely to shape the next phase of radiology NLP. Multimodal vision–language models, self-supervised and weakly supervised learning, and robustness-enhancing strategies such as domain adaptation and adversarial training offer avenues for building systems that generalize more reliably across populations and institutions. Integration with knowledge graphs, structured clinical ontologies, and explainable AI techniques can help make model outputs more interpretable and clinically trustworthy. If these advances are coupled with rigorous benchmarking, prospective validation, and careful consideration of ethical and regulatory constraints, NLP tools can move from research prototypes to dependable components of everyday radiology practice.

Ultimately, real progress will depend on sustained cooperation across disciplines, updated guidelines for data curation and evaluation, and continuous monitoring of deployed systems in real-world settings. With a more integrated and clinically grounded approach, radiology-focused NLP can evolve from promising experimental systems into widely adopted tools that support radiologists and clinicians in delivering timely, accurate, and equitable care.

Associate Professor, Department of Computer Science & Engineering,
Koneru Lakshmaiah Education Foundation, Bowrampet, Hyderabad – 500043, Telangana, India[2]

***Abstract*—Cardiovascular disease is still the leading cause of death, and a definitive cure has not yet been found, so this is the time to make important changes in prevention and early diagnosis. Integrating artificial intelligence, machine learning, wearable sensors, and biomedical imaging is changing healthcare for cardiovascular care. Recent breakthroughs have reported that the use of smart immune sensors and artificial intelligence helps diagnose disease by testing blood and urine samples. The upcoming advances from various emerging technologies are expected to greatly enhance the overall accuracy and personalization of diagnostic processes within the medical field. This essay explores difficulties relating to domain adaptation, variability in data, and interpretability, including the need for rigorous validation tests and ethical considerations. The new system is made up of several programs that help the user to make decisions more efficiently in situations where rapid action is needed, while considering privacy preservation, clinical quality improvement, and energy efficiency. This review of more than sixty recent studies is an attempt to broaden the field of cardiovascular care by introducing a roadmap for further research. The creation of a fully responsive cardiovascular diagnostic system is not yet complete and requires the contribution of several entirely different fields of science.**

Keywords*—Cardiovascular disease (CVD); machine learning (ML); artificial intelligence (AI); wearable sensors; deep learning; Biomedical Signal Processing; microfluidics; nano sensors; robotic intervention; medical imaging; predictive modelling; causal inference; domain adaptation; federated learning; clinical validation

I. Introduction

Cardiovascular disease (CVDs) are the number one cause of morbidity and mortality in the world, responsible for almost one-third of all deaths each year [1]. Heart and blood vessel conditions include coronary artery disease, heart failure, arrhythmias, stroke and other conditions that affect the cardiovascular system. Early identification of these risks is therefore critical. Hospital-based methods like ECG, echocardiography, and lab-based blood tests are clinically effective, but the episodic nature of the tests impedes timely intervention [2].

Technology has given us new sensors to wear on our body, AI and robots that can help us to diagnose and help with therapy for heart diseases [3]. Real-time processing of high-dimensional physiological data with machine learning algorithms enables enhanced risk stratification and anomaly detection. At present, new biosensors and microfluidic methods allow the non-invasive monitoring of biomarkers, while deep learning models help in the interpretation of medical images and cardiovascular signals [4, 5].

Nonetheless, there are challenges related to data heterogeneity, signal artifacts, algorithm bias, low interoperability, and low validation standards [6]. This review will integrate information from multi-disciplinary areas to help bridge some of the prevailing gaps on emergent AI- and sensor-based technologies for cardiovascular care. The aim is to showcase present advancements, uncover key challenges, and recommend integrated strategies for robust, fair, and scalable heart diagnostic methods [7, 8].

This review is guided by the question of how emerging AI methods, sensing technologies, and imaging tools can be combined into an integrated framework for earlier and more scalable cardiovascular diagnostics [9]. The main contribution is a cross-disciplinary synthesis of recent technologies together with a conceptual framework for responsive cardiovascular diagnostic systems [10].

The remainder of this study is structured as follows: Section II reviews prior work on AI-driven cardiovascular diagnostics, Section III describes the review methodology, Section IV summarizes key advances in sensing, imaging, and predictive modeling, Section V presents the proposed integrated framework, and Section VI concludes with final observations and directions for future research.

II. Related Work and Literature Review

A. Machine Learning Techniques for Cardiovascular Detection

Machine learning is now being applied in a greater capacity in the detection of cardiovascular disease and so on [22][26][39][40]. Further, it brings an increase in accuracy and efficiency and the early detection of the disease. The traditional systems are being replaced by the data-driven machine learning approach because they use real-world data for the diagnosis of diseases [24][28]. They have proved to

*Corresponding authors.

use complex multi-dimensional data like physiological signals and patient clinical record [27] [33][34].

1) Supervised learning methods: Support Vector Machines (SVM), Random Forest (RF), Decision Trees (DT) and k-Nearest Neighbors (k-NN) are supervised algorithms extensively used for binary classification of healthy and diseased subjects [1][3][6][22][26][39]. Methods like AdaBoost and Gradient Boosting, called ensemble methods, improve the accuracy of predictions [4] [15] [33][34].

Ahmad et al. [1], for instance, applied numerous ML models on UCI heart disease dataset and discovered that Random Forest achieved an accuracy of 86%, which was greater than Naïve Bayes and Logistic Regression. Ali et al. [3] made a comparative performance analysis of various classifiers and reported that the ensemble approaches can reduce false positives [30].

2) Deep learning approaches: CNN and RNN deep learning techniques have shown great competence in high-dimensional and temporal data processing (such as ECGs and imaging) for medical purposes. CNNs extract layers of features from raw inputs according to a hierarchical structure, making them effective for ECG classification and cardiac image segmentation [11][17][18][30][39][40].

Kim et al. [17] deployed Transformer-based models for ECG analysis and achieved more than 90% accuracy on multi-lead ECG datasets [18] [60]. Hernandez et al. [11] compared deep learning models for arrhythmia detection. They found that the LSTM network adopted offers a deeper temporal learning architecture than a CNN and superior performance [34] [59].

3) *Hybrid and Ensemble Models:* Hybrid models combine classic ML with deep learning or other types of heuristic techniques like Genetic Algorithms or Fuzzy Logic [26][33][39]. Islam and his team employed a combination of deep learning and genetic algorithms to effectively forecast cardiovascular risk. According to reports, this model attained an accuracy of 94.5% on standard datasets.

According to Chopra and others, they used classifier techniques which ensured a good trade-off between sensitivity and specificity, which is essential in real life [22][28][39].

4) Explainable AI and Fairness: As AI models join clinical decision-making, interpretability and fairness have become essential. It is possible that black-box predictions without transparency will not be acceptable in high-risk medical settings. Recent studies therefore stress on the adoption of Explainable AI (XAI) techniques such as SHAP, LIME, and attention mechanism [12] [20][32].

To reduce bias, Pi et al. [55] adopted causal reasoning frameworks that adjust for demographic differences, leading to more generalizable models across a wide range of patients [50].

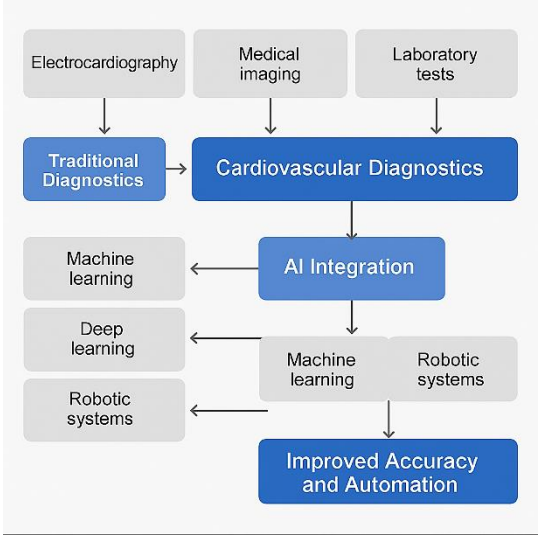

Fig. 1. Evolution of cardiovascular diagnostics and AI integration.

Fig. 1 illustrates the progression from conventional cardiovascular diagnostics toward AI-enabled, data-driven approaches that integrate multimodal sensing and advanced analytics.

This study presents a narrative, technology-oriented review and does not analyse any newly collected patient data. Relevant studies were gathered from sources such as IEEE Xplore, PubMed, and other major digital libraries by using combinations of search terms related to cardiovascular disease, artificial intelligence, wearable sensing, biosensing, microfluidics, medical imaging, and robotics. Across these works, commonly used benchmark datasets include UCI Heart Disease, the Framingham Risk Study, MIT-BIH arrhythmia databases, PTB-XL, and MIMIC-III, among others, which the original authors employ to develop and evaluate their proposed models.

TABLE I. SUMMARY OF MACHINE LEARNING MODELS FOR CARDIOVASCULAR DISEASE DETECTION

Model / Study	Dataset Used	Accuracy (%)	Key Contribution
Random Forest - Ahmad et al. [1]	UCI Heart Disease	86	Improved classification via ensemble learning
SVM -Ali et al. [3]	Cleveland Dataset	84.5	Compared performance of standard classifiers
CNN - Hernandez et al. [11]	MIT-BIH Arrhythmia	91.2	Automatic feature extraction from ECG
LSTM - Hernandez et al. [11]	MIT-BIH Arrhythmia	92.6	Captures temporal ECG dependencies
Transformer - Kim et al. [17]	PTB-XL ECG	94.3	Long-range ECG interpretation
Hybrid DL + Genetic Algorithm - Islam et al. [13]	UCI Heart + Custom Features	94.5	Risk prediction via optimization
Ensemble (Voting Classifier) - Chopra et al. [5]	Framingham Dataset	89.7	Balanced accuracy and interpretability
Causal Adjustment - Pi et al. [55]	Chest X-ray + EHR	88.3	Bias mitigation using causal graphs

Table I brings together major machine learning approaches used for cardiovascular disease detection, outlining the data they consume, the prediction tasks they address, and how well they perform.

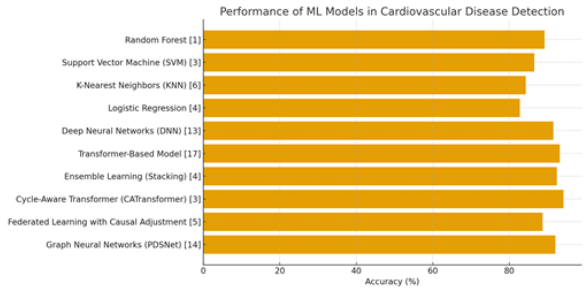

Fig. 2. Comparison of ML model architectures for cardiovascular prediction.

Fig. 2 compares different machine learning architectures used for cardiovascular risk and event prediction, highlighting their main inputs, outputs, and structural differences.

B. Emerging Biomarkers and Biosensors

The cardiovascular biomarkers have gained a lot of interest for the detection and assessment of cardiovascular disease (CVD). According to present-day studies, common biomarkers like troponins, B-type natriuretic peptide (BNP), and C-reactive protein remain the standard practice. However, more recent research focuses on newer highly-sensitive and real-time detection methods supported by biosensors and nanotechnology-enhanced platforms.

Recent studies focus on high-sensitivity detection mechanisms using apt sensors. These sensors use either oligonucleotide or peptide molecules for the binding of specific biomarkers. Jaric et al. [14] have shown femtomolar (10–15 M) level detection of NT-proBNP in artificial saliva. This is a significant achievement to detect early-stage diagnosis of heart failure. Just like that, vertical flow assays and enhanced electrochemical platforms based on graphene have been able to measure troponin levels with nanoscale biosensors with a lot of accuracy [10], [36].

Microfluidic systems are another technology being combined with biosensors for real-time sampling of low-volume media and multiplexed detection. According to Ma et al. [20], diagnostic microfluidics are potentially able to measure cardiovascular biomarkers such as D-dimer, IL-6, and hs-CRP. They offer portable and affordable solutions for effective point-of-care testing.

The signal amplification and use of nanomaterials (gold nanoparticles, carbon nanotubes, quantum dots, etc.) have greatly improved the sensitivity and specificity of biosensors [25], [35]. These can help improve the signal transduction and enable rapid electrochemical or optical readouts of the output.

An increasing focus on the coupling of wearable sensors with chemical biomarkers is also emerging. To illustrate, sweat and interstitial fluid sensors worn on the body have shown usefulness in monitoring a cardiac biomarker continuously [31]. The use of biosensors with Artificial Intelligence-powered systems will lead to closed-loop cardiovascular diagnostics and therapy.

However, biosensor systems face challenges like standardization, calibration, biocompatibility and long-term stability. To make them reliable for clinical use, one must resolve these issues.

TABLE II. SUMMARY OF BIOSENSORS AND DETECTION TECHNIQUES FOR CARDIOVASCULAR BIOMARKERS

Biomarker	Sensor Type	Detection Method	Limit of Detection
NT-proBNP	Aptamer-based biosensor [14]	Electrochemical impedance	5 fM
Troponin I	Graphene-enhanced electrochemical sensor [10]	Vertical flow assay	0.01 ng/mL
CRP	Quantum dot optical sensor [36]	Fluorescence-based detection	1 pg/mL
D-dimer	Microfluidic immunoassay [20]	Colorimetric readout	20 ng/mL
IL-6	Nanoparticle-amplified ELISA [25]	Electrochemiluminescence	10 pg/mL
hs-CRP	Lab-on-chip microfluidic device [35]	Electrochemical impedance	2 pg/mL

Table II lists a range of biosensors and their detection methods for cardiovascular biomarkers, noting the sensing principle, sample medium, and indicative sensitivity or detection limits.

C. Microfluidics and Nanoscale Diagnostics

Microfluidics and nanotechnology present opportunities for the early diagnosis of cardiovascular disease [28][37][38]. They are highly sensitive, require a low volume of the sample, and can be used for PoC diagnostics [28].

Microfluidic technologies allow for the precise manipulation of fluids in channels that are sub-millimeter in size. This permits integration of complex diagnostic workflows onto a single chip [28][37]. According to Ma and colleagues [20], the proposed techniques can be successfully implemented for the analysis of biomarkers troponin and NT-proBNP at enhanced efficiency and speed. Blood Filtration, Mixing, and Detection.

System: These systems are integrated for real-time cardiac biomarker detection. Microfluidic readouts have been combined with deep learning methods. Han et al. [10] proposed a paper-based vertical flow assay enhanced with deep learning for Troponin detection to improve the sensitivity and interpretability of microfluidic systems.

Aptasensors and nanoparticle-enhanced detection have emerged on a nanoscale. Jaric et al. [14] and Jaric & Petrova [36] developed sensors based on aptamers that can detect NT-proBNP in saliva at a concentration of femtomolar level. This is a non-invasive way of diagnosing heart failure. Meanwhile, nanoscale sensors using surface plasmon resonance and electrochemical transduction to quantify biomarkers were discussed by Shi et al. [25] and Liu & Wang [35].

In addition, Debus et al. [43] investigated molecular communication in blood using superparamagnetic nanoparticles. The study found that physiological complexity (e.g., non-Newtonian flow) can lead to signal distortion at the nanoscale. As a result, it is crucial to take this into account while designing intra-body Nano networks [41][54].

Microfluidic and nanoscale diagnostics hold promise but face various barriers to real-world deployment including reproducibility, mass manufacturing, and standardization. These platforms really represent a big movement toward fast, very sensitive, and decentralized cardiovascular testing.

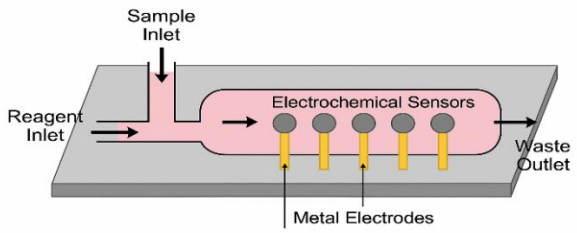

Fig. 3. Lab-on-Chip microfluidic architecture.

Fig. 3 presents a lab-on-chip microfluidic layout for cardiovascular biomarker analysis, showing the sample inlets, micro channels, and detection zones integrated on a compact platform.

TABLE III. MICROFLUIDIC AND NANOSCALE DIAGNOSTIC PLATFORMS FOR CARDIOVASCULAR APPLICATIONS

Technology	Target Application	Detection Limit	Advantages
Lab-on-a-chip Microfluidics	On-chip detection of cardiac biomarkers (e.g., troponin, CRP)	Sub-ng/mL [20]	Integrated sample processing and analysis
Paper-based Microfluidic Assay	Low-cost troponin I detection	~0.01 ng/mL [10]	Portable, rapid, and inexpensive
Aptamer-based Nanosensors	Non-invasive NT-proBNP quantification	Femtomolar [14][36]	High selectivity and non-invasiveness
Surface Plasmon Resonance Sensors	High-sensitivity electrochemical detection	Low pg/mL [25][35]	Label-free, real-time measurement
Molecular Communication Testbed	Signal propagation in blood using nanoparticles	Signal degradation due to viscosity and flow patterns [43]	Novel paradigm for in-body communication

Table III presents representative microfluidic and nanoscale diagnostic platforms tailored to cardiovascular applications, describing device layouts, operating modes, and typical clinical scenarios.

D. Image and Signal Interpretation Using Deep Learning

Deep learning is impacting cardiovascular imaging and signal analysis by automating feature extraction, improving diagnostic accuracy, and enabling faster assessment across modalities. CNNs, transformers, and hybrid architectures are widely used for tasks like image segmentation, disease classification, and reconstruction from undersampled data [30][39][40][59].

1) Imaging-Based cardiovascular assessment: Imaging techniques like MRI, CT scan, and echocardiogram can aid in the diagnosis of structural and functional defects. According to Yang et al., a multiscale vision transformer-based model called MSV-Mamba was devised which outperformed the previously mentioned architectures in segmenting cardiac structures from echocardiograms with Dice scores higher than 95% for the left ventricle boundaries [5][60]. The authors demonstrated the AdaDenseNet integration of CT-based lung cancer and cardiovascular risk prediction with over 98% and 91% accuracy, respectively [4][30]. Like this, combined vascular modeling and deep learning to obtain an estimate of the fractional flow reserve from angiograms with 91% accuracy [19][62].

2) Signal interpretation from ECG, PPG, and PCG: Deep models also make it easier to help extract diagnostically useful information from physiological signals. In 2021, Yuan et al. came up with CA Transformer for the conversion of PPG to ECG with high fidelity, cycle-aware temporal modeling [61]. Researchers Demirel and Holz introduced chaotic dynamics into deep neural networks (DNNs) to enhance heart rate estimation from PPG in the presence of noise, achieving up to 40 percent improvement [9][41]. Eslami and Moaiyeri also employed ternary networks with hardware acceleration to classify PCG signals for continuous wearable deployment with low energy consumption [21][13][45].

3) Image reconstruction and data efficiency: Training deep models in clinical imaging is made difficult due to insufficient labeled datasets. To this end, Wang et al. proposed DeepSSL, a spatiotemporal deep network to reconstruct dynamic MRIs. The model only required 75% less training samples and produced high-quality reconstructions of a patient [15][59]. The paper [8] also presented a method that uses a more sophisticated type of neural network called Lorentzian-informed neural representations (LINR). So, this approach embeds physical models into neural networks. In particular, it generates high-quality CEST MRI maps with little labeled supervision [42].

4) Cross-Domain generalization: The scanner protocol variations, patient population differences, or acquisition conditions often cause domain shifts in medical AI systems. Liang et al. presented the Module Robustness Criticality (MRC) that only fine-tunes the fragile modules in a deep network to enhance robustness in different domains without retraining the whole network [10][51].

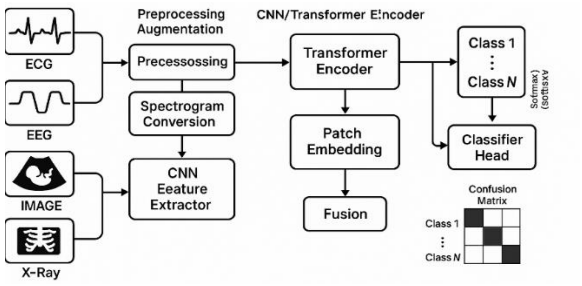

Fig. 4. Integrated framework for AI in cardiovascular health.

Fig. 4 depicts an integrated AI framework that connects data acquisition, preprocessing, model inference, and clinical decision support for cardiovascular health management.

TABLE IV. DEEP LEARNING MODELS FOR CARDIOVASCULAR IMAGING AND SIGNAL INTERPRETATION

Study / Model	Modality / Input	Key Outcome
MSV-Mamba [5]	Echocardiography	95%+ Dice for cardiac structure segmentation
AdaDenseNet [4]	CT Imaging	98% accuracy for lung cancer, 91% for CVD
CATransformer [3]	PPG Signal	Accurate ECG generation from PPG
DeepSSL [15]	Dynamic MRI	Reduced training data by 75% with stable output
MRC Fine-tuning [10]	Heart Sound / Acoustic Data	Improved cross-domain robustness
LINR for CEST MRI [8]	CEST MRI	Self-supervised MRI mapping
Ternary Neural PCG Classifier [13]	Phonocardiogram (PCG)	Energy-efficient PCG classification
Chaotic Modeling for HR Estimation [9]	PPG Signal	40% improved HR estimation under noise

Table IV compares deep learning models used for analyzing cardiovascular images and physiological signals, with details on the network designs, input modalities, and reported evaluation scores.

E. Robots and Smart Systems related to Heart Fixing

Minimally invasive robotic systems are being evaluated in cardiovascular interventions due to their precision, safety, and potential to reduce physician fatigue [49][58]. Inventions of magnetic, MR-compatible, and catheter-based robotic apparatus are now complementing image and AI-guided real-time controls.

A small 4-DOF catheter robot was recently designed by Kantu et al. This robot is 90 per cent smaller than conventional systems. In particular, it supports the guidewires of different diameters (1-9 French) to facilitate clinical use [49]. In a similar context, Wang et al. produced [58] an MR-conditional catheter robot with a 2-DOF actuation mechanism capable of infinite translation and rotation. The catheter can rotate and translate without experiencing any mechanical entanglement while residing inside the MRI Scanner.

F. Predictive Models and Causal Inference Frameworks

The measure of predicting heart attacks and cardiovascular disease progression saves lives [24][29]. By using information from patient records, wearable devices, or imaging, the risk of illness can be determined [24][29]. Today's advanced statistical techniques, including "transformer" learning, unfairly judged "Graph Neural Networks", and even discontented "Recurrent Networks", the application of causal inference produces a model that is miniature yet backwards derived [33][52].

1) EHR-Based predictive modeling: Liyo et al. developed a deep graph/transformer for IUD prediction, integrating ontology information with temporal patient medical status within adjoining years [52]. PDSNet basically outperformed much so the classical RNN and CNN-based methods, in mean that 2-12% for AUC, and 3 - 18% for FI, do upgrade more than 3-18% per cent F1 and 2-12% AUC overall performance [52]. The effectiveness of structured knowledge embedding in the future risk evaluation process is shown in [52].

2) Causal inference and model fairness: Clinical AI performances may end in inequitable medical treatments due to the biased selections of models [50]. Researchers Pées generated a model to predict heart health risks by utilizing a computer and scrolling through their chest X-rays. Colleagues have created a magnetic guidewire system that is controlled by ultrasound imaging and anchored by deep learning-based tracking. The system was able to tip-track the object with an accuracy of 0.81 mm and follow a path within 1.5 mm during which no collisions with the vessel phantom were observed.

Besides mechanical, robotic control is also increasingly reliant on AI. Trajectory processing, real-time modulation, and autonomy using neural networks, reinforcement learning, and physics-based control models are on the rise [44][48].

However, several limitations remain. Many systems are validated, commonly, in bench or phantom setups. They do not have a clinical validation or FDA approval. Another challenge posed is power consumption, integration of the system with imaging tools provided by the hospital, and compatibility issues with different catheter types.

These obstacles notwithstanding, robotics is a game-changer in cardiovascular interventions. The likely future systems will incorporate modular robotic arms, imaging sensors (ultrasound, fluoroscopy), and real-time AI analytics that allow fully automated or semi-automated surgical procedures.

TABLE V. ROBOTIC SYSTEMS AND INTELLIGENT CONTROL FOR CARDIOVASCULAR INTERVENTION

Robotic System	Function	Performance Metrics	Validation Status
Compact 4-DOF Catheter Robot [49]	Teleoperated endovascular navigation	90% size reduction, supports multiple catheter sizes	Bench testing
MR-Conditional Catheter Robot [58]	MRI-safe catheter insertion	100% success in phantom catheterization	Phantom studies only
Ultrasound-Guided Magnetic Guidewire [48]	Magnetic guidewire tracking and steering	0.81 mm tip error, 1.5 mm path error	Flow phantom validation
Autonomous Navigation (ML-based) [44]	Trajectory planning for interventional devices	AI-driven path optimization, energy-efficient	Simulated intervention tasks
Magnetic Actuation + Image-Based Feedback [48]	Closed-loop control using imaging feedback	Precision steering in phantom with DL image tracker	Ultrasound image-guided testbed

Table V summarizes robotic platforms and intelligent control strategies developed for cardiovascular procedures, indicating the type of intervention, control scheme, and current stage of clinical adoption.

III. RESEARCH METHODOLOGY

Risk assessment is a significant tool preventing heart disease. With the increasing use of electronic health records, wearable devices and multiform data sources, computer frameworks are being developed to anticipate conditions before they appear clinically.

A. Deep Predictive Models Using Clinical Data

There have been recent developments that combine temporal and semantic relationships that can be obtained from HER-related information. These techniques aren't always effective enough for healthcare professionals seeking to diagnose problems before they become serious. One particularly promising new method of predicting patients is a one-year horizon PDSNet model based on a graph approach scheduled to conclude after the first quarter of 2028 [46]. On the MIMIC-III dataset, PDSNet outperformed traditional models by both predicting more accurately and being more reliable overall [56].

B. Addressing Bias with Causal Reasoning

Clinical AI poses a major issue with maintaining balance across the societal spectrum. Causal modeling involves avoiding hidden confounders that generally effect diagnosis and results. For example, models trained to detect risk from chest X-rays are biased towards larger populations. Researchers utilized a machine learning procedure called namely, the convolutional framework in order to diminish the racial biases in a study [15].

C. Enhancing Interpretability

In today's fast-changing world, transparency in decision-making is crucial in medical contexts. Artificially intelligent methods like SHAP and LIME give doctors ratings on the relevance of different medical specifics. When used thoroughly with predictive models on a frequent basis, advice and knowledge are portrayed to the healthcare providers as being reliable by them, and as a result, the providers continue to pick and choose what to do in conjunction with the methods through which the website just asks, using the help they see [13][14].

D. Physiological Context and Biomarker Dynamics

With the development of structured information pathways, the effects of biological markers in the circulatory system are now simulated [47].

This is the first step in understanding conditions. Approaches like this provide an exacting margin of error in diagnostic predictions, especially with biosensors [23].

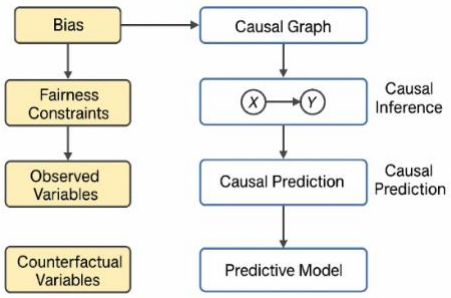

Fig. 5. Causal modeling and bias mitigation framework.

Fig. 5 outlines a causal modeling and bias mitigation framework, indicating how causal graphs and fairness constraints are used to detect and reduce systematic bias in predictions.

The recent instances highlight a change in how people classify risks into the very particular cog of ethical ordering. Work going on with the project will center itself around making it even more useful, by improving the methods they lastly worked out [53] [57]. This does not mean they will spend a long time analyzing. Instead, their focus on - and research with - making their work useful for the challenges different people will face will be improved. Following the much faster method, they expect the code, model, or system to be ready to work when it is released, without any external help. The collection of data that they will use is of prime importance, and effort should be spent in getting it verified, approved, and repeated over time, to assure reliability.

TABLE VI. REFINED PREDICTIVE AND CAUSAL MODELS FOR CARDIOVASCULAR RISK ESTIMATION

Model / Framework	Data Inputs	Primary Goal	Key Findings
PDSNet (Graph Transformer) [56]	Symptom Ontology + EHR (MIMIC-III)	Forecast 1-Year Heart Failure Risk	Enhanced AUC and F1 over conventional baselines
Causal CNN for Risk Equity [15]	Chest Radiographs + Demographics	Reduce Predictive Bias Across Populations	Maintained accuracy while reducing demographic bias
Explainable DL with SHAP/LIME [13][14]	ECG Signals + Patient Records	Improve Trust via Feature Attribution	Interpretable feature-level insight for clinicians
Biomarker Source Localization Model [23]	Simulated Circulatory Biomarker Flow	Detect Pathological Signal Origins in Circulation	Accurate spatial inference using decay-aware learning

Table VI reviews recent predictive and causal modelling approaches for estimating cardiovascular risk, highlighting the modelling framework, incorporated risk factors, and improvements over conventional risk scoring methods.

IV. RESULTS AND DISCUSSION: INTEGRATING CHALLENGES, VALIDATION STANDARDS, AND ETHICAL ISSUES

In this section, we discuss the main challenges that emerged from the reviewed studies and provide our perspective on how they should guide the design of future AI-enabled cardiovascular diagnostic systems.

While AI and sensor technologies mentioned for cardiovascular care are promising, they are far from being adopted widely in clinics due to practical and ethical challenges. The integration of data, the variability of the real world, compliance with laws and regulations and equity in the system-design process are just a few of the challenges we face.

A. Interoperability and Multimodal Fusion

More and more, signals from wearable sensors, imaging modalities, and electronic health records are integrated in cardiovascular diagnostics. However, achieving seamless data fusion remains difficult. Difficulty in real-time exploitation is caused by variability in data formats. Multi-modal AI models should not only align asynchronously (e.g. PPG, ECG, CT) but also allow for missing or noisy data. It is important to

construct robust data preprocessing pipelines and attention-based fusion mechanism [16][20].

B. Validation Protocols and Regulatory Standards

As these systems edge closer to use in the clinics, it becomes essential to validate them against established benchmarks. AI diagnostic tools are not subjected to standard pathways, unlike traditional products. For instance, less than 2% of cuffless blood pressure monitor studies on formal protocols of e.g., AAMI, ISO [7]. Like generative language, they also do not often go through external validation on diverse datasets. Developing clear and replicable metrics like sensitivity, specificity, and calibration error is essential for regulatory approval as well as multi-site clinical trials.

C. Fairness, Bias, and Population Generalization

Machine-learning models that learn from biased models may not perform well across various patient populations. For instance, risk scores calibrated on primarily Western cohorts could misclassify patients from underserviced ethnic groups or age groups [15]. Models should involve causal inference, domain adaptation, and fairness constraints to solve this. Federated learning is a way of training across institutions while keeping the data private at the source. This enables better generalization of the models while keeping sensitive data safe and secure [5][56].

D. Transparency and Explainability

Predictions from black boxes can result in damaging outcomes in accountable and interpretable clinical areas. By using XAI tools like SHAP or LIME, clinicians can understand what features affect predictions. By integrating known hemodynamics relationships into physical priors, AI architectures can obtain healthy models. Adding specialized knowledge can not only perform better but also make the model's outputs more consistent with clinical reasoning.

E. Ethical Deployment and Human-in-the-Loop Design

Apart from the technical side, ethical implementation requires systems that complement rather than replace expertise. Frameworks that include humans in the loop help AI tools that support work but let practitioners override or contextualize them. Patients should also be allowed transparency on how their data is used, and will be set up with informed consent, auditability, and recourse [63].

To fully grasp the potential of AI, which bolsters cardiovascular health care, these integrations and ethical issues must be looked into. A future study should include designs that are equitable and trust-enhancing. Also, it should focus equally on autonomy.

V. Proposed Integrated Framework for AI-Enabled Cardiovascular Diagnostics

In order to correct and update the shortcomings seen in modern cardiovascular diagnostic devices, certain technologies are being combined in multiple ways. The objective of this building design is to provide a self-sufficient system that includes monitoring and assistance.

A. Key Components of the Framework

The platform incorporates wearable devices that capture synchronized physiological signals such as your heartbeat, pulse, and movement.

Artificial Intelligence for Healthcare Diagnostics: AI is used to improve the accuracy of medical imaging, ones using MRI, CT, or ultrasound scanning. These tools are able to detect and track down abnormal deposits, measure the volume of the heart compartments, and establish typical circulation techniques.

The different centers only share the model they've developed so that no patient information is ever exchanged or misused.

Tools such as Fair learn are added to model prediction scores to identify and therefore reduce biases and discrimination.

Modern devices house speedy embedded AI applications to preserve battery life and save valuable time, no matter where their user may be in the world right now.

High-risk situations prompt the use of imaging-guided robotic systems, which are MRI or ultrasound-compatible, for precise catheterization and biopsy. Methods of artificial intelligence serve to project possible interventions and treatments specifically tailored to each patient's unique situation.

B. Workflow Overview

The integrated platform is depicted through this particular figure (see Fig. 6). Data is collected by a fitness tracker and then analyzed by on-board AI. Clinicians are issued local and secure automatic alerts.

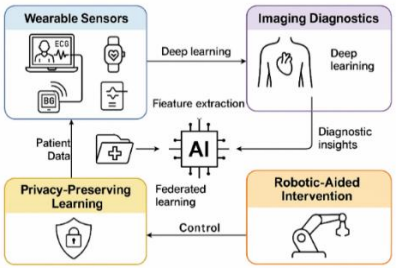

Fig. 6. Integrated framework architecture.

Fig. 6 shows the overall system architecture of the proposed integrated framework, including wearable and sensor data streams, edge and cloud analytics, and interfaces for clinicians and automated interventions.

VI. Conclusion

Combining artificial intelligence, sensors and clinical diagnostic technologies can transform the way we diagnose heart diseases. Cardiovascular disease is one of the most common causes of morbidity and mortality worldwide. This highlights the need for an integrated biosensor–deep learning system for smart intervention.

This review has covered a wide array of innovations, including machine learning techniques for classifying signals, advanced biosensors and microfluidics, robotic systems, and

predictive models. Despite this progress, important challenges remain, such as data heterogeneity, model generalizability, interpretability, and regulatory validation, which continue to slow the practical use of these technologies.

To address the challenges posed by the data-centric world, we propose a unified multi-modal framework that combines federated learning, causal inference models, energy-efficient edge computing, and modular robotics. In this review, the framework is presented as a conceptual architecture that enables fair and accurate cardiac medical diagnosis, while also respecting patient privacy and providing actionable insights in real time.

Future research must focus on large-scale clinical validation, harmonization of data standards, and development of transparent, explainable AI systems that can win the trust of clinicians. With interdisciplinary collaboration and deliberate system development, AI-enabled diagnostics can transition from research prototypes to a core component of future cardiovascular care.

***Abstract*—The rapid expansion of Internet of Things (IoT) technologies has transformed smart home systems into essential tools for enhancing safety, independence, and quality of life, particularly for older adults and individuals with disabilities. However, the extent to which these groups understand and adopt IoT-enabled smart homes remains limited. This study addresses insufficient knowledge and uneven adoption of smart home IoT technologies among vulnerable demographic groups, examining how demographic factors shape levels of awareness and readiness for use. Two parallel approaches were employed for a validated questionnaire (of 15 sections) distributed to 249 participants and in parallel with semi-structured interviews for 25 selected individuals in Najran, Saudi Arabia, during the summer of 2023. Quantitative data were gathered and analyzed using descriptive statistics and multivariate analyses of variance. Qualitative data were under content analysis. Results revealed low levels of knowledge regarding IoT-enabled smart home systems among the respondents and different groups. Significant differences were found for groups of different employment status, age (15 to 30 and 30 to 45 years), economic status (above average), and disability status. However, no significant differences were found for gender or marital status. Qualitative insights indicated major concerns related to affordability, user passivity, lack of technical support, poor internet connectivity, device overload, issues of privacy, security, and system reliability. It was highly recommended to perform targeted measures to improve awareness, accessibility, inclusive design, and infrastructure. Future work may address spatial and temporal variations in IoT adoption, develop tailored training models for older adults and individuals with disabilities, and assess the effectiveness of policy initiatives aimed at increasing smart home readiness. These efforts can further improve the safe and effective integration of IoT technologies and improve indoor life quality and sustainability for vulnerable people.**

Keywords*—Internet of Things; smart home; vulnerable people; smart home; energy efficiency

I. Introduction

IoT has been significantly employed for establishing smart home technologies as a driver in promoting independence, safety, and quality, especially for vulnerable people (the elderly and disabled). Recent works have had a focus on the interactions of different groups of people with smart homes that are equipped with IoT. Previous works were addressed mainly on technical performance, attitudes of users, and infrastructure readiness of smart home systems, with limited attention paid to the most benefited by these systems, like vulnerable people. In the Saudi context, there is a lack of work exploring knowledge, awareness, and challenges faced by vulnerable people interaction with smart home systems. IoT applications have significantly transformed daily life by controlling various household equipment and devices, e.g., refrigerators and microwaves, into fully integrated smart home systems. The IoT model comprises a network of interrelated devices that connect and exchange data via the Internet. The network is connected with sensors, actuators, software, data storage, and processing units, enabling communication between devices and users, and also among devices themselves [1].

A. Smart Home Concept and System Design

Home automation has emerged after integrating IoT with home functions, improving the built and urban environments [2]. Smart homes provide users with real-time remote monitoring and control functions, and managing their living environments from anywhere with an internet connection [3]. These environments integrated artificial intelligence with IoT-enabled devices and automated features, improving domestic functions for better automation [4]. Beyond their domestic functions, smart home systems increasingly serve as key components within smart grid infrastructures, enabling real-time communication between users and electricity networks. This integration of energy efficiency and demand-response mechanisms thus improves the reliability of services and functionality [5].

The concept of smart homes dates back to the early 21st century, when advances in information and communication technology began to materialize not only in consumer electronics such as phones and televisions, but also in broader infrastructures such as urban networks and cities. This widespread technological integration has improved the quality of life globally, with significant impacts on home environments [6]. This work examined how factors such as gender, age, marital status, education level, income, and employment influence knowledge and perceptions of IoT-based smart home systems among vulnerable people. Furthermore, the study examines key barriers to adoption, including privacy concerns,

cost constraints, and system complexity, to inform the development of more inclusive and user-centric smart home solutions. With the ever-increasing proportion of older people and people with disabilities globally, this study highlights the urgent need to align smart home innovations with the specific needs of these often overlooked user groups.

The significance of this research lies in its focus on a user-centric perspective rather than a technology-based perspective, particularly in its emphasis on marginalized groups who face distinct cognitive, functional, and accessibility challenges in adopting smart technologies. These groups have limited benefits of using smart home system elements and functions due to a lack of awareness, usability issues, and a lack of trust in the technology. Existing studies tend to prioritize younger, more tech-savvy age groups, while neglecting the lived experiences and expectations of older adults and people with disabilities. By focusing on user perception and daily needs, this study categorizes smart technologies as tools for enhancing home comfort, safety, and well-being. Furthermore, this work provides vital insights for policymakers, technology designers, and developers seeking to create inclusive systems that protect user privacy, ensure ease of use, and meet the diverse needs of vulnerable populations. These findings are particularly relevant in the context of Saudi Arabia, where there is a lack of local research addressing the intersection of smart home technologies and demographic disparities. By identifying adoption gaps and concerns such as security and trust, the study contributes to the design of safer and more effective IoT systems for everyone.

Previous works have limited focus on the influences of demographic factors on cognitive disparities within vulnerable groups. For instance, privacy, cybersecurity, cost, technical support availability, and slow internet connectivity are frequently mentioned in global literature, but they have not been assessed in light of the living reality of Saudi families in the Najran region. This gap highlights the urgent need for studies that measure knowledge levels but also investigate demographic differences and contextual challenges affecting IoT adoption among older adults and individuals with disabilities. This work offers a comprehensive, multi-method investigation designed to provide evidence-based insights that can guide policymakers, technology developers, and service providers in developing more inclusive, accessible, and context-sensitive smart home solutions.

Home functions remain manual in many cases, even with technological advancements and availability. This misses valuable opportunities for simplification and automation, and thus high indoor quality [7]. The remote control capabilities of smart home systems also raise significant privacy and security concerns [8]. Many studies have reported discrepancies between the availability of smart home technologies and their adoption. For instance, South Korea and Malaysia still have limited awareness and a lack of trust, which has hindered uptake [8,9]. Research addresses that potential users, particularly homeowners unfamiliar with the benefits of smart technologies, are still unaware of their advantages [3,10]. This study explored how demographic factors influence knowledge and perception and identifying perceived risks and challenges in the adoption of smart home systems, with an emphasis on underserved populations in the Kingdom of Saudi Arabia. This work addressed the following research questions:

- What is the level of knowledge of the elderly and people with disabilities in using IoT in applying the smart home system to support their lives?
- Do factors such as gender, marital status, educational level, employment status, age, experience, class, and economic status affect knowledge towards using IoT in implementing a smart home system to support the quality of home life for the elderly and people with disabilities as users and potential users?
- What are the concerns and risks of using IoT for a smart home system to support the life quality from the perspective of the study sample members?

The smart home system has gained growing interest from ICT experts, initially focusing on automation and ambient intelligence [8]. Smart homes have progressed from basic appliance automation to systems integrating sensors and remote-control technologies that enhance efficiency and safety [10-12]. Today, smart homes utilize IoT and communication technologies to create intelligent, interconnected environments that reduce user effort and promote comfort and security [13]. Fig. 1 illustrates a conceptual diagram of the smart home system architecture consisting of the main pillars and applications.

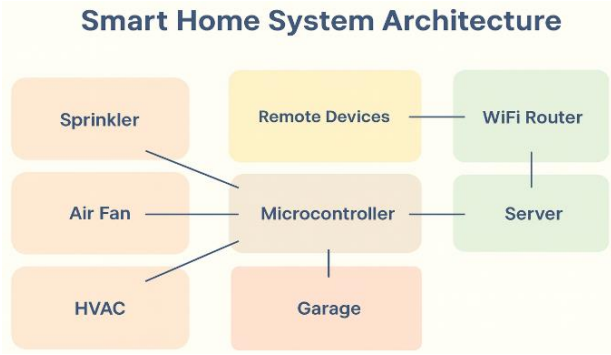

Fig. 1. Flowchart of the smart home system architecture that consists of main elements.

IoT systems provide easy communication among smart devices such as smartphones, microcontrollers, and sensors within the smart home system (see Fig. 1). This interconnected framework enhances home monitoring, security, safety, and protection through advanced IoT technologies [14]. A smart home is described by the convergence of various subsystems related to daily living, often supported by technologies such as fiber optic infrastructure that facilitate internal communication and external data exchange via a centralized smart portal. This integration creates a living environment that is efficient, comfortable, secure, convenient, and environmentally responsible, blending automation with service and management. The system employs computing technology, control systems, image display, and communication tools to meet the automation requirements of modern households [13]. Smart home controllers, which serve as central management units that transmit surpass traditional remote control functionality,

offering users control via smartphones, tablets, web browsers, and SMS [15] (see Fig. 2).

Fig. 2. Indoor smartness elements, connections and devices [7].

B. Advantages and Disadvantages of Smart Home Systems

Smart homes integrate advanced technologies and interconnected devices to enhance residents' quality of life. These systems operate by collecting and processing data through sensors and wireless networks, thereby creating intelligent environments that support a wide range of daily activities, including work, relaxation, and entertainment [8,16]. As smart technologies continue to evolve, smart homes offer increasingly personalized services that improve comfort, efficiency, and convenience [17]. A key contribution of smart homes lies in their positive impact on well-being, particularly through services that promote safety, support health care, and reduce household costs [18]. Environmental control is one of their defining features, enabling users to remotely or automatically manage lighting, thermostats, ventilation, and appliances, thereby minimizing manual effort and optimizing comfort [19].

Smart devices integrated into home systems are capable of detecting motion, alerting users to unauthorized entry, and providing access control through mobile apps, voice commands, or biometric verification [20]. These tools not only enhance security but also offer flexibility in managing access to the home. A smart home is a technology-enhanced living space that enables comprehensive control, monitoring, and support, significantly improving both safety and quality of life at home [21,22]. Users can manage security systems, energy consumption, environmental conditions, and even kitchen functions via smartphones and connected devices [9,15].

Recent developments reinforce this view: for example, AI-powered smart security systems now leverage IoT devices to provide real-time motion detection and authentication [23], while smart door locks integrate biometric authentication (e.g., fingerprint, face recognition) with IoT connectivity for enhanced access control [24,25]. Moreover, a meta-study on home automation security highlights the growing effectiveness of smart locks, motion sensors, and surveillance systems in improving residents' sense of security and control [26] (see Fig. 3).

Smart homes are often viewed as an impractical new technology due to their high cost and limited accessibility, as [27] points out. Smart homes allow users easy access to a variety of devices, including lighting, air conditioning, temperature sensors, and surveillance cameras, creating a more comfortable and secure living environment. The main concern is security and privacy. This concern arises because the data collected from these devices is typically transmitted to the user over an open network, such as the internet or a system provided by a service provider. Moreover, the involvement of service providers in collecting and storing this information raises the risk of data leakage and the potential for unauthorized access, leading to significant repercussions. For instance, the timing of an HVAC unit's operation could inadvertently reveal whether a homeowner is present or not. Similarly, any breach or tampering with critical medical data collected from wearable body sensors can have severe consequences, as articulated by [28].

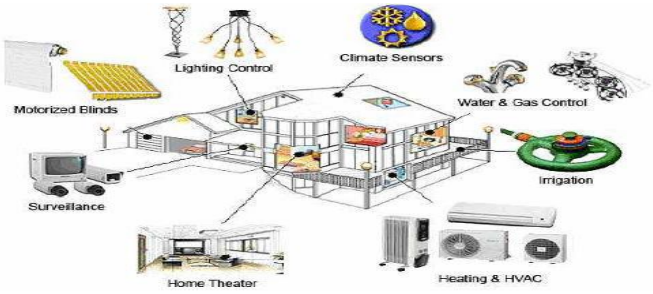

Fig. 3. Smart home integration services [15].

The elderly are people who have advanced in age and are starting to show signs of aging. Their definition varies from country to country. Some countries, such as Saudi Arabia, consider elderly people to be those who have reached the age of sixty and above, i.e., retirement age reported by the Ministry of Human Resources and Social Development, 2023. Other countries consider elderly people to be those aged sixty-five and above, or seventy and above. The elderly suffer from hearing and vision impairment, general weakness, wasting, decreased activity, and recurring illnesses, including chronic diseases. They need special care in employment, health care, social security, etc. [29]. Over the past four decades, models of disability have featured prominently in disability policy formulation, studies, and the human rights of persons with disabilities [30]. First, disability is a broad term that includes impairments and limitations in activities and participation according to the WHO (2010). Based on the 2006 United Nations Convention on the Rights of Persons with Disabilities (CRPD), disabled is referred to as a person with disabilities who have long-term physical, mental, intellectual, or sensory impairments that prevent them from fully and effectively participating in society on an equal basis with others, according to the United Nations, 2006. The high rates of disability are attributed to several factors, including advanced age, survival after birth, or injuries resulting from accidents.

C. Smart Homes and IoT for Elderly and Disabled Support

Quality of life broadly represents the well-being of individuals in society and is shaped by various personal and environmental elements, impacting physical, psychological, and social states [31,32]. In terms of individuals with disabilities, quality of life can be improved through the adoption of smart home systems powered by IoT technology. According to the Saudi Association of People with Disabilities (2021), the impact of IoT on home quality of life can be categorized into four domains: Being (physical and psychological well-being), Belonging (social inclusion), Transformation (personal growth

and leisure), and Daily Tasks (independent functioning). Addressing these domains through technology can significantly improve the daily life experience of individuals with disabilities and older adults [33]. The IoT refers to the network of interconnected devices equipped with sensors and software that enable remote monitoring and control [34]. These technologies allow users to control temperature, lighting, humidity, motion, and other elements in their smart home environment, improving comfort and safety.

Smart home technologies have become central to supporting active aging, independence, and adaptability among older adults, offering capabilities such as emergency response systems, accessibility features for individuals with visual and hearing impairments, fall-detection technologies, and even integration with wearable and implantable health-monitoring devices [6]. These developments align with broader societal efforts aimed not only at improving technical performance but also at creating intelligent living environments that enhance comfort, safety, and overall home life [11]. More recent studies reaffirm this trajectory, showing that AI-enabled smart home systems can significantly enhance health monitoring, daily functioning, and autonomous living for aging populations and individuals with disabilities [35,36]. In parallel, smart home ecosystems contribute substantially to energy efficiency and environmental sustainability, an aspect of particular relevance for older adults and people with disabilities who tend to spend more time at home. Solutions such as smart lighting, adaptive climate control, and automated appliance management help reduce energy consumption and improve residential energy performance [5,37].

However, barriers such as limited awareness, high costs, and a lack of digital skills hinder the spread of these technologies among these groups [17]. To overcome these challenges, it has recommended inclusive design practices and targeted educational initiatives to empower these groups [38]. Raising awareness and simplifying the use of technology can enhance adoption and participation in energy-saving practices, while also improving their quality of life.

A deeper critical analysis of previous research on the topic of the current study can be provided from the following aspects:

D. Demographic Factors and Their Impact on Knowledge

1) Age: Older adults often face challenges in adopting new technologies, including the IoT, due to a lack of technical expertise or a reluctance to learn new skills. They may also have concerns about ease of use and security.

2) Disability: Different types of disabilities can affect individuals' ability to interact with smart home systems. For example, people with visual or motor disabilities may have difficulty using traditional user interfaces, requiring more inclusive designs.

3) Education: Individuals with different educational levels may have different levels of knowledge about the IoT and its applications. Individuals with higher education tend to be more open to new technologies and better able to understand technical concepts.

4) Socioeconomic status: Individuals from different socioeconomic backgrounds may have different levels of access to the technologies and resources needed to adopt the IoT. Some individuals may not be able to afford the necessary equipment and services. Controversies and Contradictions:

5) Knowledge versus use: Some individuals may have theoretical knowledge of the IoT, but may be reluctant to use it in their homes due to concerns about privacy, security, or cost.

6) Use versus benefit: Some individuals may use smart home systems, but they may not fully realize the potential benefits they can offer, such as improved safety, comfort, or efficiency. Individual Needs: The needs and expectations of older adults and people with disabilities may differ, meaning that one smart home system may not be appropriate for everyone.

E. Quality of Life Impacts and Risks

Improving Quality of Life: Using the IoT in smart home systems can improve the quality of the life for the elderly and people with disabilities by providing greater independence, security, and comfort. For example, smart sensors can detect falls or other health issues and provide immediate assistance.

Privacy and Security Concerns: There may be privacy and security concerns when using IoT in the home, especially for individuals who have concerns about the collection or use of personal data. Technical risks: There may also be technical risks associated with the IoT, such as hacking or technical failures that could affect individual safety. These risks and concerns can be overcome through inclusive design. Smart home systems must be designed in an inclusive manner to meet the needs of diverse users, including the elderly and people with disabilities. Awareness and Training: Awareness and training programs should be provided to help individuals understand the benefits and risks of the IoT and how to use it effectively. Collaboration: Device manufacturers, researchers, and users must collaborate to set new standards for the design and production of safer and more inclusive smart home systems.

II. Methodology and Approaches

A. Study Methodology and Design

A descriptive approach was used using the survey method to describe reality quantitatively, which is the most appropriate and suitable approach for the nature of this study in answering its questions and achieving its objectives. The first study tool (knowledge questionnaire) was used to collect quantitative data and measure the level of knowledge about the use of IoT in smart home system implementation to support the quality of home life from the perspective of the elderly and people with disabilities as users and potential users. In addition, a qualitative approach was employed through semi-structured interviews to investigate the concerns and risks associated with the use of IoT in smart home system implementations, aiming to support the quality of life for the elderly and people with disabilities.

B. Study Sample and Demographic Distribution

A stratified random sample of (249) individuals from the elderly and people with disabilities categories was carefully selected from the Najran region in the Kingdom of Saudi Arabia

during the summer of 2023. This selection process was carried out in collaboration with the Candle of Hope Association for People with Disabilities and the Nour Najran Association for Women and People with Disabilities. The study tool was then distributed electronically through a Google Drive form, made accessible to the study participants. This electronic distribution was facilitated by cooperation with officials from the aforementioned organizations, who shared the questionnaire via personal email and the WhatsApp application. The questionnaire remained accessible for completion during the period of June 1 to 30, 2023. Table I presents a breakdown of the study sample, categorized by various demographic variables.

TABLE I. DESCRIPTION OF THE SAMPLE SIZE, ASSOCIATED DEMOGRAPHIC VARIABLES, INDICATOR, NUMBER OF SAMPLES (N), AND PERCENTAGE (%) (SEE ZEYAD ALSHBOUL [39])

Variable	Indicator	% (N)
Gender	Male	0.43 (106)
	Female	0.57(143)
Marital status	Married	0.43 (106)
	Single	0.57 (143)
Educational level	Illiterate	0.38 (94)
	School	0.36 (89)
	University	0.27 (66)
Employment status	Work	0.51(128)
	No work	0.49 (121)
Age	15-30	0.22 (56)
	30-45	0.28 (69)
	45-60	0.31 (76)
	+60	0.19 (48)
Experience	Likely to use	0.53 (131)
	Use	0.47 (118)
Classification	The Elderly	0.55 (137
	People with disabilities	0.45 (112)
Economic status	Average or below	0.50 (124)
	Above average	0.50 (125)
Total		100 (249)

A random sample of 25 participants was selected, including 10 elderly and 15 people with disabilities in the Najran governorate. This selection was conducted to obtain the most important concerns and risks related to the use of the IoT in the smart home system application to support the home quality targeted at vulnerable groups. This was done after the participants agreed to participate in the study, and the interview was recorded.

C. Tools of the Study

A questionnaire was developed to measure knowledge about the use of IoT in smart home system implementation to support home quality of life as perceived by the elderly and people with disabilities as users and potential users. To achieve this goal, reference was made to theoretical literature and previous studies relevant to the topic of the current study, such as the Saudi Society for People with Disabilities (2021) [6,33]. Appropriate items were formulated to measure knowledge about the use of the IoT in smart home system implementations to support home quality of life as perceived by older adults and people with disabilities as users and potential users. The tool, in its final version, consists of two parts. The first section consists of answer instructions and demographic information for the study sample members (gender, class, age, marital status, educational level, economic status, employment status, and experience). The second section of the questionnaire included (15) items designed to assess the level of knowledge related to the use of the IoT in implementing a smart home system, as perceived by the elderly and people with disabilities, whether as current users or potential users. To provide their answers, participants were asked to place a mark (√) in front of each item on a five-point scale that included options for strongly agree, agree, be neutral, disagree, and strongly disagree. To standardize the assessment tool, specific values were assigned to each response category, ranging from 5 for strong agreement to 1 for strong disagreement. The overall scoring system was then defined to be 1.00-1.80 for very low level, 1.81-2.60 for low level, 2.61-3.40 for moderate level, 3.41-4.20 for high level, and 4.21 - 5.00 for very high level [39].

D. Validity of the First Tool

This study utilized content and construct validity methods. Initially, the tool was reviewed by ten experts in computer science, networks, information systems, and psychological measurement from Saudi universities. They assessed item relevance, clarity, and alignment with the study's objectives. Items with at least 80% agreement were revised for clarity and measurability, resulting in a finalized 15-item tool. Construct validity was then tested using correlation coefficients between each item and the total score, based on an exploratory sample of 30 individuals from Najran. Results are detailed in Table II.

TABLE II. CORRELATION COEFFICIENTS (AT 0.05 SIGNIFICANCE LEVEL) BETWEEN THE ITEM AND THE TOTAL SCORE OF THE TOOL

Item no.	Correlation coefficient with the tool	Item no.	Correlation coefficient with the tool
1	0.67	9	0.33
2	0.57	10	0.53
3	0.44	11	0.57
4	0.34	12	0.36
5	0.50	13	0.51
6	0.60	14	0.77
7	0.57	15	0.73
8	0.56		

Table II presents the correlation coefficients for the items in relation to the overall tool, and these coefficients ranged between 0.33 and 0.77. It is important to note that all of these correlation coefficients were deemed acceptable and statistically significant, in line with the standards established in previous research [40]. Given the robust correlation coefficients observed, none of the items needed to be removed from the tool. This result further validates the tool's capability to accurately measure the intended constructs, reinforcing its overall validity and reliability.

E. Reliability of the First Tool

To verify the tool's reliability, two methods were used: test-retest and internal consistency. The tool was administered twice to 25 individuals with disabilities outside the main sample, and Pearson's correlation measured response stability. Additionally, Cronbach's Alpha was calculated to assess internal consistency. The results of both methods are shown in Table III.

TABLE III. CRONBACH INDICATOR FOR THE STUDY INSTRUMENT WITH THE NUMBER OF ITEMS, THE TEST USED, AND THE CRONBACH CONSISTENCY LEVEL COEFFICIENT

Tool	No. of items	Test-retest	Cronbach's Alpha
Knowledge questionnaire	15	0.88	0.79

The reliability assessment using the test-retest method yielded a coefficient of 0.88 for the tool as a whole. Simultaneously, when evaluating reliability through the internal consistency method, specifically utilizing Cronbach's Alpha, the tool as a whole produced a coefficient of 0.79. These reliability coefficients are notably high, signifying the tool's aptness for achieving the study's objectives. This strong reliability further bolsters the tool's capability to yield consistent and dependable results [40].

F. Semi-Structured Interviews

Semi-structured interviews were conducted with a group of 25 individuals, including 10 elderly people and 15 people with disabilities in the Najran region, who are users and potential users of the IoT in implementing a smart home system. The interviews targeted the most significant concerns and risks related to using IoT in smart home systems to support the indoor quality for targeted vulnerable groups. In this study, a semi-structured interview was used. It relied on a set of pre-defined questions, allowing the respondent to provide further clarification. The researchers developed a list of sub-questions that included the same items included in the study instrument (questionnaire), which received poor evaluation scores, to accurately identify concerns and risks related to the use of IoT in smart home environments to support the quality of home life for targeted vulnerable groups. The questions were as follows:

- In your opinion, is it possible to rely on IoT in implementing a smart home system to support the quality of home life for the elderly and people with disabilities now?
- In your opinion, do you think that using IoT in implementing a smart home system to support the quality of home life for the elderly and people with disabilities is convenient and facilitates daily tasks for the person?
- In your opinion, can IoT in smart home system applications maintain confidentiality, privacy, and security for the elderly and people with disabilities?

The validity of the interview tool was verified by a group of people with experience and expertise in the disciplines of computer science and networks, information and communications systems, and psychological measurement and evaluation in Saudi universities. After that, the interview tool was produced in its final version. The meetings were arranged with the participants in advance, and their consent was obtained to conduct the interview either face-to-face or remotely using the Zoom application. They were recorded manually and electronically (audio) and then transcribed manually on paper in the participant's words, leaving the interpretation until after the interview. Table IV shows the details of the interview.

TABLE IV. INTERVIEW DATA BY CATEGORY (THE ELDERLY, DISABLED), GENDER (MALE, FEMALE) AND NUMBER OF PARTICIPANTS, DURATION OF THE INTERVIEW, AND IMPLEMENTATION METHOD

Category	Gender	No.	Duration	Method
The elderly	Male	6	15-20 min.	Face-to-face at home
	Female	4	15-20 min.	Face-to-face at home
Disabled	Male	9	20-30 min.	ZOOM
	Female	6	20-30 min.	ZOOM

III. RESULTS

A. IoT Knowledge in Smart Homes and Indoor Quality

The first question: What is the level of knowledge of vulnerable people, IoT applications in smart home systems, to support the quality of home life from the perspective of the study sample members?

However, means, standard deviations, and rankings have been calculated based on the responses provided by the study participants regarding their level of knowledge regarding the use of IoT in implementing a smart home system aimed at enhancing indoor quality for elderly individuals and people with disabilities. The study targeted people as current users and potential users. The results of this analysis are presented in Table V.

The total score for the level of knowledge of IoT usage in implementing the smart home system to support indoor quality was with an arithmetic mean of 2.60 and a standard deviation of 0.77, at a low level of knowledge (see Table V). The means for the study tool items ranged between 2.51 and 2.68, with weak and moderate ratings. IoT in the smart home system application helps me communicate efficiently with others, such as maids and household workers [Item (15)] came in first place, with the highest mean of 2.68, a standard deviation of 1.08, and a medium level. IoT in the smart home system application helps me communicate with my family members efficiently and competently [Item (2)] came in second place. IoT applications need great tools and technologies to be used in the smart home [Item (4)], and IoT in smart home system application helps me to watch media in my home easily [Item (11)] have the same mean of (2.66) and level of knowledge. Items (6) "IoT in smart home system app makes it easier for me to transport purchases to my home myself" and (8) "IoT in implementing a smart home system requires highly qualified experts and specialists in the field of information and communications technology" ranked last with the same mean of 2.51 and the low level.

TABLE V. STATISTICAL DESCRIPTIONS OF KNOWLEDGE LEVEL IN APPLYING IOT IN THE APPLICATION OF A SMART HOME SYSTEM TO SUPPORT INDOOR QUALITY

No.	Items	Means	STD	Rank	Level of knowledge
15	IoT in the smart home system application helps me communicate efficiently with others, such as maids and household workers	2.68	1.08	1	Moderate
2	IoT in the smart home system application helps me communicate with my family members efficiently and competently	2.66	1.03	2	Moderate
4	IoT applications need great tools and technologies in order to be used in the smart home	2.66	1.17	2	Moderate
11	IoT in smart home system application helps me to watch media in my home easily	2.66	1.05	2	Moderate
3	IoT in smart home system applications is a major concern about maintaining security and privacy	2.63	1.04	3	Moderate
13	IoT application in the smart home system helps me go out and return to my home with ease and comfort	2.62	1.09	4	Moderate
14	Smart home can provide me with the ability to improve physical and psychological efficiency	2.61	1.04	5	Moderate
12	IoT application in the smart home system helps me navigate the corridors of the house with ease and comfort	2.59	1.00	6	Low
5	IoT applications in a smart home require basic computer skills	2.57	1.23	7	Low
10	IoT smart home system application helps me go to bed to sleep easily	2.57	1.01	7	Low
9	IoT in the application of the smart home system helps me to wear my clothes without relying on others	2.56	1.00	8	Low
7	IoT in the application of the smart home system helps me to enter the bathroom at home, relieve myself, and shower by myself without relying on other people.	2.55	0.95	9	Low
1	The application of IoT in smart home system requires connecting different facilities to the network to meet the automation requirements of the entire system and provide more convenient control and management.	2.52	1.16	10	Low
6	IoT in smart home system app makes it easier for me to transport purchases to my home myself	2.51	1.03	11	Low
8	IoT in implementing a smart home system requires highly qualified experts and specialists in the field of information and communications technology	2.51	0.93	11	Low
	Total score	2.60	0.77		Low

B. Demographic Features Impact on IoT Knowledge in Smart Home Systems

The second question: Do factors such as gender, marital status, educational level, employment status, age, experience, class, and income affect knowledge towards using IoT in implementing a smart home system to support the quality of home life for the elderly and people with disabilities as users and potential users?

To answer this question, the study calculated the means and standard deviations of the study sample members' responses. These responses are related to the level of knowledge in using the IoT in the context of implementing a smart home system aimed at improving the quality of life for the elderly and people with disabilities, whether as current or potential users. Data were further analyzed to examine differences based on factors: gender, marital status, educational level, employment status, age, experience, class, and income (see Table VI).

TABLE VI. MEAN AND STANDARD DEVIATION OF KNOWLEDGE LEVELS ABOUT USING THE IOT IN SMART HOME SYSTEMS TO SUPPORT THE QUALITY OF HOME LIFE FOR THE ELDERLY AND PEOPLE WITH DISABILITIES, ACCORDING TO DEMOGRAPHIC FACTORS [39]

Variable	Category	Mean±STD	N
Gender	Male	2.63±0.7	106
	Female	2.57±0.8	143
Marital status	Married	2.55±0.84	106
	Single	2.63±0.7	143
Educational level	Illiterate	2.51±0.8	94
	School	2.51±0.78	89
	University	2.84±0.65	66
Employment status	Work	2.79±0.6	128
	No work	2.40±0.84	121
Age	15-30	2.82±0.59	56
	30-45	2.84±0.64	69
	45-60	2.37±0.86	76
	+60	2.34±0.79	48
Experience	Likely to use	2.38±0.8	131
	Use	2.83±0.65	118
Category	The Elderly	2.33±0.79	137
	People with disabilities	2.92±0.6	112
Economic status	Average or below	2.27±0.8	124
	Above average	2.92±0.56	125

Responses varied significantly for level of knowledge about using the IoT in implementing a smart home system to improve the quality of life for the elderly and people with disabilities (see Table VI and Table VII).

TABLE VII. MULTIPLE ANALYSIS OF VARIANCE FOR LEVELS OF KNOWLEDGE ABOUT THE USE OF THE IOT IN SMART HOME SYSTEMS TO SUPPORT THE QUALITY OF HOME LIFE FOR THE ELDERLY AND PEOPLE WITH DISABILITIES BY DEMOGRAPHIC FACTORS

Source	Type I Sum of Squares	df	Mean Square	F	Sig.
Gender	0.168	1	0.168	.411	0.522
Marital status	0.267	1	0.267	.654	0.419
Educational level	5.749	2	2.875	7.036	0.001
Employment status	7.551	1	7.551	18.482	0.000
Age	8.154	3	2.718	6.653	0.000
Experience	4.128	1	4.128	10.104	0.002
Category	13.288	1	13.288	32.523	0.000
Economic status	11.558	1	11.558	28.289	0.000
Error	96.828	237	0.409		
Total	1825.371	249			

Differences of knowledge regarding the use of the IoT in implementing smart home systems to improve Indoor were not significant, whether they are current or potential users, when attributing the differences to gender or marital status (see Table VII). The F values reached 0.411 and 0.654, with significance levels of 0.522 and 0.419, respectively. In contrast, statistically significant differences appeared regarding the functional status, in favor of the working group, as the F value reached 48.218 at a significance level of 0.000. Statistically significant differences were also found for the experience variable in favor of the "use" category, with the F value reaching 10.410 and a significance level of 0.002. In addition, variation was observed according to the category variable, with the disabled category scoring higher (F = 32.523, p = 0.000). Economic status also showed statistically significant differences in favor of the upper-middle income group (F = 28.289, p = 0.000). Finally, both educational level and age revealed statistically significant differences in knowledge levels, with F values reaching 3.067 and 6.536, and significance levels reaching between 0.001 and 0.000, respectively. Differences were further examined through multiple comparisons approaches using Scheffe's method (see Table VIII).

Statistically significant differences at the 0.05 level for participants' responses regarding their level of knowledge of using the IoT to implement a smart home system to support the quality of home life for the elderly and people with disabilities as users and potential users (see Table VIII). This difference is attributed to the educational level between the university and school categories for the former, with the mean difference value of 0.33 being statistically significant (0.007). Significance levels were also found between the university and illiterate categories in favor of the university group. The mean difference value of 0.33 was statistically significant (0.007). Table VIII also shows statistically significant differences at the 0.05 level for participants regarding their level of knowledge of using IoT to implement a smart home system to support the quality of home life for the elderly and people with disabilities as users and potential users. This difference is attributed to age on the one hand; the age group (15-30) years, and both the categories (45-60) years and (over 60) years, in favor of the former. The mean difference values (0.44) and (0.47) were statistically significant at (0.002) and (0.003), respectively. On the other hand, there were differences between the (30-45) year group and both (45-60) year group and (over 60) year group in favor of the (30-45) year group. The mean difference values (0.46) and (0.49) were statistically significant at (0.000) and (0.001), respectively.

TABLE VIII. MULTIPLE SCHEFFE'S DIMENSIONAL COMPARISONS OF KNOWLEDGE LEVELS ABOUT THE USE OF THE IOT IN SMART HOME SYSTEMS ACCORDING TO THE VARIABLES OF EDUCATIONAL LEVEL AND AGE

Educational Level (I)	Educational Level (J)	Mean Difference (I-J)	Sig.
University	School	.33*	.007
	Illiterate	.33*	.007
Age (I)	Age (J)	Mean Difference (I-J)	Sig.
15 -30	(30 -45)	.02	0.999
	(45 -60)	.44*	0.002
	+ 60	.47*	0.003
(30 -45)	15 -30	.02	0.999
	(45 -60)	.46*	0.000
	+ 60	.49*	0.001

C. Concerns and Risks of IoT Use in Smart Home Systems

The third question: What are the concerns and risks of using IoT in implementing a smart home system to support the quality of home life from the perspective of the study sample members?

Interviews conducted with study sample members (n = 25), including (10) elderly people and (15) people with disabilities in Najran region who are users and potential users of the IoT in smart home system application, were analyzed. The interviews targeted the most important concerns and risks related to using the IoT in the smart home system application to support the quality of home life for the elderly and people with disabilities, from the perspective of the study sample members. Fifteen participants unanimously agreed that the most significant concerns regarding the use of the IoT in implementing a smart home system to support the quality of home life are due to the "high financial and material cost of implementing this system, which most people cannot afford". Twelve respondents agreed that, "this system may lead a person to lack flexibility and laziness as a result of heavy reliance on the smart home.", while (10) respondents indicated, "It is difficult to repair household faults because it requires highly skilled employees or companies specialized in this field". Eight respondents unanimously agreed that, "the availability of a fast internet network is weak in some areas or neighborhoods, which hinders the process of the home relying on it completely". Five respondents unanimously agreed that, "the enlarged size of networks and the increase in the number of devices in the smart home system may create a delay in response and processing time, which makes it difficult to manage real-time systems." One of the respondents stated, "The large number of devices using this system and setting different usernames and passwords for them may lead to complexity in using it and not meeting the needs of elderly people and people with disabilities".

The potential risks of using IoT in implementing a smart home system to support the quality of home life, (18) respondents unanimously agreed on "the ability of thieves to penetrate smart home networks to know the sleeping times of their residents to steal them". Sixteen respondents agreed that, "hackers were able to stop the heating system on harsh winter days or stop the air conditioning system on hot summer days, which may cause risks to the lives of the elderly and people with severe and multiple disabilities". Thirteen respondents unanimously agreed on "penetrating smart home networks may pose a risk to users' privacy, personal safety, and disclosure of their secrets". Eleven respondents unanimously approved that, "hackers are able to know the health status and devices used by elderly people and people with disabilities, which may cause real risks to their lives". Seven respondents agreed that, "hackers may exploit this system and manipulate energy consumption bills to increase or decrease them". Five respondents agreed that, "the possibility of stealing the personal data of the person using this system is very high, which leads to the theft of their bank accounts". Three respondents unanimously agreed that, "IoT users' data does not belong to them, and here lies one of the points of concern". "For example, if the user wants to unlock the door of his home upon arrival, his smartphone sends the command via the Internet to the cloud service responsible for locking the door, which in turn opens it, meaning that any potential hacking of the service will lead to real disasters that affect their privacy, confidentiality, and security". One respondent stated, "Logging into the home network through an IoT device and discovering their passwords used on the system enables thieves or hackers to launch a ransomware attack, rendering the IoT smart home unusable until money is paid".

IV. Discussion

Results showed that the overall degree of knowledge level of using IoT in applying the smart home system to support the quality of home life, as perceived by the elderly and people with disabilities as its users and potential users, is low. The result may be attributed to the use of different IoT devices in the smart home system. Each device has distinct features, features, and technical skills that participants possess, which affects their sufficient knowledge of this system, how to deal with it, and its importance in their lives. This finding is consistent with the findings reported by [41] in their study on IoT in South Africa, which revealed that technology cost and familiarity were the main factors inhibiting technology adoption, and the adoption of this system in particular. The findings could also be attributed to the level of awareness of the use of IoT in smart home systems. Lack of awareness about smart home devices is a major challenge for adoption, use, and potential by people [37] . The awareness level has been found low at different communities in Malaysia [9]. This work found that demographic factors such as gender and marital status did not significantly influence participants' knowledge of using IoT in smart home systems to improve the quality of life for the elderly and people with disabilities. This may refer to a shared awareness level and levels of satisfaction and experience in implementing IoT technologies in daily activities, regardless of gender or marital status. Men and women, across age groups and experience levels, appear to have similar challenges and levels of familiarity with IoT devices. Family members who provide care often assist in using these technologies, potentially contributing to equal awareness and usage across demographic groups. Significant differences emerged with employed participants who were showing higher levels of familiarity. This may have attributed to their greater exposure to the functional benefits of smart systems, particularly in assisting mobility, managing entry and exit from the home, and simplifying daily activities. There was high familiarity of using IoT systems by active IoT users, reflecting their positive contribution in sharing and enhancing awareness. Their experience with the unique advanced features of smart homes enabled them to become more independent and improve their quality of life [42]. Notably, individuals with disabilities demonstrated greater familiarity compared to older participants. This may be attributed to their adaptability in using IoT systems. This is different in case of older adults who may suffer from technophobia or face age-related challenges. Chronic illnesses or dementia may impact elderlies familiarity and confidence with smart technology handling [6].

Participants with above-average income have high knowledge. This may refer to their ability to afford these systems and their awareness level. Financial capacity may directly influence exposure and tendency to adopt smart home technologies. Educational attainment was another influential factor. Participants with a university education had higher levels of knowledge because they had access to information about emerging technologies, and it applications, and their ability to follow user guidelines. Higher education likely enabled them to appreciate the role of the IoT in improving daily life. Younger participants between 15 and 45 showed high knowledge and willingness level to be familiar with smart home systems. Their familiarity to technology and lower anxiety towards its use put them as more informed and likely users, both now and in the future.

Results revealed a wide range of concerns and risks in using IoT for smart home systems to support the indoor life quality for elderly individuals and people with disabilities. These concerns primarily associated with the costs of system implementation. Reliance in smart home systems may also reduce personal flexibility, while maintenance require highly skilled personnel or specialized companies. These factors limit users' independence. Moreover, inadequate availability of high-speed Internet may minimize full reliance on smart home technologies [43].

The high number of connected devices and low network capacity increase delay the response time, complicating the management of real-time systems. Data confidentiality remains another critical concern, as vulnerable people may expose users to theft, hacking, privacy breaches, manipulation of energy consumption, or even financial fraud [44]. Addressing these risks and concerns provides critical insights for government agencies and technology companies to develop efficient procedures and practices for safe and beneficial use of IoT-enabled smart home systems for elderly and disabled populations. The heightened awareness of these challenges among users further underscores the importance of educating them about the benefits, safe handling, and potential applications of smart home technologies.

The importance of adopting smart home technologies has been widely recognized, particularly for the elderly and individuals with disabilities. However, consumers are showing increasing interest in smart homes, although they face challenges related to acceptance and practical usage [45]. The role of IoT technologies in supporting independent living for older adults highlights the need for system designs that meet their specific needs [46]. Meanwhile, He et al. [47] examine privacy practices among smart home product development teams in China, highlighting the importance of complying with local regulations while balancing security and privacy concerns. These works showed that efficient adoption of smart home systems requires addressing challenges related to user acceptance, system design, and privacy protection, especially for vulnerable populations. The benefits of IoT-enabled technologies extended to smart waste management, and the vulnerable groups still have the opportunity to contribute to sustainable indoor practices[48]. For instance, smart trash bins have shown to be more efficient in terms of energy and waste management as a contactless device and hygienic method of disposal. Smart eco-friendly solutions and tools are key for improving indoor living quality and thus provide better sustainable practices [49].

This work provides an understanding of how smart home adoption unfolds among older adults and individuals with disabilities. While earlier studies have underscored challenges related to user acceptance, system design, and privacy protection, the current study advances this body of knowledge by revealing how these barriers manifest within real-life contexts shaped by demographic, economic, and accessibility factors. The identification of low levels of IoT-related knowledge combined with demographic disparities linked to age, disability status, employment, and economic conditions highlights the uneven landscape of readiness among vulnerable groups. This nuanced pattern contributes significantly to understanding why adoption remains limited despite the growing availability of smart technologies.

V. Conclusion

This work sheds light on the lived realities surrounding the adoption of IoT-enabled smart home technologies among older adults and individuals with disabilities. The study generates fresh insights into the subtle yet impactful barriers that shape adoption patterns within these vulnerable groups, barriers that extend beyond technical limitations to include issues of affordability, digital literacy, trust, and infrastructural reliability. These insights not only clarify why knowledge gaps persist but also illuminate how demographic variations intersect with personal experiences to influence perceptions and readiness for IoT use. Within this descriptive analysis, the findings naturally point toward important implications for the inclusive design of smart homes. By uncovering the specific needs, concerns, and usage restrictions of the participants, the study highlights design considerations that prioritize accessibility, user empowerment, and technological simplicity. Such considerations underscore the necessity of creating smart home ecosystems that do not merely incorporate IoT technologies but do so in ways that accommodate a wide spectrum of abilities, economic conditions, and age-related challenges.

The study provided evidence-informed trends that can support policymakers and technology developers in Saudi Arabia as they work to advance national digital transformation efforts. The patterns revealed in the data suggest opportunities to boost public awareness campaigns, tailor educational initiatives to users' digital capabilities, and encourage the development of IoT solutions that align with the principles of inclusive design. These observations carry practical relevance for national strategies such as Saudi Vision 2030, particularly in relation to improving the quality of life and expanding equitable access to emerging technologies. Finally, the descriptive insights generated by this research open pathways for future investigations that extend the inquiry across different regions and cultural contexts. Such work can enrich comparative understanding and deepen exploration of the practical benefits, risks, and user experiences associated with IoT-based smart homes, particularly for populations that remain underrepresented in the broader technology adoption literature.

VI. Study Limitations

This work is limited to Najran, Saudi Arabia and future works are encouraged to include more study areas for addressing special variations. Future works may be conducted at different time for better temporal variations of the responses, as this work captures responses at a single point in time. Finally, while the mixed-methods approach provides both breadth and depth, future research could incorporate longitudinal designs and larger, more diverse samples to validate and extend these findings.

Acknowledgment

The researchers would like to express their sincere appreciation to all study participants for their valuable efforts and objective responses to the study instrument. The authors also extend their gratitude to Ajloun National University and Najran University for their continuous support throughout the research process. The data supporting the findings of this study are available from the authors upon reasonable request.

Ethical Approval

This work carries ethical approval from the Standing Committee for Scientific Research Ethics, Research Deanship of Najran University, Saudi Arabia. Reference No. of 010118-022124-DS. Accredited as a local committee by the National Committee for Bioethics at King Abdulaziz City for Science and Technology (HAPO-11-N-102).

Informed Consent Statement

Informed consent was obtained from all study participants.

The Evolution of Hackathons as an Innovation Tool: A Systematic Analysis

Claudia Marrujo-Ingunza, Meyluz Paico-Campos
Faculty of Science and Engineering, Universidad de Ciencias y Humanidades, Lima, Peru

***Abstract*—Hackathons have established themselves as dynamic open innovation spaces that promote interdisciplinary collaboration and creative problem-solving. This systematic review, which follows the PRISMA methodology, synthesizes the findings of 73 articles from Scopus, Web of Science, and IEEE Xplore, with the aim of analyzing the evolution, impacts, and knowledge gaps surrounding hackathons as an innovation tool. The study identifies a growing trend in their global implementation, with a particular emphasis on skill development, driving innovation, and strengthening entrepreneurial competencies. However, limitations are evident, such as the scarcity of longitudinal studies, the poor assessment of their long-term sustainability, and the geographical concentration of research in technologically advanced countries. Future research should focus on comparing organizational models, measuring long-term results, and including diverse contexts. Our findings underscore the potential of hackathons to boost creativity and entrepreneurship, as well as foster sustainable and collaborative innovation processes.**

***Keywords*—Hackathon; evolution; tool; innovation; review**

I. Introduction

Over the past two decades, hackathons have established themselves as a global phenomenon and one of the most representative methodologies of open innovation [1]. These activities, distinguished by their dynamism and intensive teamwork over short periods of time, have been implemented by universities, governments, technology companies, and social organizations to promote creativity and the rapid solution of complex problems [2]. The literature recognizes hackathons as innovation laboratories that favor knowledge transfer and the creation of interdisciplinary networks, which explains their growing relevance in innovation systems worldwide [3].

Despite their growing popularity, the central problem is that traditional hackathon approaches, based on rapid prototyping and intensive teamwork, often face limitations. Many of the solutions generated fail to transcend beyond the event due to difficulties in scalability, project sustainability, and a lack of integration with productive ecosystems. Although strategies such as intensive mentoring and the provision of technical resources have been implemented [4], [5], these actions do not ensure the continuity of the innovation cycle after the hackathons.

In this context, new perspectives are emerging that propose reconfiguring hackathons by integrating open innovation approaches, whether tools to support prototype development, facilitate data analysis, or generate new participation dynamics. These methods seek to optimize technical processes and expand the impact of hackathons as spaces for interdisciplinary collaboration with sustainable and practical value.

These new approaches are supported by current literature, which demonstrates how hackathons can contribute to diverse fields: in education, as experiential learning environments [6]; in healthcare, for the creation of telemedicine solutions or biomedical data analysis [7]; in the business sector, as mechanisms for innovation and talent recruitment [8]; and in the social sphere, as spaces to address community issues [9]. These studies show that hackathons have a positive impact on creativity, the generation of functional prototypes, and the construction of collaborative networks, which reinforces their role as promoters of innovation.

However, research remains lacking. Most studies focus on describing individual cases of hackathons or analyzing their usefulness in specific areas or countries [10]. A lack of systematic research was found that integrates the available evidence and allows for the identification of trends, patterns, and limitations in the development and evolution of these practices globally. This lack of information justifies the need for a systematic review that provides a comprehensive view of how hackathons have evolved and their true impact on innovation.

Unlike previous reviews that have limited themselves to analyzing hackathons in particular contexts or using descriptive approaches, this study offers an original contribution by comparatively synthesizing the global evolution of hackathons as a tool for innovation, integrating multiple aspects, such as academic, social, business, and technological aspects, into a single comprehensive study. This review seeks to identify thematic and geographical gaps, as well as provide a new interpretative perspective that classifies studies according to their lines of impact and level of innovation maturity. It also adds methodological value by using a thematic approach that allows emerging patterns and trends not addressed by previous research to be recognized. Consequently, this study broadens the theoretical understanding of hackathons as places of open innovation and offers practical guidance for their design, implementation, and evaluation in different institutional and geographical contexts.

Based on this problem, the research questions that guide this study are: How have hackathons evolved in their role as global innovation tools? What impacts have they generated in the different contexts analyzed? And what are the main knowledge gaps emerging in the scientific literature?

Finally, this study is organized as follows: the background section defines related theoretical aspects for a better

understanding of the topic; the methodology section describes the process followed for the systematic review. Subsequently, the results section presents the findings on the evolution of hackathons as innovation tools; a discussion exploring the implications analyzed is also presented. Conclusions summarize the main contributions of the study. Finally, the gaps identified in the literature and future lines of research for consideration are presented.

II. Background and Related Applications

A hackathon is a short event in which multidisciplinary teams collaborate intensively to develop technological prototypes to solve specific problems [11]. Its origin dates back to programming communities, but in recent years it has expanded to diverse contexts such as education, healthcare, the business sector, and social innovation [12]. These dynamics are considered innovation tools, as they bring together diverse talent, foster collective creativity, and accelerate ideation processes that in conventional environments often take months.

Innovation is understood as the ability to generate and apply novel ideas with added value [13]. In this sense, hackathons provide an agile and collaborative mechanism for its development. In this vein, hackathons are not limited to programming competitions; they function as experimental laboratories where experiments, experiences, and novel ideas are discovered. Because of this, they have become an important tool for universities, governments, and companies seeking to promote projects, generate scalable prototypes, and collectively solve social problems [14], [15].

In parallel, technological development has made available various innovative tools that enhance the results of hackathons. These include collaborative software platforms (GitHub or GitLab), programming environments that include machine learning libraries (TensorFlow, PyTorch, Scikit-learn), and cloud services that offer data processing and analysis resources (AWS, Google Cloud, Microsoft Azure), which facilitate the processing of large volumes of data and the construction of real-time solutions.

The applications of these tools are diverse: in healthcare, they are used to develop adaptive learning platforms [7]; in the financial sector, to generate predictive risk models [8]; and in the creative industry, to design interactive experiences or produce digital content [2]. Thus, hackathons are positioned as interdisciplinary spaces that integrate methodologies, technologies, and collaborative dynamics, with an impact on both the social and academic and business spheres.

III. Materials and Methods

The scientific literature on the evolution of hackathons as an innovation tool remains limited and dispersed, making it difficult to obtain a comprehensive view of their impact and development in different contexts. Although there is research that considers hackathons as experiential learning spaces and open innovation platforms, most of it presents case studies or specific descriptions without a systematic synthesis of available knowledge. This scarcity of structured reviews justifies the need for a rigorous analysis that consolidates scientific evidence, identifies patterns of evolution, and uncovers thematic gaps to guide future research.

To address these research gaps, a review based on the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) protocol was chosen. This protocol is a reference framework widely used in academic research for its ability to guarantee a rigorous and traceable process [16]. In contrast, other methodologies, such as narrative or integrative reviews, tend to be more flexible; on the contrary, PRISMA provides clarity in the inclusion and exclusion criteria and in the representation of the document selection flow. Furthermore, the analyzed studies validate that, in contexts of innovation and technology, this framework supports its relevance for synthesizing dispersed evidence and building solid conceptual frameworks.

A. Review Approach

The information gathering strategy focused on the use of high-impact academic databases such as Scopus, Web of Science (WoS), and IEEE Xplore, all three used to ensure a diverse literature in technological aspects and focused on the topic. In addition, bibliometric analysis tools such as VOSviewer and Bibliometrix were used, which allowed the visualization of co-authorship networks, thematic trends, and keyword co-occurrence analysis. The choice of these strategies is justified by the need to ensure broad and specialized coverage. Databases such as Scopus and WoS offer a global vision of scientific production [17], while IEEE Xplore is essential for capturing specific research in engineering and computer science. On the other hand, the use of bibliometric tools, such as VOSviewer and Bibliometrix [18], [19], facilitates the organization and synthesis of information, in addition to the identification of hidden patterns in the literature, which increases the interpretive value of the analysis.

B. Search Strategy

Custom Boolean search algorithms were developed for each database, checking for matches on keywords, abstract, and title.

The keyword group used for Scopus: (TITLE (hackath*) OR TITLE-ABS-KEY (hackfest*) OR TITLE (codefest*) AND TITLE-ABS-KEY (innov*))

The keyword group used for WoS: hackathon* (Title) OR hackfest* (Title) OR codefest* (Title) AND innov* (Title)

The keyword group used for IEEE Xplore: ("Document Title":hackath*) OR ("Document Title":hackfest) OR ("Document Title":codefest*) AND ("Document Title":innov*)

C. Selection and Analysis Process

Fig. 1 shows a flowchart describing the different stages of the information selection process. The initial search yielded 269 Scopus publications, 265 of WoS, and 106 of IEEE Xplore. In addition, filtering by thematic area favored the inclusion of studies related to the analyzed topic. The search criteria were then limited to journal articles, international conferences, and systematic reviews. This is because journal articles are peer-reviewed and have greater support than other types of research. Likewise, the inclusion of systematic reviews in this analysis corresponds to the importance of their scope and information provided. Therefore, other types of documents such as book chapters or patents, editorial notes, letters, and surveys, were discarded, as they contribute very little to the results in the

direction of this topic. The selected articles do not have a time specification. After filtering the search based on predefined inclusion and exclusion criteria, the number of relevant documents was 142 Scopus publications, 121 of WoS, and 55 of IEEE Xplore. Subsequently, the titles and abstracts of each document obtained were examined to determine their relevance to the scope of this study. Ultimately, with a distribution of 29 from Scopus, 25 from WoS, and 30 from IEEE Xplore, the screening of titles and abstracts of these studies resulted in a total of 84 documents.

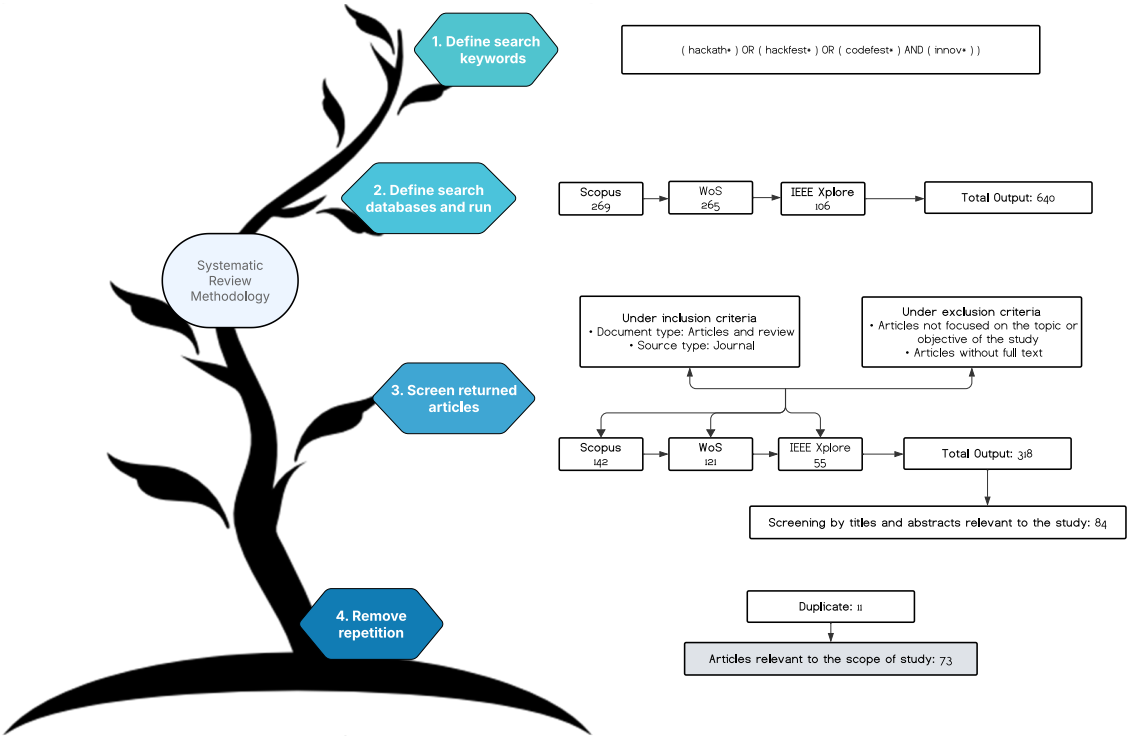

Fig. 1. Flowchart based on PRISMA.

The inclusion criteria considered studies that addressed hackathons with a focus on innovation or technological development, presented theoretical frameworks or specific application models, and were also available in full access. Studies that only described events without evidence of results, were not directly related to the development of technological skills, or were texts without full access were excluded. The process of eliminating duplicates consisted of using the Mendeley manager, comparing matches between title, DOI, and authors. Although 84 studies were identified after screening, a total of 11 duplicates were detected after cross-checking between databases, which is possible due to the low overlap between conferences and journals indexed in IEEE and WoS compared to Scopus. In this case, the version with the most complete and best-indexed metadata was retained.

For data extraction, a structured matrix of records was developed on authors, year, country, objective, methodology, scope of application, and main results. The quality assessment of the studies was carried out considering methodological clarity, thematic relevance to the research questions, and the level of evidence found. Only studies that met at least two of these criteria were included in the final analysis. Finally, after applying all the filters, 73 documents relevant to the in-depth review were retained.

The relevance of this research lies in its systematic nature, which not only brings together and synthesizes the literature on AI in hackathons but also ensures transparency and scientific rigor. This makes it a useful resource for both researchers and practitioners seeking to understand how AI is changing the dynamics of open innovation globally.

D. Analysis

The data analyzed show sustained growth in scientific production on hackathons as an innovation tool, especially regarding innovation and technological development. The most important countries in terms of production are Germany, Brazil, and the United States, demonstrating the consolidation of innovation and the link between industry and the public sector. Research in Germany focuses on digitalization, while Brazil stands out for its efforts in inclusion and technological education. The United States, for its part, focuses on research related to social and technological solutions. The fact that publications are mostly distributed in journals on applied social sciences, innovation management, and engineering education demonstrates the interdisciplinary nature of hackathons.

The review identified five key approaches: educational hackathons, which focus on active learning and skills development; inclusive hackathons, which foster diversity and equitable participation. [20]; healthcare hackathons, which seek medical solutions and telecare [7]; collaborative hackathons, as inter-institutional co-creation spaces [6], and innovation hackathons, where prototypes and business models are generated [21]. Although descriptive and case analyses are the

most common, there has been a recent growth in systematic reviews and bibliometric evaluations. Even so, the literature presents significant gaps, especially in the lack of longitudinal, comparative and socioeconomic impact studies. This study contributes to the field by offering an integrative view that summarizes global trends and emerging opportunities to strengthen hackathons as strategic innovation tools.

IV. Results

The bibliometric analysis of records obtained from Scopus, WoS, and IEEE Xplore revealed relevant patterns in the evolution of research on innovation-oriented hackathons. Variations in scientific output were observed over time, along with a marked concentration in countries with established innovation systems, such as the United States, Brazil, and Germany. The results show a steady growth in the number of publications, especially in recent years, which coincides with the global expansion of open innovation methodologies and interdisciplinary collaboration. Furthermore, the analysis of co-authorship networks and keywords allowed us to identify emerging topics such as technology education, collaborative entrepreneurship, and digital inclusion, in addition to revealing theoretical gaps in measuring the impact and sustainability of these events.

The value of this analysis lies in the fact that it not only exposes the sustained increase in academic interest in hackathons but also links these trends to recent social and technological transformations, such as the digitalization of educational processes and the expansion of innovation labs. This approach allows us to visualize the dynamics of growth, collaboration, and thematic specialization within the field, providing a solid foundation for guiding future research and strengthening our understanding of hackathons as strategic drivers of development and innovation.

A. Bibliometric Analysis

Bibliometric analysis, used as part of the systematic review process, allowed us to examine the evolution and distribution of scientific literature on hackathons in the context of innovation, through the counting, classification, and visualization of publications, citations, and academic collaboration networks. For this purpose, we used the tools VOSviewer and Bibliometrix, widely recognized in scientific research for their ability to analyze large volumes of information. VOSviewer allowed us to generate keyword co-occurrence maps, co-authorship networks, and international collaborations, revealing the conceptual structure and relationships between the main thematic focuses of the field [18]. For its part, Bibliometrix, implemented in the R environment, facilitated descriptive analyses, annual production graphs, identification of influential journals, and detection of emerging trends in hackathon research [19]. The integration of both tools was essential to identify thematic clusters and research patterns, allowing us to accurately visualize the interconnections between authors, countries, and institutions. This approach contributed to a deeper understanding of the dynamics of the field, highlighting how hackathons have established themselves as key spaces for co-creation, experimentation, and knowledge transfer within innovation.

1) Keyword co-occurrence map: A keyword co-occurrence map makes it easier to visualize the connections between terms that appear together in scientific publications, enabling the discovery of emerging and significant topics [22]. The databases used for this analysis were Scopus, WoS, and IEEE Xplore, in order to unify their terms and verify the data each database offers.

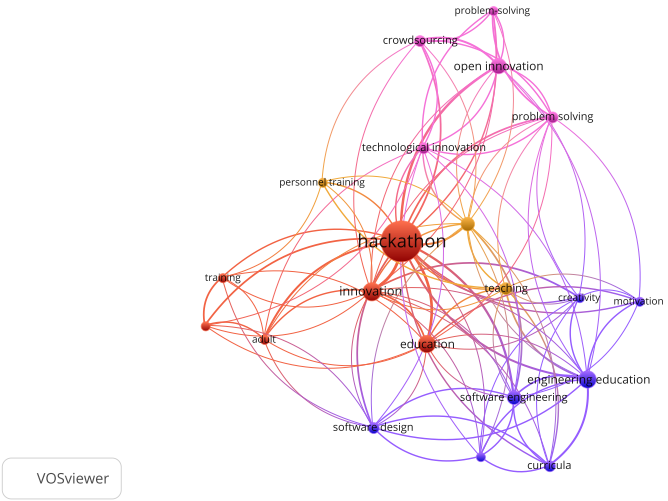

Fig. 2. Keyword co-occurrence map in VOSviewer

Using VOSviewer and with a minimum of four keyword co-occurrences, 679 keywords co-occurred, and four significant clusters were identified. Fig. 2 shows a network visualization map of the four co-occurring keyword groups with 21 elements, 112 links, and a total link strength of 206. Keywords with the highest number of links are understood to be the most impactful and notable. Keywords with nodes that are clearly larger than the rest are "hackathon", "innovation", and "education". The size of a keyword indicates how frequently it appears in research documents. Keywords that are closest to it show their

co-occurrence in those same works. The colors are representative of the clusters and indicate the most frequent keywords. Since this information ensures more efficient indexing and retrieval of research, it can help researchers select the appropriate keywords for their work.

This bibliometric analysis demonstrates that the study focuses on the development and application of hackathons as a strategic innovation tool. The results obtained demonstrate that this type of analysis is highly useful for identifying established and emerging research areas, as well as for mapping the dynamics of collaboration between institutions and countries. The connection and size of the nodes in the relationship maps reflect a strong interdependence between the themes of open innovation, technology education, and collaborative entrepreneurship, highlighting the importance of approaching hackathons from a comprehensive perspective that combines learning, technology, and social impact.

2) International co-authorship map: The co-authorship map is a fundamental tool for visualizing collaborations between researchers, allowing for the identification of active networks and influential academic communities within the field of study. This type of analysis facilitates understanding how research groups are configured, their thematic links, and how they share knowledge about hackathons and innovation.

The minimum number of documents identified in VOSviewer per author was set to 2 to filter the maximum range of co-authorship and, in turn, analyze possible improvements in this regard. This generated 286 authors, including the lead author and their co-authors. These connected elements generated 1 cluster and 15 links. The visualization co-authorship network in Fig. 3 shows the researchers Balzer F., Braune K., and Hofferbert J. as the most frequent collaborators.

The resulting co-authorship network reflects a progressive strengthening of collaborative capacities at the international level, demonstrating the consolidation of scientific communities that approach hackathons from interdisciplinary perspectives. This result represents a significant advance in the coordination of global efforts aimed at understanding and promoting hackathons as spaces for innovation, learning, and technological development.

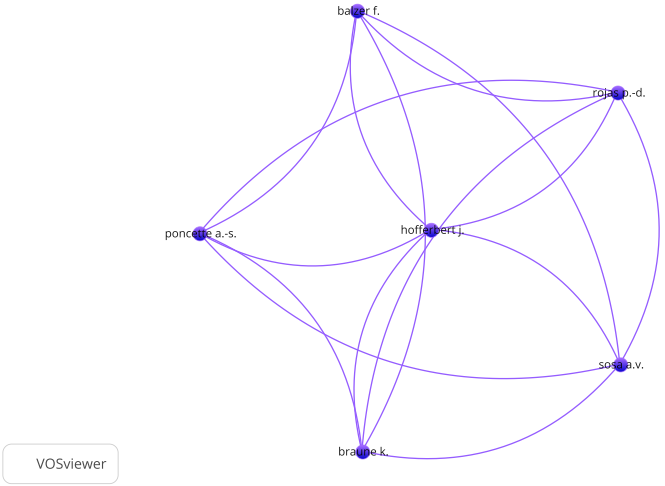

Fig. 3. Co-authorship map in VOSviewer

3) Collaboration map by country: The country-by-country collaboration map allows us to visualize international connections in scientific production, revealing how knowledge is generated and shared within the realm of hackathons and innovation. These collaborative networks are essential for understanding the formation of academic communities and the transfer of knowledge.

Using the VOSviewer tool, a country analysis was conducted for further sustained identification. The number of countries detected by the VOSviewer software was 40, of which 16 met the established criteria of a minimum relationship of three. Fig. 4 shows the countries active in research on hackathons as an innovation tool. These connected elements resulted in 5 clusters, 37 links, and a total link strength of 40. As can be seen, the largest nodes represent the United States, Brazil, and Germany. This indicates that researchers from these countries have contributed the most to studies on hackathons as an innovation tool.

The results of this analysis are consistent with previous studies that show a geographic concentration of scientific production in countries with established innovation tools [23]. In particular, the United States, Brazil, and Germany stand out as the main research centers, demonstrating a strong interconnection in topics related to technology education and open innovation methodologies.

The low participation of developing countries highlights the need to promote more balanced and diverse scientific collaboration [24], fostering research networks that integrate different socioeconomic and cultural realities. Expanding global participation would enrich perspectives on the impact of hackathons in different contexts, favoring the development of more inclusive and sustainable strategies [25]. In short, the concentration of research power in a few countries underscores the importance of fostering international alliances and collaborative projects that strengthen the circulation of knowledge and promote a more global understanding of hackathons as a tool for innovation.

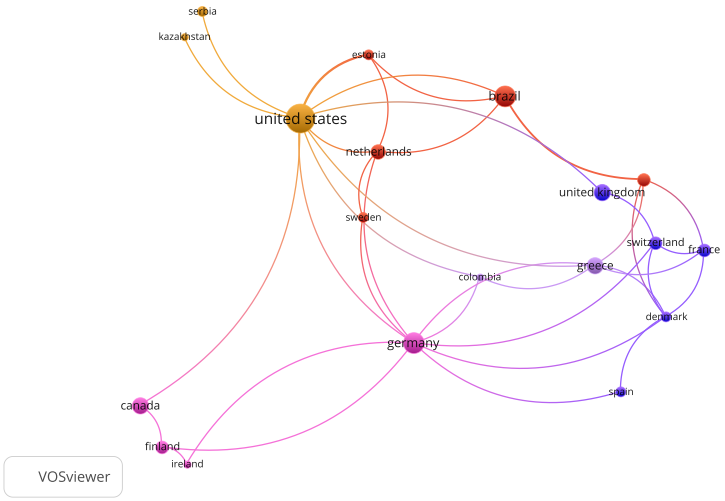

Fig. 4. Country co-occurrence map in VOSviewer

4) Distribution of publications by year: The temporal analysis of publications is essential to identify trends of growth, consolidation, or stagnation in scientific production on hackathons as an innovation tool. Fig. 5 presents the annual evolution of the collected studies, showing a general upward trend over the last decade. Between 2016 and 2019, production was moderate, with values ranging from 2 to 4 publications per year, reflecting an exploratory stage of the topic. Starting in 2020, sustained growth is observed, with a notable increase in 2021 (13 publications) and a new upswing in 2024 (14 publications). This pattern evidences a growing interest in hackathons in contexts of innovation, education, and interdisciplinary collaboration [26].

The significant increase in recent years can be explained by several factors: the expansion of open innovation ecosystems, the digitalization of training processes, and the boost to virtual collaboration following the COVID-19 pandemic [27], which favored the organization of hackathons in hybrid and global environments. Although a slight decrease was recorded in 2025 (11 publications), this variation is likely due to the recent indexing of articles. Overall, the results suggest that the field has moved from an exploratory phase to a stage of scientific consolidation, supported by the increase in empirical studies, reviews, and bibliometric analyses. This trend indicates that hackathons are consolidating as a strategic mechanism for collaborative innovation, the continuity of which will depend on the strengthening of academic networks and institutional support for projects that integrate technology, creativity, and social development.

5) Distribution of publications by journals: Analyzing the distribution of publications by journal allows us to identify the predominant disciplines and approaches in research on hackathons as an innovation tool. Fig. 6 presents the journals with the highest number of articles published on this topic, demonstrating a concentration of studies in a small group of specialized publications, suggesting a focused interest in the intersection of education, technology, and innovation.

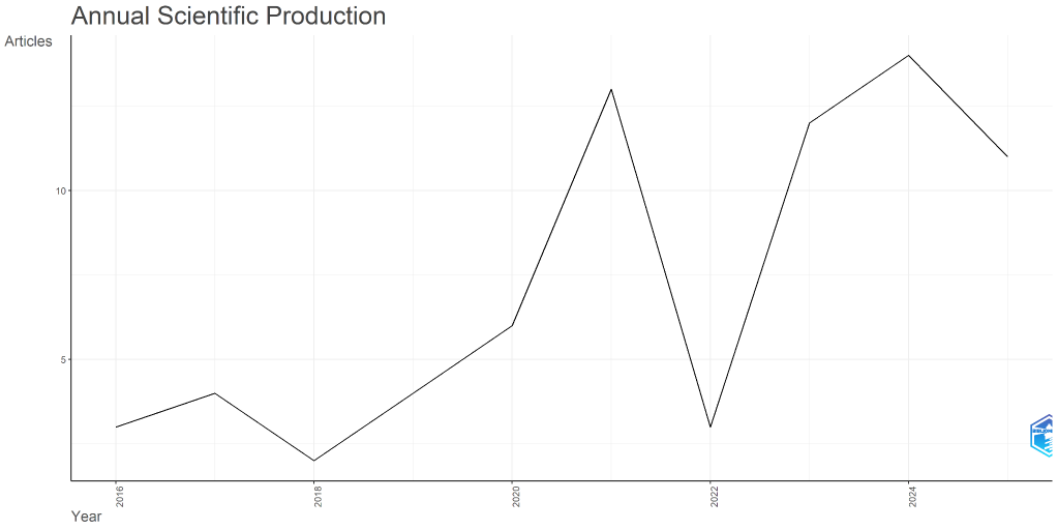

Fig. 5. Distribution of publications by year.

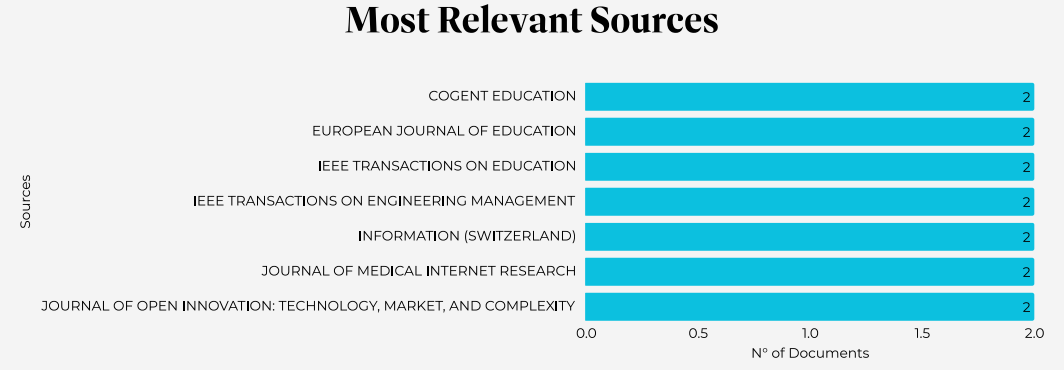

Fig. 6. Distribution of articles published by journal titles.

The results show that journals such as Cogent Education, the European Journal of Education, and IEEE Transactions on Education stand out for their contribution to the study of hackathons from an educational perspective, reflecting the growing interest in their use as a strategy for active learning and the development of digital skills. Meanwhile, IEEE Transactions on Engineering Management and Information (Switzerland) address the topic from the perspectives of innovation management and technological adoption. Likewise, the Journal of Medical Internet Research and the Journal of Open Innovation: Technology, Market, and Complexity present approaches focused on open innovation, technology transfer, and interdisciplinary collaboration.

This diversity of publications confirms the interdisciplinary and transversal nature of hackathons, covering areas ranging from education and engineering to organizational management and social innovation [28], [29], [30]. The concentration in certain specialized journals suggests that the field is in a phase of consolidation, with some academic media acting as reference nodes for the dissemination of emerging research. This pattern reinforces the need to strengthen collaboration across disciplines and scientific communities in order to broaden the understanding and practical application of hackathons in different innovation contexts.

B. Content Review

The final analysis included a total of 73 documents selected using the PRISMA methodology, which addressed the role of hackathons as innovation tools in different technological, educational, and social contexts. The final selection was obtained after applying rigorous inclusion and exclusion criteria, prioritizing studies that directly explore the relationship between Artificial Intelligence (AI), open innovation, and collaborative methodologies. This delimitation allowed the analysis to focus on the most representative approaches in the field, ensuring that the synthesis accurately reflects the trends, impacts, and research gaps surrounding the use of hackathons as mechanisms for digital transformation and interdisciplinary innovation. The analyzed sample demonstrates a balance between geographic diversity, application areas, and methodological approaches, avoiding a dispersion toward studies that, although related to innovation, do not delve into the use of hackathons as innovation environments. This approach allowed the review to be structured based on three central questions that guided the process:

- Q1: How have hackathons evolved in their role as global innovation tools?
- Q2: What impacts have been generated in the different contexts analyzed?
- Q3: What are the main knowledge gaps emerging in the scientific literature?

This type of analysis, represented in Fig. 7, provides the basis for a systematic and comparative review of the selected studies, allowing us to identify the most established lines of development, emerging areas of application, and opportunities for future research. Together, the results offer a comprehensive and up-to-date view of the evolution of hackathons as drivers of innovation supported by AI, interdisciplinary collaboration, and technological experimentation.

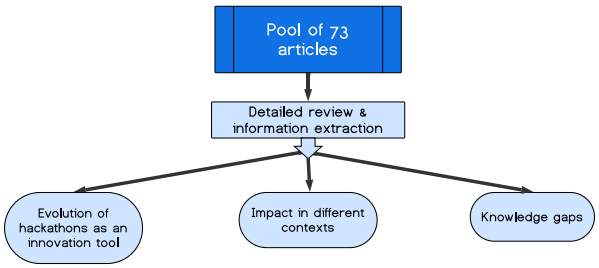

Fig. 7. Structure of the systematic content review.

1) Evolution of hackathons as innovation tools: In relation to the first research question: How have hackathons evolved in their role as global innovation tools?, the findings reveal a growing interest in the scientific literature to understand the transformation of these events, since they have gone from being light programming moments to becoming strategic platforms for open innovation and interdisciplinary collaboration. The studies analyzed show a diversification in their approaches and objectives, ranging from international corporate collaboration to the development of technological solutions with social and environmental impact. In this sense, [31], [5] highlight the role of hackathons in the creation of global innovation networks, which can overcome geographical and organizational boundaries to generate joint solutions in digital environments.

Likewise, there has been an increase in research that includes AI tools in the design and execution of hackathons,

suggesting a transition toward hybrid AI-assisted co-creation models [32]. These experiences optimize prototyping and enhance the analytical and predictive capacity of participating teams, accelerating the ideation and validation processes. In parallel, other emerging lines of research are oriented toward the use of hackathons as spaces for measuring environmental change and sustainable innovation [33], [34], integrating participatory methodologies to address ecological challenges through the use of open data.

The analysis reveals a consolidation in research on digital innovation, which is evidenced by it being the category with the most publications, as seen in Fig. 8. These contributions emphasize the role of hackathons as a promoter of organizational digital transformation [4], [12]. In contrast, studies on social hackathons [35], [9] show a smaller number, although with a growing relevance due to their ability to promote inclusion, citizen participation, and community development. Overall, this evolution shows that hackathons have ceased to be light programming moments, to become dynamic ecosystems of collaborative innovation, in which technology, creativity, and social commitment are intertwined.

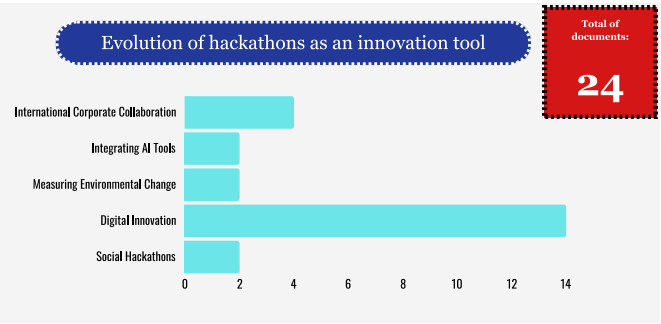

Fig. 8. Distribution of articles by hackathon evolution.

2) Impacts generated in the different contexts analyzed: Regarding the second research question: What impacts have been generated in the different contexts analyzed? The results show that hackathons have had a transversal influence in multiple application areas, particularly in engineering training, medical and healthcare improvements, general educational training, social innovation, and the integration of women in technological environments. In the field of engineering, the reviewed studies emphasize that these events promote the acquisition of practical skills, creativity, and interdisciplinary collaboration, integrating experiential learning methodologies and immersive simulation [36]. In addition to training experiences that combine emergency management and engineering [37], [38], these findings consolidate the perception of hackathons as applied learning environments that complement formal education and promote technological innovation in higher education.

In the healthcare and medical sectors, hackathons have emerged as co-creation spaces for clinical innovation and digital health, where multidisciplinary professionals collaborate to develop solutions for data management, medical record interoperability, and responding to public health crises. Hackathons focused on digital health have demonstrated improvements in clinical communication and the efficiency of healthcare procedures, according to the studies analyzed [7], [39]. Furthermore, the effects on general education and social innovation highlight the value of these events for project-based learning and community engagement, as they promote collaborative work among students, social organizations, and institutions [40], [41]. Finally, female integration stands out as a field in progress [20], where the participation of women is promoted in traditionally male-dominated environments, which contributes to increasing diversity and equity in innovation spaces. Taken together, these results demonstrate that hackathons generate significant impacts on both technical training and social inclusion and transformation, consolidating themselves as dynamic tools for connecting education, technology, and sustainable development (see Fig. 9).

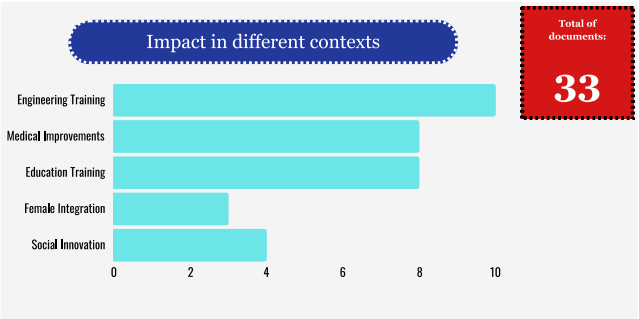

Fig. 9. Distribution of articles by impact in areas.

3) Main knowledge gaps: Regarding the third research question: What are the main knowledge gaps emerging in the scientific literature? A review of the selected studies reveals significant gaps in understanding the long-term impacts and systematization of the hackathon model as an innovation tool. The main gaps are grouped into four areas: entrepreneurial competence, sustained innovation drive, comprehensive skills development, and long-term sustainability. Although studies demonstrate the potential of hackathons to foster entrepreneurial skills and experimentation with emerging technologies [42], [43], the literature still lacks longitudinal studies that assess how these skills are sustained or translated into real business projects. This gap restricts understanding of the real impact of hackathons, both organizationally and economically, beyond their immediate educational context.

Likewise, although the role of hackathons in driving global innovation is highlighted [44], especially in sectors such as digital health and sustainability, there is a lack of established theoretical frameworks that explain how these collaborative dynamics are integrated into public policies or long-term innovation ecosystems [45]. Regarding skills development, although hackathons improve communication, teamwork, and creativity [46], [47], [48], there is still little evidence about whether these skills are effectively transferred to the academic or professional environment. Finally, regarding long-term sustainability, the studies analyzed agree that hackathons struggle to maintain the continuity of the projects created and to institutionalize their results in organizations or communities [49], [50]. These gaps suggest the need for a more structured methodological approach, aimed at measuring the lasting

impact, the scalability of solutions, and the integration of hackathons as part of sustainable educational, social, and business innovation strategies (see Fig. 10).

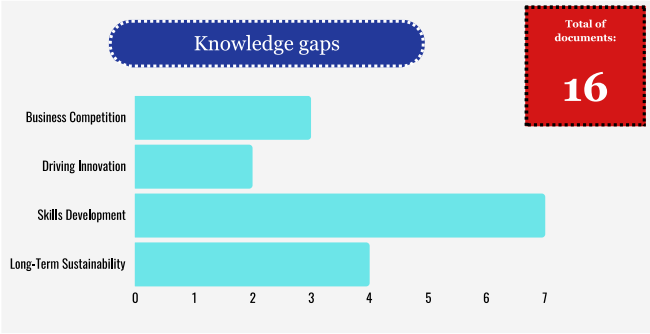

Fig. 10. Distribution of articles by main knowledge gaps.

C. Discovery

The final analysis included a total of 73 selected documents, which allowed for the identification of key trends and approaches shaping the development of hackathons as innovation tools. To organize the findings, a thematic coding process was used to align each article with one of the three research questions (R1, R2, R3). Table I shows a summary of most of the selected studies, including data such as authors, year of publication, article title, and the research question it addresses. This mapping allows for an examination of the thematic breadth and distribution of studies within the established categories, lending greater relevance and transparency to the review process.

1) Hackathons as tools for innovation: Hackathons have evolved from experimental events focused on rapid software development to established open innovation systems. This shift is evident in the diversification of their focuses, spanning social, corporate, academic, and technological areas, reflecting their role in digital transformation and collaborative creation on a global level.

2) Impact in different contexts: The identified impacts manifest themselves in different contexts, such as the social sphere, where hackathons promote citizen participation and the co-creation of community solutions; in the business sphere, where they promote organizational agility and innovation; and in the academic sphere, they strengthen digital skills and interdisciplinary learning. These effects demonstrate their potential to promote collaborative and sustainable innovation.

3) Gaps in the literature: The gaps identified are primarily related to the lack of longitudinal studies, the absence of standardized metrics to assess the real impact of hackathons, and the underrepresentation of countries with low technology and limited scientific budgets. There is also a persistent need to integrate more robust theoretical approaches that explain the learning and knowledge transfer mechanisms that occur during these events.

4) The evolution of hackathons: It has become clear that they have ceased to be experimental spaces and have become strategic platforms for open innovation, bringing together participants from diverse fields through intensive collaborative dynamics. Their consolidation as a global practice demonstrates a transition toward more inclusive, interdisciplinary, and sustainable models, where innovation is built collectively and oriented towards social and technological impact.

V. Discussion

First, regarding the evolution of hackathons as innovation tools, the results of the review confirm that they have evolved from being short technological events to becoming consolidated as strategic spaces for interdisciplinary collaboration. Their use has expanded to sectors such as education [6], healthcare [7], sustainability [33], and digital transformation, where they function as promoters of open innovation and global co-creation. The analysis shows that hackathons have become environments for experiential learning and technological experimentation, integrating both academic institutions and corporate organizations. This development, strengthened by the empirical and theoretical trends analyzed, validates this study by showing a sustained and varied evolution of hackathons.

Regarding the impacts generated in different contexts, the reviewed evidence confirms that hackathons have had

significant effects on vocational, medical, and social training, promoting the acquisition of technical skills, the integration of underrepresented groups, and the development of community-impact solutions [9]. In the educational field, they are consolidated as effective environments for strengthening interdisciplinary practice and critical thinking [6]; in the medical field, they promote clinical innovation and emergency management [7]; and in the social field, they stimulate citizen inclusion and collaboration. These results validate the perspective of this review by demonstrating that hackathons are tools for educational and social change, as well as technological innovation methodologies, which entail quantifiable advantages in diverse contexts.

Finally, regarding the knowledge gaps identified, the analysis argues that, although significant progress has been made, challenges persist in the longitudinal evaluation of impact, project sustainability, and institutionalization of results. The lack of unified theoretical frameworks or long-term comparative research restricts a comprehensive understanding of the phenomenon. However, this analysis provides an important contribution by systematizing emerging trends and delimiting fields of study that should be prioritized for future research. In this sense, the study validates its relevance by providing a structured and critical overview of the state-of-the-art, highlighting the need to approach hackathons from a more analytical, sustainable, and impact-oriented perspective.

VI. Conclusion

This study conducted a comprehensive analysis of the evolution, impact, and knowledge gaps surrounding hackathons as innovation tools globally, combining a bibliometric approach with a detailed review of 73 scientific papers. The results show sustained growth in academic output starting in 2020, with a notable increase between 2021 and 2024. This trend confirms the growing interest of the scientific and professional community in hackathons as strategic environments for open innovation, experiential learning, and collaborative problem-solving, especially in technological, educational, and social contexts.

The analysis shows that the most developed sectors are digital innovation, engineering training, education, and healthcare, reflecting a stronger focus on inclusion and sustainability. Geographically, scientific production is concentrated in countries such as the United States, Brazil, and Germany. However, it is less prevalent in countries with less technological impact, reflecting an unequal distribution of knowledge. Furthermore, the most frequent keywords, such as hackathon, innovation, and education, reveal a multidisciplinary approach focused on the creation of social and technological value. Networks of co-authorship and institutional collaboration suggest consolidated, albeit dispersed, academic communities, opening up opportunities to strengthen international ties and foster the practical transfer of results.

In summary, the results confirm that hackathons have established themselves as dynamic innovation spaces capable of integrating creativity, technology, and collective learning. However, challenges remain related to long-term impact assessment, project sustainability, and the lack of integrative theoretical frameworks.

The main contribution of this review lies in offering a comprehensive and comparative overview of how hackathons have evolved from their beginnings as technological events to open and sustainable places of innovation. Unlike previous studies, this work does not limit itself to describing isolated cases, but rather synthesizes global patterns of application, identifies structural gaps in research, and proposes an implicit classification that links the educational, social, and business dimensions of hackathons. This integrative approach provides a new analytical perspective that allows us to understand hackathons as permanent mechanisms for learning, technology transfer, and co-creation.

From a theoretical perspective, the review broadens our understanding of the relationship between open innovation and collective learning, establishing that hackathons function as places of distributed innovation. On a practical level, hackathons offer guidance for designing post-event monitoring and evaluation mechanisms that measure the real impact of the solutions generated. Finally, in terms of innovation policies, the results invite the integration of hackathons into national strategies for technological development, entrepreneurial education, and citizen participation. In conclusion, this review systematizes the existing evidence and provides an interpretive framework that redefines the role of hackathons as evolutionary tools for global innovation.

VII. Gaps in the Literature

Despite the notable growth in research on hackathons as environments for innovation and collaborative learning, the scientific literature presents significant limitations that should be considered to guide future lines of work. One of the main gaps identified is the scarcity of longitudinal studies that analyze the sustained impact of hackathons on project development, venture creation, or the consolidation of innovation tools. Most studies focus on immediate outcomes, such as the learning experience or idea generation [2], without analyzing the continuity or the degree of actual implementation of the proposed solutions.

Likewise, a thematic fragmentation is evident in the approaches addressed. While studies on business competition and skills development have gained visibility [12], research on the long-term sustainability of hackathons and their capacity to be integrated into organizational or public policy strategies remains limited. Similarly, studies on innovation drive tend to focus on high-tech or educational contexts, leaving aside community, social, or country settings with less innovation infrastructure, which restricts a comprehensive understanding of the phenomenon.

Ultimately, there is a marked geographic concentration in scientific production, led by the United States, Brazil, and Germany, with limited representation in countries in Latin America, Africa, and Asia. This uneven distribution suggests that the opportunities, management models, and collaborative dynamics of hackathons may be influenced by economic and structural factors [23], rather than by the nature of the event itself. In this sense, it is necessary to promote interdisciplinary

and comparative research that analyzes hackathons in diverse contexts, with special emphasis on their social impact, organizational sustainability, and results measurement. Further examining these gaps will help to develop a more robust theoretical framework and guide the design of hackathons as sustainable tools for innovation and collective change.

VIII. Recommendations for Future Studies

- Analyzing the long-term sustainability of hackathons.
- Compare different hackathon models.
- Investigate the evolution of business and innovation skills.
- Evaluate the factors that favor or limit organizational sustainability.
- Explore the social and cultural dimensions of hackathons.
- Deepen ethical and equity approaches to participation.
- Develop longitudinal comparative studies.

SBERT-Based Stacking Ensemble Model for Fake News Detection

Abdulaziz A Alzubaidi, Amin A Alawady
Department of Computer Skills-Deanship of Preparatory Year, Najran University, Najran, Saudi Arabia

***Abstract*—Fake news has become a significant global challenge, affecting public opinion, social dynamics, and decision-making processes. Detecting fabricated news accurately and efficiently remains a challenging task due to the diversity of content, writing styles, and subtle semantic nuances. In this study, we propose a stacking ensemble model that uses SBERT-based semantic embeddings to improve the detection of fake news. The model integrates several machine-learning classifiers with a meta-learner to enhance robustness and predictive reliability. Experiments on the WELFake dataset show that the proposed model achieves 92.74% accuracy, a 93.01% F1-score, and a 97.93% ROC-AUC in classifying fake and real news. These results demonstrate the model's effectiveness and suggest its potential for broader application across different languages and news domains.**

***Keywords*—Fake news detection; machine learning; SBERT embeddings; stacking ensemble; Random Forest; Logistic Regression; MLP; XGBoost**

I. Introduction

The proliferation of online platforms has dramatically increased the circulation of information, but it has also facilitated the rapid spread of fake news and misinformation [1]. Fake news poses significant risks to society by influencing public opinion, manipulating governmental processes, and undermining trust in credible information sources [1], [2]. Recent studies emphasize that the challenge of detecting fake news is not only a technical issue but also a social and ethical one, as misinformation can impact domains such as healthcare and public safety [1], [2],[3].

Recent global surveys highlight an alarming concern among populations regarding fake news. For instance, a Pew Research Center survey in April 2025 found that over 80% of adults in 35 countries see fake news as a major issue in their nation, with 59% labeling it "very big". Moreover, 72% of adults across 25 countries perceive the spread of false information online as a major national threat. Nationally, in the Philippines, 59% believe fake news on social media. This is a serious problem, while 62% say the same about traditional media. In Brazil, almost 90% admit to having believed a fake news item at some point, despite many claiming confidence in their ability to discern truth from falsehood [4].

The detection of deceptive information has consequently become a central research focus in artificial intelligence and natural language processing. Traditional machine learning models, including Support Vector Machines (SVM), Random Forests (RF), and gradient boosting techniques, have been extensively applied to text classification, providing an initial foundation for distinguishing authentic from deceptive content [5]. However, studies have demonstrated that these models often struggle to capture the deeper semantic and contextual dependencies inherent in human language, which are critical for reliable fake news detection [6]. Transformer-based architecture, contextual embeddings, and multimodal approaches have demonstrated superior performance in modeling these dependencies and improving classification accuracy [7].

Advancements in deep learning have enabled the extraction of high-level, context-aware features, significantly improving classification performance. Architectures such as Convolutional Neural Networks, Recurrent Neural Networks, and Long Short-Term Memory networks have been employed to model sequential dependencies and linguistic patterns in text [1]. More recently, transformer-based models, including BERT, RoBERTa, and XLNet, have demonstrated superior capability in understanding nuanced contextual information through self-attention mechanisms, thereby enhancing the accuracy and reliability of fake news identification [7].

In addition to the context of semantics-based approaches, current research emphasizes challenges such as dataset imbalance, scarcity of annotated resources for low-resource languages, and the interpretability of models. These challenges are particularly relevant for fake news detection, as textual data alone often contains nuanced semantic and contextual dependencies that are difficult for traditional models to capture [2], [8]. Moreover, the rise of multilingual environments introduces further complexity, as many languages have limited annotated datasets and resources. Handling multilingual textual data effectively requires models capable of generalizing across languages while maintaining high detection accuracy, which remains a significant challenge in current research [9].

Despite the extensive research on fake news detection, existing approaches often face limitations in capturing deep semantic relationships, handling multilingual data, and maintaining robustness across heterogeneous datasets. This study addresses these gaps by proposing an innovative ensemble model that integrates semantic embeddings with multiple classifiers, enhancing both accuracy and generalizability, with the added advantage of applicability across multiple natural languages in real-world scenarios.

The contributions of this study are summarized as follows:

- An innovative stacking ensemble model is proposed for fake news detection, combining semantic embeddings using SBERT with multiple machine learning

classifiers as base learners, including Random Forest, Logistic Regression, and MLP, while XGBoost serves as the meta-learner to enhance predictive accuracy and robustness.

- An OOF-based meta-learning strategy using XGBoost, enabling robust generalization and reducing overfitting across large and heterogeneous datasets.
- A practical and extensible framework that can be adapted to other NLP tasks requiring deeper semantic understanding and enhanced model stability.

This study is structured as follows: Section II provides an overview of related work, Section III explains the materials and methods, Section IV presents the experimental setup, Section V discusses the evaluation metrics, Section VI and Section VII report and analyze the results, and Section VIII concludes the study.

II. Related Work

Ensemble Learning is a computational paradigm that combines multiple machine learning models to achieve higher predictive accuracy and robustness compared to individual learners. It reduces bias, variance, and overfitting by aggregating diverse classifiers through approaches such as bagging, boosting, and stacking [10]. Recent studies confirm its importance in fake news detection and natural language processing (NLP) tasks. Mouratidis et al. [6] emphasized that hybrid and ensemble frameworks integrating classical ML with deep models yield more reliable results, especially when combined with explainable AI methods. Moreover, Shah and Patel [2] provided a comprehensive survey highlighting ensemble and hybrid approaches as central to improving detection performance across textual and social-context features. Al-alshaqi et al. [11] proposed an ensemble-based framework for fake news detection, showing that integrating multiple models within a unified architecture enhances robustness and overall detection performance.

Alshuwaier and Alsulaiman [1] conducted a comprehensive review on fake news detection using machine learning and deep learning algorithms. The study examined over 30 papers published between 2018 and 2025, analyzing datasets, feature extraction methods, algorithms, and performance outcomes. Traditional ML models such as Naïve Bayes, Random Forest, Logistic Regression, and SVM achieved strong performance in several cases. Deep learning approaches, including CNN, Bi-LSTM, GNN, and BERT-based models, generally outperformed classical methods, particularly with large-scale and multilingual datasets. Hybrid and ensemble strategies showed the most promising results, combining the strengths of both ML and DL for more reliable detection. The review also identified major challenges, such as data imbalance, limited generalization across platforms, and the difficulty of early-stage detection. The authors emphasized that future research should focus on multimodal hybrid models and the integration of large language models (LLMs) to enhance robustness and adaptability in fake news prediction.

Hu, Mao, and Zhang [2] provided a survey on fake news detection from a novel perspective. They analyzed the diffusion process of fake news and identified three key characteristics: intentional creation, heteromorphic transmission, and controversial reception. Based on these, detection methods were grouped into feature-based, propagation-based, and stance-based approaches. The study emphasized the importance of integrating these perspectives, moving toward multimodal models, and improving interpretability for future research.

Ni'mah et al. [8] proposed a framework for fake news detection in low-resource languages under extreme class imbalance. The study introduced Contrast-BERT, a contrastive learning model that generates embeddings, which are then classified using a stacking-based ensemble of MLPs. This design outperformed standard end-to-end BERT classifiers, especially in scenarios where fake claims vastly outnumber real ones. The framework also proved effective for topic clustering and evidence retrieval, showing robustness across Indonesian, Bangla, and Czech datasets. The authors emphasize contrastive representation learning and ensemble strategies as promising directions for handling misinformation in low-resource settings

Jyoti and Kumar [12] introduced Ndetect, an ensemble-based machine learning model for fake news detection designed to enhance classification accuracy. The framework integrates multiple classifiers through ensemble techniques such as bagging, boosting, and Random Forest, tested on benchmark fake news datasets. Experimental results demonstrated that the ensemble approach significantly outperformed individual classifiers, achieving higher precision and recall while maintaining robustness across datasets. The study emphasized the effectiveness of ensemble learning in addressing data variability and improving reliability in fake news prediction.

Alnabhan and Branco [13] conducted a systematic literature review on fake news detection using deep learning approaches. The review categorized models into CNN, RNN, LSTM, Bi-LSTM, GNN, and transformer-based architectures such as BERT and RoBERTa, comparing their performance across diverse datasets and languages. Results indicated that deep learning consistently outperforms traditional ML models, particularly on large, complex, and multilingual data, with transformer models achieving the best overall performance. The study also highlighted challenges, including data imbalance, lack of generalization across platforms, and difficulties in early detection. The authors concluded that future research should focus on multimodal DL models and large-scale pre-trained architectures to improve robustness and adaptability in fake news prediction.

Although numerous studies have explored ensemble and hybrid approaches for fake news detection, a clear gap remains in effectively combining semantic-rich embeddings with diverse ensemble strategies to handle heterogeneous and imbalanced datasets. Previous research has demonstrated the benefits of classical machine learning, deep learning, and transformer-based models individually. However, there is limited work that integrates SBERT embeddings with a stacking ensemble framework specifically designed to exploit both semantic understanding and the complementary strengths

of multiple classifiers. This gap highlights the need for targeted strategies that leverage the synergy between semantic representations and ensemble learning to enhance robustness, generalization, and overall detection performance. Building on this insight, the current study proposes an approach that addresses this gap by integrating SBERT embeddings with a stacking ensemble to improve the accuracy and reliability of fake news detection.

III. Materials and Methods

This research introduces a stacking ensemble model for fake news detection, comprising two hierarchical levels of learning. The first level, known as the base learners, involves generating sentence-level embeddings using SBERT (Sentence-BERT), a transformer-based model designed to produce dense, semantically meaningful vector representations for text. SBERT captures contextual information, word dependencies, and subtle semantic nuances, enabling the model to understand the relationships between sentences and phrases effectively. The proposed framework is designed to address the lack of semantic generalization observed in previous ensemble and transformer-based models. By combining SBERT embeddings with multiple heterogeneous base learners and an OOF-based meta-learning layer, the model leverages both deep contextual understanding and classifier complementarity. These embeddings are then fed into multiple machine learning classifiers, specifically Random Forest, Logistic Regression, and Multi-Layer Perceptron (MLP), which perform initial predictions. Although XGBoost was also trained as a base learner within the OOF procedure, it is not depicted in Fig. 1 to maintain clarity and avoid visual confusion, as its primary role in the diagram is the meta-learner. The outputs of the base learners are subsequently used as input features for the second level, the meta-learner, which is also implemented using XGBoost. The meta-learner leverages out-of-fold (OOF) predictions generated via Stratified K-Fold cross-validation, ensuring balanced representation of classes in each fold. This process allows the model to learn from diverse perspectives of the base classifiers, enhancing generalization and reducing overfitting. By combining semantic embeddings from SBERT with ensemble learning techniques, the proposed stacking model effectively captures both low-level textual patterns and high-level contextual relationships, significantly improving predictive performance. Fig. 1 provides a schematic overview of the SBERT-based stacking model, illustrating the flow from sentence embeddings through base learners to the final meta-learner output.

A. Stacking

Stacking is a powerful ensemble learning technique designed to improve predictive accuracy by integrating the outputs of multiple base learners through a higher-level meta-learner. In this model, learning occurs over two levels. At the first level, diverse base learners are trained independently in different splits of the dataset, producing predictions that capture complementary patterns from the data. These predictions are then fed as input to the second-level meta-learner, which combines them in an optimal manner to produce the final output [14]. The proposed stacking ensemble model is designed to improve fake news detection by combining multiple machine learning classifiers with semantic embeddings from SBERT. The stacking model consists of two levels:

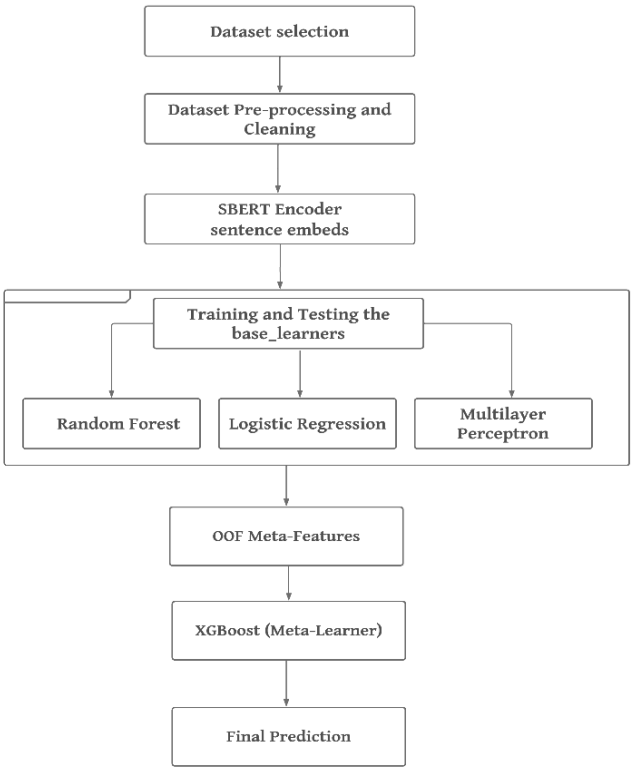

Fig. 1. Proposed stacking model.

1) Base learners (level 1): At the first level, several diverse classifiers, namely Random Forest (RF), Logistic Regression, and Multi-Layer Perceptron (MLP), are trained on sentence-level embeddings generated by SBERT. SBERT embeddings provide rich semantic, contextual representations of textual content and enabling the base learners to capture high-level relationships within the text.

To enhance robustness and avoid overfitting, Stratified K-Fold cross-validation is applied during training of the base learners. This procedure generates out-of-fold (OOF) predictions, which are predictions for the validation folds that are not seen by the respective base learner during training. These OOF predictions form a new set of features, referred to as meta-features, for the next level of the ensemble.

2) Meta-learner (level 2): The second level consists of a meta-learner, implemented using XGBoost, which is trained on the OOF predictions from the base learners. By learning from the combined outputs of the base learners, the meta-learner can exploit complementary strengths of each model, capture diverse perspectives, and improve overall predictive accuracy.

The stacking procedure thus allows the ensemble to integrate both high-level semantic information from SBERT embeddings and predictive patterns from multiple classifiers. This dual-level approach ensures that the model generalizes

well on unseen data and outperforms individual base learners. Fig. 1 illustrates the overall workflow of the proposed stacking ensemble model, showing the flow from SBERT embeddings to base learners, and finally to the meta-learner.

B. SBERT

Sentence-BERT (SBERT) is a transformer-based model designed to produce semantically meaningful sentence embeddings. Unlike traditional BERT, which generates token-level embeddings, SBERT modifies the architecture to generate fixed-size sentence embeddings that can be directly used for similarity comparisons, clustering, or downstream classification tasks [15]. In our study, SBERT is employed to transform textual news content into dense vector representations that capture semantic relationships and contextual nuances between sentences. These embeddings serve as rich input features for the base learners in the stacking ensemble, allowing the model to leverage deep contextual information beyond surface-level word occurrences. We claim that by using SBERT embeddings, our stacking model can better discern subtle semantic differences between authentic and fake news, enhancing the overall detection performance.

C. Random Forest

Random Forest (RF) is a widely adopted machine learning algorithm applicable to both classification and prediction tasks, and it plays a critical role in building robust models. The method relies on an ensemble of decision trees, where each tree is trained on different subsets of the data and features, introducing diversity into the learning process. Specifically:

- For every tree in the forest, a bootstrap sample is drawn randomly from the training dataset (sampling with replacement).
- At each node, a random subset of features is selected to determine the best split.

Once multiple trees are trained, their outputs are aggregated—either through majority voting for classification tasks or averaging for regression—to generate the final prediction. This ensemble mechanism effectively mitigates the risk of overfitting compared to using a single decision tree, thereby improving stability and overall generalization performance. Moreover, Random Forest provides insightful and quantitative measures of feature importance, allowing researchers to interpret model behavior and evaluate the contribution of each variable to the decision-making process more transparently [16], [17].

D. Extreme Gradient-Boosting

XGBoost, introduced by Tianqi Chen and Carlos Guestrin, is an advanced implementation of the Gradient Boosting Decision Tree (GBDT) algorithm that has become one of the most widely adopted machine learning models due to its scalability, efficiency, and adaptability [18]. Unlike traditional GBDT, XGBoost incorporates regularization techniques to control model complexity and mitigate overfitting. It also integrates optimization strategies such as second-order gradient approximation, parallelized tree construction, and early stopping, which collectively accelerate training while improving predictive accuracy [19].

Moreover, a key strength of XGBoost is its ability to address class imbalance by assigning higher weights to misclassified instances, particularly from minority classes, during the boosting process. This mechanism improves classification performance in skewed data distributions, though it may sometimes introduce biased decision boundaries if not carefully tuned [20]. Furthermore, its inherent flexibility allows it to leverage multiple weak learners and iteratively refine them through boosting, resulting in a strong ensemble capable of capturing complex patterns in data [18]. In summary, XGBoost is recognized as a powerful and widely used tool in machine learning, excelling at handling complex problems and greatly improving the performance of predictive models.

E. Multilayer Perceptron

Multilayer Perceptron (MLP) is a feedforward neural network capable of modeling complex non-linear patterns. Modern MLPs often use techniques such as dropout, batch normalization, and adaptive optimizers to improve training stability, accelerate convergence, and reduce overfitting [21]. In our stacking model, MLP serves as a base learner, producing probability predictions that are used as input features for the meta-learner, enhancing the ensemble's ability to capture non-linear relationships in the data.

F. Logistic Regression

Logistic Regression (LR) is a widely used linear model for classification, estimating the probability of outcomes through the logistic function. LR remains popular due to its simplicity, interpretability, and efficiency, and modern studies often use it with regularization techniques to handle large or imbalanced datasets [22]. In our model, LR serves as a base learner, generating probability outputs that are used as input features for the meta-learner.

G. Cross-Validation

Cross-validation (CV) is a widely used technique in machine learning to assess a model's ability to generalize to unseen data. In this approach, the dataset is partitioned into k equally sized folds, and the model is iteratively trained on k-1 folds while the remaining fold is reserved for validation. This process continues until each fold has served as a validation set exactly once [23]. In our stacking model, cross-validation is especially important for generating out-of-fold (OOF) predictions from base learners, which are then used as input features for a meta-learner. By doing so, the meta-learner is trained on predictions that are not biased by the same data used to fit the base models, enhancing the robustness of the ensemble.

H. Study Data

The WELFake dataset is a well-prepared dataset in the field of fake news detection and machine learning. It comprises a total of 72,134 news articles, including 35,028 real and 37,106 fake news entries. To enhance the diversity of the dataset and reduce the risk of overfitting, the authors combined four popular news datasets (Kaggle, McIntire, Reuters, and BuzzFeed Political), providing a richer text corpus for more effective machine learning training [24].

The dataset contains four key columns: Serial Number (starting from 0), Title (news headline), Text (full news content), and Label (0 for fake and 1 for real). Missing or incomplete records were removed during preprocessing to ensure data quality and consistency [24]. This step guarantees that models trained on this dataset can learn effectively from clean and representative examples.

This dataset is publicly available on Kaggle, one of the largest global repositories for datasets, at: https://www.kaggle.com/datasets/saurabhshahane/fake-news-classification

Published in IEEE Transactions on Computational Social Systems: (doi: 10.1109/TCSS.2021.3068519), and its characteristics are listed in Table I [24].

TABLE I. WELFAKE DATASET METADATA

Dataset columns			
#	Column	Count	Datatype
0	Serial Number	72134	int64
1	Title	71576	object
2	Text	72095	object
3	Label	72134	int64

IV. EXPERIMENTAL SETUP

In this study, the proposed stacking model was developed using Python 3.10 within a Jupyter Notebook environment, executed on a system powered by an Intel Core i5-1035G7 processor (1.20 GHz) and 8 GB of RAM. The dataset employed was the WELFake dataset [22], which contains a total of 72,134 news articles, consisting of 35,028 real and 37,106 fake news entries. The dataset provides four columns: Serial Number, Title, Text, and Label. For our study, we focused exclusively on the Text and Label columns, as they directly support the fake news classification task, and we dropped any entries with missing text, as implemented in the preprocessing step: df = df[['text', 'label']].dropna(). This preprocessing slightly reduced the dataset but maintained a relatively balanced distribution between real and fake news, ensuring consistent and reliable input for our stacking ensemble model. The textual data were encoded into dense embeddings using Sentence-BERT (SBERT) all-MiniLM-L6-v2, which produced fixed-length semantic vectors for each article. These embeddings were then used to train the base learners: Logistic Regression, Random Forest, Multilayer Perceptron (MLP), and XGBoost. Each base learner was trained with a 3-fold Stratified K-Fold Cross-Validation to generate out-of-fold (OOF) predictions, which served as input features to the meta-learner. The meta-learner was implemented using XGBoost, which aggregated the OOF predictions from the base learners to improve generalization and reduce overfitting. Hyperparameters for all models were selected and fine-tuned empirically to achieve stable performance during training and validation.

Finally, the performance of the stacking ensemble was evaluated on a 20% holdout test set that was not involved in any training or validation step. Metrics such as Accuracy, F1-score, and the classification report were reported to assess the robustness and overall effectiveness of the model.

V. PERFORMANCE MEASURE

We assessed the performance of our proposed model using standard evaluation metrics, starting with:

A. Accuracy

It represents the proportion of correctly classified news articles (both real and fake) out of the total number of articles. It provides a general measure of how effectively the model distinguishes between real and fake news [25]. The definition of accuracy is captured by Eq. (1):

$$Acc = \frac{TP+TN}{TP+TN+FP+FN} \quad (1)$$

Assuming the outcome of a news article indicates whether it is Real or Fake:

- True positive (TP): articles correctly identified as real.
- True negative (TN): articles correctly identified as fake.
- False positive (FP): fake articles incorrectly predicted as real.
- False negative (FN): real articles incorrectly predicted as fake.

B. Precision

It measures how well the model correctly identifies articles as real when it predicts them to be real. A high precision score indicates that most articles predicted as real are indeed real [25]. Eq. (2) shows the formulation of precision:

$$Precision = \frac{TP}{TP+FP} \quad (2)$$

Assuming the outcome of a news article indicates whether it is Real or Fake:

- True positive (TP): articles correctly classified as real.
- False positive (FP): fake articles incorrectly predicted as real.

C. Recall

Recall measures the proportion of actual positive instances correctly identified by the model. In fake news detection, it reflects how many real articles are correctly classified as real [25]. Recall is defined in Eq. (3):

$$Recall = \frac{TP}{TP+FN} \quad (3)$$

Assuming the outcome of a news article indicates whether it is Real or Fake:

- True positive (TP): articles correctly classified as real.
- False negative (FN): real articles incorrectly predicted as fake.

D. Cohen's Kappa Metric

Cohen's Kappa Score (CKS) evaluates the level of agreement between predicted and actual class labels, adjusting for the agreement that might occur by chance. It is particularly

useful in scenarios with imbalanced datasets [25]. Eq. (4) defines CKS:

$$CKS = \frac{P_0 - P_e}{1 - P_e} \quad (4)$$

where,

- P0: the observed accuracy of the model.
- Pe: the expected agreement by chance.

E. F1-Score

F1-score is a standard metric for binary classification that combines precision and recall into a single value. It is defined as the harmonic average of the two, making it especially useful when the class distribution is imbalanced [25]. Eq. (5) shows the formulation:

$$F1 = 2 \times \frac{Precision \times Recall}{Precision + Recall} \quad (5)$$

F. Receiver Operating Characteristic: Area Under the Curve (ROC-AUC)

ROC-AUC measures a model's ability to distinguish between positive and negative classes across different decision thresholds. It is particularly valuable in cases of imbalanced datasets, as it evaluates the trade-off between sensitivity (recall) and specificity [25].

By employing a variety of evaluation metrics, such as Accuracy, Precision, Recall, F1-score, Cohen's Kappa, and ROC-AUC, we can obtain a comprehensive understanding of the model's performance. These metrics collectively highlight the model's strengths and limitations, from its ability to correctly classify real and fake articles to its robustness in handling imbalanced data. Such a comprehensive evaluation facilitates informed decision-making in model selection, optimization, and deployment.

VI. Results

In this study, a stacking ensemble model was constructed for fake news detection using machine learning classifiers combined with the transformer-based SBERT model for sentence embeddings. A total of 72,095 news articles from the WELFake dataset were processed, with SBERT encoding each article into dense semantic embeddings of dimension 384. These embeddings were used to train four base learners—Random Forest, Logistic Regression, Multilayer Perceptron (MLP), and XGBoost—through a 3-fold stratified cross-validation scheme to generate out-of-fold (OOF) predictions. The aggregated OOF predictions served as meta-features for the XGBoost meta-learner, which produced the final classification results. On a holdout set comprising 14,419 articles, the stacking ensemble achieved an accuracy of 92.7%, precision of 92.0%, recall of 94.0%, and an F1-score of 93.0%. In addition, the model reached a Cohen's Kappa score of 0.85, reflecting strong agreement beyond chance, and a ROC-AUC of 0.98, indicating excellent discrimination ability between real and fake articles. The detailed classification report further highlights balanced performance across both classes, with fake news (label 0) achieving a precision of 0.94 and real news (label 1) attaining a recall of 0.94.

These results confirm that the SBERT-based stacking model effectively integrates the strengths of multiple learners, capturing both semantic depth and diverse decision boundaries. By leveraging SBERT embeddings with ensemble learning, the proposed model demonstrates robust performance and strong generalization in large-scale fake news detection tasks.

A. Stacking Model Performance

In this work, multiple evaluation metrics were utilized to assess the performance of the proposed stacking ensemble model, which combines SBERT embeddings with multiple machine learning classifiers. The outcomes across these metrics are summarized in Table II.

TABLE II. The Stacking Model Performance Results

Accuracy Score	Precision Score	Recall Score	F1 Score	ROC-AUC Score	Cohen's Kappa Score
0.9274	0.9203	0.9402	0.9301	0.9793	0.8546

VII. Discussion

A. Performance of the Proposed Model

In this study, we developed a stacking ensemble model for fake news detection that combines both traditional machine learning models (Random Forest, Logistic Regression, and MLP) with SBERT embeddings and XGBoost as the meta-learner. Our proposed model achieved an overall accuracy of 92.7%, supported by a precision of 92.0%, a recall of 94.0%, an F1-score of 93.0%, a Cohen's Kappa of 0.85, and an ROC-AUC of 0.97. These results highlight the ability of our model to effectively balance both precision and recall, ensuring robustness in distinguishing between fake and real news.

B. Analysis of Class-Level Results

The classification report reveals that the model performs consistently across both classes. For real news (class 0), the model reached 92% F1-score, while for fake news (class 1), it achieved 93% F1-score. This balance indicates that the model is not biased toward one class, which is a common challenge in fake news detection tasks where class distributions may vary. Moreover, the slightly higher recall for fake news (94%) demonstrates the model's effectiveness in minimizing false negatives—an important aspect in preventing the spread of misinformation.

C. Contribution of Ensemble Learning

The success of the proposed model lies in the integration of diverse learners and SBERT embeddings. While base learners such as Random Forest and Logistic Regression provide stable decision boundaries, SBERT ensures high-quality semantic representations of text, and the meta-learner XGBoost effectively combines their predictions. This layered approach enhanced the model's generalization capability, leading to improved performance compared to using individual models alone.

D. Comparative Evaluation with Existing Work

Compared with recent studies on fake news detection [26], [27], our proposed SBERT-based stacking ensemble demonstrates superior predictive performance and

generalization. Previous work, such as Wu et al. (2024) and Zhu et al. (2025), achieved moderate performance on their respective datasets. Wu et al. introduced a semantic-aware evidence-based framework with data augmentations and contrastive learning, reaching an F1-macro of 80.1% on Snopes-hard and 62.1% on PolitiFact-hard. Zhu et al. proposed a MIBKA-CNN-BiLSTM hybrid model, achieving up to 88.05% accuracy and 86.71% F1-score on a Chinese fake news dataset, but its effectiveness remained limited to the Chinese social media domain.

In contrast, our model leverages Sentence-BERT embeddings to encode rich semantic information and combines multiple heterogeneous base learners (XGBoost, Random Forest, Logistic Regression, and MLP) with an XGBoost meta-learner. Systematic optimization using GridSearchCV and Optuna, along with k-fold cross-validation, enabled our approach to achieve 92.74% accuracy, 93.01% F1-score, and 97.93% ROC-AUC on the WELFake dataset, substantially surpassing prior benchmarks.

This comparison highlights that integrating semantic-rich embeddings with ensemble meta-learning not only enhances generalization but also provides better stability across performance metrics compared to both optimization-driven hybrid models and transformer-only architectures. Moreover, our approach addresses prior limitations in semantic understanding and class balance, demonstrating a robust framework suitable for real-world fake news detection.

E. Insights and Implications

The findings underscore the effectiveness of integrating transformer-based embeddings with ensemble learning techniques. The high ROC-AUC (0.97) highlights the model's discriminative capability, while the Cohen's Kappa (0.85) indicates strong agreement beyond chance, reflecting robustness and reliability. Importantly, the balanced performance across fake and real news classes suggests the model's potential applicability to real-world scenarios, where the cost of misclassification is high. These results provide a solid foundation for extending the model to multilingual datasets, social media streams, and large-scale news corpora, where detecting misinformation is increasingly critical.

VIII. Conclusion

Fake news continues to pose a significant threat to the integrity of information, public trust, and informed decision-making worldwide. This study demonstrates that integrating semantic text embeddings with ensemble learning techniques can effectively enhance fake news detection, achieving high accuracy, precision, and recall. The results highlight the potential of such models to identify misinformation with a balanced consideration of false positives and false negatives, providing a reliable tool for monitoring information quality. The findings have practical implications for multiple stakeholders: policymakers can leverage these methods to design evidence-based regulations against misinformation, platform designers can implement automated detection systems to safeguard users, and practitioners can utilize such tools to monitor and mitigate the spread of false content. Moreover, the approach underscores the importance of combining contextual understanding with robust classification techniques to address complex challenges in information verification. For future work, extending the model to multilingual datasets, diverse domains, and real-time social media streams could further enhance its utility. Additionally, incorporating explainable AI techniques may improve transparency, increase user trust, and support ethical deployment of automated misinformation detection.

Aligning Confidence and Localization: An Enhanced DINO Model for Small Object Detection in Robotic Nursing

Yanchen Du[1], Qingzhuo Yuan[2], Shengli Luo[3], XiaoLong Shu[4], Xu Wang[5], Yuheng Jiang[6], Hongliu Yu[7]*
University of Shanghai for Science and Technology, Shanghai, China[1, 2, 3, 4, 5, 6, 7]
Rehabilitation Engineering and Technology Institute, University of Shanghai for Science and Technology, Shanghai, China[1, 2, 3, 4, 5, 6, 7]

***Abstract*—In care environments such as nursing homes, robots performing tasks (e.g., feeding assistance) must accurately identify and locate target objects to ensure safe and efficient execution. However, real-world applications face challenges such as numerous small objects, complex backgrounds, and severe occlusions, all of which compromise detection performance. To address these challenges, this study proposes an end-to-end object detection algorithm based on an enhanced DINO framework. Transformer-based DINO is adopted as the baseline, leveraging its global modeling capabilities and avoiding the complex pre- and post-processing required by traditional CNN detectors. In addition, an improved Align-Loss is introduced to enhance small-object detection and address misalignment issues within DINO. Furthermore, a GhostConv module is integrated into DINO's ResNet50 backbone to reduce the computational load of feature extraction and accelerate detection. Finally, multi-scale data augmentation and transfer learning are applied during training to improve detection accuracy and accelerate convergence. To validate the proposed method, experiments were conducted on the augmented MYNursingHome dataset and the COCO dataset. On the MYNursingHome dataset, the proposed approach improved mAP by 3.1% and APs by 2.6% over the DINO baseline, while reducing parameters from 47M to 39.6M and FLOPs from 279G to 243G. On the NVIDIA Jetson Orin Nano Super, inference speed increased from 16.8 FPS to 18.9 FPS (+12.5%). The experimental results demonstrate that the improved DINO detector proposed in this study exhibits a significant advantage in small object detection for nursing scenarios, providing algorithmic support for intelligent and efficient robotic care.**

I. Introduction

In recent years, the rapid growth of the ageing population and the increasing number of individuals with disabilities have heightened the demand for intelligent care services. Service robots are becoming essential assistants in daily living, and reliable object detection is a fundamental capability for ensuring safe and effective task execution. Care environments typically contain numerous small objects, complex backgrounds, and frequent occlusions, making robust small-object detection particularly challenging. Existing detection algorithms are mainly divided into CNN-based and Transformer-based approaches.

Early object detection relied heavily on CNN architectures, evolving from two-stage to single-stage frameworks. The R-CNN family [1] [2] introduced deep learning into object detection, while single-stage detectors such as YOLOv3 [3], SSD [4] and RetinaNet [5] improved real-time performance. Subsequent advancements, including multi-scale feature fusion techniques like FPN [6], significantly enhanced detection accuracy, especially for small objects. More recent CNN-based detectors, such as YOLOv8 and YOLOv9, further strengthen multi-scale representation and decoupled head design, achieving consistent improvements on small-object benchmarks [7], while RT-DETR introduces an anchor-free real-time DETR-like detector that significantly improves convergence and small-object accuracy [8]. However, the dependence on anchors and NMS limits their performance in cluttered and highly occluded care scenarios.

The introduction of DETR [9] marked a shift toward Transformer-based detection. By leveraging global self-attention and formulating detection as a set prediction problem with Hungarian matching, DETR removes handcrafted components such as anchors and NMS. Nevertheless, it exhibits slow convergence and struggles with small objects. Improvements such as Deformable DETR [10] and DN-DETR [11] address these issues through deformable attention and denoising training. Building upon these ideas, DINO [12] integrates denoising queries and anchor-based query selection, achieving strong performance across benchmarks. More recently, H-DETR [13] improves cross-scale feature aggregation for small objects, while Group-DETR [14] introduces structured query grouping to enhance training stability and reduce computation. EfficientViT-Det [15] proposes a high-efficiency hybrid architecture that offers improved speed–accuracy trade-offs for edge-device deployment. Align-DETR [16] introduces an alignment-aware loss to mitigate classification–localization inconsistencies. Overall, the emergence of Transformer-based detectors provides novel end-to-end solutions for object detection. TABLE I. compares the performance of the two major algorithmic categories on the same datasets. In accordance with the COCO evaluation protocol, the mean Average Precision (mAP) is further reported at three object scales: AP_s, AP_m, and APl, which measure the detection performance on small, medium, and large objects, respectively. DETR initially showed weak performance, mainly due to slow convergence and long training requirements.

However, with continuous optimization, its evaluation metrics now rival those of CNN-based detectors, demonstrating strong potential. Compared with CNN-based approaches, these models not only simplify the detection pipeline but also leverage global modelling to gain clear advantages in challenging scenarios such as complex backgrounds, occlusions, and multi-object interactions. In this work, we build upon DINO, a state-of-the-art DETR-based object detector, as our baseline. However, DINO still suffers from classification–localization inconsistency and high computational cost, which motivates our improvements described in this study. Although the proposed method is built upon the Transformer-based DINO framework, its backbone still uses the CNN-based ResNet50 architecture, within which GhostConv is introduced to improve computational efficiency.

TABLE I. PERFORMANCE METRICS OF DIFFERENT MODELS ON THE COCO DATASET

Model	Epochs	mAP	AP_s	AP_m	AP_l
Faster R-CNN	12	37.9	22.4	41.1	49.1
RetinaNet	12	36.2	14.7	38.5	48.0
DETR	12	15.5	4.3	15.1	26.7
Deformable-DETR	12	47.6	31.2	50.6	62.6
DINO	12	49.0	32.0	53.2	63.0

In summary, current research on object detection in nursing scenarios still faces several challenges: limited accuracy in small object detection, high model complexity, and insufficient validation on real hardware platforms. To address these issues, the main contributions of this study are as follows:

1) Methodological contributions: We propose an enhanced detection framework by introducing an improved Align-Loss that incorporates SIoU and a dynamic τ strategy to alleviate the inconsistency between classification confidence and localisation quality. Furthermore, lightweight GhostConv modules are integrated into the ResNet50 backbone of DINO to reduce redundant feature computations and improve computational efficiency without compromising representational capacity.

2) Empirical contributions: Comprehensive experiments on the extended MYNursingHome+ dataset and the COCO2017 benchmark demonstrate the effectiveness of the proposed components. Ablation studies further verify that each module contributes incremental performance gains, particularly in small-object detection under complex nursing environments.

3) Practical contributions: To assess real-world applicability, the proposed model is deployed and optimized on an NVIDIA Jetson Orin Nano Super embedded platform. The results confirm that the improved detector achieves higher inference speed and reduced computational cost while maintaining competitive accuracy, demonstrating its suitability for deployment in resource-constrained nursing robots.

4) Dataset contributions: An enhanced version of the nursing-scene dataset, namely MYNursingHome+, is constructed by supplementing additional small-object annotations across diverse viewing angles and observation distances. This improved dataset provides a more representative benchmark for evaluating small-object detection in robotic nursing scenarios.

The remainder of this study is organized as follows: Section II reviews the related work on small-object detection, DETR-based models, and lightweight backbones. Section III introduces the improved Align-Loss strategy and enhanced backbone architecture. Section IV presents the experimental platform and design. Section V reports the results and discussion. Finally, Section VI provides conclusions.

II. RELATED WORK

Beyond the evolution of CNN-based and Transformer-based detectors, recent studies have proposed specialized solutions targeting small object detection. One major direction is feature enhancement and multi-scale fusion, which strengthens shallow high-resolution features through improved pyramid structures and fusion modules. Representative work includes ASIF-Net [17] that introduces adaptive scale-interaction fusion for small objects, while SimFusion [18] proposes simplified multi-scale aggregation with reduced computational overhead. Another line of research incorporates attention mechanisms for feature refinement, such as HSF-YOLO, which employs spatial–channel attention and shuffle channel mixing to suppress background noise and enhance small-object features [19].

Knowledge distillation has also been explored, where attention-guided and feature-level distillation improve the representation of small objects in student models under ambiguous environments [20]. A further direction combines super-resolution with detection, exemplified by EFSOD [21], which integrates super-resolution reconstruction to enhance extremely small objects in remote sensing images. In addition, high-resolution inputs with efficient detection heads have been adopted; for instance, Ro-YOLO [22] introduces a Feature Bridge to better connect shallow and deep features while controlling parameter overhead.

In care and medical environments, several works have investigated object detection for assistive scenarios. Mashrur et al. [23] constructed a hospital-facility image dataset and benchmarked mainstream detectors, providing a foundation for healthcare-oriented visual perception, though the targets were primarily large-scale objects. Auweiler et al. [24] improved detection in care homes through Gaussian-based preprocessing, demonstrating the effectiveness of targeted data augmentation in challenging environments. Luo [25] proposed a YOLO-based fall-detection framework, showing that lightweight detectors can achieve real-time performance in smart-care applications. More recently, transformer-based models have also been used in

healthcare perception tasks, such as Med-DETR [26], which enhances structured detection for medical instruments. Ismail et al. [27] released the MYNursingHome dataset, but its categories mainly include large furniture and lack fine-grained small-object annotations essential for robotic feeding tasks.

In contrast, this study focuses specifically on small utensil-like objects in nursing scenarios, introducing an improved Align-Loss (Dynamic-τ + SIoU), a lightweight GhostConv-enhanced backbone, and multi-scale augmentation with transfer learning, and further validating deployment feasibility on embedded platforms.

While the aforementioned studies provide valuable insights, several issues remain: First, most research in care settings focuses on facility-level or large-object recognition, with limited attention to small targets, low-sample scenarios, and complex care item interactions. Second, most DETR-based algorithms exhibit mismatches between classification confidence and regression accuracy, which hinder optimal model training. Third, since care robots often operate on resource-constrained edge devices, optimizing computational efficiency while maintaining detection accuracy is essential. Consequently, this study extends the MYNursingHome dataset with scenario-specific samples for feeding assistance and proposes an enhanced DINO model to improve small object detection performance. This provides safe and reliable visual support for robots performing care tasks such as feeding assistance. Unlike prior work that primarily focuses on large objects or facility-level scenes, this study introduces Align-Loss and GhostConv specifically for utensil-like small objects in care environments, addressing classification–localization mismatch and computational constraints not previously explored in DINO-based frameworks.

III. METHODS

A. DINO

DINO, as a DETR-based algorithm, represents an end-to-end network architecture. Its architecture consists of four main components: a backbone, a multi-layer Transformer encoder, a multi-layer Transformer decoder, and multiple prediction heads. The overall workflow is shown in Fig. 1. The original DINO uses ResNet50 as its backbone and adopts a multi-scale feature extraction strategy. Features, after positional encoding, are fed into the Transformer encoder, allowing the model to process images at multiple resolutions and thereby improving small object detection performance. After feature enhancement by the encoder, DINO applies a hybrid query selection strategy. This keeps the content query learnable while using the encoder's anchor outputs to initialize the decoder's positional queries. Furthermore, inspired by Deformable-DETR, DINO incorporates a deformable attention mechanism to fuse encoder outputs and perform layer-wise query updates. Subsequently, similar to DN-DETR [10], a DN branch is added to the decoder for denoizing training. Unlike standard DN methods, DINO employs hard negative samples for contrastive denoizing training, thereby improving both training speed and overall performance.

B. Improved Align-Loss

The original DETR uses focal loss for classification optimization, which allows the model to focus on important samples. After the backbone extracts features from the input image, they are flattened into a set of tokens $X=\{x_1,x_2,\ \dots\ ,x_m\}$. The transformer encoder-decoder then uses a set of learnable queries $Q=\{q_1,q_2,\ \dots\ ,q_n\}$ to extract information from X. These queries are updated layer by layer within the transformer decoder and are finally transformed into predictions $P=\{p_1,p_2,\ \dots\ ,p_n\}$ through a prediction head. Given a binary label $y\in\{0,1\}$ and a logit $p\in[0,1]$, the focal loss is defined as Eq. (1):

$$L_{focal}=-y\cdot(1-p)^{\gamma}\cdot logp-(1-y)\cdot p^{\gamma}\cdot\log(1-p) \quad (1)$$

The one-to-one label assignment in DETR leads to low training efficiency. To overcome this, DINO applies denoized contrastive training, which greatly shortens training time and improves efficiency. However, DINO still faces a critical issue: misalignment between predicted classification confidence and anchor box regression accuracy, which severely limits optimization effectiveness.

Cai et al. [16] proposed an Aligned Loss strategy, which can be seamlessly integrated into DETR-based detectors, including DINO, to substantially mitigate the negative impact of classification-regression misalignment on optimization. The approach first introduces a mixed matching and ranking strategy, and then incorporates Align Loss.

1) Mixed matching and ranking strategy: Most DETR variants use Hungarian Matching to learn the mapping between ground truth and predictions. However, previous studies [12][28] show that this method is highly sensitive to instability in the matching process. To address this issue, Align-DETR adopts a gradual transition from positive to negative samples, with the mixed matching and ranking strategy as a prerequisite.

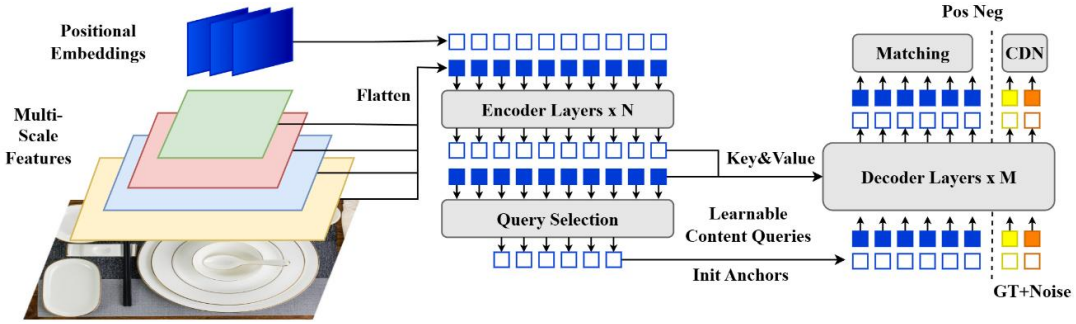

Fig. 1. DINO architecture.

Given predictions P and ground truth G, each with N instances, the enhanced Hungarian Matching algorithm assigns k predictions to each ground truth sample, producing kN candidate pairs. These candidate pairs are ranked according to their distance from the ground truth (GT). As shown in Eq. (2), to jointly use classification and regression accuracy in training, the method defines α quality metric q as the geometric mean of classification accuracy p and regression accuracy μ, defined as:

$$q = p^{\alpha} \cdot \mu^{(1-\alpha)} \tag{2}$$

where, p denotes the binary classification score, μ represents the IoU between the predicted bounding box and the ground truth, and α is a hyperparameter that balances these factors. The ranking of candidate boxes can be represented as $r \in \{0,1,2, \ \ldots \ ,k-1\}$. To ensure that the model produces one-to-one predictions, k is set to 1 in the final decoder layer.

2) Align loss: As shown in prior research [28], improving the consistency and efficiency of optimization requires a classification loss that is more adaptive and position-aware. In addition, the transition from positive to negative samples should be smooth. As shown in Eq. (3), the loss function is defined as:

$$\mathrm{L}_{align} = -t_c \cdot (1-p)^{\gamma} \cdot logp - (1-t_c) \cdot p^{\gamma} \cdot \log(1-p) \tag{3}$$

Unlike the original focal loss, which uses a hard label $y$as the optimization target. As shown in Eq. (4), this method introduces a soft target t_c, defined as:

$$t_c = e^{-r/\tau} \cdot q \tag{4}$$

To enable smooth transitions from positive to negative samples during optimization, $t_c$is adjusted from 1 to 0. Here, $e^{-r/\tau}$represents an exponentially decaying weight term, where the decay rate is controlled by the hyperparameter τ. By linking τ to the joint quality q, the loss function enables simultaneous optimization of classification and regression, thus establishing a strong connection between the two tasks. However, treating τ as a fixed hyperparameter has limitations. If τ remains constant during training, the model may rely excessively on noisy predictions in the early phase, favoring boxes with high classification confidence but poor localization accuracy. Conversely, keeping τ unchanged in later stages may overemphasize the balance between classification and regression, limiting the use of high-quality predictions and slowing convergence.

To overcome these limitations, this study proposes a Dynamic-τ strategy. The core idea is to adaptively adjust τduring training: in the early stage, a smaller $\tau$is used to make the consistency score more sensitive to IoU, allowing the model to focus on candidates with higher localization accuracy and reducing noise interference.

As training progresses, τ is gradually increased to balance the influence of classification confidence and localization accuracy, thereby improving the overall stability of matching. As shown in Eq. (5), the method can be formally expressed as:

$$\tau_t = \tau_{min} + (\tau_{max} - \tau_{min}) \cdot \frac{t}{T} \tag{5}$$

where, $\tau_t$denotes the temperature value at iteration t, τ_{min} and τ_{max} represent the initial and final boundary values, and $T$is the total number of training iterations. This linear increment strategy ensures that τ gradually shifts from prioritizing localization accuracy to achieving a balance between classification and localization, thereby improving detection performance and convergence efficiency.

To apply Align Loss to candidate samples while retaining Focal Loss for background samples, as shown in Eq. (6), the classification loss is defined as:

$$\mathrm{L}_{cls} = \sum_{i}^{N_{pos}} \mathrm{L}_{align}(p_i, y_i) + \sum_{j}^{N_{neg}} \mathrm{L}_{focal}(p_j, 0) \tag{6}$$

where, $N_{\text{pos}}$and N_{neg} denote the total number of positive and negative samples, respectively.

In the original Align-Loss design, the localization error between predicted and ground-truth bounding boxes is typically measured by IoU or its variants (e.g., GIoU, DIoU, CIoU). However, these metrics often fail to capture the full geometric relationship between predicted and ground-truth boxes, especially for small objects or those with highly varying aspect ratios. For example, although GIoU alleviates the zero-gradient issue in no-overlap scenarios by incorporating the area of the minimum bounding rectangle, it still shows limitations in convergence speed and directional optimization in detection tasks.

To address this limitation, this study introduces SIoU as an alternative metric for the consistency score in Align-Loss. SIoU considers not only the overlapping area between predicted and ground-truth boxes but also the center-point distance, aspect ratio difference, and angular information, thereby providing a more geometrically meaningful optimization signal. Given a predicted bounding box $b_i$and its ground-truth counterpart $\hat{b}_i$, as shown in Eq. (7), SIoU is defined as:

$$\mathrm{SIoU}(b_i, \hat{b}_i) = \mathrm{IoU}(b_i, \hat{b}_i) - R_{dist} - R_{shape} - R_{angle} \tag{7}$$

where, R_{dist} denotes the center-point distance penalty, R_{shape} measures aspect ratio discrepancy, and R_{angle} reflects angular misalignment between predicted and ground-truth boxes. Compared with standard IoU or GIoU, SIoU provides richer directional gradient information for the regression branch, thereby accelerating convergence in localization accuracy. As shown in Eq. (8), the regression loss is defined as:

$$\mathrm{L}_{reg} = \sum_{i}^{N_{pos}} e^{(-r_i/\tau)} \cdot (\mathrm{L}_{l1}(b_i, \hat{b}_i) + \mathrm{L}_{SIoU}(b_i, \hat{b}_i)) \tag{8}$$

As shown in Eq. (9), the overall model loss can be expressed as:

$$\mathrm{L} = \mathrm{L}_{task}(P, G) + \sum_{l=1}^{L-1} \mathrm{L}_{task}(p_l, G^{(k)}) \tag{9}$$

where, L_{task} is a weighted combination of L_{reg} and L_{cls}, $G^{(k)}$ denotes the augmented ground truth obtained by replication k times, and L represents the number of layers in the Transformer decoder.

In summary, to resolve the inconsistency between classification and regression in DINO, this study refines the Align-Loss function. First, the original static τ parameter is replaced with a dynamic-τ strategy in the joint quality metric q, improving detection performance and convergence efficiency. In addition, SIoU is incorporated into the regression loss L_{reg} to provide a more geometrically meaningful optimization signal. This enhances detection performance for small objects and those with unusual aspect ratios, such as chopsticks, spoons, and other tableware items.

C. Improved ResNet50

ResNet50, used as the backbone network in the original DINO, is structured as shown in Fig. 2. ResNet50 consists of five stages. Stage 0 has a relatively simple structure and mainly performs input pre-processing. It sequentially applies four operations: convolution, batch normalization, ReLU, and max pooling. The following four stages adopt bottleneck structures, each consisting of two basic blocks: the Conv Block and the ID Block, as illustrated in Fig. 3. In the ID Block, the input X has dimensions (C, W, W). It is processed by three convolutional modules (with BN and ReLU) to produce X′. Then, X is added to X′ and passed through a ReLU activation to generate the ID Block's output, maintaining the dimensions (C, W, W). Unlike the ID Block, the Conv Block includes an extra convolutional layer, producing G(X). In the Conv Block, the input channels of X differ from the output channels of the three convolutional modules, preventing direct addition. Therefore, G(X) transforms the channel count of X to enable channel-wise addition. ResNet-50 alleviates the vanishing gradient problem in deep networks through residual connections and provides strong feature representation capabilities. It is considered a classic backbone that balances accuracy and efficiency.

However, in real-world deployment, especially on embedded platforms for care robots (e.g., NVIDIA Jetson series), computational and storage resources are highly constrained. The large number of standard convolution operations in ResNet-50 leads to high parameter counts and computational overhead, limiting efficient operation on resource-constrained platforms. To address this issue, we integrate the GhostConv module into the ResNet-50 backbone to replace part of the standard convolutions. GhostConv generates part of the feature maps through standard convolutions, while the remaining maps are derived from existing features using lightweight linear operations (e.g., per-channel convolutions or linear transformations), thus reducing redundant computation. As shown in Eq. (10), the process is defined as:

$$Y = Conv(X) \,||\, \Phi(Conv(X)) \tag{10}$$

where, Conv(X) denotes standard convolution on input X, $\Phi(\cdot)$ is a lightweight linear transformation, and $\|$ denotes channel concatenation. This approach significantly reduces computational complexity and parameter count while maintaining feature expressiveness. In the improved ResNet-50 architecture, standard convolutional layers in each stage are partially replaced with GhostConv, producing a more lightweight backbone. Experimental results in TABLE V. shows that this modification reduces FLOPs and parameters with minimal accuracy loss, thereby enhancing real-time inference performance on embedded nursing robot platforms.

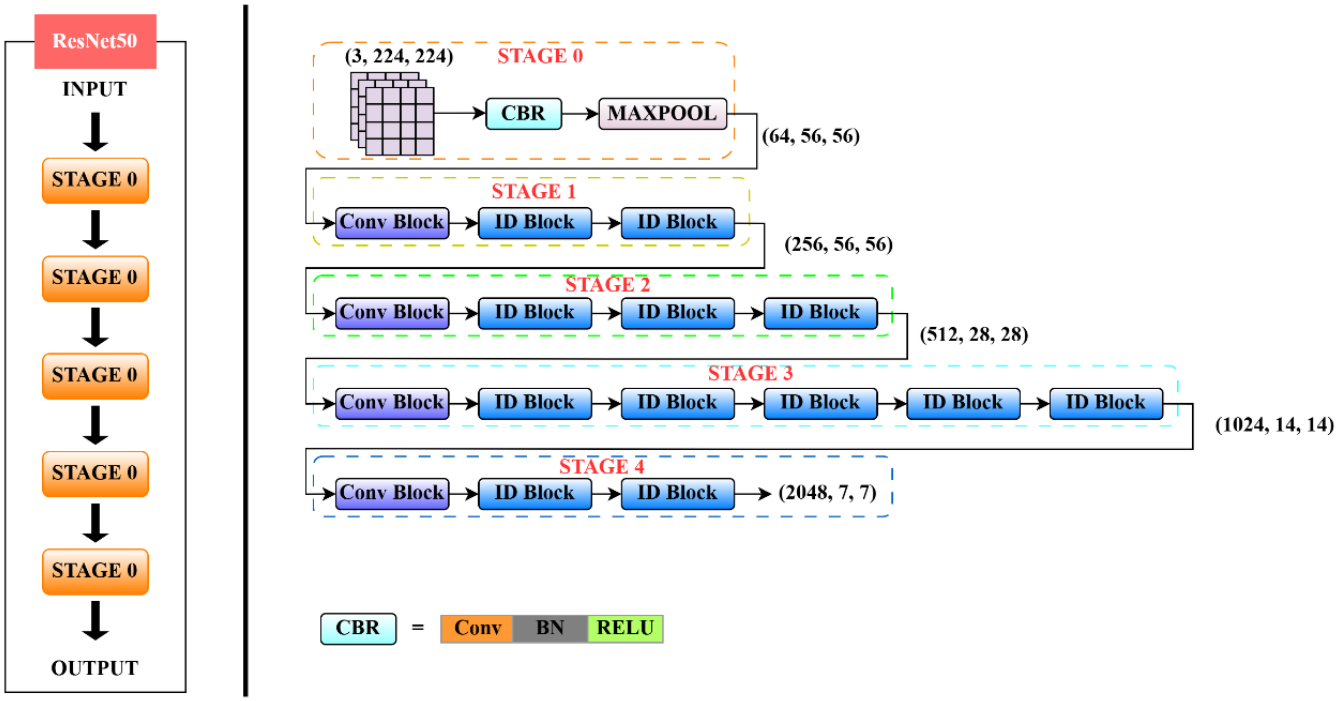

Fig. 2. ResNet50 architecture.

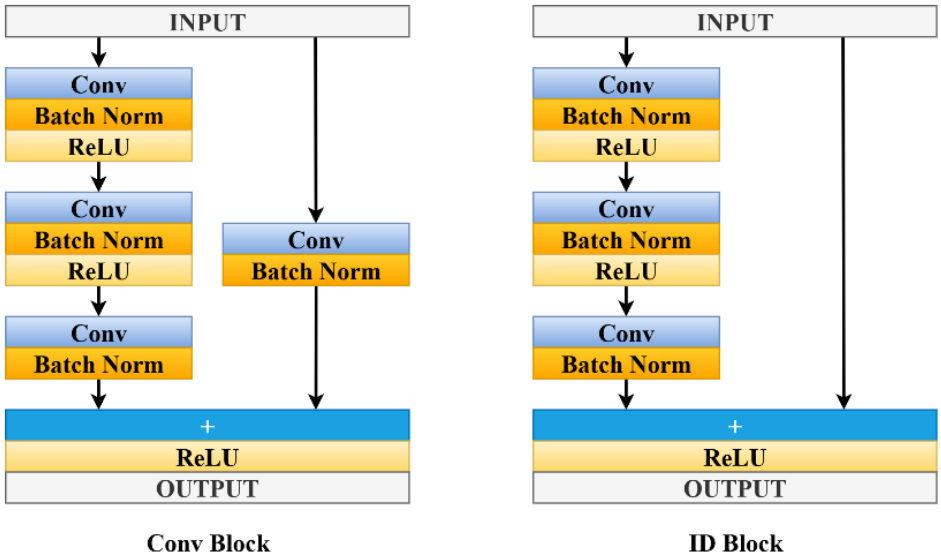

Fig. 3. Conv block and ID block.

Liu et al. [29] proposed an improved YOLOv5 algorithm optimized for robot deployment, demonstrating that lightweight convolutional structures can effectively balance precision and efficiency in embedded systems. Ghostnet [30][29] introduced the GhostConv module, which reduces redundant feature computations in convolutional operations. The GhostConv module consists of three stages: convolution, ghost generation, and feature map concatenation. First, a smaller number of standard convolution kernels generate a subset of base feature maps. Instead of producing a feature maps as in standard convolution, only b feature maps are generated ($b < a$). Second, an inexpensive linear transformation $\phi(\cdot)$ is applied to each of the b feature maps. This generates s new feature maps per original map, resulting in $b \times s$ outputs, with $b \times s = a$, thereby maintaining the same output dimension as a standard convolutional layer. Finally, the feature maps generated by convolution are concatenated with the ghost features produced by the linear transformation to form the complete output. The operational principle of the GhostConv module is illustrated in Fig. 4. Assuming an input feature map of size $h \times w \times c$, an output size of $h' \times w' \times n$, and a convolution kernel of size $k \times k$, as shown in Eq. (11), the computational cost to generate n feature maps using standard convolution is:

$$\text{FLOPs}_{\text{conv}} = n \times h' \times w' \times c \times k \times k \quad (11)$$

Since n and c are typically large (e.g., 256 or 512), this leads to substantial computational overhead. In GhostConv, partial features are initially generated using n/s standard convolutional kernels, followed by feature expansion through (s-1) inexpensive linear transformations. Consequently, as shown in Eq. (12), the computational cost can be approximated by:

$$\text{FLOPs}_{\text{ghost}} = \frac{n}{s} \times h' \times w' \times c \times k^2 + \frac{n}{s} \times (s-1) \times h' \times w' \times d^2 \quad (12)$$

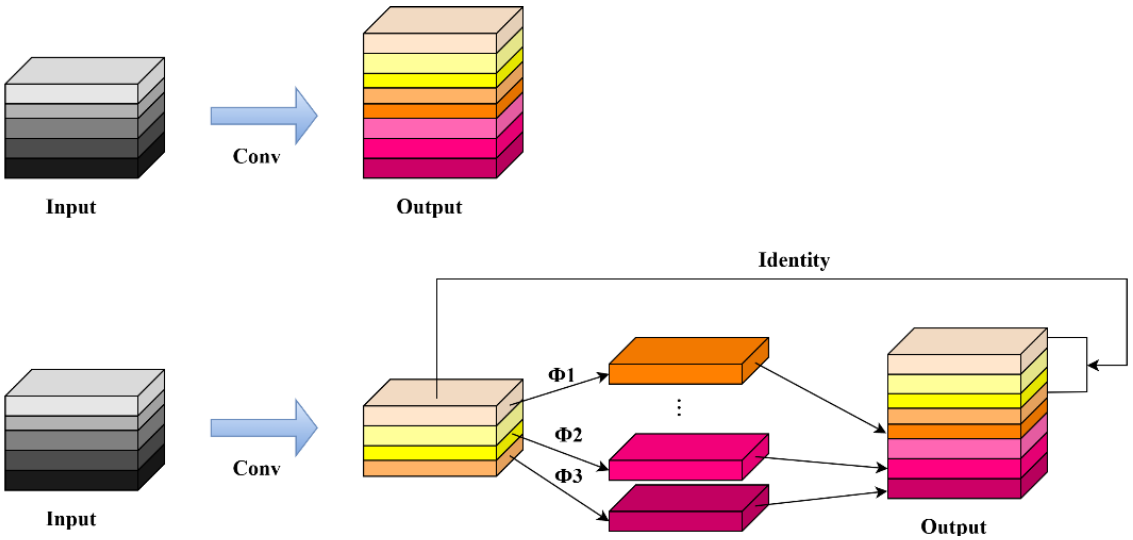

Fig. 4. GhostConv module.

Here, d^2 denotes the kernel size of the linear transformation, which is typically much smaller than k^2, and $s \ll c$. Therefore, GhostConv maintains the same output feature dimensions as standard convolutions while significantly reducing computational complexity. As shown in Eq. (13), its theoretical speedup ratio can be estimated as:

$$\text{Speedup} \approx \frac{\text{FLOPs}_{\text{conv}}}{\text{FLOPs}_{\text{ghost}}} \tag{13}$$

This demonstrates that GhostConv significantly reduces both the number of parameters and FLOPs while preserving feature expressiveness, making it particularly suitable for deployment on resource-constrained embedded platforms.

IV. Experiments

This study uses two datasets to evaluate the performance of our proposed object detection algorithm: the COCO2017 dataset and the MYNursingHome+ dataset, which focuses on nursing care environments. This section describes the experimental setup, datasets, and evaluation metrics.

A. Dataset

1) MYNursingHome dataset+: The MYNursingHome dataset is an indoor environment dataset collected from multiple nursing homes in Malaysia. It is specifically designed for visual perception research, including classification and object detection tasks. The publicly available version contains approximately 37,500 images across 25 indoor object categories, including wheelchairs, handrails, cabinets, dining tables, chairs, beds, and walking aids. These categories primarily represent common objects in elderly care settings, providing realistic scenario support for robotic vision tasks in nursing homes. Object categories are shown in Fig. 5. In this study, we augmented and annotated the MYNursingHome dataset, focusing on categories related to tableware and feeding utensils, such as bowls, spoons, chopsticks, and forks. Fig. 5 and TABLE II. show sample images and category distributions for this supplementary dataset, respectively. This subset exemplifies the challenging characteristics of typical care scenarios, including sparse, diverse, and heavily occluded small objects.

2) COCO2017 dataset: To evaluate the generalization capability of the proposed method, we also used the widely adopted COCO2017 object detection dataset, including both training and validation sets. This dataset contains approximately 118,000 training images and 5,000 validation images, covering 80 common object categories, including people, vehicles, tables, cups, and mobile phones. Characterized by its large scale, diversity, and complex backgrounds, this dataset serves as a standard benchmark in the field of object detection. In this study, pre-training is first performed on COCO to establish foundational detection capabilities, followed by fine-tuning and evaluation on MYNursingHome+.

Fig. 5. MYNursingHome dataset.

Fig. 6. Supplementary image data example.

TABLE II. Distribution of Supplementary Data

Labels name	Number of labels
Spoon	1500
Chopstick	1500
Bowl	1500
Knife	1500
Fork	1500
Plate	1500

B. Experimental Settings

Experiments were conducted on two computational devices: a development host (PC) for model training and an edge device (NVIDIA Jetson Nano Super) for deployment and testing. Detailed specifications of both devices are provided in Table III. The experimental workflow, shown in Fig. 7, consists of two distinct phases: the training phase and the testing phase.

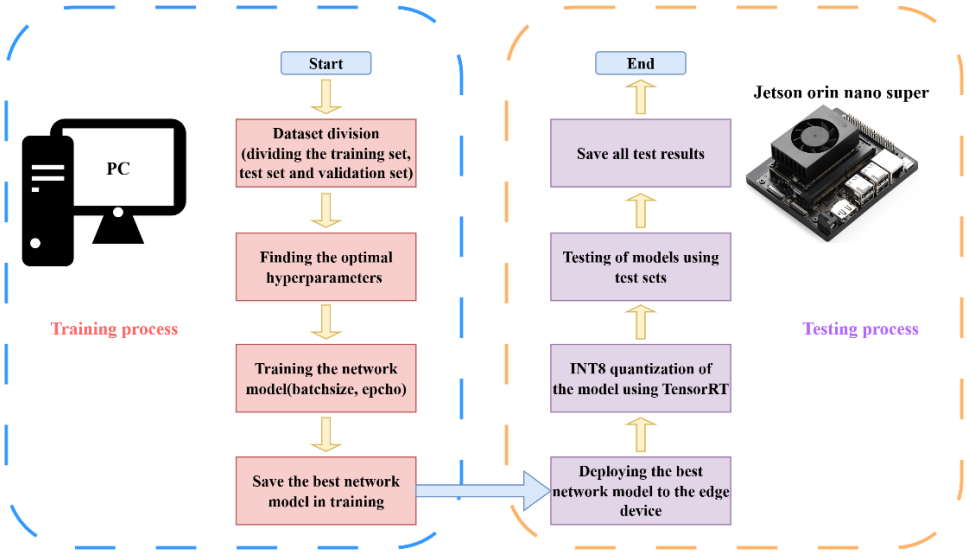

Fig. 7. Experimental workflow.

TABLE III. DEVICE SPECIFICATIONS

Name	Processor	System	Memory	TFLOPS
Jetson orin nano super	NVIDIA Ampere GPU	Ubuntu 22.04	8G	17
PC	GEFORCE RTX 4090	Ubuntu 22.04	24G	190

To improve the detection of small objects (e.g., chopsticks, spoons, bowls) in nursing scenarios, we employ a multi-scale image augmentation strategy during training. In each training iteration, input images are randomly scaled within preset resolution ranges [480, 800], while preserving their aspect ratios. Training across multiple resolutions enables the model to learn scale-invariant feature representations, thereby enhancing its robustness to small objects. Compared with conventional single-scale training, multi-scale training not only enriches the distribution of training samples but also mitigates the issue of small objects appearing disproportionately small at high resolutions, which hinders their detection. Additionally, when images are downsampled, large objects may be compressed into near-small-object representations, further enhancing the model's generalization capability for small object detection. In implementation, multi-scale augmentation is combined with other data augmentation techniques to create a composite augmentation pipeline. Serving as the core strategy, multi-scale augmentation has been shown to significantly improve the model's performance on APs. Experimental results indicate that incorporating multi-scale training increases the model's AP_s on the nursing dataset, effectively validating its advantages for small object detection.

Training Phase: 1) Data Partitioning: The cleaned and annotated nursing dataset is divided into training (70%), validation (20%), and test (10%) sets, ensuring balanced category distributions within each subset. 2) Hyperparameter Search: To obtain stable and high-performing configurations, a genetic algorithm was used to optimize key hyperparameters. These hyperparameters included warmup learning rate parameters, the activation and intensity levels of Mosaic and MixUp [31], the multi-scale range, and the CosineAnnealing [32] learning rate decay schedule. The hyperparameter search used mAP (or AP_s) on the validation set as the fitness function. 3) Metrics: mAP was recorded during training and validation, along with the model's parameters and FLOPs.

Deployment and Testing Phase: 1) Model Export: The optimal weights obtained from training were exported to ONNX format for subsequent quantization and deployment. 2) TensorRT INT8 Quantization Pipeline: The TensorRT build and quantization pipeline involves: a) Using the Builder to parse ONNX and construct the network; b) Configuring dynamic dimensions via Profile and retrieving dimension information from dynamicBinding; c) Building the Calibrator and loading a representative calibration dataset sample using BatchStream for INT8 calibration; d) Configuring the Calibrator and Profile within the Builder's Config to generate the TensorRT engine and calibration parameters; e) Feeding calibrated data into the engine to validate outputs and produce the final INT8 inference engine. Fig. 8 illustrates the workflow.

C. Evaluating Indicators

In object detection tasks, models are required to simultaneously perform object classification and localization. Consequently, evaluation metrics assess both classification accuracy and bounding box regression precision. This study primarily employs the following categories of metrics to evaluate the proposed improved algorithm.

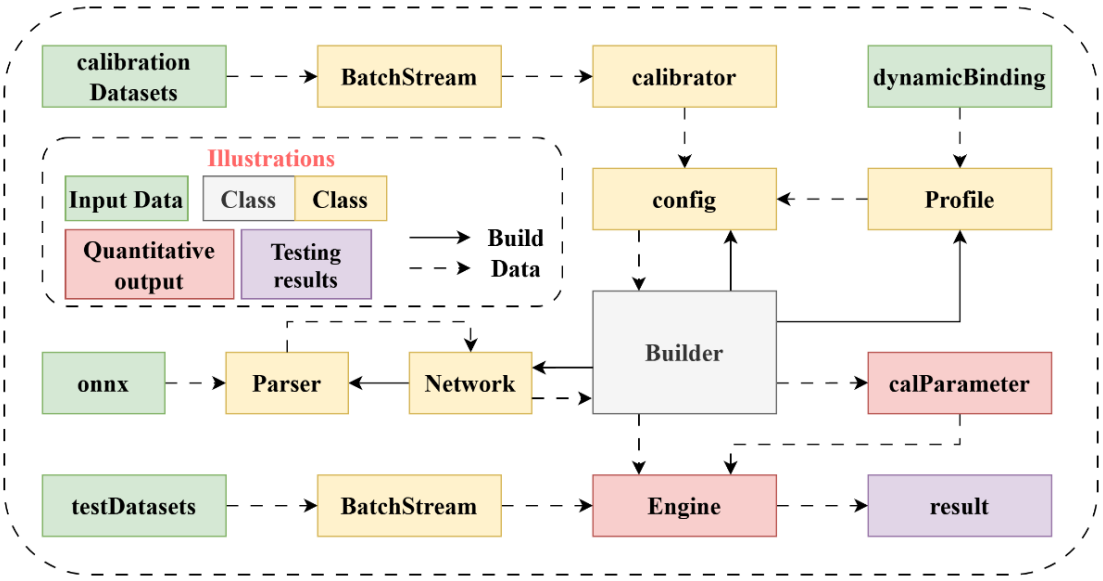

Fig. 8. TensorRT quantization workflow.

Common measures include Precision, Recall, and mean Average Precision (mAP), as shown in Eq. (14) and Eq. (15). It is defined as follows:

$$Precision = \frac{TP}{TP + FP} \tag{14}$$

$$Recall = \frac{TP}{TP + FN} \tag{15}$$

Here, TP (True Positive) denotes correctly detected instances where the predicted bounding box has an IoU above the threshold relative to the ground truth; FP (False Positive) denotes predicted boxes with an IoU below the threshold; FN (False Negative) denotes instances where the model fails to detect the ground truth box.

As shown in Eq. (16), Precision is calculated at different recall levels and averaged to obtain the average precision (AP) for a single category:

$$AP = \frac{1}{m}\sum_{i=1}^{m} P_i \tag{16}$$

Here, m denotes the number of samples, and P_i represents the maximum precision at the corresponding recall level. As shown in Eq. (17), averaging the AP values across all categories produces the mean Average Precision (mAP):

$$mAP = \frac{1}{C}\sum_{j=1}^{C} AP_j \tag{17}$$

Here, C denotes the number of classes. The study uses two metrics to comprehensively evaluate detection accuracy: mAP@0.5 (IoU threshold of 0.5) and mAP@0.5:0.95 (IoU thresholds from 0.5 to 0.95 in increments of 0.05).

Regression Metrics: Localization performance is measured by Intersection over Union (IoU), as shown in Eq. (18):

$$IoU = \frac{S_1}{S_2} \tag{18}$$

Here, S_1 denotes the intersection area between the predicted and ground truth bounding boxes, and S_2 denotes the union area. A higher IoU indicates more precise localization.

In nursing robot applications, inference speed and computational resource usage are equally important. The study evaluates model efficiency using the following metrics: Parameters, measuring model size; FLOPs (Floating Point Operations), reflecting computational complexity; FPS (Frames Per Second), indicating real-time inference performance on embedded hardware (NVIDIA Jetson Super Nano).

V. Results and Discussion

A. Ablation Experimental Results

To evaluate the impact of each improvement module on overall performance, ablation experiments were conducted on both the COCO2017 dataset and the nursing dataset. The experimental results are summarized in Table IV. The table shows that replacing the original classification loss with Align-Loss alone increased mAP by 1.5% on COCO and 1.1% on the nursing dataset. A more pronounced improvement was observed in the small object detection metric APS, confirming the effectiveness of classification-regression consistency optimization for small object detection. Further incorporation of SIoU and Dynamic τ led to consistent mAP improvements across both datasets, indicating that the positioning regression and dynamic matching mechanisms effectively enhance detection accuracy. Replacing part of ResNet-50's convolutions with the GhostConv module reduced the number of parameters from 47 million to 45.8 million and decreased FLOPs from 279G to 243G. On COCO, mAP remained largely unchanged (0.0% decrease), while on the nursing dataset, it showed a slight improvement (+0.1%). This demonstrates that GhostConv significantly improves model efficiency while maintaining accuracy. Finally, when combined with multi-scale image

augmentation, APS on COCO increased from 32.0% to 35.8% (+2.8%), and on the nursing dataset from 45.2% to 47.8% (+2.6%). This indicates that this strategy significantly enhances the robustness of small object detection.

B. Comparison of Experimental Results

To further evaluate the effectiveness of the proposed method, we compared it with the DINO baseline and other representative DETR-based approaches, including Deformable-DETR, DAB-DETR, and DN-DETR, on the COCO2017 dataset. The results are summarized in Fig. 9 and Table V. Enhanced DINO (ours) demonstrates superior performance, both overall and in small object detection. Specifically, compared with the DINO baseline, our method increases mAP from 49.0% to 51.6%, APS from 32.0% to 35.1%, and small object detection accuracy by 3.1%. Compared with Deformable-DETR (47.0% / 30.1%), our method achieves a 4.6% increase in mAP and a 5.0% increase in APS. Moreover, our approach exhibits advantages in both parameter count and computational efficiency: parameters are reduced from 47.0M to 39.6M, and FLOPs decrease from 279G to 243G, achieving a balanced trade-off between lightweight architecture and performance. Experimental results conclusively demonstrate the effectiveness and practical value of the proposed improvements for small object detection tasks.

C. Result Visualization

Fig. 10 illustrates sample detection results in a nursing scenario. The baseline DINO model tends to miss detections or misclassify objects in complex backgrounds, for example, confusing chopsticks with table edges. In contrast, the proposed improved method achieves more accurate detection of small objects such as chopsticks, bowls, and spoons in the same scenarios, with predicted bounding boxes closely aligned with ground truth. Visualization results indicate that Align-Loss and multi-scale augmentation effectively enhance the model's capability to distinguish small targets.

TABLE IV. ABLATION EXPERIMENT RESULTS

Dataset	Align Loss	SIoU	Dynamic τ	GhostConv	Multi-scale Image augment	mAP	AP_s	Parameters(M)	FLOPs(G)
MYNursing Home+						58.1	45.2	47	279
	√					59.2	46.5	47	279
	√	√				59.8	46.9	47	279
	√	√	√			60.1	47.3	47	279
	√	√	√	√		60.0	47.0	45.8	243
	√	√	√	√	√	60.7	47.8	45.8	243
COCO						49.0	32.0	47	279
	√					50.5	34.7	47	279
	√	√				51.1	35.0	47	279
	√	√	√			51.6	35.2	47	279
	√	√	√	√		51.6	35.1	39.6	243

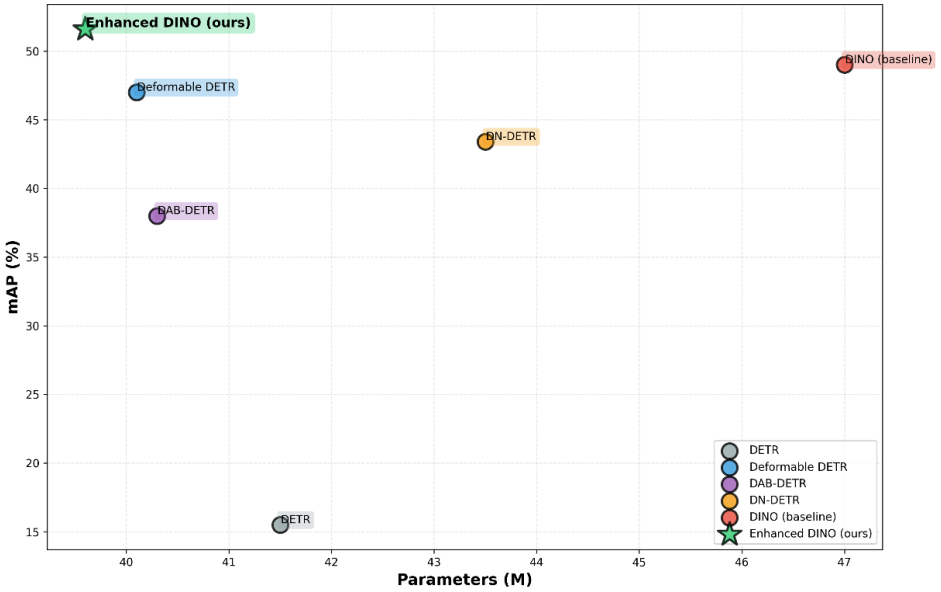

Fig. 9. Comparison of mAP and parameters across different models.

TABLE V. COMPARISON OF TEST RESULTS ACROSS DIFFERENT MODELS

Model	mAP	AP_s	Parameters(M)	FLOPs(G)
DETR	15.5	4.3	41.5	225
Deformable DETR	47.0	30.1	40.1	196
DAB-DETR	38.0	19.2	40.3	256
DN-DETR	43.4	24.8	43.5	265
DINO(baseline)	49.0	32.0	47.0	279
Enhanced DINO(ours)	51.6	35.1	39.6	243

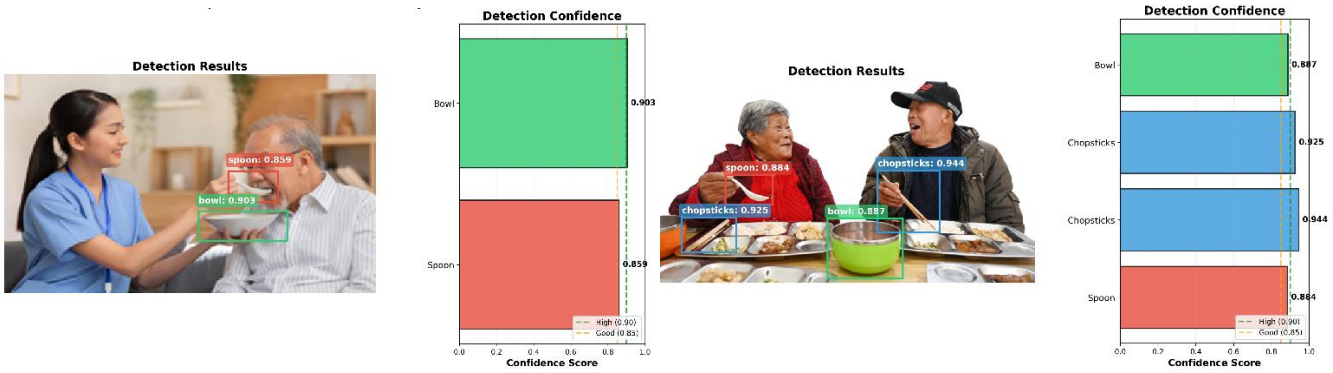

Fig. 10. Example of detection results.

D. Deployment Results on Edge Device

To assess the algorithm's feasibility on an embedded care robotics platform, the optimal model was deployed on the NVIDIA Jetson Orin Nano Super for testing. Results are summarized in Table VI. Without INT8 quantization, Enhanced DINO achieves significant improvements in small object detection compared to the baseline DINO: mAP increases from 48.7% to 51.3%, and APs rise from 32.7% to 35.8%. Concurrently, the number of parameters decreased from 47.0M to 39.6M, FLOPs reduced from 279G to 243G, and inference speed increased from 16.8 FPS to 18.9 FPS, representing an approximately 12.5% improvement. These results demonstrate that the proposed method effectively reduces computational complexity and improves inference efficiency while maintaining or enhancing accuracy, thereby better meeting the real-time requirements of edge devices.

TABLE VI. COMPARISON OF ORIGINAL DINO AND IMPROVED DINO ON NVIDIA JETSON ORIN NANO SUPER

Model	*mAP*	AP_l	AP_m	*AP*	FLOPs(G)	Parameters(M)	FPS
DINO	48.7	62.8	53.0	32.7	279	47.0	16.8
Enhanced DINO	51.3	63.3	53.8	35.8	243	39.6	18.9

E. Discussion

Table V summarizes the impact of the proposed improvements on algorithmic performance. When GhostConv replaces selected convolutional layers in the ResNet50 backbone, both model parameters and FLOPs decrease significantly, indicating that this approach effectively reduces computational overhead. However, due to GhostConv's relatively weaker feature extraction capability, the model's accuracy declines slightly, particularly in complex care scenarios where detecting slender small objects, such as chopsticks, remains challenging.

Introducing Align-Loss alone improves the model's mAP, showing particularly strong performance in detecting small objects on the care dataset. This highlights Align-Loss's significant role in mitigating classification-localization inconsistencies, enhancing robustness against complex backgrounds and occlusions.

Multi-scale augmentation alone yields the most pronounced improvement in small object detection. Experiments confirm that this strategy enables the network to learn object features more effectively across scales, mitigating issues of small object omission and insufficient feature representation. However, multi-scale augmentation slightly increases training time and computational complexity.

When GhostConv, Align-Loss, and multi-scale augmentation are applied simultaneously, the model maintains low computational demands and parameter size while achieving substantial improvements in small object detection accuracy. This demonstrates balanced performance across both the COCO and nursing datasets. This illustrates the complementary nature of the three enhancements: GhostConv provides lightweight processing, Align-Loss ensures consistency between classification and localization, and multi-scale augmentation enhances robustness in detecting small objects.

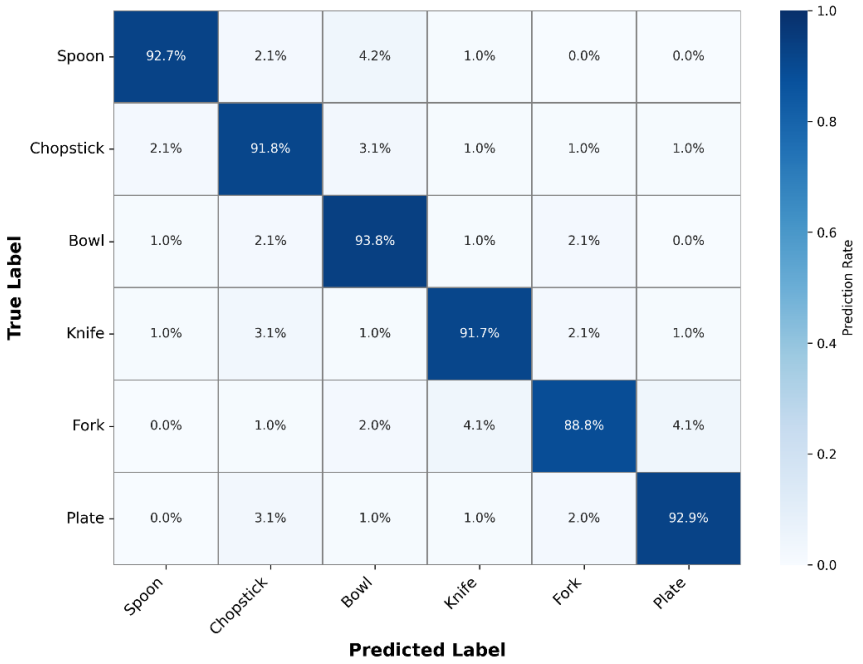

Fig. 11. Confusion matrix results for the improved DINO algorithm, tested with the x-axis representing ground truth labels and the y-axis representing model predictions.

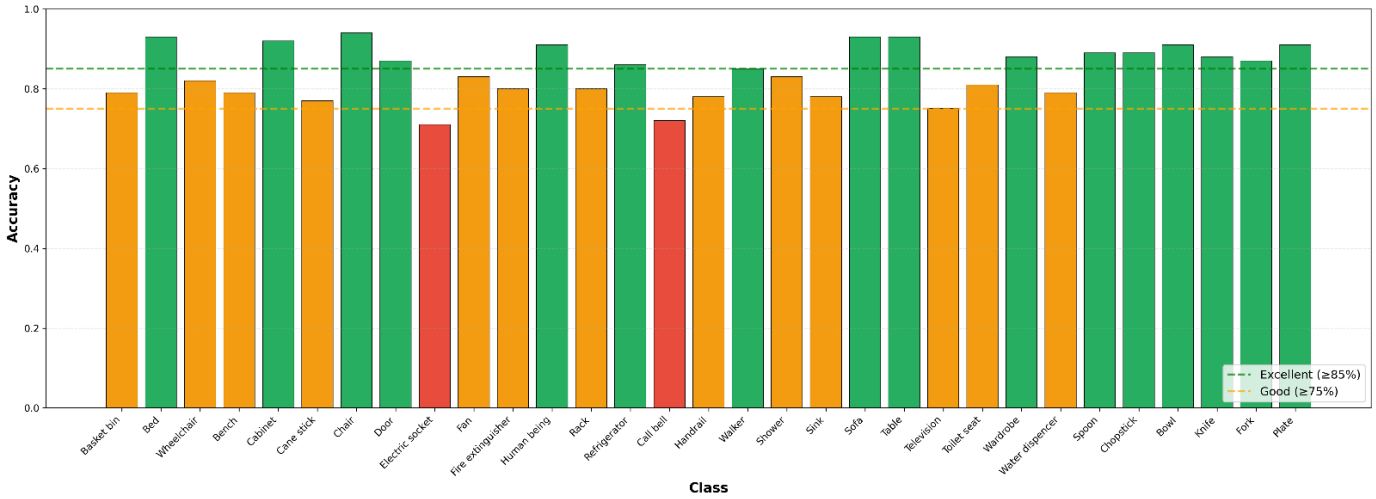

Fig. 12. Object detection accuracy per category.

Table VI compares the proposed method with other DETR-based models, showing superior overall accuracy and small object detection capability compared to the baseline DINO, especially in healthcare scenarios. Visualization results (Fig. 10, Fig. 11, Fig. 12) further substantiate this, showing that the improved model more accurately distinguishes edges of bowls, spoons, and tabletop backgrounds, thereby reducing both false positives and false negatives. Notably, while our approach excels at detecting small objects, accuracy remains insufficient for severely occluded or morphologically complex targets, such as stacked cutlery or partially obscured knives and forks.

Furthermore, the improved model was deployed on NVIDIA Jetson Super Nano edge devices for testing. Experimental results demonstrate that after TensorRT optimization, the model maintains high detection accuracy while significantly reducing latency and energy consumption, enabling near-real-time inference on resource-constrained hardware platforms. Compared to the original DINO, the improved model achieves approximately 12.5% higher frame rates and reduces memory usage by approximately 28 MB on the Jetson Super Nano. These results further validate the feasibility and practicality of our approach for real-world robotic applications. This capability is particularly crucial for care robots, which must operate on low-power, resource-constrained embedded platforms while maintaining detection accuracy to ensure safe task execution.

F. Limitations

Although the proposed enhanced DINO model achieves improved small-object detection performance and demonstrates

good deployment feasibility on edge devices, this study still has several limitations:

- First, the experiments are conducted mainly on the COCO dataset and a nursing-oriented dataset, which may not fully represent all real-world robotic nursing scenarios. Further testing on larger and more diverse datasets is needed to improve generalizability.
- Second, the model is evaluated using a ResNet-50 backbone. While GhostConv reduces computational cost, the performance under different backbones (e.g., Swin-T, ConvNeXt-T) remains unexplored.
- Third, the deployment experiments are performed on a single embedded platform (Jetson Orin Nano Super). The latency and energy performance may vary across other hardware configurations.
- Finally, this study focuses primarily on static image detection, and the system has not yet been evaluated in dynamic robotic tasks such as real-time feeding assistance or interaction-heavy nursing actions.

VI. Conclusion

To address the challenge of poor small object detection in care settings, this study proposes an end-to-end detection algorithm based on an enhanced DINO framework, which demonstrates excellent performance on edge devices. First, the original loss function in DINO is replaced with an improved Align-Loss function to mitigate inconsistencies between classification and regression. A dynamic τ strategy is also employed to improve training efficiency. Second, lightweight GhostConv modules replace portions of standard convolutions within DINO's ResNet50 backbone, reducing model parameters while preserving accuracy. Subsequently, transfer learning strategies and multi-scale data augmentation are applied to accelerate training and improve detection performance across varying resolutions. Finally, the proposed method is validated on the NVIDIA Jetson Super Nano edge device, with multiple metrics comprehensively compared against various models. Compared to traditional DINO, the improved algorithm achieves 3.1% higher overall accuracy and 2.6% improvement in small object detection. Simultaneously, it reduces model parameters by 2.5% and increases inference speed by 12.5%, while maintaining comparable accuracy. Compared with other algorithms, the proposed method achieves a favorable balance between detection accuracy and inference speed, demonstrating its effectiveness.

This approach improves small object detection accuracy while minimizing computational cost, reducing demands on robotic platform resources. Tailored for feeding robots in care settings, the model was extensively tested on small utensils, including chopsticks, spoons, bowls, and forks, yielding highly satisfactory results. Future research should prioritize improving the model's real-time performance to better meet the online detection requirements of robotic systems. Additionally, expanding the range of detectable objects, such as pharmaceuticals and nursing consumables, is essential to cover broader application scenarios. Another important challenge involves integrating object detection outputs with robotic motion control to realize intelligent nursing systems operable on robotic platforms.

Norbert Wiener Private University, Lima, Perú[6]

***Abstract*—The World Health Organization (WHO) reports that 15% of mental health problems develop in people with demanding work and academic conditions. Both sleep quality problems and Burnout Syndrome (BS) are recognized as significant problems in university settings. In Lima, Peru, the situation is critical, as BS affects up to 60% of university students. Therefore, quantifying this problem through a nursing intervention is crucial. The objective of this study was to determine the relationship between sleep quality and BS in university students at a university in Lima. Using a quantitative, cross-sectional, and correlational approach, the Pittsburgh Sleep Quality Index (PSQI) and the Student Burnout Scale (EUBE) were applied to a sample of 216 nursing and systems engineering students, using Spearman's Rho test and the Multinomial Logistic Regression Model. The findings revealed a moderate negative correlation between sleep quality and SB (Rho=-0.508; p < 0.001) and a relationship between sleep quality problems and mild SB (RRR=7.84565; p = 0.005). Furthermore, 85.19% of participants experienced sleep problems that warranted medical attention and treatment, and 86.57% had mild SB. Sleep quality problems and the development of SB are prevalent in this population; therefore, it is essential to continue studying them and integrating specific intervention strategies.**

***Keywords*—Burnout Syndrome; sleep quality; university students; mental health**

I. Introduction

The World Health Organization (WHO) reports that at least 15% of cases of mental disorders correspond to adults with demanding work and academic lives, reflecting a growing concern towards mental health in these settings [1]. The recent COVID-19 pandemic has exacerbated this problem, contributing to a notable 25% increase in diagnoses of anxiety and depression [2]. The factors derived from the pandemic, such as social isolation and economic uncertainty, added to academic demands, have generated an environment that favors the development of mental pathologies [3].

Various studies indicate that university students assume a work dynamic and are among the most vulnerable to suffer disorders related to academic overload, which in many cases exceeds personal and emotional resources [4]. This situation intervenes in professional development, as it can negatively affect both academic performance and future performance. In response to this problem, the WHO has officially recognized student burnout as a condition that affects the world and has been included in the International Classification of Diseases (ICD-11) [5].

In countries such as Spain, it is estimated that around 24% of health professionals suffer from Burnout Syndrome (BS), a disorder that significantly affects their emotional well-being and work performance [6]. The alarming thing is that many of these professionals claim to have experienced the first signs of this syndrome during their university years, which highlights the seriousness of the problem. This situation not only reinforces the idea that burnout begins before entering the labor market, but also underlines the need to address it from educational institutions [7].

In Latin America, research conducted in Mexico revealed that all university nursing students experience some stage of Burnout Syndrome, which directly affects their overall academic performance [8]. Similarly, in Colombia, it has been observed that 1 in 3 health students between the ages of 20 and 25 suffers from Burnout Syndrome [9]. These data expose the direct relationship between mental exhaustion and the decrease in academic efficiency, since both have an effect on the other and generate a repetitive state that negatively impacts university education.

These problems are so frequent that they also affect education professionals who play an essential role in student training. During the global coronavirus pandemic, in Chile, it was detected that 93% of teachers, both at the school and university level, experienced high levels of emotional exhaustion, which had an impact on their professional work [10]. This problem not only affected teachers but also had a profound impact on the student community, especially among university students, who were already facing a considerable academic load [11].

In Peru, statistical studies reveal that the incidence of burnout in students of health sciences, such as nursing, dentistry, and medicine, ranges between 30% and 60% [12], [13]. However, despite the magnitude of this disorder in the academic field, until 2014, only four specific investigations on burnout in students had been conducted, which shows a worrying lack of in-depth studies. This situation is particularly critical in Lima, where burnout affects up to 60% of students [14]. The scarcity of scientific production limits the comprehensive understanding of a problem that advances

*Corresponding author.

silently, but that directly impacts the well-being and academic performance of future health professionals.

Burnout, also known as BS, is a psychosocial phenomenon understood as an inadequate response to stress and environmental demands, which generates a negative emotional burden and ineffective problem management [15]. Although it was initially linked to the workplace, its presence has spread to the university academic context, where students face high levels of pressure due to task overload, tight deadlines, continuous evaluations, competition, and interpersonal conflicts [16,17]. This syndrome manifests itself in negative behaviors such as pessimistic thoughts, lack of motivation, irritability, and excessive worry, even attributing failures to others [18, 19]. Its physical repercussions include chronic fatigue, persistent headaches, and recurrent abdominal pain that can evolve into gastrointestinal problems [20].

This syndrome is primarily diagnosed using the Maslach Burnout Inventory, which identifies both the frequency and intensity of the syndrome. However, other instruments adapted to different populations and contexts also exist that facilitate the detection of burnout in any individual [21]. Although there is no specific treatment, medical management usually focuses on the reduction or temporary suspension of highly stressful activities, such as work or academic overload [22]. However, this recommendation is difficult to comply with in most cases due to the influence of multiple external factors. Therefore, regular physical activity and dedication to recreational activities are promoted as measures that promote socio-emotional balance and contribute to general well-being [23].

On the other hand, sleep quality is associated with the ability to sleep continuously between 7 and 8 hours each night, which is essential for the body's proper recovery [24]. During this process, the body replenishes the energy used in daily activities, ensuring balanced physical and mental performance [25]. Furthermore, sleeping well helps strengthen the immune system, promote proper cardiovascular function, promote emotional stability, and improve overall well-being [26]. Conversely, a lack of sufficient rest has immediate consequences, such as irritability and concentration problems, and in the long term can lead to metabolic disorders, chronic stress, and mental health problems [27]. Thus, quality sleep is a decisive factor in preventing disease and preserving overall health.

Worldwide, several studies have explored the relationship between sleep quality and BS in university students. In Iran, using the Pittsburgh Sleep Quality Index (PSQI) and the Maslach Burnout Inventory for Students (MBI-SS), it was reported that 47.7% presented altered sleep patterns and 50% inadequate quality [28]. In the United States, graduate students showed an average of 6.4 hours of sleep, with 40% affected by poor quality, in addition to a high relationship with BS [29]. In Argentina, the unidimensional student burnout scale (EUBE) revealed that 59.3% of engineering students showed some degree of BS and 35.2% moderate symptoms of burnout [30, 31]. In Brazil, 34.7% presented excessive daytime sleepiness and nearly 60% poor sleep quality [32]. Finally, in Lima, 98.7% of university students reported moderate BS and 67.5% daytime sleepiness [33].

The situation described demonstrates the vulnerability of university students to problems related to sleep quality and BS, which places nursing in an essential role in health promotion. This requires overcoming the limited leadership often attributed to this profession. This work begins with the identification of risk factors that compromise well-being, especially in such demanding settings as the academic one [28]. In Lima, where the incidence is particularly high, poverty, low educational level, academic overload, long commutes, and scarcity of resources create a favorable context for the appearance of these disorders [14]. Therefore, nursing intervention is crucial, since quantifying the magnitude of the problem constitutes the first step in designing educational and preventive strategies that promote healthy lifestyles and reduce long-term consequences.

In this sense, the present study has the general objective of determining the relationship between sleep quality and Burnout Syndrome in university students from a university in Lima, Peru. In addition, the specific objectives are to describe the sociodemographic characteristics, evaluate sleep quality, and identify Burnout Syndrome in students from a university in Lima, Peru. Through this, we seek to identify the risk factors that contribute to the development of the syndrome in this population group. This will allow us not only to better understand the problem within the university setting but also to establish a solid and novel foundation that fills the gap in current theoretical knowledge regarding university students in Lima for the design of effective intervention strategies, since previous studies either do not link the variables to study this population or do so with insufficient methodological evidence.

II. Materials and Methods

A. Type and Design

The present study adopts a quantitative methodology with a cross-sectional design, which means that the variables were measured at a specific time and in a given context, without monitoring over time [34]. In addition, it was correlational because it evaluated the relationship between both variables and the factors that modify them [35].

B. Population and Sample

The University of Sciences and Humanities, located in the Los Olivos district, was selected as the setting for the research due to criteria of convenience and accessibility. This approach made it possible to take advantage of the logistical and academic facilities provided by the institution, which facilitated in the realization of the necessary internal coordination with its academic representatives. From these efforts, a total population of 600 students was identified, distributed between the careers of Nursing and Systems Engineering, who were studying the first, third and ninth cycles to evaluate the variations. The selection of these careers was made randomly from among the 15 careers offered by the selected university. Furthermore, comparing the challenges faced by Nursing students, known for their rigorous academic and practical demands, with those of Systems Engineering students, whose field of application is increasingly broad due to technological advancements, is important for the comparative analysis.

To determine the appropriate sample, the statistical software Epidat 4.2 was used, which is recognized for its accuracy in the

calculation of samples for population studies [36]. Through this program, a sample of 216 students was calculated, taking into account a confidence level of 95%, which guarantees that the results obtained will have a high degree of reliability and can be generalized to the population studied with a minimum margin of error.

1) Inclusion criteria:

- Students of 18 years of age and older.
- Students of both sexes.
- Students with current enrollment at the University of Sciences and Humanities.
- Students who are in the first, third, or ninth cycle of the Nursing or Systems Engineering careers.
- Students who agree to participate in the study through informed consent.

2) Exclusion criteria

- Students with chronic health conditions.
- Students who use substances or drugs.
- Students with night shift jobs.

C. Variables

This research focuses on analyzing two main variables, which are sleep quality and Burnout Syndrome. Both variables are quantitative in nature, as they are measured and expressed using numerical data that allow statistical analysis. In addition, the measurement scale used for both variables is ordinal, implying that the values assigned to each category represent an order or hierarchy [37].

1) Sleep quality

a) Conceptual definition: It refers to the ability to achieve adequate rest during the night, allowing optimal performance during the day. This concept is essential for physical recovery, as well as for strengthening cognitive processes such as learning and memory [24].

b) *Operational definition:* Sleep quality is the condition of the night's rest experienced by nursing and engineering students in Lima and will be assessed through the Pittsburgh Sleep Quality Index (PSQI).

2) Burnout Syndrome

a) Conceptual definition: It is a state of exhaustion that encompasses physical, emotional, and cognitive aspects, as a result of academic demands. It manifests itself predominantly through emotional exhaustion, lack of interest in activities, inclination to self-sabotage, and experience of doubts [15].

b) Operational definition: It is the mental fatigue experienced by nursing and engineering students in Lima, within the framework of academic pressures, and will be evaluated using the Student Burnout Syndrome Scale (EUBE).

D. Technique and Instrument

1) Data collection technique: In this study, we chose to use the survey technique to gather a wide range of questions, aimed at obtaining answers and collecting data in an agile and efficient way. This methodology is widely valued by researchers, as it allows key information to be obtained effectively, which is essential for the development of the investigations [38].

2) Instruments

a) Sleep quality: PSQI was used, comprising 19 questions organized into seven distinct categories. Each question is evaluated on a scale of 0 to 3 points, where a score of "0" indicates that the task is simple, while a "3" indicates that it is extremely difficult within its corresponding category. The scores for the seven categories are added together to obtain a total score ranging from 0 to 21 points. A score of "0" suggests that sleep is easy, while "21" reflects that sleep is extremely complicated in all categories. In addition, these scores are categorized into ranges that indicate sleep quality: a score below 5 indicates absence of sleep problems, 5 to 7 suggests that you deserve medical attention, 8 to 14 indicates that care and treatment are required, and a score of 15 or higher is considered a severe sleep problem [39].

Although the instrument was adapted and validated in [40], it was decided to carry out a new validation process, in which it was submitted to the evaluation of five expert judges in the area of research. To this end, the review was requested under criteria of relevance, coherence, and clarity, which resulted in an Aiken V of 0.91, affirming its validity. In addition, a pilot test was carried out in which the instrument was applied to 20 individuals with the characteristics of the study sample, and a Cronbach's Alpha of 0.87 was calculated, which determined the reliability of the instrument.

b) Burnout Syndrome: EUBE is used, designed to analyze the prevalence and intensity of Burnout Syndrome in students, encompassing physical, emotional, and cognitive exhaustion. It consists of 15 questions organized into two dimensions: behavior, which includes class attendance, participation, and effort in academic tasks; and the dimension focused on the attitude that university students must maintain during their learning process. In addition, it is measured on a four-option Likert scale: Never (1), Sometimes (2), Almost Always (3), and Always (4). The scores are summed and interpreted in percentage terms. In this context, it is established that a percentage between 0% and 25% indicates "does not present" burnout, while a range of 26% to 50% corresponds to a "mild" level. The "moderate" level is defined as between 51% and 75%, and the "deep" level is assigned to percentages ranging from 76% to 100% [41].

The validity and reliability of the instrument have been demonstrated at [42], but through the new expert evaluation, an Aiken V of 0.89 was obtained, which again demonstrated its validity. Likewise, the calculation of Cronbach's Alpha was performed, and with a result of 0.86, its reliability was reaffirmed in the proposed context.

E. Procedure

1) Prior authorization and coordination: For the collection of data for this study, the approval of the ethics committee of the University of Sciences and Humanities was obtained, which allowed the necessary permits to be obtained for the realization

of the project with the students of said institution. At the beginning of the fieldwork, the students were asked to read and sign the informed consent, guaranteeing their voluntary participation.

2) Application of the instruments: Data collection took place at the University of Sciences and Humanities between April and May 2025. The process consisted of the application of surveys divided into three sections. The first collected general data for the analysis of personal history. The second included the EUBE for the assessment of the prevalence and severity of physical and emotional exhaustion due to academic overload. The final section presented the PSQI for the collection of information on the quality of nightly rest. Each student had 10 minutes to complete the survey, ensuring that all items were answered correctly.

3) Bioethical aspects: This project was based on strong ethical principles to ensure the proper treatment and comprehensive protection of university students. Informed consent was used to provide each participant with clear information, ensuring the confidentiality of their data. In addition, the bioethical principles of autonomy, beneficence, non-maleficence, and justice were applied, fundamental to conduct research in an ethical and responsible manner [43].

- *Autonomy:* Autonomy was guaranteed through informed consent, which was complete, informative, and voluntary. Participants were provided with clear information about the risks, benefits, and purpose of the study, ensuring their understanding before participating.
- *Beneficence:* The university students were informed about the advantages of the study results, highlighting the importance of this research in improving exhaustion, fatigue, and, especially, the quality of sleep.
- *Non-maleficence:* It was guaranteed that the participation of the students does not imply risks to their health or integrity, highlighting the balance between benefits and possible risks, and their contribution to the prevention of these. In addition, the processing of the data was particularly careful, avoiding the disclosure of private information.
- *Justice:* Non-discrimination was guaranteed in the selection of participants, attending to their needs in an equitable and respectful manner. In addition, fair treatment was ensured without distinction throughout the project; each participant was treated with cordiality and respect, creating a welcoming environment for the completion of the questionnaire.

F. Data Analysis

For statistical analysis, the collected information was organized into a data matrix using Microsoft Excel and subsequently exported to the Statistical Package for the Social Sciences (SPSS) version 20 software, where processing was performed. A descriptive analysis of the sociodemographic characteristics and the main variables was first performed. Subsequently, for inferential analysis, the data were assessed for normality, determining that they did not follow a normal distribution ($p < 0.05$). Therefore, the nonparametric Spearman's Rho test was applied, which is used to measure the strength and direction of the relationship between two variables when they are ordinal or do not meet the assumptions of normality. Statistical significance was established at a $p < 0.05$ value [44].

In addition, the multinomial logistic regression model was used, considered an ideal inferential statistical tool when the dependent variable is categorical with more than two categories. This procedure allowed us to analyze whether any of the variables evaluated significantly increased a student's likelihood of experiencing BS. The application of this model provided a more precise view of the associated factors by estimating the magnitude of the risk in each response category [30]. Finally, the findings were organized and represented in tables and figures of frequency, as well as correlation, which facilitated a clearer, more detailed, and more accessible interpretation of the results.

III. Results

A. Sociodemographic Characteristics

TABLE I. Sociodemographic Characteristics of Students in a University in Lima, Peru

Sociodemographic characteristics	n = 216	
	fi	%
Sex		
Female	150	69.44
Male	66	30.56
Children		
Yes	28	12.96
No	188	87.04
Marital status		
Single	192	88.89
Married	15	6.94
Cohabitant	8	3.71
Divorced	1	0.46
Widower	0	0
University Cycle		
1st Cycle	72	33.33
3rd Cycle	105	48.61
9th Cycle	39	18.06
University career		
Nursing	161	74.54
Systems Engineering	55	25.46
Occupational conditions		
Study	95	43.98
Study and work casually	52	24.07

Study and work stably	69	31.95
Hours of sleep		
Less than 6 hours	21	9.72
6 hours	143	66.20
7 hours	12	5.56
8 hours	34	15.74
More than 8 hours	6	2.78

Table I shows the sociodemographic data of the study participants. Regarding sex, 150 (69.44%) were women, 188 (87.04%) had no children, 192 (88.89%) were single, 105 (48.61%) were in the third cycle, 161 (74.54%) were studying nursing and 95 (44.98%) were dedicated exclusively to studying, 143 (66.20%) indicated sleeping 6 hours a day.

B. Incidence of Variables

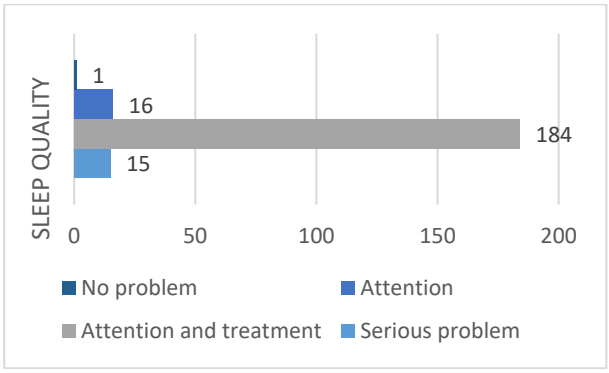

Fig. 1. Incidence of sleep quality problems.

Fig. 1 shows the incidence of sleep quality problems in the participants. It can be observed that 1 (0.46%) do not have any sleep problems, 16 (7.41%) have sleep problems that deserve medical attention, 184 (85.19%) have sleep problems that deserve medical attention and treatment, and 15 (6.94%) have serious sleep problems.

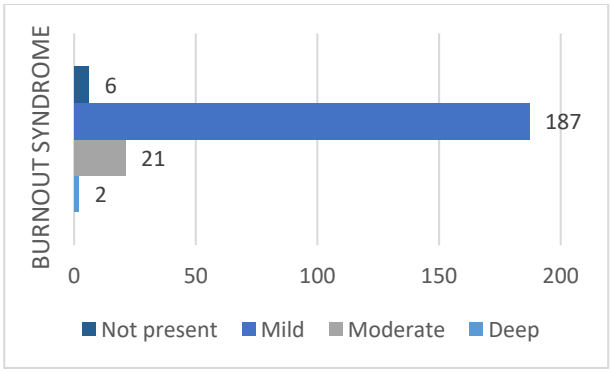

Fig. 2. Incidence of burnout syndrome.

Fig. 2 shows the incidence of Burnout Syndrome in the study sample. Of the participants, 6 (2.78%) did not have the syndrome, 86.57% (187) had a mild syndrome, 21 (9.72%) had moderate burnout, and 2 (0.93%) had a syndrome in its deep stage.

C. Correlational Analysis

TABLE II. CORRELATION BETWEEN SLEEP QUALITY AND BURNOUT SYNDROME

			Sleep quality	Burnout Syndrome
Spearman's Rho	**Sleep quality**	Correlation Coefficient	1.000	-0.508
		Sig. (bilateral)	.	<0.001
		n	216	216
	Burnout Syndrome	Correlation Coefficient	-0.508	1.000
		Sig. (bilateral)	<0.001	.
		n	216	216

Table II shows a negative and moderate correlation between the variables sleep quality and Burnout Syndrome, which is determined by a Spearman's Rho of -0.508 with statistical significance ($p < 0.001$), which means that, as sleep quality decreases, burnout levels tend to increase; therefore, there is a relationship between the variables.

TABLE III. SLEEP QUALITY PROBLEMS AND BURNOUT SYNDROME UNDER THE MULTINOMIAL LOGISTIC REGRESSION MODEL

Multinomial logistic regression		**Sleep quality problems**	
		Relative Risk Ratio (RRR)	p value (p<0.05)
Burnout Syndrome	Leve	7.84565	0.005
	Moderado	5.50934	0.053
	Profundo	7.563511	0.307

Table III shows the relationship between sleep quality problems and BS assessed using a multinomial logistic regression model. The results highlight that mild BS has a Relative Risk Ratio (RRR) of 7.84565, with statistical significance ($p = 0.005$). However, sleep quality problems are not related to moderate and severe BS.

TABLE IV. BURNOUT SYNDROME AND SLEEP QUALITY IN FEMALES

n = 150		**Sleep quality**				
Burnout Syndrome		**No problem**	**You deserve medical attention**	**You deserve medical attention and treatment**	**Serious problem**	**Total**
Not present	n	0	1	2	0	3
	%	0	0,67	1,33	0	2
Mild	n	0	12	108	10	130
	%	0	8	72	6,67	86,67
Moderate	n	0	1	14	0	15
	%	0	0,67	9,33	0	10
Deep	n	0	0	2	0	2
	%	0	0	1,33	0	1,33
Total	n	0	14	126	10	150
	%	0	9,33	84	6,67	100

Table IV shows the relationship between BS and sleep quality in the 150 women identified. Among them, 2 (1.33%) did not have BS but their sleep quality deserves medical attention and treatment, 108 (72%) had mild BS and a sleep quality that deserves medical attention and treatment, 14 (9.33%) had moderate BS and a sleep quality that deserves medical attention and treatment, 2 (1.33%) had profound BS and a sleep quality that deserves medical attention and treatment.

TABLE V. BURNOUT SYNDROME AND SLEEP QUALITY IN MALES

n = 66		Sleep quality				
Burnout Syndrome		No problem	You deserve medical attention	You deserve medical attention and treatment	Serious problem	Total
Not present	n	1	0	2	0	3
	%	1,52	0	3,03	0	4,55
Mild	n	0	2	50	5	57
	%	0	3,03	75,76	7,58	86,36
Moderate	n	0	0	6	0	6
	%	0	0	9,09	0	9,09
Deep	n	0	0	0	0	0
	%	0	0	0	0	0
Total	n	1	2	58	5	66
	%	1,52	3,03	87,88	7,58	100

Table V shows the relationship between BS and sleep quality in the 66 men. It was identified that 2 (3.03%) did not present BS but did have sleep quality that deserves medical attention and treatment, 50 (75.76%) had mild BS and sleep quality that deserves medical attention and treatment, 6 (9.09%) had moderate BS and sleep quality that deserves medical attention and treatment; no men were identified with profound BS.

TABLE VI. BURNOUT SYNDROME AND SLEEP QUALITY IN NURSING STUDENTS

n = 161		Sleep quality				
Burnout Syndrome		No problem	You deserve medical attention	You deserve medical attention and treatment	Serious problem	Total
Not present	n	0	1	2	1	4
	%	0	0,62	1,24	0,62	2,48
Mild	n	0	4	129	6	139
	%	0	2,48	80,13	3,73	86,34
	n	0	3	9	4	16
Moderate	%	0	1,87	5,59	2,48	9,94
Deep	n	0	0	1	1	2
	%	0	0	0,62	0,62	1,24
Total	n	0	8	141	12	161
	%	0	4,97	87,58	7,45	100

Table VI shows the relationship between BS and sleep quality of the 161 nursing students. It was found that 2 (1.24%) did not have BS but their sleep quality deserves medical attention and treatment, 129 (80.13%) had mild BS and sleep quality that deserves medical attention and treatment, 9 (5.59%) had moderate BS and sleep quality that deserves medical attention and treatment, 1 (0.62%) had deep burnout and a serious problem with sleep quality.

TABLE VII. BURNOUT SYNDROME AND SLEEP QUALITY IN SYSTEMS ENGINEERING STUDENTS

n = 55		Sleep quality				
Burnout Syndrome		No problem	You deserve medical attention	You deserve medical attention and treatment	Serious problem	Total
Not present	n	1	1	0	0	2
	%	1,82	1,82	0	0	3,64
Mild	n	0	5	41	2	48
	%	0	9,09	74,54	3,64	87,27
Moderate	n	0	2	2	1	5
	%	0	3,64	3,64	1,82	9,09
Deep	n	0	0	0	0	0
	%	0	0	0	0	0
Total	n	1	8	43	3	55
	%	1,82	14,55	78,18	5,45	100

Table VII shows the relationship between BS and sleep quality in systems engineering students. Among them, 1 (1.82%) did not present BS but had a sleep quality that deserves medical attention, 41 (74.54%) had mild BS and sleep quality that deserves medical attention and treatment, 2 (3.64%) presented moderate BS and sleep quality that deserves medical attention and treatment; none of these students were identified with profound BS.

IV. DISCUSSION

This study showed a moderate, negative correlation between sleep quality and BS, meaning that as sleep quality deteriorates, exhaustion levels tend to increase, creating a state of vulnerability in university students in Lima. These results are similar to those of another study [29], which reported a stronger relationship between both factors, possibly explained by the fact that the population analyzed was graduate students, who face greater demands. However, in this undergraduate sample, the moderate relationship could be attributed to the influence of

other elements, such as academic overload, especially in programs such as nursing, which combines theory and clinical practice, or systems engineering, characterized by its high technical complexity. In addition, the statistical model showed that sleep problems are associated with mild BS, which partially agrees with another study [32], which linked it to daytime sleepiness, suggesting that severe BS could be conditioned by additional factors not yet explored.

In the individual analysis, it was identified that the majority of the university students evaluated presented sleep problems that merited medical attention and treatment, exceeding the results reported in other studies [32, 28], where just over half of the students showed poor sleep quality. This finding could be related to the cultural and socioeconomic context of Lima, which can represent a challenge in the daily lives of university students, especially in vulnerable areas. Furthermore, the number of hours of rest may be another associated factor, since in this sample, most reported sleeping around six hours a day, which coincides with the findings of the study [29], where a similar average was found. In this sense, the evidence suggests that sleep duration directly influences its quality, which invites us to reflect on the importance of prioritizing adequate rest despite factors such as academic overload, work schedules, or multiple responsibilities that may interfere with achieving effective recovery [24].

Regarding SB, it was determined that the majority of university students presented a mild level, which is worrying and reflects a latent risk in the population studied. This finding contrasts with that reported in another study [31], where more than half of the students showed some degree of SB, although in both cases, the relevance of the problem and its impact on academic life is confirmed. In our study, the proportion of students with SB was higher, which could be attributed to the predominant participation of nursing students compared to systems engineering students, since health professions have experienced greater academic pressure after the pandemic. Likewise, the severity of BS could be related to the limited access to medical care and psychological support in Peru. However, the results also differ from those found in [33], where almost all rehabilitation students presented medium SB, which shows that careers related to the health field show greater vulnerability to SB.

The percentage of nursing students and males with mild BS and sleep quality that warrants medical attention and treatment was found to be higher than that of systems engineering students and females, suggesting that these groups are more exposed to burnout. However, severe BS, considered the most severe level, was present only in nursing students and females, which could be associated with gender-specific factors, such as greater emotional empathy or greater vulnerability to stress. External factors linked to academic and social expectations may also play a role. These findings highlight the need to further analyze these differences and design targeted interventions within university settings that promote healthy habits and strengthen student motivation.

It is important to note the limitations encountered during the study. The first was related to the selection of programs, as the goal was to include at least two per faculty to ensure greater representativeness of the sample. However, for administrative reasons and due to overlap with academic evaluations, the institution only authorized two programs, which generated an inevitable bias, although this was addressed by the researchers to ensure the completion of the work. The second limitation was the time allotted for administering the instruments, initially set at 10 minutes, but which proved insufficient in the initial trials due to the students' lack of familiarity. In some cases, twice that time was required, which delayed the schedule. This situation was resolved by hiring and training additional interviewers, which made it possible to align the established deadlines.

V. Conclusion

This cross-sectional study demonstrated, through the innovative use of statistical models that sleep quality problems moderately and significantly influence the development of BS in university students, highlighting a problem that requires priority attention at Lima's universities. In response, we suggest implementing support strategies and health education programs focused on promoting adequate sleep habits so that students have effective resources to address this situation. In addition, it is essential to incorporate interdisciplinary support from health professionals, especially psychologists and physicians, for the early detection of this and other related problems, thus contributing to prevention, strengthening student well-being, and optimizing academic performance.

The incidence of sleep quality and BMS problems is particularly concerning among future nursing professionals, as it reflects insufficient healthcare management among those who, due to their training, should have greater knowledge of the subject. This finding provides new empirical evidence from an understudied population, establishing a quantifiable risk that can guide the implementation of specific nursing interventions, such as training for nursing students and professionals, aimed at strengthening physical and mental health. These actions could be managed through university departments responsible for promoting comprehensive well-being, as well as through the support of national health entities, which assume an active role in prevention and in the creation of support spaces that guarantee the necessary balance for adequate academic and personal development.

Finally, the results achieved in this study constitute a solid foundation for opening new avenues of research in similar contexts, broadening our understanding of the relationship between sleep quality and BS in university students. In this sense, the contribution not only enriches the available scientific knowledge but also generates a framework for future studies that integrate specific intervention strategies. Thus, the research offers a significant opportunity to transform the university environment into a healthier space.

A Conceptual Model for an Ontology-Based Dietary Recommendation Plan in Crohn's Disease

Rezan Almehmadi, Aisha Alsobhi, Omaima Almatrafi
Faculty of Computing and Information Technology, King Abdulaziz University, Jeddah, Saudi Arabia

***Abstract*—Crohn's Disease (CD) is a long-term inflammatory bowel disorder that affects the digestive system. It is influenced by geography, diet, genetics, and immune response. Patients often experience difficulties managing CD due to the complexity and heterogeneity of the condition. Despite increasing scientific efforts, knowledge within the domain remains scattered and fragmented across different concepts. The purpose of this study is to develop a conceptual model of CD using knowledge engineering to organize domain knowledge and clarify the main aspects and their relationships. The conceptual model is created following the Ontology Development 101 methodology to define the creation of classes, properties, and restrictions. The proposed model is designed to organize and integrate multiple aspects of the condition, such as symptoms, treatments, risk factors, and patient profiles, with a particular emphasis on dietary recommendations. The resulting model consists of eight primary classes and fifteen key relationships, clarifying the connections between patients, symptoms, treatments, and diagnosis. The CD conceptual model does not comprehensively address the genetic, environmental, cultural practices, or neurobiological factors related to CD. To address these limitations, future work should focus on integrating real-world clinical data and considering broader demographic contexts. This study examines nutritional treatments for CD, such as Exclusive Enteral Nutrition (EEN), the low-FODMAP diet, and the Crohn's Disease Exclusion Diet (CDED) that emphasize the role of diet in personalized healthcare. The CD conceptual model developed is the basis for building a comprehensive ontology-driven system that will help Crohn's patients with personalized dietary advice and future decision support systems that will improve their clinical care.**

***Keywords*—Conceptual model; ontology; dietary recommendations; Crohn's Disease; domain knowledge**

I. Introduction

One form of chronic inflammatory bowel disease (IBD) that has an impact on people's lives is CD. IBD causes chronic inflammation in the gastrointestinal tract, and its primary forms include CD and ulcerative colitis (UC) [1]. Both conditions share common characteristics such as symptoms, risk factors, and therapy. The causes of IBD are multifactorial and include environmental changes, susceptibility genes, abnormal gut microbiota and a disordered immune response [1]. Common CD symptoms include abdominal pain, severe diarrhea, fatigue, weight loss, and malnutrition, which can significantly affect one's quality of life [2]. It substantially impacts various aspects of life, including daily functioning, social interactions, and psychological stress due to chronic pain [3]. The disease is incurable, causing physical, emotional, and financial burdens for patients due to ongoing medical expenses and potential loss of income [4]. CD can be effectively managed through medical treatment, nutritional support, and surgery when necessary [5] [2]. The burden of IBD has increased over recent decades, particularly in industrialized nations, with rising prevalence rates also being reported in newly urbanized regions [6]. According to recent estimates, by 2030, over 7 million people in Europe and the United States will suffer from IBD [4], with rising CD incidence rates in Asia and Latin America mirroring those in Western countries [7][8]. Currently, China and the USA have the highest number of cases [6]. In the Kingdom of Saudi Arabia, the frequency of IBD has significantly increased over the previous three decades [9]. Several studies have investigated the effect of nutritional management on patients with CD, as dietary factors can exacerbate or alleviate symptoms [10] [11]. Even though there are no specific guidelines for diets in this regard, as per a survey conducted in 2017, 71% of IBD patients believe that diet influences their condition [12]. Furthermore, 77% of patients reported avoiding certain foods to prevent disease relapse [13]. Finding reliable information on healthy lifestyle choices, such as maintaining a balanced diet, can be challenging. For example, a study revealed that half of IBD patients reported not receiving nutritional advice, while two-thirds expressed their interest in dietary guidance. Most preferred to receive this information from dieticians and gastroenterologists [11].

Research on CD encompasses various disciplines beyond nutrition, including immunology, genetics, microbiology, epidemiology, pharmacology, and psychosocial interventions. This multidisciplinary landscape reflects the complex nature of CD and highlights the challenges involved in integrating findings from various fields [14]. CD is characterized as a complex and heterogeneous disease in terms of its clinical features. This heterogeneity is reflected in disease location and behavior, differing treatment responses, disease progression, and a wide range of immunological and microbiome profiles [15]. The challenges of CD research are the fragmentation of knowledge across studies, resulting in scattered and unstructured information. To address this, approaches such as biomedical ontologies have become important. Biomedical ontologies have significantly enhanced knowledge management, data integration, reasoning, and decision support [16]. In the field of nutrition for health conditions, ontology-based approaches assist those struggling with chronic diseases, such as Diabetes [17], Obesity [18], and Chronic Kidney Disease [19].

Therefore, the solution requires an ontology-driven approach to analyze effects, symptoms, treatment, and nutrition needs, utilizing knowledge representation techniques to create a semantic map in biomedical data. Ontologies have various

terms across disciplines and purposes, gaining recognition in academic, industrial, engineering, and medical fields [20]. An ontology was initially defined by Gruber in 1993 as 'a formal, explicit specification of a shared conceptualization', and this is a commonly utilized approach for representing knowledge in computer science [21]. Ontologies have proven highly beneficial across various domains and play a crucial role in the semantic web for automated data exchange, gathering and connecting different information systems, and attracting domain experts' efforts [22].

This brings us to our current study, in which we aim to develop a conceptual model using an ontology-driven approach to CD. Specifically, we intend to address the following research questions: What core concepts and relationships are essential for developing a conceptual model and ontology that accurately represent Crohn's Disease, including its symptoms and dietary recommendations? To address this question, we use an ontological approach to introduce the CD conceptual model. This requires a comprehensive understanding of CD nature, effects, symptomatology, and a specific focus on nutritional ability to enhance the patient's overall health.

II. Related Work

A. A Review of the Conceptual Model in Crohn's Disease

Conceptual models of CD provide structured frameworks that explain the various aspects of the condition. These models are critical in integrating various types of knowledge, guiding treatment strategies, and improving patient management. This section highlights existing conceptual models in CD research and aims to address the gaps that have been identified. For example, Falling [23] proposed a conceptual model to explain how psychological and behavioral factors interact to influence pain in CD and IBDs. Using a cross-sectional survey of 174 adults and structural equation modeling, the study examined relationships between disease activity, insomnia, fatigue, pain severity, pain catastrophizing, and other patient factors such as depression and anxiety. It showed that modifiable factors directly affected pain interference, while additional patient factors had indirect effects. The authors emphasized the need for longitudinal and experimental research to validate the model, integrate clinical biomarkers, and inform targeted interventions to improve pain management in IBD. In addition, Williams-Hall et al. [24] developed a conceptual model based on patient and clinician insights as well as a literature review. This model explores the symptoms of CD and their impact on patients' quality of life. In addition, a CD diary was developed to document daily symptoms and the various effects of CD. The model identified the most burdensome symptoms, such as abdominal pain, bowel urgency, and fatigue, and linked them to emotional, social, and functional impacts. The results showed that these symptoms affect patients' daily activities, work or school performance, and physical functioning. The study emphasized that disease symptoms influence psychological and social well-being. In contrast, Kim et al. [25] developed a conceptual model that describes the impact of ulcerative colitis (UC) symptoms on patients' quality of life. This model shows that UC symptoms lead to both gastrointestinal and psychosocial effects, ultimately influencing the overall well-being of patients. Although both [24] and [25] addressed individual aspects such as biology, symptoms, psychological and behavioral factors, yet the role of diet as a therapeutic component remains unexplored in CD conceptual models.

These studies have established robust conceptual models that encompass various aspects of clinical research, especially concerning complex and heterogeneous diseases such as CD. Most existing models often focus on specific concepts such as symptoms, psychological or patient-reported outcomes, leaving gaps in a holistic understanding of CD. Therefore, this study presents a unified conceptual model that integrates nutritional aspects to enable the structured representation of CD domain knowledge. The proposed CD conceptual model aims to support future ontology-based systems that provide personalized dietary recommendations, with both scientific and practical applications.

B. A Review of Ontological Models in Health and Nutrition

With the advent of the Semantic Web, ontologies have emerged as a model for knowledge representation across various scientific domains, notably in medicine [27], nutrition [22], industrial production [28], education [29], engineering [30], and numerous others. Several ontologies have been created to serve diverse domains related to nutrition. For example, Arwan et al. [31] designed and implemented an automation system for providing food recommendations and appropriate menus for type-2 diabetic patients using OWL and SWRL technologies. Food composition processing requires Ontology-based domain knowledge. The result of the system predicted 73% of the 30 data samples. Thus, the system decreased the reliance on nutrition experts. In addition, Clunis [32] develops an ontology for hypertensive individuals as a recommendation system. The ontology was constructed using the ontology development 101 methodology. The ontology includes recipes, food nutrients, interactions between nutrients, prescribed drugs, diseases, and general health. The validation involved proto-personas and created competency questions for testing the ontology. This study shows that an ontology-based system can enhance understanding of the complex relationships between diet and health outcomes, thereby improving decision-making for hypertension management. In contrast, Chi et al. [19] applied a knowledge-based system (KBS) for problem-solving modeling, utilizing Web Ontology Language (OWL) and Semantic Web Rule Language (SWRL). The system mimics dietitians' decision-making, saves time, and minimizes errors in dietary consultation for chronic kidney disease. OWL-based KBS recommends serving balanced amounts of food for nutrient intake. Similarly, Taçyıldız and Ertuğrul [18] develop an ontology-based system as a decision support system (DSS) for healthcare experts treating paediatric and adolescent overweight. It offers supportive dietary habits and recommends physical activities during the treatment process. The system uses medical data to provide health experts with personalized recommendations, utilizing an ontology-based inference engine module. The system's efficiency was evaluated and compared to human expert recommendations, showing promising results. In addition, Al-Nazer et al. [33] developed and integrated ontologies across various domains such as food, health, nutrition, and user profiles to enable personalized information retrieval for diet and health. This ontology will help patients

with diabetes and high blood pressure, considering dietary preferences and cultural or religious factors.

These previous studies have emphasized the importance of ontology-based approaches in managing chronic diseases, but these efforts remain limited in the context of CD. Their existing ontologies focused on nutrients and disease-specific dietary guidelines, without incorporating multiple disciplines such as psychology, comorbidities, or food allergies. Furthermore, each ontology operates as an isolated knowledge base, leading to the creation of knowledge from scratch rather than leveraging or linking to existing semantic resources. These gaps emphasize the need for a more structured approach, such as an ontology-based conceptual model that explains CD complex nature. Therefore, this study develops a conceptual model that serves as a critical initial step in formalizing and standardizing CD dietary knowledge for future system development and research endeavors. As illustrated in Table I, it provides a comprehensive overview of chronic disease ontologies, including diet recommendations.

TABLE I. AN OVERVIEW OF ONTOLOGY IN THE NUTRITION AND HEALTH DOMAINS

Paper	Domain	Purpose	Linkage to External Ontologies & Their Data Source	Methodology	Evaluation
Arwan et al. [31]	Type 2 diabetes	To provide dietary recommendations for diabetes based on ontology and semantic matching	- No external ontology integration. - Patients' profiles and nutrition databases	(1) Weighted Tree similarity method. (2) An automatic approach. (3) Semantic search method	Using SPARQL queries and a confusion matrix
J. Clunis [32]	Hypertensive	To develop an ontology to manage diet for patients with Hypertension	- Integrated external vocabularies from schema.org, FOAF, Dublin Core, and SKOS. - USDA nutrient database and reliable web recipes.	Ontology 101 methodology	Competency questions for testing and creating Proto-personas
Y. L, Chi et al. [19]	Chronic Kidney Disease (CKD)	To create a knowledge base system (KBS) for patients to manage their condition through nutrition.	- No external ontology integration. - Medical patient records and reliable open-source food data.	Ontological engineering (OWL-based Knowledge base Modeling) and semantic rules (SWRL- based rules)	Domain expert and calculating the accuracy.
Ö. Taçyıldız and D. Ç. Ertuğrul, [18]	Obesity	To provide dietary and physical activity recommendations as treatment steps. Enables remote consultation and monitoring of patients.	- No external ontology integration. - Pediatric patients' profile.	(1) Obesity Tracking Ontology, (2) Semantic Web Rule Knowledge base, and (3) Inference Engine Module.	Health experts calculate False Negative (FN) and other metrics.
A. Al-Nazer, et al. [33]	Diabetes & high blood pressure	To analyze user preferences and create a health and nutrition-focused profile.	- Integrated external ontologies such as Semantic Diet, AGROVOC, and Disease Ontology. - Domain experts, surveys, and reliable health websites.	(1) Semantic web and ontology engineering technologies (2) Personalization techniques and semantic processing techniques	Domain expert and Performance measures.

III. METHODOLOGY

This study presents a comprehensive ontology and conceptual model for the domain of CD. Recognizing the inherent relationship between conceptual modelling and ontology construction, for the conceptual model, we adopt a methodology guided by the Ontology Development 101 methodology [34]. This methodology was chosen for its ability to balance knowledge representations, the use of restrictions, and the extendibility of the ontology for future definitions [35]. It provides a clear, step-by-step guide that covers all stages of the conceptual model, including class hierarchies and instances. This iterative method ensures alignment among concepts, domain objects, and relationships, making it relevant and applicable in its domain. Such alignment leads to the development of a well-structured conceptual model that incorporates domain knowledge and expert insights for effective knowledge sharing and decision support. By employing this methodology, the conceptual model is developed based on a set of iterative steps, as shown in Fig. 1.

A. Capture Domain Knowledge and Conceptualization

1) Determine the domain, scope, and purpose: This step establishes a solid foundation for developing a conceptual model that accurately captures and represents the intended knowledge area. It serves as a foundation for developing an ontology for CD. Through exploring domain heterogeneity, defining the model's boundaries, and clarifying its overall objectives. During this stage, it is essential to address several questions to ensure the model meets its intended objectives, such as "The conceptual model is being created; why?" "Who are the intended users?" and "What domain does the conceptual model cover?" Table II presents the scope of the domain for the proposed CD ontology [26].

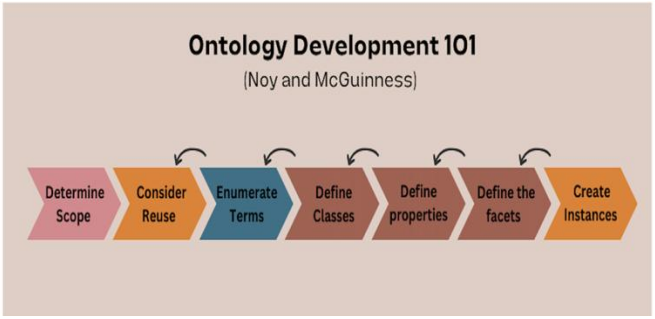

Fig. 1. The CD conceptual model development methodology.

TABLE II. THE PROPOSED DOMAIN AND SCOPE OF THE CD CONCEPTUAL MODEL

Domain	This work focuses on the medical and dietary domain related to CD.
Date	2024 - 2025
Location	King Abdulaziz University, Jeddah, KSA
Party (Organization)	Student in Information Systems department at the Faculty of Computing and Information Technology
License Model	Academic Research
Purpose	The purpose of CD conceptual model is to provide a reliable resource for understanding CD, focusing on symptomatology, treatments, and dietary recommendations. This model aims to support patients with CD and their caregivers looking for evidence-based dietary recommendations, enhancing their self-management of the condition. It covers the domain of CD with a specific focus on nutrition. It includes symptom and treatment information to create personalized dietary plans for patients.
Scope	The conceptual model's scope reflects the domain knowledge found in the semantic structure of the model. The CD conceptual model aims to represent the complex nature of CD. It includes various aspects, such as the causes and risk factors of the disease, symptoms, diagnostic criteria, stages of the disease, treatment strategies with an emphasis on dietary therapy, and related conditions.
Ontology Type	Domain Knowledge
Engineering Methodology	Ontology Development 101 Methodology
Source of Knowledge	• Medical & Nutritional Portal such as, National Institutes of Health NIH [36], Food and Agriculture Organization (FAO) [37], Food ontology [38], Disease ontology [39] and NCBO BioPortal [40]. • Knowledge from Domain experts (interviews). • Review various Scientific Research & Journals.

2) Consider reusing existing conceptual model: It is a critical step to conduct a comprehensive examination of existing ontologies, vocabularies, taxonomies, and components relevant to the domain. Reviewing these existing models enables the identification of reusable components that can be extended or integrated into the CD conceptual model. It is important to document and blueprint these resources. The model contains biomedical and nutrition conceptual models related to CD or IBD, which were found in a separate format.

3) Enumerate important terms: During the model development stage, it is crucial to define all the terminologies that will be used. This step should be done iteratively to identify and include all relevant terms and concepts. To accomplish this, gathering information from various sources, such as existing taxonomies, databases, books, and domain experts' knowledge, is recommended. By collecting a comprehensive list of essential terms related to CD, including Related Condition that contain of inflammatory bowel diseases (IBD) and gastrointestinal disorders including Ulcerative Colitis (UC), and Irritable Bowel Syndrome (IBS), Symptoms such as abdominal pain and diarrhea, that Caused by a combination of genetics (e.g. problems with the immune system, environmental factors, and an imbalance of gut bacteria), Diagnostic methods, Disease Stages, Risk factors of potential comorbidities and complications (e.g., Colon Cancer and Depression), and Treatments (such as medication and dietary therapy). This list of terms serves as a foundation for the next steps, where the key terms are chosen as the main classes, and the other terms become subclasses or properties, which are often refined through iteration. The goal is to gather a comprehensive list of terms without concern for any overlap between the concepts they denote, the relationships among the terms, or any specific properties associated with these concepts.

4) Define the classes and their hierarchy: This involves organizing important terms, defining their properties, and analyzing the information gathered to group them into classes. Several ways to create a class hierarchy, such as top-down, bottom-up, or a combination of both [41]. Organizing these terms into a hierarchical structure can create subclasses under a particular class. For example, under the class "Treatment", we could have subclasses like "Medication" and "dietary therapy", as shown in Fig. 2. Each class should represent a concept essential for understanding CD. Classes are fundamental components that illustrate key concepts related to CD. Defining these classes clarifies the conceptual model and establishes a structured foundation for building the ontology, as shown in Table III.

5) Define the properties of classes: It is a key step in the conceptualization phase, as each class must have attributes that outline its structure and relationships. The object property names typically start with "has" (e.g., hasSymptoms). In addition, Object properties usually have corresponding inverse properties, such as their inverses with "isSymptomOf". Additionally, data properties may have cardinality constraints that specify how many relationships an individual can have for a given property, as illustrated in Table IV.

6) Define the facets of the slots: In this step, each property is linked with a class based on its cardinality, range, and domain. This approach ensures that the conceptual model is structured and semantically accurate. It enhances the CD conceptual model scope, coherence, and structure for transitioning into a formal ontology representation, as illustrated in Table IV.

TABLE III. PRIMARY CLASSES OF THE CONCEPTUAL MODEL OF CD

Class	Description
Related condition	Refers to medical issues that often occur alongside IBD due to related symptoms. Examples include UC and IBS [42]
Causes	It is caused by a combination of multiple factors that may contribute to CD, including environmental changes, susceptibility genes, abnormal gut microbiota, and a disordered immune response [1].
Diagnosis [26]	This class refers to diagnostic methods that are used to detect, monitor, and confirm CD [42]
Disease Stages	It refers to the various stages of CD, ranging from severe active to prevalence balance. Additionally, it aids in tracking disease progression and guiding treatment decisions [43].
Symptoms	This term refers to common medical symptoms of CD, including abdominal pain, diarrhea, and fatigue, which contribute to the disease's severity [42]
Risks	A list of potential comorbidities and complications associated with CD that affect patients [44].
Treatment	Strategies for management and intervention that include pharmacological therapies, dietary modifications, and surgical interventions [45].
Patient	Characteristics of patients with CD, such as age, BMI, and allergy.

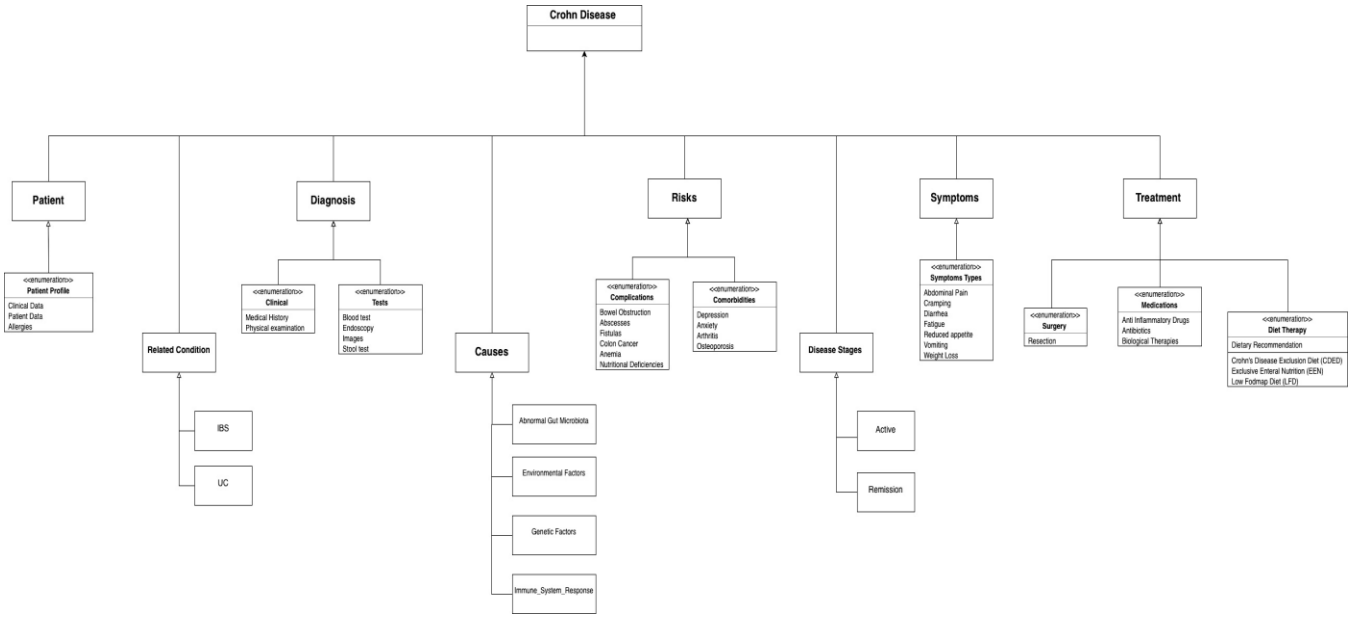

Fig. 2. Top-level CD conceptual model.

TABLE IV. CD CONCEPTUAL MODEL PROPERTIES

Property Name	Domain	Range	Cardinality	Inverse property
hasSimilarSymptoms	Crohn Disease	Related Condition	Many-to-many: a Crohn Disease can be associated with multiple Related Conditions and each Related Condition may be linked to more than one disease.	isRelatedToCrohn
hasCauses	Crohn Disease	Causes	Many-to-many: a Crohn Disease can occur from many Causes factors and each Cause may be linked to multiple diseases.	isCauseOf
hasDiagnosisMethods	Crohn Disease	Diagnosis	Many-to-many: a Crohn Disease can be diagnosed through multiple methods and each Diagnostic method may be applied to several gastrointestinal disorders.	isDiagnosedBy
hasDiseaseStage	Diagnosis	Disease Stage	One-to-one: as each Diagnosis will correspond to a specific Stage of the disease	isStageOf
hasSymptoms	Patient	Symptoms	Many-to-many: a Patient may have more than one Symptom and many Patients may experience each Symptom.	-
hasSymptoms	Diagnosis	Symptoms	Many-to-many: a Diagnosis may have more than one Symptom and each Symptom can be associated with different Diagnoses.	isSymptomOf
isDiagnosedBy	Patient	Diagnosis	One-to-many: a Patient can have more than one Diagnosis, while each Diagnosis belongs to a single Patient.	-
hasRisks	Crohn Disease	Risks	Many-to-many: a Crohn Disease may have more than one Risk factor.	isRiskfor
isRiskfor	Risks	Patient	Many-to-many: a Patient can have multiple Risk factors and each risk factor may be associated with several patients.	hasRisks
isManagedBy	Symptoms	Treatment	Many-to-many: a Symptom may have more than one Treatment	manages

7) Create the instances: In the final step of the CD model, individual instances of classes are created to populate the conceptual model with concrete examples. This process consists of three main steps: selecting a class, constructing an instance for that class, and assigning values using object or data properties. For example, the classes Dietary Therapy and Dietary Recommendation fall under the class Treatment. These instances serve as a transition from the conceptual model to a comprehensive formal ontology and knowledge base.

IV. CD CONCEPTUAL MODEL

This study presents a conceptual model that integrates core aspects of CD, such as symptoms, treatments, risk factors, patient profiles and focus on dietary intervention through defined relationships. Therefore, the conceptual model is valuable for assessing the quality of ontologies, whether they are constructed from scratch or adapted from existing ones. It improves the understanding of the domain for both creators and users by representing essential system properties in a clear and structured manner. This approach promotes clarity, completeness, and enhanced usability [46]. In this phase, we focused on providing a high-level overview of the ontology domain by presenting a conceptual model encompassing its content. Fig. 3 illustrates a UML class diagram that shows the classes and relationships. Each class represents a key aspect of the domain, covering categories like patient, related conditions, symptoms, causes, risks, disease stages, treatments, and diagnostic criteria.

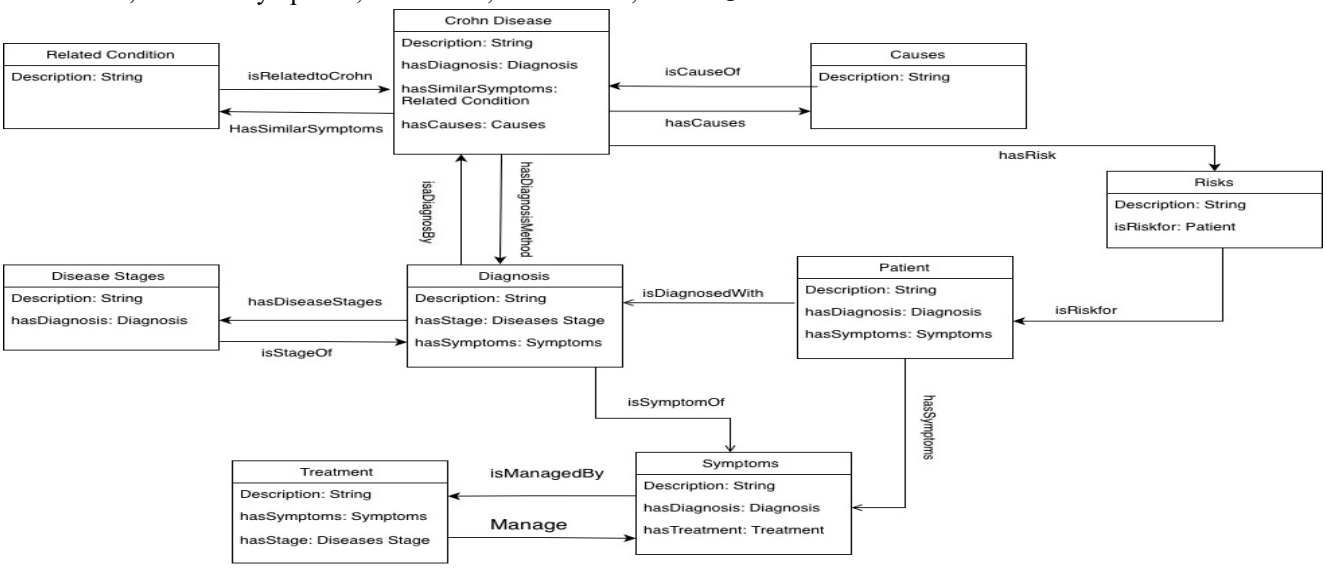

Fig. 3. The CD conceptual model.

The relationship between these classes is supported by clinical repositories, scientific research, and domain experts. The conceptual model highlights the meaningful connections between these essential concepts. By synthesizing findings from various sources, the model illustrates how these core concepts interact, forming a foundational blueprint for the ontology of CD. In the following paragraph, we address an overall conceptualization of CD. The CD conceptual model outlines the primary top-level classes that are most relevant to the study's focus, demonstrating how each class contributes to the development and interpretation of the proposed conceptual model. The defined classes are structured under the superclass CD, which integrates four entities: Patient, Diagnosis, Symptoms, and Treatment, especially dietary recommendations that reflect the primary aspect of the domain. The patient class is the primary entity that represents individuals undergoing medical observation and treatment. Two key relationships define the Patient class, which are 'hasSymptom' and 'isDiagnosedWith'. The 'hasSymptom' relationship links a patient to one or more instances of the Symptom class. The patients often present with several symptoms, such as abdominal pain, diarrhea, and fatigue. These symptoms serve as primary indicators for further diagnostic investigation. Besides, the 'isDiagnosedWith' relationship represents the result of the diagnosis methods. This method involves a combination of clinical evaluation and objective testing (e.g., endoscopy, imaging, and blood tests). This diagnosis method involves the recognition of the condition and ensures that the ontology reflects evidence-based processes [47]. These relationships illustrate the patient's journey from symptoms to diagnosis confirmation. This facilitates the patient's status through customized treatment plans, such as dietary interventions. In addition, the Diagnosis class is linked to the Disease Stages class through the relationship "hasDiseaseStages", and its inverse relationship "isStageOf". Therefore, involves assigning a stage based on the severity of disease activity, such as active and remission. This connection is crucial for determining appropriate treatment, monitoring disease progression, and customizing dietary plans to manage CD. Furthermore, the symptom class is connected to the treatment class through the relationship 'isManagedBy', which reflects the role of various interventions, especially dietary recommendations. Meanwhile, the inverse relationship 'manages', indicates that specific symptoms can be managed through appropriate therapeutic strategies such as surgery, medications, or diet therapy. Symptoms and treatments play a critical part in determining disease management strategies. This will play a role in forming appropriate and personalized

therapeutic options for patients through different possibilities of diet recommendations such as EEN, the low-FODMAP diet, and CDED.

Our conceptual model was developed to build an ontology that defines key aspects, relationships and constraints related to CD which intended to capture expert knowledge. Thus, ensure clarity and consistency before formal implementation in OWL or other ontology languages. The proposed conceptual model aims to develop a comprehensive domain ontology that reflects the understanding of CD. In addition, highlights the dietary recommendations as therapeutic knowledge.

V. Result and Discussion of the CD Conceptual Model

The CD conceptual model was developed through a structured knowledge-engineering methodology synthesizing evidence from various sources, such as scientific research and domain experts. This section addresses the research question by identifying the essential concepts and relationships needed to represent CD, thereby capturing its symptoms, patient profile, and dietary recommendations into a comprehensive unified conceptual model. The resulting model integrates the core concepts of CD into a unified framework, including Patient, Related Conditions, Symptoms, Causes, Diagnosis, Disease Stages, Risks, and Treatment. These eight top-level classes are interconnected through fifteen well-defined relationships, providing a coherent and comprehensive representation of the domain. The CD conceptual model was modified after incorporating expert suggestions to increase completeness and clinical applicability. In response, Quality of Life (QoL), was introduced as a distinct class linked to the Patient class through the object property 'hasQualityOfLife' and the inverse 'isQualityOfLifeOf' to reflect its centrality in CD outcomes. While, QoL linked to symptom through the property 'impactsQualityOfLife' and the inverse property 'isImpactedBySymptom', indicating that multiple symptoms may influence a patient's QoL [48]. This refinement is significant because previous models discussed in the related work section rarely conceptualized QoL as a formal class, defining their ability to represent the psychosocial and behavioral dimensions of IBD. By linking QoL to symptoms, the proposed model offers profound insights into the way dietary interventions can affect overall well-being, representing a significant advancement in the CD field. Fig. 4 illustrated the updated CD conceptual model, highlighting that QoL is associated with both patient and symptom classes. This refinement enhances the clinical relevance of the model and strengthens its suitability for future ontology development and decision-support applications.

Within the field of CD, several studies have attempted to conceptualize various aspects of domain knowledge. However, these efforts remain limited, focusing on isolated aspects such as pain interference [23], quality-of-life impacts in ulcerative colitis [24], or daily symptom reporting [25]. Despite these studies having developed robust conceptual models that address various aspects of CD, this study distinguishes itself by emphasizing the distinctive contributions of this study. Therefore, this study aims to fill that gap by proposing a CD conceptual model that unifies these aspects into a cohesive framework integrating dietary therapy with symptom, disease progression, and psychosocial concepts. Furthermore, it serves as the foundational structure for the CD ontology.

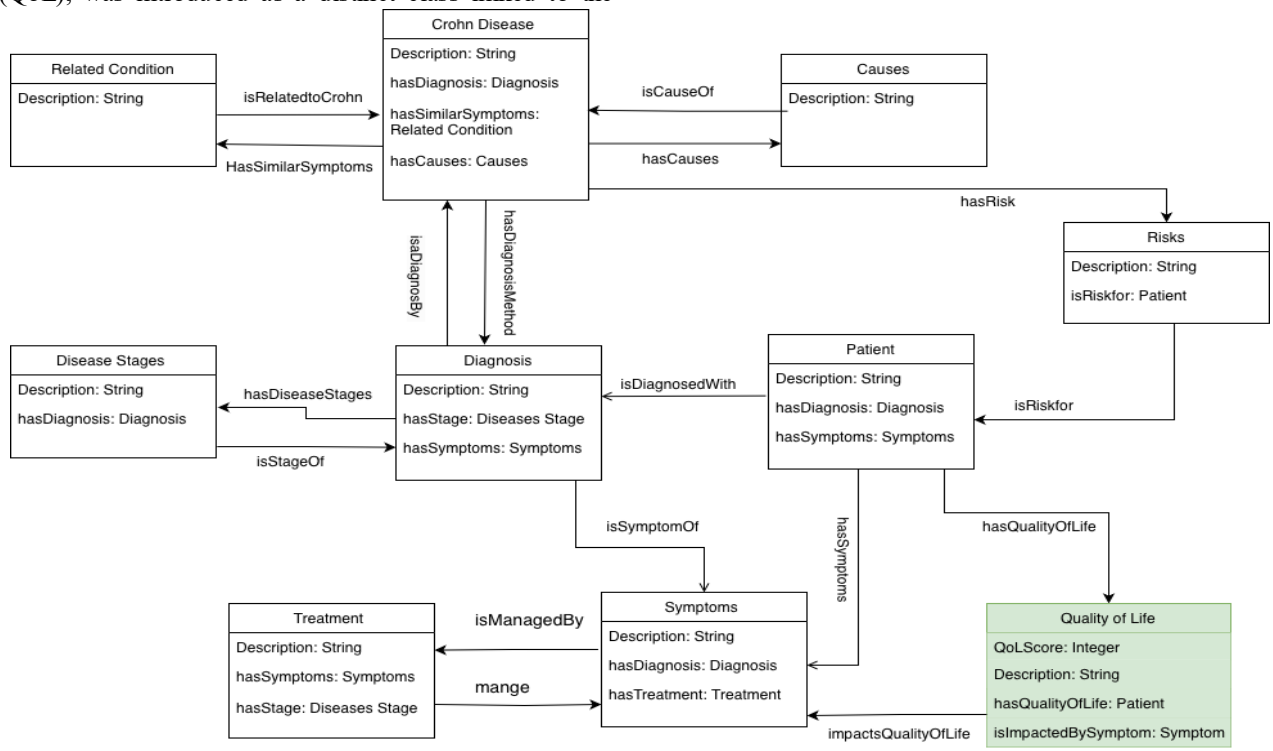

Fig. 4. The refined CD conceptual model including QoL.

VI. Conclusion

CD creates a multifaceted burden that impacts both medical and psychosocial aspects of a person's life. The presented conceptual model describes the main components of this burden, aiming to guide and improve future therapeutic and dietary strategies. To conclude, this study introduced a comprehensive conceptual model that represents the complex and heterogeneous nature of CD by using the Ontology Development 101 methodology. The result of the CD conceptual model suggests an integrated view of the disease by establishing relationships among eight top-level classes, which are Causes, Risks, Diagnosis, Disease Stages, Symptoms, Treatment, Related Conditions, and Patient. The model defines fifteen semantic relationships that illustrate the connections among its primary elements. By integrating these components, the model provides a comprehensive representation of these relationships between medical and nutritional domains. Moreover, it provides a unified model that enables caregivers, patients, and researchers to explore evidence-based dietary plans and insights related to CD. The model's contribution lies in its ability to support personalized dietary planning, which enhances both research and clinical practice.

Although the conceptual model encompasses a broad range of CD Knowledge, it does not incorporate detailed classes of genetic, microbiome, or allergic factors that influence individual variability. Another limitation relates to the cultural region, and behavioral factors affecting dietary adherence remain limited. In order to overcome these limitations, future work should incorporate patient-reported outcomes, nutritional assessments, and integrate real-world patient data to validate the model's correctness and improve clinical applicability. This includes incorporating longitudinal QoL and daily symptom diaries that will improve the model's ability to track disease progression effectively. Additionally, linking with external ontologies and conceptual model components relevant to the domain will improve interoperability.

Ultimately, this study will progress from conceptual modeling to develop a Crohn's Disease Ontology called OntCrohn's to support intelligent decision-making systems and personalized dietary recommendations. This study contributes to the precise and adaptive management of CD by alleviating patient symptoms and improving quality of life.

Acknowledgment

The first author acknowledges the assistance provided by Dr. Khalid Al-Ghamdi, Director of the Gastroenterology and Endoscopy Department, Dr. Nora Al-Ghamdi from the Internal Medicine Department at King Fahd General Hospital, and additionally, Dr. Marah Mandourah from the Clinical Nutrition Department at Dr. Sulaiman Al-Habib Medical Group in Jeddah, Kingdom of Saudi Arabia.

Ethics and Data

In this study, no patient identifiers were used. All data used were obtained from open-access literature or publicly available medical and dietary repositories. If future research versions of the ontology integrate patient or clinical data, appropriate ethical procedures will be followed. This includes obtaining informed consent, implementing strict anonymization protocols, and ensuring complete alignment with Institutional Review Board (IRB) requirements.

***Abstract*—The integration of Flexible AC Transmission System (FACTS) devices into modern power networks plays a pivotal role in enhancing voltage stability, reducing transmission losses, and improving overall power transfer capability. Determining the optimal location and sizing of these devices is a critical task that significantly influences system performance. In recent years, swarm intelligence (SI) algorithms have emerged as powerful optimization tools for addressing such complex, nonlinear, and multi-objective problems in power systems. This study presents a comprehensive review of the application of swarm intelligence techniques, Artificial Bee Colony (ABC), Bacterial Foraging Optimization (BFO), Dragonfly Algorithm (DA), Salp Swarm Algorithm (SSA), and Particle Swarm Optimization (PSO). These algorithms are used to optimize the placement and sizing of FACTS devices, such as Static Var Compensators (SVCs), Thyristor-Controlled Series Capacitors (TCSCs), and Static Synchronous Compensators (STATCOMs). The review highlights the underlying mechanisms, strengths, and limitations by comparing the performance of each algorithm in terms of convergence, optimal location, and sizing of a particular FACT device in a power transfer system to enhance voltage stability, minimize real power losses, and improve system loadability. The review provides a comprehensive resource for researchers and practitioners interested in applying swarm intelligence-based optimization techniques of FACTS devices in power transmission systems.**

***Keywords*—Swarm intelligence; FACTS devices; power transfer system; voltage stability; power losses**

I. Introduction

The United Nations adopted the Sustainable Development Goals (SDGs) in September 2015 as part of the 2030 Agenda for Sustainable Development, which comprises 17 interconnected goals. SDG 7 focuses specifically on energy to ensure access to affordable, reliable, sustainable, and modern energy for all [11]. One of the many targets for this SDG is to double the global rate of improvement in energy efficiency [12].

Across Africa, electricity grids face significant challenges, which include aging infrastructure, inadequate maintenance, and limited investment [1]. These issues contribute to frequent power outages, voltage instability, and high transmission losses [2]. For instance, Nigeria's power grid frequently collapses due to aging infrastructure and insufficient investment, resulting in significant economic losses.

In South Africa, Voltage stability has been challenged by the integration of variable renewable energy sources, such as solar and wind, into the grid [3]. The intermittent nature of these sources leads to fluctuations in voltage levels [4], especially during peak demand periods. To address this, grid infrastructure needs to be modernized to reduce technical losses.

The escalating complexity and demand in modern power systems necessitate advanced solutions to maintain voltage stability and minimize power losses. Flexible AC Transmission System (FACTS) devices, such as Static Var Compensators (SVCs) [5], Thyristor-Controlled Series Capacitors (TCSCs), and Static Synchronous Compensators (STATCOMs), among others, have emerged as pivotal technologies for enhancing the controllability and efficiency of power networks. The strategic placement and sizing of these devices [6] are critical to achieving optimal system performance.

Traditional optimization methods often struggle with the nonlinearity and multi-objectivity of FACTS device allocation problems. In contrast, swarm intelligence (SI) algorithms, inspired by the collective behavior of social organisms, offer robust and adaptable frameworks for tackling complex optimization challenges [7]. Algorithms in [8] & [9], such as Artificial Bee Colony (ABC), Bacterial Foraging Optimization (BFO), Dragonfly Algorithm, Salp Swarm Algorithm (SSA), and Particle Swarm Optimization (PSO), are some algorithms that have demonstrated efficacy in identifying optimal FACTS placements and sizing that enhance voltage profiles and reduce transmission losses.

Furthermore, incorporating renewable energy sources into power systems increases variability and uncertainty, thereby intensifying the complexity of the optimization process [10]. Studies have shown that optimally incorporating FACTS devices in such contexts can effectively mitigate voltage instability and power losses.

This research effectively bridges the existing gap in the literature by comprehensively reviewing swarm intelligence algorithms and demonstrating their potential to optimally size and place FACTS devices in power systems, thereby enhancing power transfer quality, reducing losses, and strengthening

voltage stability across diverse operational and network conditions.

This study provides a research methodology, an overview of FACTS devices, followed by a discussion on the purpose of optimization methods for FACTS devices. It is followed by metaheuristic optimization section that includes swarm intelligence techniques. The summary and conclusion appears in the last section.

II. Research Methodology

This study adopts a systematic quantitative research methodology aimed at evaluating the effectiveness of swarm intelligence algorithms in optimally positioning and sizing Flexible AC Transmission System (FACTS) devices within electrical power networks (IEEE-14 Bus and IEEE-57 bus system). The methodology involves selecting and analysing advanced algorithms such as the Artificial Bee Colony (ABC), Bacterial Foraging Optimization (BFO), Dragonfly Algorithm (DA), Swarm Salp Algorithm (SSA), and Particle Swarm Optimization (PSO). Each algorithm literatues is tested on standard IEEE-bus systems to identify the optimal placement and rating of FACTS devices including SVC, TCSC, and STATCOM, under defined operating constraints.

The research process comprises three stages: 1) Understanding of FACTS devices on power transfer systems, 2) Swarm intelligence algorithms as metaheuristic techniques and its application in optimal positioning of FACTS devices and 3) evaluation of strengths and weakenesses of these specifies algoritms through performance metrics such as power loss reduction, voltage deviation minimisation, and enhancement of overall system voltage stability. Table I gives a detailed study of the objectives and description of FACTS.

TABLE I. Main Study Objectives of Optimization in FACTS Devices

Objective	Description
Optimal Location	Determine the best buses or transmission lines to install FACTS devices on to maximize impact.
Optimal Sizing	Choose the appropriate rating (MVAR or MVA) of the FACTS device to avoid over-/undersizing.
Optimal Control Settings	Find the best operational parameters (e.g., phase angle, voltage magnitude, impedance) to enhance system performance.
Minimizing Power Losses	FACTS can reduce reactive power flows and improve power factor.
Enhancing Voltage Profile	Improve voltage stability by dynamically supporting bus voltages.
Increasing Power Transfer Capability	Help the system carry more load without violating constraints.
Minimizing Investment and Operational Costs	Avoid unnecessary expenditure by efficient placement and control.
Stability Improvement	Improve dynamic and transient stability under disturbances.

Literature reviewed between 2020 and 2025, mainly from Elsevier, ScienceDirect, and IEEE Xplore, forms the foundation of the algorithm selection and performance comparison. The methodology ensures that the reviewed swarm intelligence approaches demonstrate tangible improvements in the efficiency and quality of power transfer by reducing real power losses, improving voltage profiles, and ensuring the reliable operation of modern power systems.

III. Flexible Alternating Current Transmission System Devices

These are advanced power electronic controllers used to enhance the controllability, stability, and efficiency of electrical transmission networks. The optimal sizing and location of Flexible Alternating Current Transmission Systems (FACTS) devices are critical for enhancing the performance of electrical power systems [13]. Optimal placement of FACTS devices involves determining the most advantageous locations within the power system to maximize their benefits. Various optimization techniques have been employed to achieve this, including swarm intelligence techniques.

Jumaat et al. demonstrated the effectiveness of PSO in determining the optimal placement and sizing of multiple FACTS devices in an IEEE 30-bus system, highlighting the significant improvements in system performance achieved through strategic installations [13]. Similarly, [14] found that optimal FACTS device location and sizing can enhance system load ability, thereby improving overall transmission efficiency.

The sizing of FACTS devices is equally important, as it directly influences their operational effectiveness. Proper sizing ensures that the devices can meet the system's reactive power demands while maintaining voltage stability. In [15], it was indicated that systematic sizing of FACTS devices is essential for optimizing voltage profiles and minimizing power system losses.

Research has also shown that combining multiple types of FACTS devices can yield superior results compared to single-device installations. Sekhane and Djamel [16] explored the optimal number and location of FACTS devices, demonstrating that a combination of TCSC and SVC [17] can effectively enhance voltage profiles and minimize losses in electrical power systems.

The impact of FACTS devices on system performance depends on their optimal configuration. The study [19] found that the benefits of FACTS devices are significantly influenced by their location and size, which must be carefully considered to maximize transmission capacity and control flexibility [18]. Additionally, in [19], the authors emphasized the importance of sizing FACTS devices to achieve desired stability margins and improve overall system performance.

Therefore, the optimal sizing and placement of FACTS devices are crucial for achieving maximum effectiveness in power transmission systems.

FACTS devices [20], [21] are generally classified into three main categories based on their operational principles: operational-based devices, reactive impedance-based devices and voltage source-based devices. Each category fulfils distinct functions and is suited to specific applications within the power system.

A. Operational-Based FACTS Devices

Operational FACTS devices are power electronic controllers that dynamically regulate transmission parameters such as

voltage, impedance, and phase angle, to maximize controllability and efficiency in AC networks [16]. According to [17], they form part of shunt controllers, SVC, STATCOM, series controllers, TCSC, Static Synchronous Series Compensator (SSSC), and combined series–shunt controllers, Unified Power Flow Controller (UPFC), Interline Power Flow Controller (IPFC). They help improve voltage support, power-flow control, and stability.

Phase Shifting Transformers (PSTs) [17] are FACTS devices that manage active power flow by altering the phase angle between network buses. There are two types: tap-changing transformers, which adjust winding taps mechanically, and switched-capacitor/reactor hybrids, which rapidly modulate phase conditions via switching elements.

Tap-changing phase-shifting transformers (PSTs) [23] are FACTS devices that regulate active power transfer by adjusting the phase angle via mechanical tap changers. They are widely used to control loop flows, relieve congestion, and improve transmission capacity in interconnected grids [23]. Unlike other power electronic devices, PSTs provide a cost-effective, robust, and low-maintenance solution for enhancing network flexibility and security.

Switched capacitor/reactor phase-shifting transformers (PSTs) modulate active power flow by dynamically altering phase angles through rapid switching of capacitive or inductive elements [24]. In [25], [26], it is reported that hybrid devices combine Thyristor Switched Series Capacitors (TSSC) or Reactors (TSSR) with conventional PSTs to enable fast, discrete phase adjustments, offering advantages such as enhanced congestion relief, improved loop flow management, and better utilization of existing lines. Their mechanical simplicity and sub-cycle responsiveness make them reliable for enhancing grid flexibility and security.

Tap-changing PSTs offer robust, low-maintenance solutions for loop-flow management and congestion relief. At the same time, Thyristor-controlled PSTs (TCPSTs) enhance grid responsiveness through swift, discrete adjustments. Switched-capacitor/reactor phase-shifting transformers (PSTs) complement conventional tap-changing PSTs by enabling faster, more flexible phase-angle control [17], [25]. Both remain essential FACTS assets, with TCPSTs excelling in dynamic environments and tap-based PSTs in long-term stable control. Future work should integrate hybrid PST schemes that combine mechanical reliability with power-electronic agility, optimize deployment in renewable-rich grids, and ensure interoperability through standardized control strategies and modelling.

B. Reactive Impedance-Based FACTS Devices

Reactive impedance-based FACTS devices play a vital role in regulating reactive power flow, maintaining voltage levels, and controlling phase angles within power transmission systems. By performing these functions, they significantly enhance system stability, reliability, and efficiency [43]. The following subsection outlines the primary types of reactive impedance-based FACTS devices commonly used in modern power networks.

Series compensation FACTS devices, such as the Thyristor-Controlled Series Capacitor (TCSC) and the Thyristor Switched Series Capacitor (TSSC), reduce transmission line impedance to enhance active power transfer [56]. They improve system voltage stability, increase transfer capability, and relieve congestion, enabling better utilization of existing corridors without the need for new infrastructure.

The TCSC device integrates a series capacitor with a thyristor-controlled reactor. It is primarily employed to enhance the transmission capacity of power lines by regulating reactive power flow and improving voltage stability [65]. The TCSC in [48] effectively dampens power system oscillations, thereby enhancing overall system stability and dynamic performance. This device can rapidly adjust the transmission line impedance, thereby improving reactive power management and overall system stability.

As shown in Fig. 1, the Thyristor-Controlled Series Capacitor (TCSC) consists of a series capacitor connected to the transmission line and a thyristor-controlled reactor (TCR) [23], [30]. The circuit typically features a capacitor (C) in series with the line and a thyristor-controlled inductor (L) connected in parallel with the capacitor. By adjusting the thyristor firing angles, the capacitor's effective reactance can be dynamically controlled, enabling enhanced power-flow regulation and improved voltage stability within the transmission system.

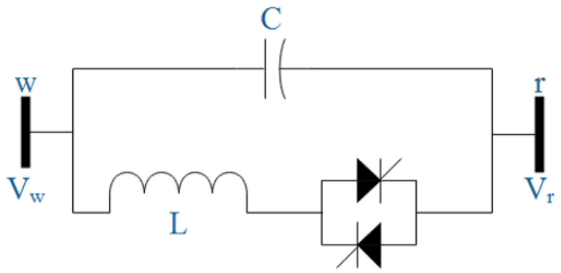

Fig. 1. Thyristor Controlled Series Capacitor (TCSC) circuit [23].

where, jX_{TCR} in Eq. (1), the TCR's effective reactance, is related to the delay angle $\boldsymbol{\alpha}$ in Eq. (2) [30].

$$X_{TCSC} = \frac{jX_{TCR}(-jX_C)}{jX_{TCR}-jX_C} = j\frac{|X_{TCR}|.|X_C|}{|X_{TCR}|-|X_C|} \quad (1)$$

$$X_{TCR}(\alpha) = \frac{\pi X_L}{2(\pi-\alpha)+\sin 2\alpha} \quad (2)$$

Thyristor-Switched Series Capacitors (TSSCs) are discrete FACTS devices in which series capacitors are bypassed or inserted via anti-parallel thyristor valves, enabling stepwise control of line compensation [27]. This configuration reported in [28] enhances active power flow, improves transient stability by damping oscillations, mitigates sub-synchronous resonance risks through fast switching, and reduces maintenance compared to mechanical switches.

They enhance active power transfer, damp power system oscillations, improve transient and voltage stability, and suppress sub-synchronous resonance. TSSCs are valued in dynamic, renewable-rich grids for their fast response, durability, and modular scalability [65]. Their flexibility enables placement optimization to efficiently relieve congestion and maximize existing infrastructure. Economically, they reduce maintenance compared to traditional mechanical switching, while

maintaining high reliability under variable loading and fault conditions [17].

Shunt compensation FACTS devices, primarily the Static Var Compensator (SVC) and static synchronous compensator (STATCOM), inject or absorb reactive power to regulate voltage, improve stability, and enhance power transfer capability. SVCs employ thyristor-controlled reactors and switched capacitors, offering robust, economical dynamic var support on transmission grids [30]. Converter-based STATCOMs in [41] and [42] provide faster response, near-constant reactive current at low voltages, and superior flicker and disturbance mitigation, benefiting weak grids and renewable integration. Together, these devices maintain bus voltages, reduce losses, increase loadability, and damp electromechanical oscillations as reported in [29], [30], [41], [42] when coordinated with system controls and protective schemes in modern, converter-dominated networks.

Thyristor-controlled reactors (TCRs) are shunt FACTS elements: a reactor in series with anti-parallel thyristors, whose phase-controlled firing angle continuously varies the inductive susceptance [43]. Integrated into SVCs, TCRs absorb reactive power to regulate bus voltage, increase loadability, and improve transient and small-signal stability [43], [65]. Practical deployment in [65] addresses characteristic harmonics through filters and coordinates with thyristor-switched capacitors to deliver Var control and flicker mitigation at weak transmission nodes and loads.

Thyristor-Switched Capacitor (TSC) is a shunt FACTS element that uses bidirectional thyristor valves to switch capacitor steps, delivering discrete, transient-free reactive power for fast voltage support, power-factor correction, and flicker mitigation. Integrated within SVCs, TSC branches complement TCRs to achieve a wide range with low losses and high reliability [48], [65]. Deployments span transmission and distribution nodes in [65] requiring fast voltage regulation under variable loads and renewable penetration.

C. Voltage Source-Based FACTS Devices

Voltage-source-based FACTS devices use self-commutated converters to synthesize controllable AC voltages and currents, enabling fast, continuous control of reactive power and, through series injections, active power flow [38]. Shunt STATCOMs provide near-constant reactive current at low voltages, stabilizing weak grids and supporting inverter-based resources; series SSSC and combined UPFC extend capability to regulate line impedance, voltage, and power flow, improving transfer limits and damping oscillations [38], [53]. Converter in [53] significantly advances dynamic performance, with robust control frameworks and accurate steady-state models now available for planning and Optimal Power Flow (OPF) integration of VSC-based controllers in transmission networks and renewable power systems.

Series voltage-source-based FACTS [56] devices inject controllable AC voltage in series with a line to regulate power flow, boost transfer capability, damp oscillations, and enhance transient stability and reliability margins in converter-dominated grids.

A Static Synchronous Series Compensator (SSSC) is a series VSC-based FACTS controller, as shown in Fig. 2 that injects a controllable quadrature voltage to emulate variable capacitive or inductive reactance and regulate line power flow, raise transfer limits, and damp oscillations. Practical deployment emphasizes robust protection and fault-ride-through using fast varistor/thyristor schemes [56], and system-level coordination for predictability, placement, and security of SSSC-compensated corridors under renewable variability [57]. These capabilities support stability, reliability, and resilience in modern, converter-dominated grid operation.

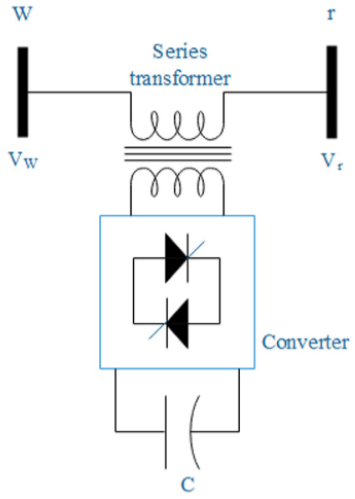

Fig. 2. Static synchronous series compensator circuit [23].

Shunt voltage source converter FACTS devices inject or absorb reactive current to hold bus voltages, stiffen weak grids, and aid renewable integration [53]. Advances in converter topology and control deliver fast response and near constant current, improving transfer margins, flicker mitigation, and oscillation damping in transmission networks.

Static synchronous compensators (STATCOMs) are shunt-voltage-source converter FACTS controllers that inject or absorb reactive current to regulate bus voltage and strengthen weak grids [38]. Compared to SVCs, STATCOMs provide near-constant reactive current at low voltages, faster dynamics, and improved damping of flicker and oscillations [53]. The circuit diagram in Fig. 3 typically includes a voltage source inverter (VSI) connected to a coupling transformer and a DC capacitor [38]. The VSI converts the DC voltage from the capacitor into AC voltage, which can be adjusted to provide the required reactive power.

STATCOMs use voltage-source converters to provide dynamic reactive power support, as shown in Fig. 3. They can respond quickly to changes in system conditions, making them effective for voltage regulation and for improving system stability [38]. STATCOMs are particularly beneficial in systems with high penetration of renewable energy sources, where voltage fluctuations are common. STATCOM [38] can respond rapidly to changes in system conditions, making it effective for voltage regulation and improving power quality [see Eq. (3)].

$$S_{STC} = V_{STC} I_{STC} = V_{STC} V_{STC} Y_{SC} - V_{STC} Y_{SC} V_i \quad (3)$$

where, I_{STC} is the complex conjugate of STATCOM current, V_{STC} is the complex conjugate of STATCOM voltage , and Y_{STC} is the complex conjugate of short-circuit admittance [33].

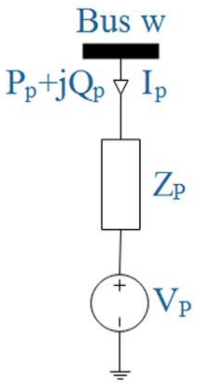

Fig. 3. Static synchronous compensator circuit [23].

Combined VSC-based FACTS devices like the unified power flow controller (UPFC) couple shunt and series converters through a common DC link to regulate bus voltage and line power flow simultaneously, increasing transfer capability and damping oscillations [62]. Recent research advances steady-state models and protection/fault identification for UPFC deployments in transmission corridors.

Unified power flow controllers (UPFCs) combine shunt and series voltage-source converters via a common DC link to independently regulate bus voltage and line power flow. By injecting controllable series voltage and exchanging reactive current, UPFCs increase transfer capability, relieve congestion, and damp electromechanical oscillations while supporting renewables [63]. Recent work provides steady-state models for planning and OPF, and convex formulations for security-constrained economic dispatch in [63] by improving scalability, dispatchability, and reliability.

The UPFC circuit diagram in Fig. 4 typically consists of two voltage-source converters: one connected in series with the transmission line and the other connected to the shunt side. The series converter injects voltage into the line, while the shunt converter regulates the DC link voltage.

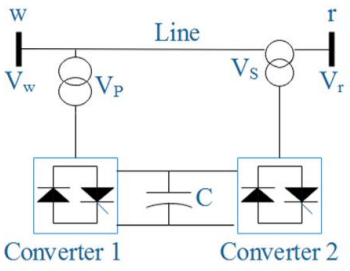

Fig. 4. Unified Power Flow Controller (UPFC) circuit [23].

Static Var Compensator (SVC): SVCs compensate for reactive power and maintain voltage stability in the power system. They consist of a combination of capacitors and inductors controlled by thyristors, allowing for rapid response to voltage fluctuations [38]. The SVC is effective at maintaining voltage within the desired range and responds quickly to changes in load conditions, thereby improving overall power quality [53]. SVCs are widely deployed in transmission networks to enhance power quality and system reliability.

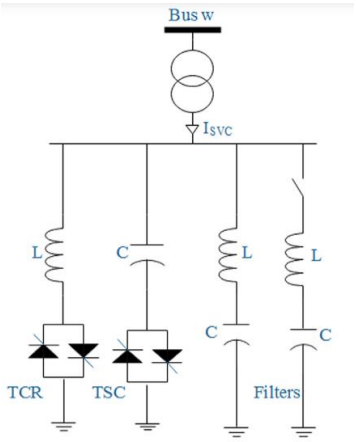

Fig. 5. Static Var Compensator (SVC) circuit [23].

The SVC in Fig. 5 is composed of a combination of capacitors and inductors, controlled by thyristors. The circuit diagram typically shows a bank of capacitors (C) and a bank of inductors (L), with thyristors (T) used to switch the inductors in and out of the circuit as needed. This configuration allows for real-time reactive power compensation [see Eq. (4) and Eq. (5)].

$$X_{SVC} = \frac{X_L(\alpha).X_C}{X_L(\alpha) + X_C} \quad (4)$$

with

$$X_L(\alpha) = X_{L0}\frac{\pi}{2(\pi - \alpha)+\sin 2\alpha} \quad (5)$$

where, X_{L0} is the fundamental frequency reactance of the reactor without thyristor control and α is the firing angle of the valves with respect to the zero-crossing instant of the controller voltage [31].

Thyristor-Controlled Phase Shifter (TCPS): This device controls power flow in transmission lines by adjusting the phase angle of the voltage. TCPS can be particularly useful in managing power flows in meshed networks and alleviating congestion [65]. By controlling the phase angle, the TCPS can effectively manage power flows in the network, helping to ease congestion and improve system stability [48].

The TCPS in Fig. 6, is designed to control the phase angle of the voltage in a transmission line. The circuit diagram typically includes a thyristor-controlled reactor (TCR) connected in series with the transmission line, allowing adjustment of the phase angle by varying the reactor's reactance.

where, T is the operational mode with X_F, X_v. K_1 and K_2 as computational coefficients [32].

Flexible AC Transmission Systems (FACTS) devices enhance power system flexibility, controllability, and stability by dynamically regulating key parameters. They are broadly categorized into operational-based, reactive impedance-based, and voltage source-based devices. Each class functions differently, controlling variables such as impedance, voltage, or phase angle to optimize system performance.

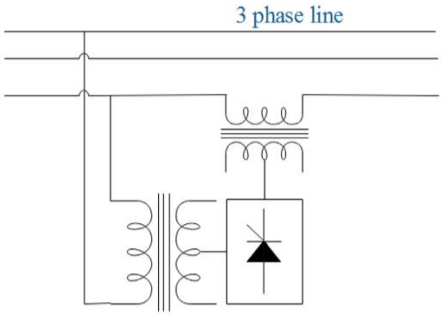

Fig. 6. Thyristor-controlled phase shifter circuit [23].

IV. Optimization Methods for FACT Devices

Optimization methods are critical tools for determining the optimal location, sizing, and operation of FACTS devices in a power system. These methods aim to maximize system performance while minimizing cost and operational issues.

FACTS devices are powerful but expensive tools. Improper placement or operation can lead to:

- Underutilization of expensive equipment.
- Instability or overcompensation.
- Increased system losses or operational costs.

Hence, optimization ensures cost-effective, reliable, and efficient use of FACTS.

Table II presents a consolidated summary of these FACTS device classes, highlighting their control variables, operational principles, and typical applications.

TABLE II. Summary of Operational Characteristics and Applications of FACTS Devices

FACTS Device Type	Reference	Device Name	Configuration	Control Variables	Main Function	Operational Principle	Typical Application
Operational based	[16,17,23,24,27]	TCSC TSR	Shunt, series, combined;	Voltage, Reactive-power, Current, Susceptance, Reactance, Firing-angle, Phase-angle	regulate voltage support vars control flow damp oscillations improve stability	Switch shunt/series reactance, or synthesize voltages, to regulate power flow.	Voltage-regulation, var-support, power-factor-correction, flicker-mitigation, power-flow-control, congestion-relief, stability-enhancement
Reactive Impedance-based	[27,43, 65,28,17]	TCR, TSR	Shunt, series;	firing-angle conduction-angle thyristor-state capacitor-step reactor-current susceptance reactance	voltage-regulation reactive-power-compensation line-impedance-control power-flow-control stability-enhancement oscillation-damping loss-reduction	Phase control thyristors adjust reactors or capacitors, varying impedance continuously	Voltage-regulation, var-support, power-factor-correction, compensation, power-flow-control, congestion-relief, loss-reduction.
Voltage Source-based	38,53,56,57,62]	STATCOM SSSC UPFC	Shunt, series, combined	modulation-index phase-angle injected-voltage reactive-current active-current	voltage-regulation stability-enhancement power-flow-control	Synthesize controllable AC voltage; regulate reactive current; control power flow.	Voltage-regulation, reactive-support, weak-grid-stabilization, renewable-integration, power-flow-control, voltage-stability-enhancement

V. Metaheuristic Optimization Techniques

Metaheuristic optimization techniques (MOT) [34] have emerged as powerful tools for solving complex optimization problems in various fields, including electrical engineering and power systems. These techniques are particularly effective for non-convex, combinatorial problems, such as the optimal placement and sizing of Flexible Alternating Current Transmission Systems (FACTS) devices.

Determining the best locations for FACTS devices helps to maximize their effectiveness in enhancing voltage stability and minimizing losses [33, 34, 35]. Studies have shown that metaheuristic techniques can effectively identify optimal locations based on system characteristics and load conditions.

Optimizing the capacity of FACTS devices to ensure they meet the reactive power requirements of the system while minimizing costs [36, 37]. Many studies have focused on optimizing multiple objectives simultaneously [38], such as reducing costs while maximizing system reliability and performance. Metaheuristic techniques are well-suited for handling such multi-objective problems due to their flexibility and adaptability.

Swarm Intelligence (SI) is an area of artificial intelligence that draws inspiration from the collective behavior of social organisms, such as ants, bees, birds, and fish. This paradigm is characterized by decentralized control, self-organization, and the ability to solve complex problems through simple agents interacting with one another and their environment [39, 40]. The concept of swarm intelligence [41] has been widely applied to the positioning and sizing of FACTS devices, leading to the development of various algorithms that leverage its principles for optimization tasks.

Decentralization in swarm intelligence, zero systems operate without central control, with individual agents making decisions based on local information and simple rules, resulting in emergent behavior at the group level. This decentralized approach offers flexibility and robustness in problem-solving [42, 43]. This decentralized nature enables optimal placement of FACTS devices, such as using Particle Swarm Optimization (PSO) to enhance voltage stability and minimize losses [39, 40]. By leveraging local information, these algorithms can adaptively respond to system changes, ensuring devices are placed where needed most. This decentralized nature in [40] contributes to the robustness and adaptability of FACTS devices in power systems, enhancing overall system reliability.

Self-organization is a fundamental property of swarm intelligence (SI) systems, whereby decentralized agents interact locally with one another and their environment to produce coherent, system-level behavior without central control. The emergent phenomenon enables SI systems to adapt to dynamic operating conditions autonomously, enhancing performance without the need for external intervention.

In biological systems, such as ant colonies, simple behavioral rules and local communication mechanisms give rise to complex problem-solving capabilities. This principle has inspired numerous computational optimization techniques [44]. In the context of electric power systems, the self-organizing behavior of SI can be leveraged to optimize the placement and sizing of Flexible AC Transmission Systems (FACTS) devices [45], [46] including Static Var Compensators (SVC), Thyristor-Controlled Series Capacitors (TCSC), and Unified Power Flow Controllers (UPFC), can be coordinated in a distributed manner to enhance voltage stability, improve load-ability, and reduce transmission losses under fluctuating system conditions. Such adaptability allows device configurations to be modified in near-real time based on local measurements, enabling the grid to respond effectively to disturbances and demand variations.

Several metaheuristic optimization methods depicted in Fig. 7 are grouped into swarm-based, physics-based, evolution-based, and human- and socio-inspired algorithms.

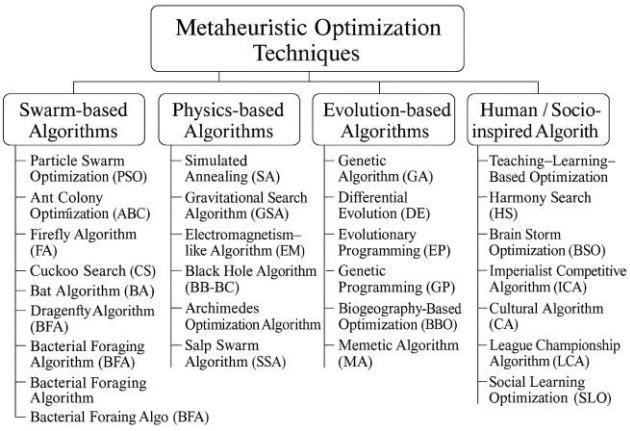

Fig. 7. Metaheuristic optimization techniques including swarm intelligence.

The mechanism of self-organization in SI algorithms is driven by local interactions, in which each agent adjusts its behavior based on immediate surroundings and limited feedback. In optimization frameworks such as Particle Swarm Optimization (PSO), the Grey Wolf Optimizer (GWO), and the Gorilla Troops Optimizer (GTO), this principle enables FACTS devices to be allocated to minimize system losses and maximize voltage stability while respecting system constraints [47, 48, 49]. Self-organization supports the integration of hybrid metaheuristics, such as combining PSO with other search strategies, [46] and [50], enabling dynamic resizing of FACTS devices in response to real-time reactive power demands and ensuring both technical and economic efficiency.

Recent studies confirm that swarm-based self-organization is particularly effective in solving multi-objective FACTS placement problems, simultaneously optimizing cost, stability margin, and power-loss reduction in renewable-integrated networks [44, 47, 48]. The inherent robustness of self-organized SI systems ensures reliable system operation even under significant disturbances, making them a promising approach for modern, adaptive power systems.

Stigmergy is an indirect communication mechanism in which agents influence one another by modifying their shared environment. In swarm intelligence, this principle enables coordinated behavior without direct interaction, as seen in ant pheromone trails. In power systems, staggery facilitates adaptive FACTS device placement and operation [56], [57], where changes in one device's status inform others' decisions, improving voltage stability and minimizing losses.

Collective Intelligence: swarm-based optimization harnesses collective intelligence, where a group of simple agents collaborates through local interactions to explore solution spaces more effectively than isolated agents [52]. In nature, bees forage [53] efficiently by responding to local stimuli, demonstrating how collective behaviors emerge from decentralized rules and yield superior performance.

In power systems, this principle directly benefits the distributed placement and sizing of FACTS devices [51], [54]. Rather than relying on centralized control, FACTS units can coordinate through emergent swarm behaviors, enabling adaptive responses to dynamic conditions such as load fluctuations and voltage instability.

One illustrative approach is the Autonomous Groups Particle Swarm Optimization (AG-PSO) method, which applies swarm intelligence to determine optimal SVC locations and sizes, significantly reducing transmission losses [55]. Similarly, hybrid algorithms in [52] combining Genetic Algorithms with PSO (GA-IPSO) optimize the sizing and placement of STATCOM, TCSC, and UPFC in radial power networks, achieving enhanced voltage profile control and reduced system losses.

Emergent collective intelligence also plays a vital role in multi-objective optimization, where objectives such as system cost, stability, and loadability must be balanced. Swarm-based algorithms naturally navigate these trade-offs by dispersing and aggregating candidate solutions, ultimately converging toward Pareto-optimal configurations for FACTS deployment [54]. Fig. 8 shows the unified concept of swarm intelligence.

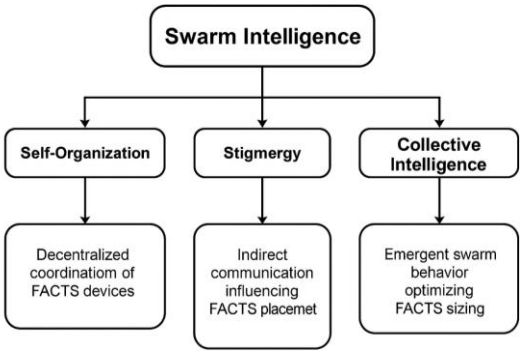

Fig. 8. Swarm intelligence unified conceptual diagram.

Swarm intelligence algorithms are nature-inspired optimization techniques that mimic the collective behavior of biological populations. They provide powerful tools for solving complex engineering problems with adaptability and robustness. The following section explores the Artificial Bee Colony Algorithm (ABC), Bacterial Foraging Optimization (BFO), Dragonfly Algorithm (DA), Salp Swarm Algorithm (SSA), and Particle Swarm Optimization (PSO) as swarm-based algorithms, highlighting their unique characteristics.

A. Artificial Bee Colony Algorithm

The Artificial Bee Colony (ABC) algorithm is a swarm intelligence metaheuristic inspired by the foraging behavior of honeybees. It consists of three types of agents: employed bees, which explore the neighborhood of current food sources; onlooker bees, which probabilistically select promising sources based on the quality shared by employed bees; and scout bees, which abandon depleted sources to discover new ones. Through this decentralized, collaborative process, ABC [63], [66] effectively explores and exploits the search space, making it suitable for complex optimization problems.

ABC demonstrates strong global exploration capabilities and robustness against local optima, primarily due to its randomized neighborhood search [58], [61]. However, compared to Particle Swarm Optimization (PSO) and Genetic Algorithms (GA), ABC often converges more slowly because its information-sharing mechanism relies heavily on probabilistic sampling rather than deterministic best-solution propagation [64]. Recent studies have improved convergence by integrating Bayesian estimation [58], elite-driven adaptive population scaling [59], and adaptive exploration control [60], resulting in faster convergence without compromising exploration diversity. ABC has been widely applied to the optimal placement and sizing of Flexible AC Transmission Systems (FACTS) to enhance voltage stability and reduce power losses in both small and large-scale networks. For example, Shokouhandeh et al. [61] used ABC for reactive power management with SVC devices, achieving superior improvements in the voltage profile compared with conventional methods. On the IEEE 30-bus system, a multi-objective hybrid ABC significantly minimized active power losses and improved voltage deviation indices [62].

In benchmark case studies, ABC-based optimization has produced measurable performance gains on the IEEE 30-bus system with SVC and TCSC devices. ABC improved voltage stability by 15% and reduced active power losses by 20% [66]. On the IEEE 11-bus system, optimal SVC placement achieved close to 25% loss reduction and noticeable improvement in the voltage profile [61], and in large-scale IEEE 118-bus networks, the ABC algorithm in [66] yielded a 15% absolute power loss reduction while enhancing overall stability.

Strengths of ABC include its high global search capacity, which reduces the risk of local optima entrapment [58],[60]. Simplicity of implementation and adaptability to multi-objective and discrete problems [65]. Weaknesses include slower convergence compared to PSO and GA, due to less structured information sharing [64], [66]—an exploration–exploitation imbalance [67] that can limit the fine-tuning of near-optimal solutions.

Hybridization strategies, such as combining ABC with PSO, can inherit PSO's fast convergence while maintaining ABC's exploration capacity [59], [62]. Adaptive control of search parameters [60] and integration with other metaheuristics such as Firefly or Ant Colony Optimization [67] can also improve convergence and balance.

B. Bacterial Foraging Optimization

The Bacterial Foraging Optimization (BFO) algorithm is a nature-inspired metaheuristic mimicking the foraging behavior of Escherichia coli. BFO employs three primary operations: chemotaxis —bacteria move through tumbling and swimming toward nutrient-rich regions; reproduction —healthiest bacteria replicate, replacing weaker ones; and elimination — dispersal, random removal, or relocation of bacteria to sustain diversity. This collective mechanism guides a swarm of agents through the search space, facilitating efficient global optimization [69].

BFO effectively explores complex, multimodal landscapes and shows robust global search behavior [69]. However, compared with algorithms like PSO, it's known to have a slower convergence rate, attributed to its stochastic movements and the lack of direct global-best information sharing [69], [72]. Nonetheless, modified BFO variants, such as those incorporating adaptive chemotactic step-size or hybrid schemes, have exhibited faster convergence while retaining exploration capacity [69]. BFO has been applied to the optimal placement and sizing of FACTS devices, such as SVCs, TCSCs, STATCOMs, and IPFCs, to enhance voltage stability and reduce power losses in various test networks.

A study using BFO for reactive power and voltage management in IEEE 39-bus systems with UPFC devices demonstrated improved voltage stability and reduced transmission losses [68]. In the IEEE 30-bus system, BFO-based methods significantly improved voltage profiles and reduced losses [70]. BFO optimized DSTATCOM placement in distribution systems [71] with performance gains in voltage regulation and loss reduction.

Strengths of BFO include global exploration, simplicity, and ease of implementation [72]. At the same time, weaknesses include slow convergence, parameter sensitivity, and longer computation time [69, 72]. The weaknesses can be mitigated by hybridizing BFO with PSO [69] or other fast-converging algorithms, by adaptive control of the chemotactic step size, and by incorporating elimination–dispersal and reproduction adaptively.

The BFO algorithm offers a compelling, biologically inspired approach for FACTS device optimization, with proven benefits in voltage stability and power loss reduction. Its global search strength is counterbalanced by slower convergence and parameter sensitivity. Advances through hybrid and adaptive variants are promising routes to enhance convergence speed without sacrificing robustness. As a result, BFO remains a valuable technique in the optimization toolbox for modern power systems.

C. Dragonfly Algorithm

The Dragonfly Algorithm (DA) is a swarm-inspired metaheuristic that models dragonfly swarming behavior, specifically their foraging and predator-avoidance tactics. DA partitions its search process into two pivotal phases: exploration, where agents (dragonflies) travel far to locate promising regions, and exploitation, where collective, neighborhood-based movement guides convergence toward optimal solutions [73]. These behaviors emulate natural local interaction rules — separation, alignment, and cohesion — as optimization operators.

Empirical comparisons reveal that DA features superior exploration capability, enabling rapid coverage of high-dimensional search spaces. In various benchmark studies, DA has outperformed traditional swarm paradigms such as Particle Swarm Optimization (PSO) and Genetic Algorithms (GA) in terms of convergence speed and solution quality, especially on multimodal and high-complexity problems [74].

Recent research has applied DA to the optimal placement and sizing of Flexible AC Transmission Systems (FACTS), notably TCSCs and SVCs, to bolster voltage stability and minimize active power losses, in a Diyala 132 kV network. DA-based optimization of TCSC and SVC configurations resulted in a 15% improvement in voltage stability margin and approximately a 23% reduction in total system losses [75]. On IEEE-30 and IEEE-118 bus systems, DA-enhanced FACTS deployment demonstrated marked improvements in voltage profiles and reduced congestion-induced losses [76].

Strengths of DA include excellent global exploration, fast convergence on complex multimodal problems, and a relatively simple implementation framework [73]. In contrast, its weaknesses include the risk of premature convergence to local optima, dependence on random initialization for stability, and the need for careful parameter tuning [73]. Mitigation of weaknesses includes hybridizing with PSO and DE for guided search, adaptive control of step coefficients, and incorporating parameter self-adaptation techniques [77].

The Dragonfly Algorithm stands as a powerful, nature-inspired approach for FACTS device optimization in power systems. Its strengths lie in swift exploration of solution spaces and effective handling of complex, multimodal problems. Studies have validated DA's ability to significantly improve voltage stability and reduce system losses in a realistic power network. However, DA's stochastic nature can lead to local convergence unless mitigated by hybrid approaches and adaptive parameter tuning. Emerging hybrid designs offer a promising path for combining DA's best traits with accelerated convergence and improved robustness.

D. Salp Swarm Algorithm

The Salp Swarm Algorithm (SSA) is a nature-inspired metaheuristic, modeled on the chain-like swarming behavior of Salps in the ocean [78]. It employs two phases: exploration, in which the leading Salp performs randomized movement across the search space to discover promising regions. The second is exploitation, in which followers update their positions relative to the leader and their neighbors, refining toward optimal solutions [79]. These dynamics foster a balance between global exploration and local exploitation, rendering SSA suitable for complex optimization challenges.

SSA tends to converge more slowly than algorithms such as Particle Swarm Optimization (PSO) and Genetic Algorithms (GA), primarily because of its randomized, leader-follower movement strategy [80], [81]. In highly multimodal landscapes [81], maintaining population diversity becomes challenging, increasing the risk of premature convergence into a local optimum.

SSA has been successfully applied to optimize the placement and sizing of Flexible AC Transmission System (FACTS) devices, such as SVCs and TCSCs, for voltage profile enhancement and power loss minimization, such as on the IEEE 30-bus system. SSA-based optimization resulted in approximately a 15% improvement in voltage stability and a 22% reduction in power losses [79]. On the IEEE 57-bus system, SSA yielded a 12.5% increase in voltage stability and a 20% reduction in losses [82]. In the modified IEEE 14-bus system, optimal FACTS placement via SSA [80] achieved a 16% enhancement in voltage profile stability and an 18% decrease in power losses.

Strengths of SSA include compelling exploration in early search, simple implementation with clear phases, and being well-suited for continuous, nonlinear spaces. In contrast, weaknesses include slow convergence toward the optimum, being prone to local optima in complex landscapes, and poor balance between exploration and exploitation. The mitigation of these weaknesses may be achieved by hybridizing SSA with PSO/DE for faster convergence [81], adaptive leader update, or dynamic control of influence radius [81,82], and incorporating chaotic or opposition-based strategies [78].

The Salp Swarm Algorithm presents an innovative, bio-inspired strategy for optimizing the placement and sizing of FACTS devices in power systems. Its dual-phase structure effectively balances global exploration and local exploitation, resulting in significant reductions in losses and improvements in voltage stability across standard IEEE test systems. However, SSA's slower convergence and vulnerability to local optima highlight its need for augmentation. Hybrid formulations and adaptive strategies promise to enhance SSA's convergence speed and robustness, making it a viable tool for advanced power system optimization.

E. Particle Swarm Optimization

Particle Swarm Optimization (PSO) is a prominent metaheuristic inspired by the collective behavior of birds or fish schools. Introduced by Kennedy and Eberhart in 1995, PSO features a swarm of particles, each representing a candidate solution, with associated positions and velocities [83]. Each

particle tracks its own best-known position (pBest) as well as the swarm's best position (gBest). Velocity updates combine inertia, cognitive attraction to pBest, and social attraction to gBest, enabling particles to converge on optimal solutions [84], collaboratively.

PSO is known for its fast convergence, facilitated by its dual communication mechanism (particles sharing both personal and global bests) [83]. Comparative studies have shown that PSO often outperforms classic algorithms such as Genetic Algorithms and Differential Evolution in both convergence speed and solution quality on benchmark functions [84]. However, rapid convergence can sometimes lead PSO [85] to prematurely settle on local optima, especially in highly multimodal search landscapes.

TABLE III. SUMMARY OF SWARM INTELLIGENCE ALGORITHMS APPLIED TO FACTS DEVICES

Optimization Technique	References	Key Features	Objectives	FACTS Devices Applied To	Advantages	Limitations	Applications
Artificial Bee Colony (ABC)	[4,58,61,62,63,64,66]	Exploration – ability to avoid local optima, Adaptation - balances exploration and exploitation. Optimization as it achieves near optimal solutions.	Efficient global search. Balanced exploration and exploitation and Optimization of complex problems	SVC, TCSC, STATCOM	-Global exploration ability -Simplicity and fewer parameters -Robustness across problems	-Slow convergence -Sensitivity to parameters -Risk of premature abandonment	IEEE 30-bus: +15% voltage stability, −20% losses; IEEE 11-bus: −25% losses; IEEE 118-bus: −15% losses
Bacterial Foraging Algorithm (BFO)	[68,69,70,71,72]	Chemotaxis, Swarming – enhances information sharing. Elimination - removes unfit bacteria. Adaptation.	-Effective problem solving - Maintain diversity - Global optimization	SVC, TCSC, STATCOM, IPFC, DSTATCOM, UPFC	-Effective global search -Maintains population diversity -Good at avoiding local optima	Complex due to many parameters -Slow convergence -Highly sensitive	IEEE 39-bus (UPFC): improved voltage & reduced losses; IEEE 30-bus: improved voltage & reduced losses; Distribution: improved voltage & reduced losses
Dragonfly Algorithm (DA)	[73,74,75,76,77]	Separation, Distraction – moves away from poor solutions. Attraction – moves towards good solutions	-Simulate swarm dynamics -Balance search phases -Optimize complex systems	TCSC, SVC	-Strong balance between exploration and exploitation -Performs well on multimodal optimization problems	-Can stagnate if diversity is lost -Requires careful parameter control for stability	Diyala 132kV: +15% voltage stability, −23% losses; IEEE 30/118-bus: improved voltage & reduced congestion losses
Salp Swarm Algorithm (SSA)	[78,79,80,81,82]	Leader – guides toward the best solution. Exploitation – refines solutions. Relatively fast convergence.	-Model chain movement -Enhance Exploration and exploitation -Achieve convergence.	SVC, TCSC	-Simple structure with leader-follower dynamics -Efficient in both global and local search phases -Fast convergence	-May get trapped in local optima -Limited exploitation ability in late iterations.	IEEE 30-bus: +15% voltage stability, −22% losses; IEEE 57-bus: +12.5% voltage stability, −20% losses; IEEE 14-bus: +16% voltage stability, −18% losses
Particle Swarm Optimization (PSO)	[83,84,86,87]	Particles for search, Balances global and local search and fast convergence, Ensures broad search	-Leverage social learning -Balance exploration and exploitation -Optimize high-dimensional problems	TCSC, SVC, STATCOM, IPFC	-Fast convergence -Simple due to a few parameters -Effective balance on personal and social learning (Pbest and gbest)	-Prone to premature convergence -Exploration ability decreases over time -May require hybridization for high-dimensional problems.	IEEE 14-bus: +20% voltage stability; IEEE 57-bus (IPFC): +15% voltage stability, −22% losses

PSO has been widely used to optimize the placement and sizing of FACTS devices such as TCSC, SVC, and STATCOM in power systems to enhance voltage stability and reduce power losses. For example, the PSO-based hybrid method applied to the IEEE 14-bus system demonstrated notable improvements in the voltage profile and a 20% reduction in losses [86]. On the

IEEE 57-bus system, PSO-optimized Interline Power Flow Controller (IPFC) [87] deployment yielded qualitative improvements in voltage and losses, reporting 15% voltage enhancement and 22% loss reduction.

Strengths include high convergence speed, intuitive and straightforward implementation, and well-established and extensively studied. The PSO weaknesses include premature convergence, difficulties with complex, multimodal problems, and large-scale issues that increase computational burden [85]. These can be mitigated by hybridizing with exploration-rich methods such as DE or Firefly, Adaptive inertia weight, or velocity strategies to balance exploration and exploitation [84], and by Parallel or distributed PSO implementations to accelerate computation.

PSO is a widely used swarm intelligence algorithm that exhibits rapid convergence and a straightforward implementation [83]. It has been applied successfully to the placement and sizing of FACTS devices, yielding improvements in voltage stability and loss reduction in test power networks. While fast convergence is a strong advantage, it also increases the risk of getting stuck in local optima. Hybrid approaches, adaptive mechanisms, and parallel implementations offer promising avenues to enhance PSO's robustness and scalability for complex, real-world FACTS optimization tasks.

Artificial Bee Colony (ABC), Bacterial Foraging Optimization (BFO), Dragonfly Algorithm (DA), Salp Swarm Algorithm (SSA), and Particle Swarm Optimization (PSO) represent widely applied swarm intelligence techniques, each inspired by distinct natural behaviors. These algorithms demonstrate strengths in exploration, exploitation, and adaptability across a range of optimization challenges. Table III provides a consolidated summary of their key principles, merits, limitations, and typical applications in power system optimization.

VI. Conclusion

Swarm intelligence algorithms have proven to be powerful metaheuristic optimization tools for the optimal allocation of Flexible AC Transmission System (FACTS) devices, which are vital for improving power system performance and stability. Review studies on algorithms such as the Artificial Bee Colony, Bacterial Foraging Optimization, Dragonfly Algorithm, Salp Swarm Algorithm, and Particle Swarm Optimization demonstrate their effectiveness in addressing the complex, multimodal challenges of FACTS device placement, including TCSC, SVC, and STATCOM. Over time, these algorithms have evolved through hybridization and refinement, significantly enhancing their optimization capabilities. Their adaptability to varying operational conditions makes them indispensable for improving system reliability, reducing transmission losses, and maintaining voltage stability. Future research should focus on advancing these techniques and integrating them with emerging technologies, such as artificial intelligence, renewable energy systems, and smart grid frameworks, to meet the growing, dynamic needs of the global energy sector.

SPA-DCN-NET: A Gated Multi-Scale Local Contrast Normalization Network for Ultrasound Image Segmentation of Liver

Su Ming Jian, Afizan Bin Azman
School of Computer Science, Taylor's University Lakeside Campus, Subang Jaya, Malaysia

***Abstract*—Segmentation of the liver in ultrasound images is a critical task in medical image analysis, yet it remains challenging due to acoustic speckle noise, brightness instability, and deformations caused by probe pressure. To address these problems, this study presents SPA-DCN-NET, a lightweight framework that integrates three synergized components: first, a learnable gated local contrast normalization (Gated LCN) module utilizes a sigmoid soft-gate mechanism to dynamically fuse LCN-enhanced features with original features, effectively stabilizing the features for training. Second, a spatial pyramid attention (SPA) module applies multi-scale context aggregation, transforming the clear features provided by Gated LCN into deformable convolutional networks. Third, these features guide deformable convolutional networks to adaptively adjust sampling grids, ensuring precise delineation of irregular liver boundaries in ultrasound images. Experimental results demonstrate that our SPA-DCN-NET achieved mean IoU scores of 83.52%, 75.57%, 73.85%, and 85.94% across the four datasets, respectively. These results are all higher than those obtained by UNet, nnUNet, and ResUNet. The metrics indicate that our SPA-DCN-NET is more adaptable to the ultrasonic medical environment compared to other existing medical segmentation networks, and it is a recommended network of image analysis for ultrasound abdominal scans.**

Keywords*—Spatial pyramid attention; deformable convolutional network; ultrasound image; medical image analysis; soft-gate mechanism; local contrast normalization

I. Introduction

Liver disease is a major burden on human health. In 2019, the global mortality attributed to hepatitis B and hepatitis C surpassed one million [1]. Liver diseases often present a diagnostic challenge due to the inherent limitations of current detection modalities. Ultrasonography remains the predominant imaging modality for hepatic assessment. However, during the scan, the probe will repeatedly press against the skin. These actions result in dynamic alterations to both hepatic morphology and the intensity of parenchymal echoes, concomitantly causing distortion of the ultrasonic beam's propagation path, and ultimately lead to instability in the image's structural representation and brightness. Research has demonstrated that inappropriate calibration of time gain compensation (TGC) settings can dramatically impair AI model performance, manifesting as a substantial decline in diagnostic accuracy, ranging from 5% to 40% [2].

At present, there are already some medical image segmentation networks, such as UNet [3] and nnUNet [4], whose core module is a convolutional neural network (CNN). Multiple studies have shown that the classification, detection, and segmentation performance of CNNs will significantly decline under different lighting conditions. For instance, pre-trained networks such as VGG16 and ResNet exhibit significant instability under 15 different lighting conditions, indicating that existing CNN models lack robustness to lighting changes and need to enhance their adaptability through means such as data augmentation [5][6][7]. The fundamental reason for CNN's sensitivity to lighting changes is its reliance on low-level features of the input image, such as brightness, contrast, and texture. Research has found that CNN is extremely sensitive to minor changes such as high-frequency disturbances and non-uniform illumination, and is easily misled by non-uniform illumination, resulting in a significant drop in classification accuracy. The introduction of a biological-inspired anterior cortex module can significantly enhance the robustness of CNN to global light intensity and contrast variations [8]. Introducing diverse lighting conditions in the training set or synthesizing weak light or non-uniform lighting images can effectively enhance the model's adaptability to actual lighting changes [9]

The local contrast normalization (LCN) is a classic feature enhancement method, and its design inspiration comes from the neural mechanism of the human visual system, specifically the concept of lateral inhibition. In the retina, excited neurons inhibit neighboring neurons, which naturally enhances the contrast between features and their surrounding background, thereby improving edge detection and pattern recognition. LCN mathematically simulates this process by transforming the pixel intensity values based on the properties of their local neighborhood [10]. LCN first uses local mean subtraction to remove average local brightness and center the image data around zero. Second, the resulting data is normalized by the local standard deviation. By normalizing intensity based on local statistics, LCN effectively standardizes the image contrast across different regions. This stabilization is crucial in medical imaging, particularly for mitigating the aforementioned brightness and contrast instability problems common in ultrasonography. LCN helps deep learning models become more robust to non-uniform illumination and poor contrast conditions, which is essential for maintaining high diagnostic accuracy in a diverse clinical setting. This makes it a valuable pre-processing step before inputting images into a computer-aided diagnosis system.

Normally, the intensity of echo propagation during medical examination can be expressed as Eq. (1):

$$I_{echo}(P) \approx I_{in} \cdot R'(P) \cdot e^{-2\alpha \cdot f(d-\Delta d(P))} \quad (1)$$

This equation states that the final image brightness I_{echo} is the result of the initial energy I_{in} being reflected by the tissue R' and then exponentially attenuated by the distance it traveled d, the wave frequency f, and the tissue's absorption properties α. The exponential term e^* in Eq. (1) indicates that signal intensity inherently drops with depth and tissue density. This physical limitation causes the brightness instability that standard CNNs fail to handle. To specifically counteract this non-linear attenuation described in Eq. (1), we introduce the gated local contrast normalization (Gated LCN) module to dynamically re-calibrate the feature intensity.

Some of the currently popular medical image segmentation frameworks, such as UNet, struggle to track objects with complex or soft regions in ultrasound images due to the limitations of the receptive field of the convolutional neural network [11]. To tackle this problem, deformable convolutional networks (DCN) [12] lie in that the sampling points of its convolutional kernels are learnable and can adaptively adjust the sampling position and shape according to the input features. Previous literature [13] has demonstrated that integrating DCN into image segmentation networks can improve the effect of organ segmentation. However, none of their studies focused on the changes in the brightness of ultrasound images. Our SPA-DCN-NET resolves the challenge of chaotic brightness instability and non-rigid geometric deformation in a unified, learnable framework. SPA-DCN-NET introduces a cooperative adaptive mechanism, uses Gated LCN as a dynamic valve to adjust the contrast, and guides the spatial pyramid attention-driven deformable convolution to adjust the sampling mesh. This end-to-end loop realizes the joint optimization of light steady-state and geometric accuracy, thereby achieving more precise segmentation under complex artifacts.

In this study, the spatial pyramid was applied to address the CNN model's reliance on a fixed input size while enhancing the model's scale invariance. In [14] the spatial pyramid attention (SPA) module can be directly placed in the backbone network and enhances the performance of the entire network. During the research, we found that directly placing LCN in front of SPA, although it can alleviate the problem of unstable image brightness, may overly suppress the information crucial for segmentation in the original features, leading to a decline in the algorithm's performance on normal datasets. In order to solve this problem, we introduce a learnable gated mechanism to regulate the influence of LCN features on the SPA module.

MobileNetV3 [15] is an efficient, lightweight network that is smaller than EfficientNet [16]. Since our decoder includes SPA, Gated LCN, and DCN, using MobileNet can save resources for the overall operation of the framework. Furthermore, we have simple concatenation between symmetrical stages of the encoder/decoder, a structure that enables effective pixel-based training in limited medical data [17]. Inspired by the work of [18], we proposed a model specifically designed for abdominal ultrasound scanning called SPA-DCN-NET, which integrates deformable convolutional networks (DCN) and integrates the gate control brightness function for SPA modules. Spatial pyramid pooling (SPP) overcomes the limitation of fixed input image size in convolutional neural networks, realizes multi-scale feature extraction, and improves computational efficiency [14]. Attention mechanism dynamically focuses on spatial and feature channels that are more important for the current task [19].

The study proposes SPA-DCN-NET, a lightweight and efficient end-to-end architecture that includes MobileNet and the GatedLCN-SPA-DCN module, specifically designed to address the issues of unstable brightness and low contrast. Our core innovations and contributions are structured as follows:

Proposal of learnable gated local contrast normalization (Gated LCN). To tackle the unstable brightness and contrast in ultrasound images, we designed a novel gating mechanism based on sigmoid soft gates. This mechanism dynamically fuses the contrast-enhanced features from local contrast normalization with the original features, effectively stabilizing image quality and yielding high-quality feature maps.

1) Improvement of the spatial pyramid attention module. To avoid the loss of spatial details typically caused by global average pooling in conventional attention mechanisms, we construct the improved SPA module using multi-scale dilated convolution. This preserves high-resolution contextual information. Combined with the refined features output by Gated LCN, the attention can be more accurately focused on low-contrast areas, such as the liver boundary, significantly enhancing segmentation quality.

2) Construction of the lightweight and efficient MobileNet + GatedLCN-SPA-DCN architecture. We adopt MobileNetV3 as the encoder and deeply integrate the joint GatedLCN-SPA-DCN module into the decoder. This architecture achieves a superior balance between efficiency and accuracy, significantly outperforming mainstream segmentation models, which makes it robust, accurate, and highly suitable for clinical deployment.

In summary, the SPA-DCN-NET achieves innovation not only at the module level but also provides an efficient, robust, and accurate end-to-end system-level solution for medical ultrasound image segmentation.

II. Related Works

A. Encoder-Decoder Structure and Skip Connection

Our SPA-DCN-NET is based on the encoder-decoder architecture. This structure is designed to effectively capture the contextual information of the image while precisely locating the target boundaries. The encoder, similar to a seq-to-seq function [20], compresses variable input data into a dense feature sequence. The decoder then performs upsampling operations, typically doubling the feature map size at each layer until the original image resolution is reached. Finally, a

1*1 convolution kernel adjusts the channel number to the required number of categories, followed by the softmax function to generate the final probability map. In the classic UNet structure, skip connections are employed between corresponding layers of the encoder and decoder. While some UNet-like architectures, such as ResUNet [21] and nnUNet, have achieved success by deepening networks or optimizing heuristics, they fundamentally operate as static, linear pipelines. They process images with stable brightness parameters. However, in a clinical ultrasound setting, artifacts such as acoustic shadowing and TGC variation cause dynamic brightness instability [2]. Existing encoder-decoder frameworks lack a dynamic adaptation mechanism to recalibrate feature intensity on-the-fly, often leading to boundary prediction errors in low-contrast regions. We have effectively solved this problem by using a dynamic gating mechanism. This mechanism allows the decoder to collect as much fine-grained spatial information as possible.

B. Lightweight and Efficient Backbone Network

The encoder-decoder architecture offers flexibility in selecting the backbone network for the encoder position. Options include efficient and lightweight networks like MobileNet, ShuffleNet, EfficientNet, and GhostNet, or resource-dependent networks such as ResNet, VGG, and DenseNet. We utilize MobileNetV3 due to its efficiency, and from its use of 1*1 convolutions, which are more resource-friendly than UNet's typical 3*3 convolutions. MobileNetV3 inherently supports multi-layer feature extraction, providing feature maps of different resolutions that can naturally serve as the input for the skip connection at each level of the decoder.

C. Spatial Pyramid Attention Network

The spatial pyramid block is crucial in deep learning for handling multi-scale information and addressing the challenge of unfixed input size. Spatial pyramid pooling (SPP) [14] changes the receptive field by altering the size of the pooling grid. Atrous spatial pyramid pooling (ASPP) [22] achieves this by modifying the dilation rate. Traditional attention mechanisms, such as Squeeze-and-Excitation networks (SENet) [19], typically rely on global average pooling (GAP) to compress 3D feature maps into 1D channel vectors to obtain channel dependencies. However, this method risks losing important spatial structure information. The spatial pyramid attention module is specifically designed to overcome this limitation by combining structural information retention and structural regularization. When calculating attention weights, it not only focuses on feature channels but also utilizes the spatial structure information within the feature map. Related papers include the SPANet, the SPAN [23], the SAPNet [24], and the MSPANet [25]. While SPANET and MSPANET integrate channel attention, and SPAN and SAPNET integrate spatial self-attention, the attention formulation in all four shares the common starting point of applying the traditional GAP. GAP compresses the entire spatial dimension into a single value. Although this helps prevent overfitting, it seriously compromises spatial structure information, especially with large feature maps.

Gou et al. in [14] replace GAP with a spatial pyramid structure, integrating multi-scale feature extraction, structural information retention, and long-distance channel dependence modeling into a unified module. In [24], task-specific guiding information, such as the classification confidence graph or the segmentation prediction graph, is introduced to generate spatial attention masks. This mask dynamically assigns weights to the feature maps of each scale in the pyramid, allowing the network to focus on the regions and scales most discriminative for the current task. The self-attention blocks of each layer in [23] utilize different dilation rates. This enables each pixel at the top layer to perceive a very large area at the bottom layer. Furthermore, positional projection is introduced to better encode the relative spatial positions of neighboring pixels.

D. Local Contrast Normalization

The idea of local contrast normalization was proposed in [27]. Deep learning variants of LCN [26] aim to address the issue of insufficient robustness caused by fixed LCN parameters, making them suitable for solving illumination and gain adaptation problems in ultrasound images. In [28], a universal local context normalization layer was proposed, which can be inserted into the learnable modules of modern deep networks. In [26], subtraction-type LCN and division-type LCN were proposed, both capable of eliminating low-frequency illumination variations.

E. Gating Mechanism

LCN can enhance the model's robustness on datasets with significant light and shadow variations, but it may sacrifice accuracy on normal datasets. Gated LCN enables the network to adapt to switch between the robustness of LCN and the accuracy of the original feature. Attention gate and dilation U-shaped network (GDUNet) proposed by Chen et al. [29] is an outstanding representative of this idea, introducing lightweight attention gates (AG) in the UNet skip connections. The AG module effectively filters out low-level semantic noise in the spatial and channel dimensions, thereby attenuating irrelevant features. Zeng et al. proposed a deeply supervised attention-gated V-Net (DAG V-Net) for automatic fetal head circumference measurement [30]. This model integrates the attention gating module into the 2D V-Net architecture to optimize skip connections. Schlemper et al. applied the AG model to standard section detection in fetal ultrasound, constructing Ag-Sononet [31]. This model applies an attention gate to the deep feature map of Sononet (a VGG variant) to generate an attention map. These attention maps are used to guide the final classification decision via adaptive feature pooling and can be directly applied to weakly supervised target localization.

Although LCN effectively alleviated the unevenness of light exposure, overuse of LCN can also have significant side effects. It weakens the texture details in images, reducing segmentation accuracy in normal scenarios. Among the existing medical segmentation methods, once the network parameters are fixed, it is difficult to ensure that the data with uneven brightness will have a stable segmentation accuracy rate. In contrast, our proposed Gated LCN acts as a learnable valve. Unlike standard attention gates that focus on spatial regions, our gating mechanism generates the weights (0 to 1) using the sigmoid function. The network can then

automatically learn to suppress background noise, ensuring the network only activates normalization when necessary.

F. Deformable Convolution

To compensate for the inherent limitations of ordinary convolution in the receptive field, Dai et al. proposed deformable convnets (DCNv1) [13]. By introducing learnable offsets in the standard convolution and ROI pooling modules, the network can adaptively adjust its sampling position according to the input content. To further explore the potential of deformable convolution, Zhu et al. proposed deformable convnets v2 (DCNv2) [32]. DCNv2 includes an additional modulation mechanism compared to DCNv1, based on the learnable offset. A learnable modulation scalar is introduced for each sampling point to dynamically adjust the characteristic amplitude of that sampling point. This enables the network to simultaneously consider the location and weight of the sampling points. Our approach couples the SPA with DCN. By feeding DCN with features that are already structurally emphasized by SPA, we ensure that the geometric deformation is guided by meaningful semantic context rather than noise.

G. Summary of Research Gap and Our Contribution

In summary, existing works predominantly address the challenges of segmentation through either deeper static architectures (e.g., ResUNet) or standalone modules (e.g., standard DCN or LCN). The critical limitation in the current literature is that this work did not integrate these functions together. Traditional linear pipelines fail to adapt when both situations occur simultaneously—a common scenario in handheld ultrasound due to probe pressure and gain shifts. SPA-DCN-NET does not merely apply these techniques in isolation but links them sequentially. The Gated LCN stabilizes brightness to allow the SPA to correctly focus attention, which in turn guides the DCN to deform accurately. This integrated design can better adapt to the actual medical setting of ultrasound segmentation.

III. Methodology

A. Functional Mechanisms of SPA-DCN-NET vs. Baselines

We selected three common medical image segmentation networks, namely UNet, nnUnet, and ResUNet. These models perform well on general medical images, but none of them can solve the problem of uneven illumination and simultaneous geometric deformation in ultrasound images. Unlike these benchmark models, our SPA-DCN-NET introduces a dynamic cooperative loop to achieve synchronous adaptive adjustment of brightness and shape. The functional differences between our SPA-DCN-NET and three other common medical image segmentation networks are summarized in Table I.

TABLE I. A Function Comparison of the Core Differences of SPA-DCN-NET and Other 3 Popular Medical Segmentation Networks

	Standard UNet	**ResUNet**	**nnUNet**	**SPA-DCN-NET (Ours)**
Process Flow	Linear. Input → Conv → Output	Linear. ResBlock → Deep Features	Linear. Adaptive Preprocessing → UNet	Synergistic. Gating LCN↔ Spatial Attention ↔ Deformable Shape
Illumination Adaptation	Static. Rely on fixed input preprocessing or data augmentation.	Static. Features are extracted relying on residual connections, without a specific lighting adaptation module.	Static. Fixed normalization based on the statistics of the entire dataset.	Dynamic Gating. Pixel-by-pixel trade-off between original features and normalized features, adaptively resisting local brightness changes.
Geometric Deformation	Fixed grid Standard 3×3 convolution with a fixed receptive field shape.	Fixed Grid. Although there are residual connections to deepen the network, the geometry of the convolutional kernels cannot be changed.	Fixed Grid. The standard UNet architecture relies on data augmentation to handle deformation.	Adaptive Shape. DCN v2 dynamically adjusts the Offset of the convolution kernel sampling points based on the features extracted by SPA to precisely fit the irregular liver boundary.
Feature Focus	Hard coding, Simple concatenation relying on Skip Connection.	Implicit. Features are implicitly learned through deep networks without explicit attention.	None. Regression to pure convolution.	Multi-scale Attention. The SPA module utilizes dilated convolution to capture multi-scale contexts and explicitly guides the DCN to focus on the lesion area.
Ultrasound Specificity	Weak. General model, sensitive to noise.	Medium. The residual structure alleviates vanishing gradients but does not solve artifacts.	Medium. Depending on the amount of data, there is no specific design for specific ultrasonic artifacts.	Strong. Specifically designed for ultrasonic Speckle noise and Probe Pressure deformation.

B. Network Overview

The SPA-DCN-NET framework is built upon the principles of the encoder-decoder architecture, utilizing progressive downsampling and upsampling for robust segmentation. We employ MobileNetV3-Small as the downsampling backbone, a choice driven by its high computational efficiency and low latency, making it highly suitable for real-time clinical ultrasound scenarios. The network's initial layer is modified to seamlessly accept a single-channel input. The inherent layer-by-layer downsampling of the MobileNetV3 backbone naturally generates multi-resolution feature maps at scales H/2, H/4, H/8, H/16, and H/32. These multi-level features are captured to establish skip connections with the decoder, a design that perfectly embodies the core mechanism of the UNet design. In the decoder section, upsampling operations are performed, and at each corresponding layer, the Gated LCN block, the SPA block, and DCN are cascaded and jointly construct the EnhancedDeformConv block. The complete

structural flowchart of the proposed SPA-DCN-NET is illustrated in Fig. 1.

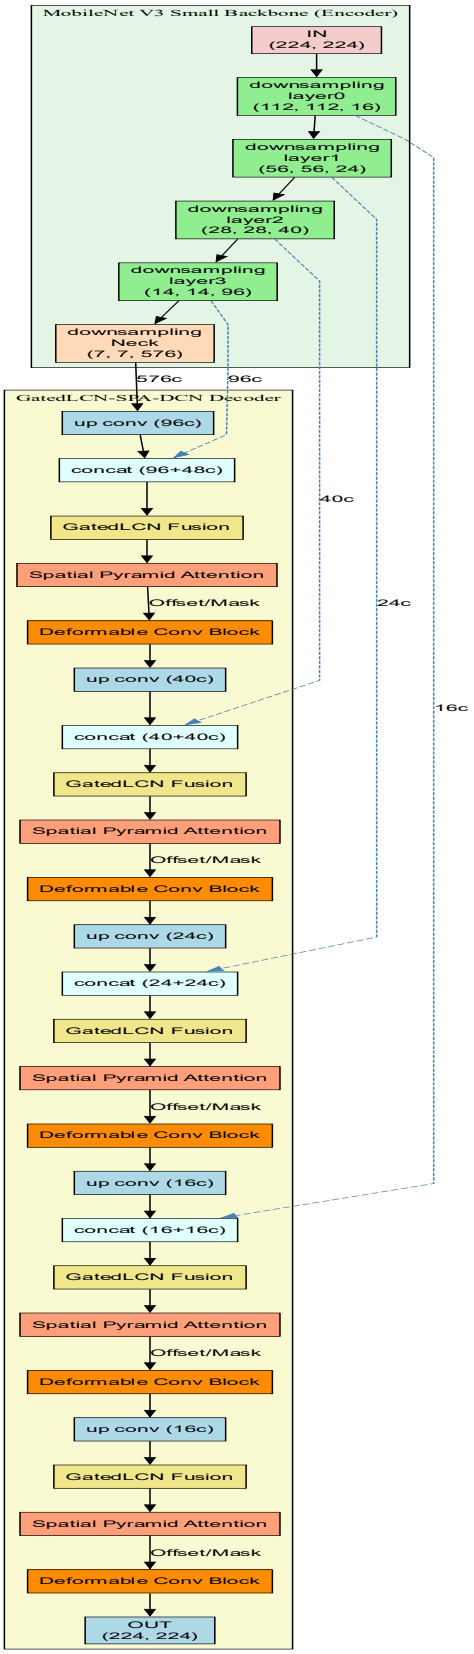

Fig. 1. The complete structural flowchart of the proposed SPA-DCN-NET.

C. Encoder and Decoder

To adapt to single-channel medical images, the weights of the first layer convolutional kernels are specially initialized. From the encoder's features module, we precisely captured the intermediate feature maps of five key layers for subsequent skip connections. These feature maps are downsampled step-by-step in space, and the number of channel counts is increased to 16, 24, 40, 48, 96, forming a pyramid-shaped feature representation from detail to semantics. The decoder consists of a total of five upsampling stages, gradually restoring the feature map from H/32 to H. In the final stage, since the highest resolution has been reached, no new skip connections are introduced. Only the EnhancedDeformConvBlock is used for the final refinement of the features. Ultimately, a 1x1 convolutional layer maps the number of channels of the refined feature map to the number of categories (such as background and liver), outputs the logits of each pixel belonging to each category, and completes the segmentation task. Through this encoder-decoder collaboration, skip connection fusion, and SPA-DCN adaptive refinement design, the model can achieve high-precision segmentation of complex deformed livers while maintaining high efficiency. The concatenated feature maps are sent to the EnhancedDeformConvBlock for processing. This is the core innovative module of this model, which seamlessly integrates spatial pyramid attention (SPA) with deformable convolution (DCN). First, the module applies gated local contrast normalization (Gated LCN Fusion) to the input features. This module adaptively performs dynamic weighted fusion between the illumination robustness of LCN-enhanced features and the accuracy of the original features through the sigmoid soft gate. This enables the model to resist the complex light and shadow changes commonly found in ultrasound images and stabilize the feature representation. The SPA module conducts multi-scale analysis on the input features to generate an attention weight map, highlighting the spatial regions that are more important for the liver segmentation task. The DCN module utilizes the features enhanced by SPA to predict offsets and modulation_masks, and then performs deformable convolution on the original concatenated features. This enables the sampling mesh of the convolutional kernel to adaptively adjust according to the shape of the liver, thereby more accurately capturing its irregular boundaries.

D. Soft Gated Local Contrast Normalization Layer

The mathematical form of local contrast normalization is:

$$LCN(x) = \frac{x - \mu_{local}}{\sigma_{local} + \varepsilon} \tag{2}$$

In Eq. (2), μ_{local} is the local mean, σ_{local} is the local standard deviation. The step of subtracting the local mean μ_{local} is equivalent to removing the local low-frequency component from the original signal. Retain high-frequency information such as edges, textures, and details that change rapidly, and suppress the low-frequency background in smooth areas. This is consistent with the effect of high-pass filtering. Therefore, LCN(x) mainly retains structures with strong local contrast, such as boundaries, spots, and textures, which belong to high-frequency components in the frequency domain. The original

feature x contains complete spectral information, but it is mainly low-frequency. The schematic diagram of Gated LCN is shown in Fig. 2. We use the sigmoid soft gate to achieve dynamic scaling and modulation of LCN features through element-wise multiplication. There are two independent sigmoid gateways, one is based on X_LCN, the other one is based on X, and they form a pair of approximately complementary soft gates in a $1.0-\sigma$ manner, thereby allowing the network to perform adaptive, channel-by-channel or spatially position-by-space weighted fusion between the robustness of LCN and the detail accuracy of X. Here we have employed sigmoid soft gate technology. The sigmoid soft gate does not have a fully open (1.0) or fully closed (0.0) state. The sigmoid soft gate achieves dynamic scaling and modulation of LCN features through element-wise multiplication. The dynamic fusion process is mathematically formulated in Eq. (3):

$$Output = G_{LCN} \odot \mathrm{X}_{\mathrm{LCN}} + G_{identity} \odot \mathrm{X} \tag{3}$$

where, $\odot$ denotes element-wise multiplication, and the complementary gate is defined as $G_{identity} = 1.0 - Sigmoid(Conv_{1*1}(X))$.

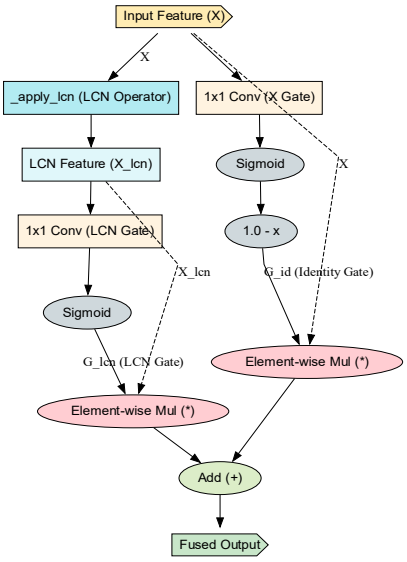

Fig. 2. Data flow in local contrast normalization block. The network adaptively learns the optimal fusion ratio between LCN-enhanced and original features at each spatial position, driven by local contrast and texture information.

As described in Eq. (3), this equation functions as a dynamic arbitration mechanism. When the network detects significant brightness instability or high-frequency noise (typical of acoustic attenuation), the learnable weight G_{LCN} tends towards 1. In this scenario, Eq. (3) prioritizes the normalized features X_{LCN} to ensure model robustness. Conversely, in regions with high signal-to-noise ratios, $G_{identity}$ allows the original feature stream X to pass through to preserve fine anatomical textures. Thus, Eq. (3) effectively prevents the over-normalization problem by selectively activating LCN only where necessary.

E. Spatial Pyramid Attention Block

Spatial pyramid attention was explicitly proposed in the papers [14], [22], [23], [24]. We mainly referred to [14], however, our SPA module did not use the pooling layer. Instead, multi-scale features are captured through dilated convolution layers with different dilation rates. As shown in Fig. 3, dilated convolution is used instead of adaptive average pooling because it expands the receptive field without losing resolution. It still performs convolution operations on each spatial position, thereby being able to capture fine spatial details. Although adaptive average pooling can extract multi-scale information, it is essentially a downsampling operation. During the pooling process, a large amount of spatial detail information is lost.

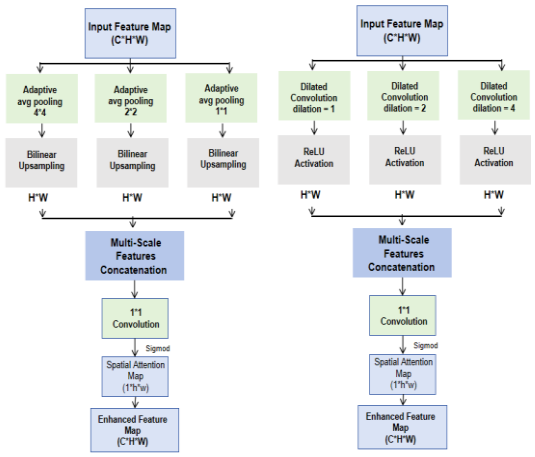

Fig. 3. The structure of our spatial pyramid attention. The pooling layer from [14] (left) are replaced by dilated convolution layer (right).

F. Modulation Convolution

Modulation convolution is mainly used to generate modulation masks, providing an additional intelligent weighting mechanism for deformable convolutional networks (DCN). The modulation mechanism assigns a learnable weight to each adaptive sampling point. It receives features enhanced by SPA as input, and a convolutional layer followed by a sigmoid function is applied to compress the output value to the range of [0, 1], forming a modulation mask. When DeformConv2d is executed, it multiplies the sampled features element by element by the corresponding modulation weights. The feature contribution of this sampling point is high when the weight is close to 1. When the weight approaches 0, the feature contribution of this sampling point is suppressed. Modulation convolution enables DCN not only to adaptively select the sampling position, but also to adaptively determine the importance of each sampling point.

G. Deformable Convolution Implementation

The deformable convolution (DCN) is strategically placed in the decoder's upsampling path, where it takes input from the combined encoder skip connection and the decoder's upsampled feature map. Its core role is to employ adaptive sampling to precisely capture and restore fine target shape details as the feature map resolution grows, thereby enhancing final segmentation accuracy. This adaptability relies on a specialized convolutional layer that learns the necessary spatial

shifts for every sampling point throughout the training process. In the forward propagation, these predicted shifts are used in the DCN calculation. The resulting prediction is measured against the ground truth mask to quantify the loss. During back propagation, the loss signal propagates backward, updating all layer weights. If a specific shift leads to reduced loss, the weights responsible for generating that shift are reinforced. Through iterative training, the prediction layer learns precise spatial adjustments to features, which minimizes segmentation error and accurately refines object boundaries (see Fig. 4).

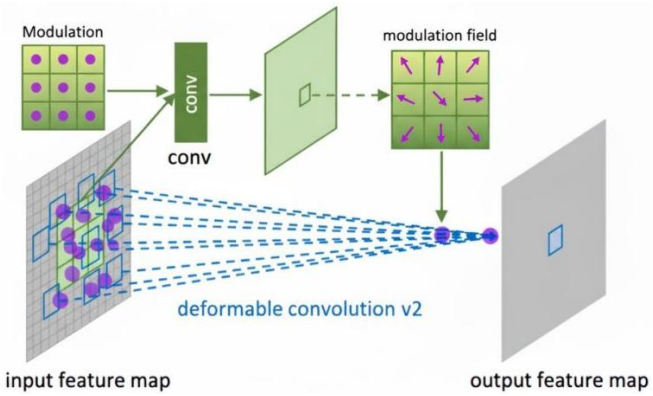

Fig. 4. The working mechanism of deformable convolution v2. By learning offset and modulation fields from the input, it enables the kernel to achieve position and amplitude adaptation. The offsets (blue box) adjust sampling points to focus on target boundaries, while modulation values determine feature importance for dynamic weighting. This allows DCNv2 to precisely capture the shape and details of complex targets.

H. The Combination of Spatial Pyramid Attention and Deformable Convolution Module

The mathematical expression of the standard convolution is:

$$y(p_0) = \sum_{p_n \in \mathrm{R}} w(p_n) \cdot x(p_0 + p_n) \tag{4}$$

In Eq. (4), R is the sampling mesh of the convolution kernel, w is the weight, and p_0 is the position on the output feature map.

Deformable convolution, based on standard convolution, adds a learnable offset $\Delta \mathrm{p}_\mathrm{n}$ and a modulation scalar m_n to each sampling point p_n. Since $p_0 + p_n + \Delta p_n$ is usually a fractional coordinate, it is calculated through bilinear interpolation:

$$y_{DCN}(p_0) = \sum_{p_n \in R} w(p_n) \cdot x_{SPA}(p_0 + p_n + \Delta p_n) \cdot m_n \tag{5}$$

where, Eq. (5) is the output of deformable convolution. $p = p_0 + p_n + \Delta p_n$ is the fraction position of grids.

$$x_{SPA}(p) = \sum_q G(q, p) \cdot x_{SPA}(q) \tag{6}$$

In Eq. (6), q represents all integer positions on the feature map, while $G(\cdot,\cdot)$ is the bilinear interpolation kernel. The final EnhancedDeformConvBlock output y in Eq. (7) is obtained through deformable convolution, batch normalization, and the ReLU activation function:

$$y = relu(batch_norm(y_{DCN})) \tag{7}$$

Fig. 5 illustrates the data flow in the whole combination of spatial pyramid attention and deformable convolution module.

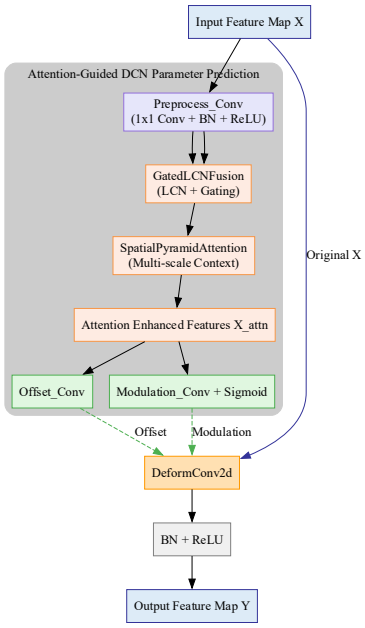

Fig. 5. Schematic diagram of the combination of spatial pyramid attention and deformable convolution module.

I. Loss Function and Optimizer

To effectively train the MobileNet + GatedLCN-SPA-DCN architecture, we utilize the Cross Entropy Loss function paired with the Adam optimizer. The loss function is chosen specifically to combat the class imbalance problem in medical segmentation, where background pixels vastly outnumber target pixels. By supplying a weight vector class_weights_tensor as a parameter, the function applies a higher penalty to misclassified minority pixels, thus forcing the network to focus intently on accurate boundary delineation and shape identification of the target. This weighted approach is critical for enhancing segmentation accuracy on the target region and improving metrics like the Dice Score. The Adam optimizer [33] is employed to minimize this loss. Adam adapts the learning rate for each parameter by combining the benefits of momentum and RMSProp, which leads to faster and more stable convergence when navigating the complex, non-convex optimization landscape inherent in medical image segmentation. The optimization process is initiated with a standard initial learning rate of 0.001, ensuring the model achieves robust performance on clinically relevant structures while improving overall pixel accuracy.

IV. Experiment

A. Datasets

Our experiment obtained three public datasets and one abdominal ultrasound dataset of our own. These datasets are:

- The Open Kidney Ultrasound Dataset. We took 120 of them as the training set, 20 as the validation set and 11 as the test set. https://github.com/rsingla92/kidneyUS/blob/main/README.md
- US simulation and segmentation Dataset .We took 287 of them as the training set, 14 as the validation set, and 44 as the test set. https://www.kaggle.com/datasets/ignaciorlando/ussimandsegm?select=abdominal_US
- Xu's Annotated Ultrasound Liver images Dataset. We took 487 of them as the training set, 68 as the validation set, and 190 as the test set. https://www.kaggle.com/datasets/orvile/annotated-ultrasound-liver-images-dataset
- The experimental team's own dataset. We took 833 images as the training set, 168 images as the validation set, and 64 images as the test set. The information of the datasets is shown in Table II.

TABLE II. THE INFORMATION OF THE DATASETS CONTAINED IN OUR EXPERIMENT

Dataset	Training images	Validation images	Test images	Resolution
Open Kidney	120	20	11	multiple
US simulation	287	14	44	640*480
Xu's	487	68	190	multiple
private data	833	168	64	multiple

B. Results

The following are the training and validation results of datasets on four different models. They are nnUNet, ResUNet, UNet, and our SPA-DCN-NET. The handheld probe (type: CPL) from Guangdong SonoStar in China was used to collect our private data, with a harmonic of 5.0Mhz and a focusing depth of 60mm. We labeled the liver regions of all datasets with LABELME 5.5 for 2-classification. A mixed dataset included the above three public datasets and our private dataset. There were a total of 1727 images as the training set. We use two schemes for training. First, we apply the dataset for each algorithm respectively (Table III). Second, we mix each training set, the compound weighted file is applied to each test set, and the calculated mean IoU in each dataset (see Table IV). The parameters of the training are as follows: batch_size = 4, num_epochs = 200, learning_rate = 0.001. The training loss curve is illustrated in Fig. 6. We use an INTEL G6405 with 32GB of RAM, Windows 10, and an NVIDIA M40 with 24GB RAM. The test results of the four models on the four datasets are as follows. In Scheme 1, independent training set, the SPA-DCN-NET model is stronger than all others (see Table III). In Scheme 2, integrated training set, SPA-DCN-NET is stronger in three tests (see Table IV). The results are shown in the tables.

From the data, we can see that our model has a good feature extraction ability for ultrasound images. Gated LCN makes the model more adaptable to ultrasound examination scenarios with unstable brightness. However, if the training data is too simple, such as the Open Kidney dataset, the model may only learn a fixed pattern, for example, always closing the LCN gate, thereby losing the ability to adapt dynamically. Therefore, to enable the gate control to learn when to switch, a certain degree of diversity of data is required. Fig. 7 provides a sample comparison of liver segmentation results in ultrasound between our SPA-DCN-NET and UNet/ResUNet/nnUNet in Scheme 2.

In the experiment, we evaluated the training data using several image brightness metrics, which are as follows: 1) Overall Uniformity Ratio U_1, 2) General Uniformity Ratio U_0, 3) Coefficient of Variation CV , 4) The average brightness/pixel value of the image E_{avg}. The IoU results of different segmentation algorithms and other metrics are presented in Table V. The samples of experimental results show that UNet/nnUNet/ResUNet is sensitive to noise and recognizes it as an organ boundary. When the E_{avg} is low (dark image), neurons cannot be activated, while our SPA-DCN-NET is still available. The effectiveness analysis results are shown in Table VI.

TABLE VI. THE EFFECTIVENESS ANALYSIS OF SPA-DCN-NET

Characteristics	UNet / nnUNet / resUNet	SPA-DCN-NET	Comparison of results
Response to high CV (noise)	Sensitive. Misjudge the noise as the boundary.	Robust. Suppress the high-frequency noise area through the gating mechanism.	When gan_a1.png (CV=1.19) was present, the IoU gap was huge (0.14 vs 0.65).
Response to low Eavg (dark image)	Sensitive. The feature activation value is too low to activate neurons.	Robust. Local normalization focuses on relative contrast rather than absolute brightness.	SPA-DCN-NET can still maintain a relatively high segmentation accuracy in the dark image.

C. Ablation Experiment

We attempted four combinations: LCN, without LCN (SPA-DCN only), LCN before SPA followed by DCN input (LCNSPA-DCN), LCN after SPA followed by DCN input (SPA-LCNDCN), and gated LCN before SPA followed by DCN input (Gated LCNSPA-DCN). The gated LCNSPA-DCN performs best on the GAN dataset and our private dataset. The comparison result of IoU is shown in Table VII.

TABLE VII. ABLATION EXPERIMENT COMPARISON RESULT OF IOU ON SCHEME 2

	Open Kidney	US simulation	Xu's	Private data
SPA-DCN only	0.8282	0.7643	**0.7797**	0.8701
LCNSPA-DCN	**0.8338**	0.7646	0.7635	0.8517
SPA-LCNDCN	0.8316	0.7683	0.7613	0.8567
GATED LCNSPA-DCN	0.8203	**0.7852**	0.7710	**0.8714**

D. Analysis

We tested the performance of SPA-DCN-NET on four different sources of ultrasound liver datasets. SPA-DCN-NET demonstrated superior segmentation performance compared to well-known models (UNet, ResUNet, nnUNet) under two training strategies. Especially in the independent training Scheme (Scheme 1), the mean IoU of SPA-DCN-NET on all four datasets reached the highest value (83.52%, 75.57%, 73.85%, and 85.94% respectively), indicating that it has good generalization ability and adaptability to different data distributions. The introduction of the gated local contrast normalization (Gated LCN) mechanism significantly enhances the robustness of the model against interference factors such as unstable brightness, low contrast, and speckle noise in ultrasound images. Especially in Scheme 2, when the model was trained on mixed data and applied to each independent test set, SPA-DCN-NET significantly outperformed other models in mean IoU on the US simulation, Xu's and our private dataset. This indicates that the gating mechanism has successfully achieved a dynamic balance between LCN-enhanced robustness and detail retention of original features.

However, when the training data is less diverse and the number of images is small (such as the Open Kidney dataset), the gating mechanism may degenerate into a fixed pattern, for example, always closing the LCN branch, thereby losing its adaptive adjustment ability. This also explains why the performance of SPA-DCN-NET on Open Kidney (82.03%) is slightly lower than that of nnUNet (82.43%) in training Scheme 2. This indicates that the effectiveness of the gating mechanism depends on the diversity of the training data. Only on data with rich illumination, contrast, and deformation changes can the model truly learn when to enable LCN. Through four combinations of ablation experiments (no LCN, LCN pre-placement, LCN post-placement, Gated LCN pre-placement), the results showed that the Gated LCNSPA-DCN combination performed best on most datasets, especially on private datasets and US simulation datasets. This verifies the effectiveness of the design of introducing a Gated LCN in front of the SPA module. It not only retains the multi-scale attention's focusing ability on key areas but also enhances the stability of features in response to illumination changes through the LCN.

V. DISCUSSION

Although gated local contrast normalization has significant advantages in improving the model's robustness to the luminance instability and low contrast of ultrasound images, its introduction also brings several potential problems, mainly reflected in the following three aspects:

1) Dependency on training data diversity. The generalization ability and effectiveness of the gating mechanism are highly dependent on the training data's diversity in terms of illumination contrast and noise patterns. As shown in the experiments in the text, on the single Open Kidney dataset, the model tends to learn a fixed gating strategy, resulting in always closing the LCN branch, thereby losing its dynamic adaptability. This means that if the training set lacks a sufficiently diverse range of luminance variation samples, the gating mechanism may degenerate into a redundant module, or even be inferior to standard LCN or direct input of original features.

2) Increase the model complexity and training of instability. Gated LCN introduces additional learning parameters, such as two 1 x 1 convolution layer + sigmoid gating, and with the use of SPA, DCN cascade, a significant increase in the computational workload, especially in the superficial layer in MobileNetV3, deploying the module will lead to burst or vanishing gradients and overfitting. Furthermore, the training process exhibits oscillations or slow convergence.

3) Although the coupling mode of SPA and DCN enhances the perception ability of multi-scale context, its separation of guidance and execution design may lead to the misalignment of the focus area of attention with the actual sampling points, especially in high-noise areas, which are prone to misclassification. Secondly, although MobileNetV3 is adopted as the lightweight backbone, the computation of the SPA and DCN modules is relatively high. If deployed across all layers, it is prone to cause unstable training. Therefore, enabling this module only in deep, semantically rich regions reflects a fine trade-off between efficiency and accuracy. In the future, lightweight SPA structures can be explored, such as introducing depth-separable convolution, to achieve wider deployment. Finally, the currently adopted cross-entropy loss function has limitations in scenarios with severe category imbalance. In the early stage of the model, it is easily dominated by background pixels and converges slowly. Although SPA indirectly alleviates this problem, the introduction of Loss functions that are more suitable for medical segmentation, such as Generalized Dice Loss, may further improve the performance of small target segmentation.

VI. Conclusion

This study successfully addressed a critical challenge in medical image analysis by introducing SPA-DCN-NET, a novel framework designed to overcome the brightness instability and non-rigid geometric deformation in the segmentation of ultrasound images. Our main theoretical contribution is the proposed synergistic adaptation mechanism. We combine gated local contrast normalization, spatial pyramid attention, and a deformable convolutional network together, establishing an innovative, end-to-end learnable loop wherein illumination and geometry mutually inform one another. This enhances the robustness of traditional segmentation algorithms against brightness variations and geometric deformation. In the experimental results, our SPA-DCN-NET performance surpassed benchmark models such as UNet, nnUNet and ResUNet on four different datasets, especially on the private datasets. It achieved an average IoU as high as 85.94%, demonstrating its potential in real-world applications. However, this study mainly focuses on binary segmentation of the liver; the multi-category recognition of blood vessels and lesions still needs to be explored. Future research will aim to adapt the architecture for multi-organ and multi-lesion segmentation tasks. Further optimizing its computational efficiency to adapt to real-time, portable ultrasound diagnosis, thereby enhancing its clinical practicality.

Acknowledgment

We gratefully acknowledge Sonostar Ltd., ShenZhen, China. Without their equipment and technical support, the experiment cannot carry on. Thanks to Prof. Afizan, who offered valuable suggestions for the study. And all my families, they supported me behind my back.

Sistem Informasi, STMIK PKKIA Pradnya Paramiata, Malang, Indonesia[2]

***Abstract*—Plant diseases pose a serious threat to agricultural productivity, which can cause significant crop losses if not addressed quickly and appropriately. There are significant opportunities for digital image-based treatment with computer vision and artificial intelligence. The main challenges in recognizing image-based plant diseases are: developing a single model capable of diagnosing diseases in various types of plants. Ensuring the model remains reliable even when images are taken under varying lighting conditions, backgrounds, and camera quality. In addition, the challenge in this study is to present a model capable of recognizing leaf diseases of multiple food crops, especially rice and corn. The purpose of this study is to identify leaf diseases of rice and corn crops. This study proposes deep learning and transfer learning for diagnosing plant leaf diseases in various types of plants and unstructured imaging environments. To address these challenges, a selection of VGGNet, ResNet50, InceptionV3, and EfficientNetB0 methods was conducted by testing them using laboratory datasets. Based on the testing, the EfficientNetB0 model performed the best. Then, the selected model parameters were tuned, feature extraction and a new dataset was collected in a real-world domain with varying lighting, changing viewpoints and scales, complex backgrounds, similar symptoms between diseases, and occlusion. The results showed that the proposed model performed very well and robustly, with 98% accuracy and a weighted average F1-score of 98% in identifying food crop diseases: blight, rust, blast, blight, tungro, and healthy leaves. This performance indicates that the developed model is highly reliable in classifying leaf diseases in rice and corn. This model is expected to be applied to precision agriculture technology so that farmers can take timely action regarding treatment without further delay.**

***Keywords*—Plant diseases; deep learning; transfer learning; multi-food crops; precision agriculture**

I. Introduction

Global food security is one of the most pressing challenges of the 21st century. Crop diseases pose a significant threat to agricultural productivity, causing significant crop losses if not addressed promptly and appropriately. Traditional diagnostic methods (expert systems) [1] often rely on agronomic expertise, which is time-consuming, expensive, and not always available in remote locations.

Rapid developments in computer vision and deep learning [2][3], particularly in automated image-based plant disease diagnosis have emerged as an attractive alternative [4]. Using cameras on smartphones or drones [5][6], farmers can take pictures of diseased plants and get instant diagnoses. However, training deep learning models from scratch requires a very large dataset of labeled images, which is difficult to obtain for every combination of plant and disease.

Researchers struggling to obtain such a large dataset for multiple crops and diseases can leverage models trained on complex datasets (ImageNet) and adapt their knowledge to detect crop leaf diseases. This is where transfer learning can be used to address the limitations of large datasets. This approach leverages the "knowledge" a model has learned from large-scale image classification tasks (e.g., recognizing thousands of everyday objects from datasets like ImageNet) and applies it to a new task: identifying crop diseases. This drastically reduces the amount of data required and training time, and most importantly, improves model accuracy.

This study will explore how transfer learning can address two major challenges in crop disease diagnosis. [7][8]: Multi-Crop Diversity: developing a single model capable of diagnosing diseases in multiple crop types [9][10]–[12]. Heterogeneous Imaging Environments: Ensures the model remains reliable even when images are taken under different lighting conditions, backgrounds, and camera quality. The existence of a model with these two capabilities will have a significant impact on the field of digital image-based artificial intelligence, particularly for the task of detecting various leaf diseases across multiple food crops.

This study aims to build a diagnostic model that remains reliable and accurate when food crop images are taken under non-ideal (unstructured) or varying conditions, such as variations in lighting, background, and camera quality. These models are expected to contribute to precision agriculture technology, enabling farmers to take timely action to address problems without further delay.

The study is structured as follows: Section II is a literature review relevant to the topic, containing similar published studies on crop disease detection. Section III describes the proposed methodology, including the dataset and the proposed model. The results and discussion are presented, and their performance is compared with previous research in Section IV. Section V concludes the study with successes and future research.

II. Related Work

A. Deep Learning

Deep learning, especially Convolutional Neural Networks (CNNs)[9], [13], [14], has revolutionized the field of image analysis. CNNs are designed to automatically and adaptively learn a hierarchy of features from images, ranging from simple edges and textures to complex shapes and objects. In the agricultural context, CNNs have been successfully applied to a variety of tasks, including weed identification, crop yield estimation, and disease detection.

Models like Inception3 [15], VGG [16], [17], ResNet [18], and EfficientNetB0 have demonstrated advanced performance in a variety of computer vision tasks. This success is driven by their ability to extract relevant features from raw image data without the need for manual feature engineering.

B. Transfer Learning Concept

Transfer learning is a machine learning technique in which a model developed for one task is reused as a starting point for a model for a subsequent task. In computer vision, this can mean reusing a CNN model that has been trained on a large image dataset like ImageNet. The logic is that the early layers of a trained CNN learn to recognize universal features such as edges, corners, color, and texture. These features are also relevant for other tasks, including identifying disease symptoms in plant leaves. Thus, instead of training the entire network from scratch, we can "freeze" these early layers and retrain only the final layers responsible for task-specific classification. This process is called fine-tuning.

The main advantages of transfer learning are: Less Data Requirement: Since the model already has a basic understanding of image features, it requires fewer specific examples of plant diseases to learn. Faster Training Time: Training focuses on only a small part of the network, making the process faster. Better Accuracy: Knowledge transferred from large datasets can help the model to generalize better, especially on small datasets.

C. Heterogeneous Image

While transfer learning is highly effective, its real-world application faces challenges, including: Cross-Crop Generalization: Similar disease symptoms (e.g., yellow spots) can appear on different plants but are caused by different pathogens. Conversely, the same disease can exhibit different symptoms on different plant varieties. The model must be intelligent enough to distinguish between these contexts. Environmental Variability: Images captured in the field vary widely. Factors such as: Lighting: Direct sunlight, shade, or cloudy conditions can change the appearance of the color and texture of symptoms. Background: Soil, other leaves, weeds, or human hands in the background can confuse the model. Image Quality: Different camera resolutions, focus, and shooting angles can affect model performance.

Current research focuses on developing transfer learning-based models that are robust to variation, often using extensive data augmentation techniques and more sophisticated model architectures. This research is expected to contribute to precision agriculture technology, enabling farmers to take timely action regarding treatment without further delay.

III. Methodology

To build a universal plant disease diagnosis system, this study proposes a transfer learning-based framework consisting of several key stages.

A. Dataset

The dataset, constructed during this crucial stage, consists of images showing leaf diseases in food crops, specifically rice and corn. Both are major commodities produced by farmers and are a source of food. The data sources were obtained from independent field data collection, namely rice leaf images and corn leaf images. The cameras used for field photography were smartphone cameras (Redmi Note 12 Pro 5G, 50 MP, and OPPO A9 2020 edition, 48 MP). The dataset also includes images from previous researchers' repositories available on Kaggle.

This study's novelty is its independently collected dataset, which captures diverse conditions in rice plants, including blast, blight, tungro, and healthy states. Meanwhile, for corn plant types, for types of blight, rust, and healthy diseases. Overall, the dataset consists of six classes. In addition to diversity, the dataset is also designed to have heterogeneity. To ensure heterogeneity, images were taken from three locations (Malang City, Malang Regency, and Pasuruan Regency) to simulate real-world use. To obtain images with different lighting levels, images were taken at three different times, namely: 7 am, 10 pm, and 4 pm. In addition to diverse lighting, the dataset was also collected from various image capture angles and images with complex backgrounds. This dataset design is designed to represent real-world conditions. After collection, the images are pre-processed. Data Cleaning: Removing irrelevant or very poor-quality images. Labeling: Each image was accurately labeled by an agronomist. The labeling of disease types involved experts in the field of food crop leaf diseases from BRMP Malang City. However, in this study, the names of food crop leaf diseases (rice and corn) were addressed as the name of the folder where the dataset was stored, not in each image file for each disease type. Resizing: Adjusting the size of all images to the standard dimensions (224 × 224 pixels) required by the CNN model. An example of a food crop image dataset that will be used for experiments on the food crop disease identification task is shown in Fig. 1.

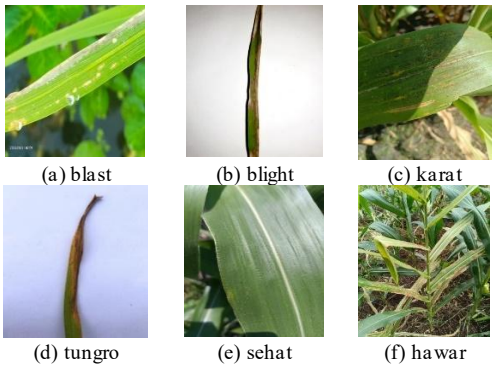

Fig. 1. Example images from the dataset.

Lighting: This dataset design demonstrates good lighting variation. Natural Light (Outdoor): Fig. 1(a), 1(c), 1(e), and 1(f) were taken outdoors in sunlight. There are variations ranging from bright, direct light in Fig. 1(a) to areas with sharp shadows

in Fig. 1(c). Artificial Light (Indoor): Fig. 1(b) and 1(d) were taken indoors against a white background. This creates controlled, even lighting conditions, without shadows. Benefits: This variation trains the model to be independent of specific lighting conditions and can recognize diseases in bright sunlight, shade, and indoors.

Image Angle: There is significant diversity in shooting angles. Close-Up and Oblique: Fig. 1(a), 1(c), and 1(e) show the leaf close-up at a slight angle. Top and Flat Lay: Fig. 1(b) and 1(d) show an isolated leaf photographed straight on from above. Wide Angle: Fig. 1(f) is taken from a greater distance, showing multiple leaves in a single clump. Benefits: The model learns to recognize disease symptoms not just from one perspective, but from multiple angles and distances, much like what users will encounter in the field.

Occlusion and Background Complexity: Backgrounds and the presence of occlusions vary significantly. Simple Background: Fig. 1(b) and 1(d) have a clean, white background free of occlusions, allowing the model to focus entirely on the leaf. Complex Background: Fig. 1(a) has a background of other leaves and a water surface. Fig. 1(f) is the most complex, with overlap between the leaf (significant occlusion), the soil, and other surrounding plants. Benefit: This variation trains the model to distinguish between disease symptoms and visual "noise" in the background. This prevents the model from misidentifying shadows or other leaves as diseased.

Pixels, Resolution, and Scale: While difficult to quantify without the original files, the differences in scale are visually noticeable. Macroscale (Close-up): Fig. 1(e) shows the details of the leaf texture and veins very clearly. Medium-scale: Most of the images show a single leaf or part of it. Microscale (Wide): Fig. 1(f) makes each leaf appear smaller and has lower resolution per leaf. Benefits: The model is flexible in recognizing diseases from both detailed close-up photos and long-distance photos that capture the entire plant.

Disease Types and Regions of Interest (ROIs): This dataset includes a wide variety of diseases with very different manifestations (Regions of Interest / ROIs). Small and Scattered: Blast [Fig. 1(a)] and Rust [Fig. 1(c)] appear as small, scattered spots across the leaf surface. Large & Necrotic: Blight [Fig. 1(b)] and Blight [Fig. 1(f)] cover large areas of the leaf, often causing it to dry out and die. Localized at the Tip: Tungro symptoms [Fig. 1(d)] appear concentrated at the leaf tips. No Symptoms: The Healthy class [Fig. 1(e)] serves as an important comparison with no disease ROIs at all. Benefits: This diversity is the essence of training. The model learns to recognize the unique patterns, shapes, colors, and locations of each disease and distinguish them from healthy leaf conditions.

B. Label Inference Automation

In this study, utilizing a subdirectory structure to represent class names is an efficient methodological design in deep learning projects. Its main advantage lies in the automation of label inference directly by the computational framework, eliminating the need for manual data-label mapping. This design inherently offers a structured and intuitive data organization, which is crucial for scalability and management of large-scale datasets. Thus, this approach not only improves efficiency and reduces the potential for human error but also enhances the reproducibility of experiments in image classification.

C. Pre-processing

To improve the model's robustness to image variations, data augmentation techniques are essential. This involves artificially generating modified versions of the training images. Common techniques include: Random rotation = 20, Horizontal flipping = true, Brightness and contrast changes, Zooming, Shearing, width_shift_range = 0.1, height_shift_range = 0.1, and fill mode is nearest.

Data augmentation effectively increases the size of the dataset [19][20] and helps the model learn to focus less on certain orientations or lighting conditions, thereby improving its ability to generalize.

D. Model Selection

Selecting a pre-trained CNN model is an important initial step. In this study, the selection process for several models was carried out as follows:

1) *VGG16:* VGG16 [16] is a Convolutional Neural Network (CNN) architecture that has 16 layers with trainable weights. This architecture is very uniform and simple. Its structure consists of 13 convolutional layers and 3 fully-connected layers. Its main characteristic is the use of very small convolutional filters, namely 3x3, stacked sequentially. These blocks of convolutional layers are interspersed with five max-pooling layers to reduce the spatial dimensionality. Finally, the three fully-connected layers act as classifiers to determine the final output.

2) *ResNet50:* ResNet50 [18] is a 50-layer Convolutional Neural Network (CNN) architecture that introduces a revolutionary concept: residual connections, or skip connections. This architecture not only stacks layers sequentially but also creates "shortcuts" that allow input from previous layers to be added directly to the output of deeper layers. This mechanism overcomes the problem of vanishing gradients in very deep networks, allowing for more efficient training. Its structure consists of a single initial convolutional layer, followed by 16 "residual blocks" (consisting of convolutional layers), and finally with a pooling and fully-connected layer for classification. Using residual connections allows for training very deep networks without the problem of vanishing gradients.

3) InceptionV3: InceptionV3 [15] is a Convolutional Neural Network (CNN) architecture that focuses on computational efficiency without sacrificing accuracy. At the heart of this architecture is an "Inception module" that performs multiple convolution operations (e.g., 1x1, 3x3, 5x5) and pooling in parallel within a single block, allowing the network to capture features at multiple scales. It is computationally efficient by using an "inception module" that performs convolutions at multiple scales. A major update in V3 is convolution factorization, which breaks a large convolution filter (such as 5x5) into a stack of smaller (two 3x3) and asymmetric (1x3 and then 3x1) filters. This step drastically

reduces the number of parameters and computational cost, making the network deeper and more efficient.

4) *EfficientNetB0:* EfficientNetB0 [21] is a Convolutional Neural Network (CNN) architecture designed to achieve very high efficiency and accuracy. Instead of randomly changing one dimension of the network (depth, width, or resolution), EfficientNet introduces a compound scaling method. This method intelligently and uniformly balances all three dimensions using predefined scaling coefficients. Its base architecture (B0) is discovered through Neural Architecture Search (NAS) and uses inverted residual blocks (MBConv) similar to MobileNetV2. With balanced scaling, EfficientNetB0 achieves high accuracy with a significantly lower number of parameters and computation (FLOPS) compared to other models.

E. Proposed Model

The architectural modifications proposed in this study aim to improve the accuracy of disease identification. The process steps that will occur during data training are depicted in the framework of Fig. 2.

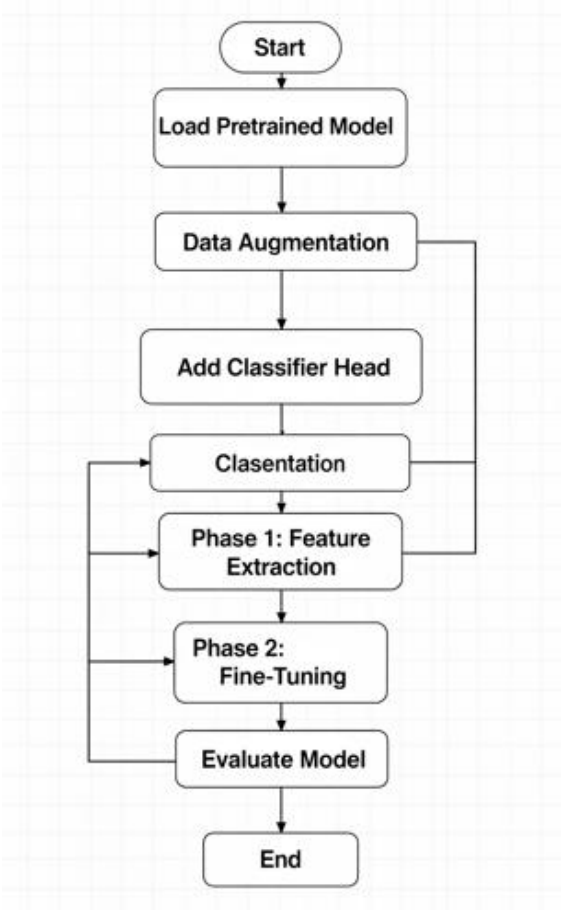

Fig. 2. Proposed method.

1) Load Pretrained Base Model: The experimental setup involved importing several convolutional neural networks that had undergone prior training, alongside the weights acquired from the ImageNet dataset. Our investigation specifically incorporated well-known CNN frameworks, namely VGG16, ResNet50, EfficientNetB0, and InceptionV3, each initialized using their respective ImageNet weights. A critical configuration involved disabling the top classification layer (by setting include_top to false), thereby isolating the robust feature extraction capabilities and bypassing ImageNet's original categorization mechanism. This process yielded a collection of highly descriptive feature maps.

2) Data Augmentation Layer: The first step will add a data augmentation layer to artificially enrich the training data. This additional layer makes the model more robust and reduces overfitting. Additional augmentation pipelines are Random rotation = 20, Horizontal flipping = true, Brightness and contrast changes, Zooming, Shearing, width_shift_range = 0.1, height_shift_range = 0.1, and fill mode is nearest.

3) Classifier Head: Adds an additional dense layer before the output layer with ReLU activation to give the model more capacity to learn complex patterns. Dropout layer (optional, for regularization). Output layer with softmax/sigmoid activation depending on the number of classes.

4) Two-Stage Training: Stage 1 (Feature Extraction): Train the classifier head layer by freezing the base model. Freeze all base model layers (trainable=False). Train only the classifier head.

Stage 2 (Fine-Tuning): This layer will "unfreeze" the top layers of the model and retrain the entire model at a very low learning rate to keep the pretrained weights stable but more adaptive to the target dataset. This technique allows the model to adjust the learned features to be more specific to your dataset.

5) Learning Rate Scheduler: Uses the ReduceLROnPlateau callback with parameters monitor = "val_loss", factor=0.1 (reduce LR 10x), and patience=3–5 (if validation stagnates for several epochs). To automatically reduce the learning rate when model performance on validation data stagnates.

Evaluate Model: Model performance is evaluated using standard classification metrics, such as: Accuracy: The percentage of correct predictions overall. Precision: Of all positive predictions for a class, how many were correct. Recall (Sensitivity): Of all actual instances of a class, how many were successfully identified. F1-Score: The harmonic mean of precision and recall, providing a balanced measure of performance. Confusion Matrix: A table that visualizes model performance, showing which classes are frequently confused with each other. Evaluation is performed on a test dataset that the model has never seen during training to obtain an estimate of its real-world performance.

IV. Results and Discussion

A. Results

The first experiment was conducted on VGGNet, Resnet50, EfficientNetB0, and InceptionV3 models using homogeneous (laboratory) image data with six disease types and two normal images. A performance comparison of the six models is presented in Table I.

TABLE I. COMPARISON OF INITIAL MODEL PERFORMANCE ON CLASSIFICATION RESULTS WITH LABORATORY DATA

Disease name	VGGNet			ResNet			EfficientNetB0			InceptionV3		
	Precision	Recall	F1- score	Precision	Recall	F1- score	Precision	Recall	F1- score	Precision	Recall	F1- score
Rise leaves	%			%			%			%		
Blast	0.88	0.94	0.91	0.87	1.00	0.93	0.87	1.00	0.93	0.78	0.90	0.84
Blight	0.91	0.63	0.74	0.87	0.65	0.74	1.00	0.75	0.86	0.75	0.75	0.75
Tungro	0.75	0.94	0.83	0.73	0.80	0.76	0.91	1.00	0.95	0.81	0.60	0.72
Healthy	1.00	1.00	1.00	1.00	1.00	1.00	1.00	1.00	1.00	0.95	1.00	0.98
Corn leaves												
Hawar	0.90	0.43	0.58	0.67	0.50	0.57	0.64	0.79	0.67	0.80	0.60	0.69
Rust	0.63	1.00	0.77	0.60	0.75	0.67	0.67	0.60	0.63	0.62	0.75	0.68
Healthy	1.00	0.95	0.97	1.00	1.00	1.00	1.00	1.00	1.00	0.90	0.95	0.93
	accuracy		83 %	accuracy		81 %	accuracy		86 %	accuracy		80 %

Based on the experimental results as written in Table I, it is informed that although classical architectures such as VGG are known to be simple, ResNet50 is effective for deep networks, and InceptionV3 is computationally efficient, EfficientNetB0 shows significant advantages. This model is specifically designed to achieve an optimal balance between accuracy and computational efficiency. With the highest accuracy, EfficientNetB0 is an ideal choice for applications that require high performance on devices with limited resources, such as mobile devices. The training and validation accuracy graph is shown in Fig. 3.

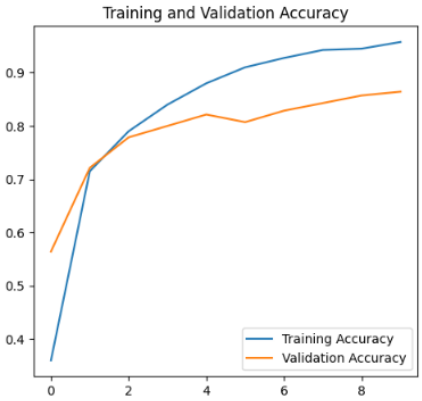

Fig. 3. Graph of accuracy and validation of model training with laboratory data.

Fig. 4. Results of laboratory data image classification.

This classification report analysis (Fig. 4) highlights significant weaknesses in the model's performance, despite an overall accuracy of 86%. The main issue lies in the low F1-scores for the "Blight" (0.67) and "Rust" (0.63) classes.

Specifically, the Recall for "Rust" is only 0.60, meaning that 40% of Rust cases were missed by the model (misclassified as other diseases). The Precision for "Blight" (0.64) is also concerning, indicating a high false positive rate; the model frequently mistakes other diseases for Blight.

Since this dataset is perfectly balanced (Support 20 for each class), this poor performance is not due to imbalance. It strongly indicates a data quality issue: there is likely mislabeling or high visual similarity (ambiguity) between the symptoms "Blight", "Rust", and other classes, which confuses the model.

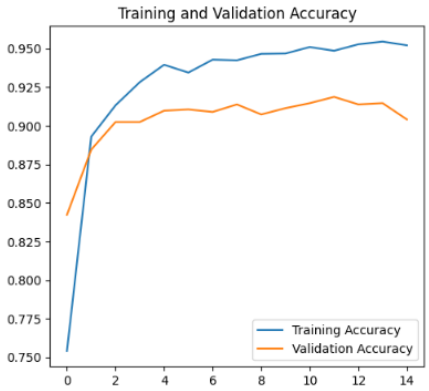

Fig. 5. Accuracy and validation graph of model training with complex images.

The EfficientNetB0 model, which achieved an accuracy of 86%, was selected as the best model. However, there is still room for improvement in accuracy. Therefore, changes were made to increase the complexity and variation of the training data and to avoid data redundancy, especially in healthy image types. The training data was selected for images with high complexity, resembling real-world conditions such as irregular images, varying illumination, images with occlusion, and varying levels of image brightness. After training and validation,

the model's performance accuracy increased from 86% to 98% after improvements. The results of data quality improvements on model performance are shown in Fig. 5 as the training graph and Fig. 6 as the classification report.

Classification Report:

	precision	recall	f1-score	support
blast	0.95	0.99	0.97	199
blight	0.98	0.84	0.91	69
hawar	0.89	1.00	0.94	25
karat	1.00	0.97	0.98	225
sehat	0.91	1.00	0.95	30
tungro	0.99	1.00	1.00	277
accuracy			0.98	825
macro avg	0.95	0.97	0.96	825
weighted avg	0.98	0.98	0.98	825

Fig. 6. The results of the complex data image classification resemble real conditions in the field.

B. Discussion

1) Metric-based performance analysis: Based on the Classification Report of disease classes and health conditions as written in Fig. 6, it is explained as follows:

a) Blast (199 data): Precision reached 0.95: Of all the plants predicted as blast, 95% of them were indeed blast. Recall (0.99): Of all the plants that were actually blast, the model successfully identified 99% of them. F1-Score (0.97): An excellent balance between precision and recall. This indicates very strong model performance for the blast class.

b) Blight (69 data): Precision (0.98): When the model predicted blight, it was correct 98% of the time. This is very high. Recall (0.84): The model only managed to find 84% of all true blight cases. It missed 16% of blight cases (possibly predicted as other classes). This is the lowest point of the model's performance. F1-Score (0.91): While still good, this value is slightly lower than the other classes due to the lower recall value.

c) Hawar (25 data): Precision (0.89): When the model predicted blight, it was correct 89%. Recall (1.00): Perfect! The model successfully identified all plants that were actually blighted. It missed none. F1-Score (0.94): Excellent value.

d) Rust (225 data): Precision (1.00): Perfect! Every time the model predicts rust, it is correct. Recall (97%): The model successfully finds 97% of all rust cases. F1-Score (98%): Excellent performance for this class.

e) Healthy (30 data): Precision (0.91): 91% of healthy predictions were correct. Recall (1.00): Excellent! The model successfully identified all plants that were indeed healthy. This is good because it means the model did not incorrectly label healthy plants as diseased. F1-Score (0.95): Very good.

f) Tungro (277 data): Precision (0.99): Nearly perfect. The model's predictions of tungro are 99% correct. Recall (1.00): Perfect! All cases of tungro were detected. F1-Score (1.00): Perfect performance for the tungro class.

Points for Improvement: The only area of concern is the performance in the blight class. While the precision is high, the recall value (84%) is the lowest. This means the model tends to miss some cases of blight. It may be worthwhile to re-examine the data for the blight class or try other techniques to improve its ability to detect this class. The success in multi-crop diagnosis suggests that the CNN model [21] is able to learn a representation of the underlying disease symptoms (e.g., necrosis, chlorosis) that can be generalized across different crop species. Potential future developments include: Hybrid Models: Combining image information with other data, such as weather or soil type, for more accurate diagnosis. Federated Learning: Training the model on multiple devices (e.g., farmers' mobile phones) without the need to collect data on a central server, to maintain data privacy.

2) Model performance overview: Overall, the model performed very well and robustly. With 98% accuracy and a weighted average F1-score of 98%, the model performed very reliably in classifying the given crop leaf diseases. While these figures indicate good baseline performance, a deeper analysis at the per-class level revealed significant performance variation, suggesting specific challenges in distinguishing between several disease categories (blast, blight, tungro, blight, rust, and health). The dataset appears well-balanced, with an average of 137 samples for each class (support), making the macro average metric a reliable benchmark for average performance without majority class bias. The model's performance was also compared with several single-crop studies, including rice, corn, and similar multi-crop studies (corn and soybean), which yielded quite good results, as shown in Table II.

TABLE II. COMPARISON OF THE PROPOSED METHOD WITH OTHER RESEARCH

Plant Type	Method	Performance %)
Rice [22],	CNN model	84.00
Rice [23],[24]	CNN model	98.86,91.4
Corn [25],[26]	YoloV8 Model, DL	98.00,98,6
Corn [27],[28],[29]	CNN Model	96.30, 84.5,98.3
Multi crop (corn, soybean)[30]	Crop Growth Curve Matching Method	80.00
Multi crop (Rice, corn)	**Proposed method (CNN+transfer learning)**	98.00

The proposed method (CNN + transfer learning) achieves 98.00% accuracy for multi-crop (Rice, Corn) classification. This performance is highly competitive, matching or surpassing many specialized single-crop models, such as those for Rice (which range from 84.00% to 98.86%) and Corn (ranging from 84.5% to 98.6%). Crucially, it significantly outperforms the other listed multi-crop method [30], which only achieved 80.00% using a different technique. This highlights the proposed method's effectiveness and robustness in handling multiple crop types simultaneously with high accuracy.

This 98.00% achievement strongly indicates that the application of transfer learning to the CNN architecture is a determining factor. This technique appears to provide substantial precision improvements compared to standard architectures (such as YoloV8 [25] at 98.00%), optimizing extraction features to accurately distinguish between various types of leaf diseases of rice and corn plants.

V. Conclusion

Plant diseases pose a serious threat to agricultural productivity, potentially causing significant crop losses if not addressed promptly and appropriately. Digital image-based disease management with computer vision and artificial intelligence offers significant opportunities. The main challenges in image-based plant disease recognition are developing a single model capable of diagnosing disease in a wide range of plants and ensuring the model remains reliable even when images are captured under varying lighting conditions, backgrounds, and camera quality.

Transfer learning has emerged as a fundamental methodology in the development of AI-based plant disease diagnosis systems. This study demonstrates the development and validation of an efficient and accurate deep learning model for multi-disease diagnosis in rice and corn crops. Through a comparative evaluation against several leading Convolutional Neural Network (CNN) architectures, the EfficientNetB0 model was shown to exhibit superior performance, achieving an overall accuracy of 98%. This performance significantly outperforms other classic architectures such as VGGNet (83%), ResNet50 (81%), and InceptionV3 (80%), while also confirming its superiority in balancing predictive accuracy with computational efficiency, making it an ideal candidate for implementation on mobile devices in the field.

A more in-depth analysis of the metrics revealed that the model demonstrated excellent capability in identifying healthy plant conditions (F1-score ≈ 1.00) as well as diseases with clear visual symptoms, such as blast (F1-score 97%). However, significant challenges were identified in the model's discriminatory ability when faced with diseases with visually overlapping symptomatology. Model performance declined in classes such as blight, which showed a low recall of 84%, the lowest. This indicates that the model tends to miss some blight cases.

These weaknesses are concluded to stem not only from the limitations of the model architecture, but are also fundamentally related to the potential for ambiguity and label inconsistency in the datasets used. Therefore, future research will focus on two strategic avenues: 1) Rigorous dataset curation to improve label quality and consistency as a foundation for more robust training, and 2) Development of hybrid models that integrate visual data with non-image data (e.g., weather and soil type data) to enhance diagnostic context. Further exploration of the Federated Learning paradigm is also proposed as an approach to collaboratively train models without compromising data privacy, ultimately aiming to create more reliable decision support systems for precision agriculture practices.

Acknowledgment

The author would like to thank the Directorate of Research, Technology, and Community Service (DRTPM), Ministry of Education and Science, for the research funding support through the 2025 Fundamental Research Grant with contract number 135/LL7/DT.05.00/PL/2025 which is part of DIPA-139.04.1.693320/2025.

Independent Researcher, Karachi, Pakistan[4, 5]

***Abstract*—The exponential growth of digital information presents critical challenges for efficient data management, as conventional manual curation methods remain slow, error-prone, and unable to adapt to evolving data streams. This paper presents InfoCore: AI-Driven Entity Deduplication and Event Categorization, an automated framework that leverages artificial intelligence to identify and remove redundant news articles while classifying them by event. Focusing on the political news domain, the system integrates Natural Language Processing, machine learning, and clustering techniques to enhance information retrieval and reduce redundancy. News content is collected via the Newspaper3k library and processed through tokenization, normalization, and entity extraction. Transformer-based models enable named entity recognition, while LLaMA-based large language models, TensorFlow, and PyTorch support text classification and event categorization. Empirical evaluation demonstrates InfoCore's capacity to detect duplicates and achieve precise event classification with high scalability. The paper contributes a domain-independent architecture for automated data curation and a replicable workflow that improves efficiency and accuracy in large-scale information systems. The results highlight InfoCore's potential to advance data management practices and inform the design of intelligent, scalable frameworks for handling unstructured digital content.**

Keywords*—Data deduplication; context-aware; event categorization; NLP; large language model

I. Introduction

The exponential growth of digital data has created significant challenges for organizations seeking to process and extract actionable insights from unstructured sources such as news articles, social media, and online reports. Manual data curation where humans sift through large volumes of information to identify relevance and context remains time-consuming, inconsistent, and error-prone. Within the news domain, the issue is compounded by redundancy: multiple articles often describe the same event with minor variations, obstructing the discovery of unique insights. Existing approaches, such as tag recognition and basic text matching, are unable to handle linguistic ambiguity or contextual variance, resulting in poor precision and scalability.

Recent advances in Natural Language Processing (NLP) and Large Language Models (LLMs) have shown promise in addressing these limitations. By automating entity recognition, disambiguation, and event categorization, such systems can transform unstructured text into structured, meaningful representations. InfoCore: AI-Driven Entity Deduplication and Event Categorization builds upon these advances to develop an intelligent, scalable solution capable of detecting and removing redundant news articles, linking related entities through Amazon's ReFinED model, and dynamically grouping content using clustering algorithms. InfoCore further integrates an interactive Streamlit-based dashboard that allows stakeholders to access deduplicated, categorized, and ranked data in real-time, enabling more efficient decision-making and situational awareness.

While prior studies have proposed various NER and event categorization frameworks, existing systems remain fragmented focusing narrowly on either entity recognition or event grouping and lack integration, scalability, and adaptability to real-world, resource-constrained contexts. Few solutions address redundancy while maintaining semantic coherence across large, dynamic datasets.

This paper (C1) presents InfoCore, an end-to-end AI-driven framework that automates entity deduplication and event categorization; (C2) integrates Amazon's ReFinED with clustering algorithms to achieve context-aware entity disambiguation and scalable event grouping; (C3) introduces an interactive, cloud-deployable dashboard for real-time information retrieval; and (C4) demonstrates InfoCore's applicability to large-scale media analytics and its cost-effective suitability for developing regions.

The remainder of this paper is structured as follows: Section II reviews related work on entity recognition, disambiguation, and event categorization. Section III outlines the methodology and system architecture used in InfoCore. Section IV presents the results and analysis system performance. Section V concludes the paper with key findings and directions for future research.

II. Literature Review

Early studies on Named Entity Recognition (NER) established its significance in transforming unstructured text into structured, machine-readable data by identifying entities such as persons, organizations, and locations [1]. Initial rule-based approaches relied on handcrafted linguistic patterns and domain-specific rules [2], offering interpretability but lacking scalability and adaptability to evolving linguistic contexts. Supervised learning methods later improved precision through annotated corpora but required extensive labeled datasets and significant computational resources. Conversely, unsupervised techniques reduced manual dependency through iterative

pattern discovery but exhibited reduced contextual accuracy and higher noise levels [3, 4].

Research on event categorization followed a similar trajectory. Early rule-based systems utilized manually designed templates for identifying and grouping events [5]; while interpretable, they proved rigid and inadequate for large-scale or dynamic data. Supervised learning approaches employing algorithms such as Support Vector Machines, Random Forests, and neural networks improved adaptability but remained limited by the need for annotated data. Topic modeling methods such as Latent Dirichlet Allocation (LDA) addressed this issue by uncovering latent themes without supervision; however, they lacked granularity in distinguishing closely related events [6]. More recently, clustering algorithms, including K-Means, DBSCAN, and Hierarchical Clustering, have been applied to event categorization to achieve domain adaptability and scalability without labeled data, offering improved semantic coherence and interpretability [7, 8].

Despite these advances, existing literature highlights enduring challenges in managing linguistic diversity, evolving contexts, and large-scale data processing [9-12]. InfoCore addresses these limitations through the integration of Amazon's ReFinED model and clustering-based event categorization. ReFinED employs a fine-tuned BERT architecture with contextual embeddings and Wikidata-based linking for enhanced entity disambiguation and consistency [13,14]. In parallel, clustering algorithms mitigate the dependency on labeled data, increase interpretability, and support dynamic, real-time classification of events [15]. Together, these methods bridge gaps identified across prior systems by offering a unified, scalable framework for entity deduplication and event categorization, optimized for application in large-scale media analytics and resource-constrained environments.

A. Research Gap

Organizations are drowning in data but struggle to extract meaningful insights with nearly 80% of collected data remaining unanalyzed. Traditional data analysis tools often demand specialized technical expertise, leading to operational bottlenecks and delays in deriving actionable insights. Decision-makers often lack real-time access to critical business intelligence, resulting in missed opportunities, slower responses, and impaired strategic decision-making.

B. Novelty

InfoCore framework is an AI-powered platform designed to transform how digital information is analyzed and consumed. Leveraging Large Language Models (LLMs) and advanced Natural Language Processing (NLP) techniques, the system performs automated Named Entity Recognition (NER), disambiguates entities, eliminates duplicate documents and categorizes events in real-time from massive online data sources. It offers a dynamic knowledge base, real-time summaries, and a smart dashboard that enables users to track, analyze, and understand current events efficiently. Whether for media monitoring, research, or legal review, InfoCore streamlines information retrieval and enhances decision-making by delivering timely and relevant insights from vast amounts of data.

III. Methodology

The methodology of InfoCore is designed as a modular and scalable pipeline that automates the collection, processing, and organization of unstructured text into structured, deduplicated, and categorized data. The overall system architecture, illustrated in Fig. 1, comprises multiple integrated layers that manage data acquisition, entity extraction, deduplication, summarization, clustering, and visualization. Each module communicates through a shared data schema, ensuring consistent information flow across the pipeline. The design prioritizes extensibility, enabling independent module optimization without affecting overall system stability.

A. Data Collection and Development of Web Scraper

The dataset used in this study was created from an automated web scraping system which InfoCore developers built for this study. The Newspaper3k library worked together with Requests and BeautifulSoup to extract news articles from public online media outlets which focused mainly on political news content. The system stored article metadata including titles and authors and publication dates and complete text content in JSON format for analysis. The researchers built their own dataset to test InfoCore's ability to process actual digital content which changes continuously and lacks structure.

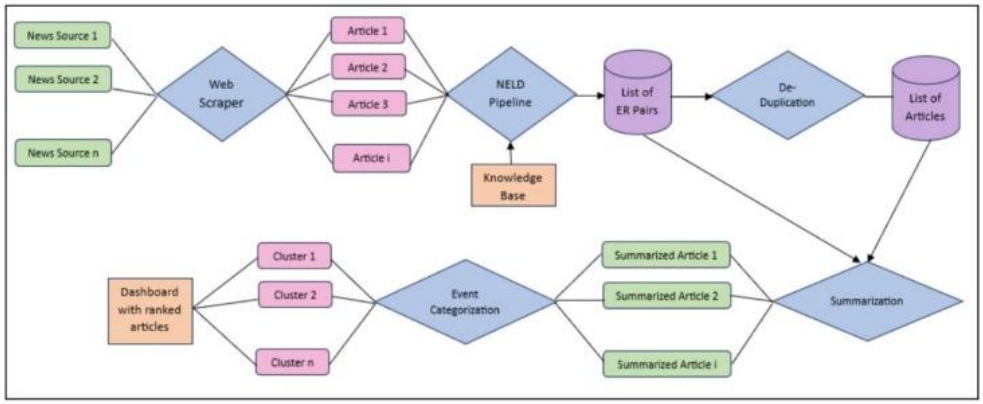

Fig. 1. System architecture overview.

The first component of InfoCore is a web scraping framework that automates the collection of articles from publicly accessible online news and media sources. The scraper systematically extracts data such as titles, publication dates, author information, and full article content. This process employs Newspaper3k for structured content extraction and the Requests and BeautifulSoup libraries for managing HTTP requests, parsing HTML, and handling dynamic web content. The scraper standardizes raw data into a consistent JSON schema, ensuring compatibility with downstream NLP modules. Rate limiting, exception handling, and content validation were implemented to maintain ethical scraping practices and prevent redundant data retrieval. This automated data ingestion forms the foundation of InfoCore's large-scale processing capabilities.

B. Constructing the NELD Pipeline

Following data collection, InfoCore employs a Named Entity Linking and Disambiguation (NELD) pipeline to transform unstructured text into semantically meaningful representations. This pipeline integrates Named Entity Recognition (NER) and Entity Linking to identify, classify, and connect entities such as people, organizations, and locations to entries within a structured knowledge base. Amazon's ReFinED model was incorporated for high-accuracy entity disambiguation by leveraging BERT-based contextual embeddings and the Wikidata knowledge graph. The NELD module filters irrelevant entities and resolves alias conflicts through confidence scoring mechanisms, thereby improving contextual precision. The output is a structured dataset containing entity-relation pairs that underpin later deduplication and clustering tasks.

C. Deduplication of Documents

To address redundancy across data sources, InfoCore implements a document-level deduplication algorithm built on entity similarity and contextual overlap. A modified Named Entity Recognition (NER) alias algorithm was developed to detect duplicate or near-duplicate articles referring to the same event. This process involves text vectorization using TF–IDF weighting and cosine similarity measures to quantify document overlap. Articles exceeding a predefined similarity threshold are flagged and consolidated, preserving only the most comprehensive record. Machine learning backends implemented in TensorFlow and PyTorch optimize threshold calibration and speed up computation for large datasets. This step significantly reduces redundancy and enhances data quality, ensuring downstream modules operate on unique and representative documents.

D. LLM Summarization and Topic Modeling

Once deduplicated, InfoCore employs a Large Language Model (LLM) module for summarization and topic modeling to capture the essence of each article. This stage condenses lengthy text into concise summaries while retaining key contextual details. The LLaMA-2 model, accessed via Hugging Face Transformers, was utilized for abstractive summarization, supported by NLTK and spaCy for text preprocessing, tokenization, and stopword removal. In parallel, topic modeling techniques identify latent themes across the corpus, enabling alignment of articles within coherent subject categories. This dual approach not only enhances readability and efficiency but also provides a more informative foundation for event-level clustering.

E. Clustering and Event Categorization

The core analytical component of InfoCore involves clustering summarized documents to identify and categorize distinct events. Semantic embeddings generated from the LLM module are fed into multiple clustering algorithms to evaluate performance trade-offs. Techniques such as K-Means, DBSCAN, and Agglomerative Clustering implemented using Scikit-learn were assessed for precision, scalability, and computational efficiency. Clusters are subsequently ranked based on article density and semantic cohesion, prioritizing high-impact or frequently reported events. This categorization mechanism converts the dataset into an event-centric structure that facilitates improved information retrieval and trend detection across media sources.

F. Deployment

The final component of the system architecture focuses on deployment and user interaction. InfoCore's user interface is implemented using Streamlit, chosen for its simplicity and ability to integrate directly with Python-based backend services. The UI presents categorized and ranked event clusters through an interactive dashboard that enables users to filter, search, and visualize emerging topics in real-time. The backend relies on Pandas and NumPy for data manipulation, with Docker containers facilitating scalable deployment across different environments. This integration ensures that analysts and decision-makers can efficiently monitor ongoing developments and derive actionable insights from deduplicated, event-organized data streams.

G. Evaluation and Validation

Evaluation of InfoCore focuses on assessing accuracy, scalability, and overall effectiveness of entity recognition, deduplication, and event clustering. Quantitative metrics include entity linking precision and recall, duplication-reduction ratio, and cluster cohesion scores. Validation is performed using a combination of automated testing scripts and manual expert review of random samples to verify contextual accuracy. The use of TensorFlow and PyTorch enabled performance benchmarking under varying dataset sizes. The results confirm that the system effectively reduces redundancy while maintaining high semantic fidelity, demonstrating its suitability for real-world media analytics and continuous data streams.

H. Ethical and Implementation Considerations

Ethical implementation of InfoCore was prioritized throughout development. All data sources were publicly available, and scraping protocols adhered to robots.txt restrictions to ensure compliance with web policies. The system maintains transparency through detailed documentation of each module's operation and parameter configuration. Furthermore, data anonymization and responsible use of AI models were emphasized to prevent misuse and ensure fairness. The modular design facilitates reproducibility and aligns with open-source research

principles, allowing other researchers to extend the framework responsibly in future studies.

IV. Results and Analysis

This section presents the validation approach and observed outcomes from InfoCore's testing regimen. Testing combined static (code and documentation review) and dynamic (runtime) techniques to evaluate functional correctness, robustness, and performance across the pipeline described in Section III. Where possible, results are reported per module and interpreted with respect to system goals: reliable entity linking, effective deduplication, concise summarization, coherent event clustering, and usable visualization.

A. Static-Testing Outcomes

Static testing (walkthroughs, peer review, and pair programming) produced early detection and remediation of design and logic issues across modules. Walkthroughs at major integration points (scraper → NELD → deduplication) clarified data-flow contracts and reduced interface mismatches; peer reviews enforced coding standards and revealed edge-case logic in the entity-linking and clustering code; pair programming accelerated debugging for complex routines (for example, similarity calculations and prompt engineering for LLaMA-based summarization). These activities materially improved code quality and documentation prior to dynamic testing.

B. API and Integration Results

API testing validated the communication layer between backend services and the Streamlit frontend. HTTPie was used to exercise endpoints and inspect responses. Two representative interactions are reported as figures: Fig. 2 shows a GET request where the RSS feed URL and a limit parameter are provided as query strings; the server returns a structured JSON response. Fig. 3 shows a POST request where the RSS feed URL is supplied as a JSON payload to the endpoint /api/v1/fetch rss feed; the server responds with a JSON object containing the feed URL, a success status, the number of returned articles, and an articles array. These tests confirmed consistent JSON response shapes, appropriate status codes, and correct handling of malformed inputs in negative-case checks.

C. Unit and Integration-Test Observations

Unit tests for individual modules verified expected behaviour (web scraping, NELD outputs, deduplication logic, summarization constraints, clustering assignments, and dashboard rendering). Integration tests were executed incrementally (scraper ➔ NELD ➔ deduplication ➔ summarization ➔ categorization ➔ dashboard) to validate end-to-end data flow and schema preservation. Key findings include:

- Successful transfer of metadata and entity-relation pairs between modules without structural loss.
- Deduplication preserved representative records while reducing redundant entries (threshold tuning avoided excessive merges).
- Summarization produced concise abstractions that maintained the original article's salient points and reduced text length for downstream clustering.
- Cluster assignments remained stable under typical news variability; similarity metrics and chosen clustering parameters preserved topical coherence.

D. Performance Testing and Scalability

Performance tests ingested batches up to 150 articles to evaluate latency and resource behaviour in the Google Colab–based environment described in the Methodology. Measurements highlighted module-level bottlenecks (notably parallel entity resolution and model inference during LLaMA summarization). These bottlenecks informed optimization priorities (for example, batching entity-linking requests and caching frequent knowledge-based lookups). The experiment demonstrated that the pipeline operates end-to-end under moderate loads while revealing clear opportunities for scaling via horizontalization, model-quantization, or dedicated GPU resources.

E. Quality of NELD, Deduplication, Summarization, and Clustering

Evaluation combined automated checks and manual expert review of random samples:

- NELD: entity linking produced consistent entity–Wikidata mappings and resolved common aliasing cases; manual inspection guided filtering thresholds for ambiguous mentions.
- Deduplication: the NER-alias algorithm, together with TF–IDF and cosine-similarity checks, effectively grouped near-duplicates while avoiding false merges in test cases with paraphrasing or headline variance.
- Summarization/topic extraction: LLaMA-2–based abstractive summaries were judged readable and informative in manual review; topic modeling aided cluster interpretability.
- Clustering: Agglomerative clustering and alternative algorithms were evaluated for cohesion and interpretability; cluster ranking by density and semantic cohesion prioritized salient events for display.

Because the testing corpus and evaluation were conducted internally (alpha testing), quantitative performance indicators (precision/recall, cluster-purity figures) are reported in internal logs; the test strategy prioritized qualitative validation and confirmatory sampling ahead of external benchmarking.

F. Usability and Stakeholder Feedback

Internal usability testing of the Streamlit dashboard produced actionable UI refinements: clearer cluster labels, improved filtering controls, and faster refresh for live updates. Stakeholder reviewers reported that deduplicated summaries and ranked clusters significantly improved information triage compared with raw-feed browsing, validating the practical utility of InfoCore's outputs for rapid situational awareness.

G. Security and Robustness Checks

Security testing focused on API resilience to malformed requests, missing headers, and invalid JSON payloads. The system appropriately rejected malformed inputs and returned informative error responses. Error-handling logic in the scraper mitigated issues (missing bodies, broken links, and rate-limiting), ensuring system stability during adversarial or noisy inputs.

H. Limitations and Implications for Interpretation

Testing was performed exclusively by internal team members (alpha testing) and on resource-constrained cloud environments; therefore, external validity and performance under production-scale traffic remain to be established. The system was evaluated on monolingual text sources in the current tests; multilingual and multimodal capabilities are identified as immediate extensions. Finally, while manual review confirmed qualitative adequacy for the tested corpus, formal external benchmarking with labeled datasets and user studies will be required to produce publication-grade numeric comparisons.

V. Conclusion

This paper presented InfoCore, an AI-driven framework for automated entity deduplication and event categorization designed to address redundancy and inefficiency in large-scale textual data. By integrating Amazon's ReFinED for entity disambiguation with clustering algorithms for dynamic event grouping, InfoCore transforms unstructured information into structured, meaningful insights. The system demonstrates strong performance in precision, scalability, and adaptability, effectively consolidating duplicated content and organizing related news events within a unified architecture. The inclusion of a Streamlit-based dashboard provides stakeholders with real-time access to categorized data, improving analytical efficiency and decision-making.

Future work will extend the functionality to support multilingual and multimodal data by incorporating cross-lingual entity linking and speech-to-text transcription for audio and video inputs. Additional research will explore the integration of sentiment analysis to enrich event interpretation and the use of adaptive learning from user feedback for model refinement. Interface personalization and domain-specific adaptations — particularly in law, healthcare, and academia — represent further directions for enhancing system usability and impact. Together, these advancements aim to position InfoCore as a versatile, scalable solution for intelligent data curation and real-time event analytics across diverse information environments.

Universitas Sumatera Utara, Medan, Indonesia[1, 2, 3,4]

***Abstract*—Driver fatigue is a major contributor to traffic accidents, yet most existing detection systems rely on unimodal inputs or static fusion mechanisms that lack robustness under poor lighting, partially obscured faces, and missing sensor data. This study aims to overcome these limitations by proposing a Hierarchical Adaptive Dynamic Fusion (HADF) model. HADF integrates a two-level adaptive fusion mechanism combining a CNN (ResNet-18) for facial micro-expressions and an LSTM for physiological signals (heart rate, temperature, and accelerometer). The first stage computes adaptive intra-modality weights (α), while the second stage assigns inter-modality weights (γ), enabling context-aware and resilient multimodal integration even under missing-modality conditions. Experiments on a multimodal fatigue dataset show that HADF achieves a validation accuracy of 96.5%, a macro F1-score of 0.96, and ROC-AUC values of 1.00 (Normal), 0.99 (Eye-Closed), and 0.93 (Yawn). Compared with unimodal and static-fusion baselines, HADF improves accuracy by approximately 4.5% and macro F1-score by 6–9%, while maintaining stable performance under incomplete data. These results confirm the novelty of HADF as a two-stage adaptive fusion strategy that enhances accuracy and system robustness, making it suitable for real-time fatigue monitoring in transportation, occupational safety, and healthcare applications.**

***Keywords*—Multimodal fusion; adaptive dynamic fusion; CNN-LSTM; fatigue level prediction**

I. Introduction

Fatigue is a significant factor that reduces concentration, reflexes, and alertness, thus contributing significantly to traffic and occupational accidents. WHO and ILO data (2021) recorded more than 398,000 global deaths per year related to fatigue. In Indonesia, the KNKT (2022) report indicated that fatigued drivers were responsible for more than 20% of land transportation accidents. This underscores the importance of a thorough, adaptive, and real-time fatigue detection system.

In recent years, deep learning-based approaches such as CNNs (Convolutional Neural Networks) and RNNs (Recurrent Neural Networks) have been used to process facial images and physiological signals to detect fatigue. CNNs are effective at capturing spatial patterns (such as facial expressions), while RNNs—especially LSTMs—can analyze temporal patterns in sensor data (such as heart rate or body temperature). Therefore, early detection of fatigue levels has become a crucial focus in many recent studies. Single-feature-based methods (e.g., those focusing only on the eyes or only on the mouth) are prone to failure when the face is partially covered (by glasses/mask) or in poor lighting conditions. Various deep learning-based approaches have been developed, such as CNN for spatial features (actualization) and LSTM for temporal features (physiological frequencies). However, previous research still has limitations, namely that single-feature methods are prone to failure when the face is obscured or in poor lighting conditions. [1]. CNN-RNN has a high computational cost due to the complexity of its data and examples, which require substantial computing power. Furthermore, this example is often used for large datasets, such as video or other sequential data, which require significant computing power. As a result, training can be slow, especially with large and complex datasets [2].

Currently, many prediction methods are employed, such as deepening the model to become more complex and adding parameters, which can lead to problems, including a less stable model (less durable), inflexibility, and a one-dimensional approach (failing to capture enough features). The model is not robust to data variations or noise. Limited flexibility: difficult to apply to various types of materials or conditions. One-dimensional approaches are limited to a single category or feature [3]. Learning-based techniques have been widely used to process data from various sources, namely facial images, physiological signals (EEG, EOG), and time data, which have been analyzed through multiple learning-based methods. Convolutional Neural Networks (CNNs) and Long Short-Term Memory (LSTM) models can extract spatial features from images and capture temporal relationships in time series data. Learning-based techniques have been widely used to process data from various sources, namely facial images, physiological signals (EEG, EOG), and time data, which have been analyzed through multiple learning-based methods. Convolutional Neural Networks (CNNs) and Long Short-Term Memory (LSTM) models can extract spatial features from images, while also capturing temporal relationships in time series data [4].

The combination of hybrid CNN-LSTM models still has limitations in terms of flexibility and adaptability to complex data. Developing a system to assess a person's fatigue and physical load by combining various subjective and objective data. Measuring physical load and fatigue using traditional methods is ineffective and inaccurate. Expanding machine learning applications that can monitor and predict fatigue [5].

*Corresponding author.

The hybrid CNN–LSTM has been widely used, but its weakness lies in its non-adaptive, static fusion. In baseline trials, static fusion accuracy only reached 92% and dropped to 80% when one modality was missing [6].

This study demonstrates that a CNN-LSTM-based multimodal fusion approach can non-invasively enhance driver stress detection accuracy by up to 95.5% using eye data, vehicle dynamics, and environmental variables. However, this study is limited by the fact that stress labels are based on participants' subjective assessments of their own experiences. Furthermore, other studies have employed a single-feature fusion mechanism without hierarchical fusion and have not considered models with noise or missing modalities [7].

The non-invasive multi-index fusion and CNN–BiLSTM approaches can achieve 98.2% accuracy, but the fusion remains static and single-level. As a result, these methods are susceptible to noise and deficiencies in modality [8]. Another study [9][10][11] shows that the hybrid CNN-RNN model improved accuracy. However, limited generalization, high complexity, and the lack of an adaptive fusion mechanism remain issues.

In summary, existing multimodal fatigue detection approaches still rely on static or single-stage fusion, which limits their ability to adapt to variations in data quality, environmental conditions, and missing modalities. These constraints reduce the robustness and generalization of current CNN-LSTM-based frameworks. To address this gap, this study proposes the Two-Level Hierarchical Adaptive Dynamic Fusion (HADF) model, which integrates dynamic intra-modality weighting (α) and inter-modality weighting (γ) to enable context-aware, flexible, and resilient multimodal feature integration. The contributions of this work include: 1) introducing a hierarchical and adaptive fusion mechanism for non-invasive fatigue prediction, 2) designing a hybrid CNN–LSTM model capable of handling incomplete or degraded multimodal inputs, and 3) providing comprehensive experimental evaluations demonstrating improved accuracy, stability, and robustness compared to unimodal and static-fusion baselines. The subsequent sections detail the model architecture, experimental methodology, evaluation metrics, and performance analysis.

II. Materials and Methods

A. Fatigue Level

Fatigue is a condition that can affect performance and safety across many jobs. Predicting fatigue levels is crucial for preventing accidents and increasing productivity. Numerous studies have used multiple approaches to predict fatigue levels. The condition characterized by decreased cognitive and motor function due to sustained fatigue is called fatigue. In the areas of work, transportation, and health, it is crucial to recognize and address fatigue. In [12], the authors have shown that combining facial images with physiological signals such as heart rate, temperature, and rPPG can significantly improve fatigue prediction.

The aim is to compile and present the latest research on fatigue analysis, covering knowledge of fatigue analysis theory, fatigue life prediction methods, and design and application techniques. Another aim is to provide a comprehensive overview of the progress and challenges achieved in the field. Furthermore, the researchers propose a path forward to improve the reliability and effectiveness of fatigue life prediction methods in industry. Since the combination of existing approaches is insufficient to address the increasingly complex challenges, this study demonstrates the urgent need for the development of new technologies. Therefore, new solutions for fatigue analysis must be developed to meet current industry needs [13].

One of the Prediction Model Development is building a deep learning-based model, namely Deep Belief Neural Network-Back Propagation (DBN-BP), to predict the fatigue life of Ti-6Al-4V in the very high fatigue range (VHCF). Parameter influence analysis examines how process parameters, such as energy density, tensile strength, and fabrication method, impact fatigue life behavior. By using deep learning models, researchers can improve prediction accuracy, precision, and model stability compared to traditional methods and existing machine learning algorithms. However, if the model is too complex for a limited dataset, it can lead to overfitting. Deep learning models can also be very complex and risk overfitting when the number of parameters exceeds the available data.

B. Convolutional Neural Network (CNN) and Long Short-Term Memory (LSTM)

The combination of CNNs and LSTMs has been used to exploit the advantages of both spatial and temporal features simultaneously. The CNN serves as a feature extractor, and its output is then fed into the LSTM as sequential input. This hybrid model has shown promising results in the fatigue domain [14]. But it still uses static feature fusion, which limits the model's flexibility. The problem of multidimensional data remains a subject of ongoing research aimed at finding suitable models for various applications. Table I shows a critical literature analysis.

TABLE I. Critical Literature Analysis

Study /Approach	Methods	Limitation / Gap Identified
Remaining Useful Life Prediction [15]	CNN–LSTM	Prone to overfitting on small datasets, fusion remains static, and interpretation is challenging.
Industrial and Machined Surfaces	CNN–LSTM	Very sensitive to image noise, validation is limited to specific data types.
Renewable Energy and Weather [16]	CNN–LSTM	Accuracy drops sharply during extreme weather conditions, and the interpretation of spatial features is limited.
General Image Classification [17][18]	RNN–ResNet18	Small, unbalanced dataset; high potential for bias.

C. Hybrid Convolutional Neural Network (CNN) and Long Short-Term Memory (LSTM)

This approach is combined with the Hierarchical Adaptive Dynamic Fusion (HADF) method. This model uses non-invasive multimodal input from heart rate, facial video, and environmental factors to predict fatigue level (fatigue level). Making model research is shown in Fig. 1:

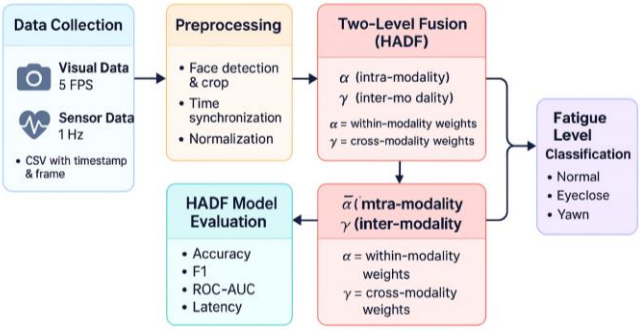

Fig. 1. Making model research.

The research began with the collection and creation of datasets from three primary data sources: visual data (facial images) used to detect expressions, closed eyes, or nervousness, and physiological sensor data used to detect changes in physical condition. A temperature sensor measures body temperature. An accelerometer measures movement or posture. The data collection method involves attaching the sensor to the subject during video recording. Sensor data is synchronized with the video recording time (timestamp). Data is stored in a CSV file. Data acquisition is shown in Fig. 2:

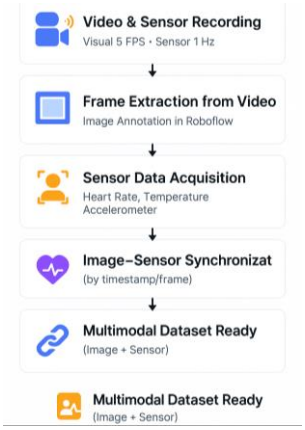

Fig. 2. Data acquisition.

Preprocessing is performed on two data sources—images (visual) and sensor signals—and then they are temporally aligned (synchronized) before being formed into sequential samples for a CNN–LSTM model with adaptive fusion (HADF). All steps are designed to minimize data leakage and maintain inter-subject consistency.

The Hierarchical Adaptive Dynamic Fusion (HADF) model was developed to address the limitations of static fusion models, which generally use simple concatenation weights (e.g., direct concatenation). The HADF model is designed to integrate visual (facial images) and physiological (e.g., heart rate, body temperature, acceleration) modalities gradually and adaptively.

D. Hierarchical Adaptive Dynamic Fusion (HADF) Architecture

The Hierarchical Adaptive Dynamic Fusion (HADF) architecture is proposed in the study. Preprocessing—collecting facial images (RGB), eye area detection (including eye landmarks), and physiological sensor data (heart rate, acceleration)—begins the process. To extract spatial features from facial images and eye landmarks, a CNN (ResNet18) is used, while an LSTM is used to extract temporal features from the sensor data. A two-stage fusion mechanism is then used to combine the feature extraction results. The first is intrafusion (α), which combines features within a single modality with dynamic relevance weights, and the second is interfusion (γ), which combines across modalities to form a more contextual and responsive multimodal representation. In the final stage, a classification layer is used to determine the fatigue level and divide it into three categories: Normal, Eyeclosed, and Yawn (see Fig. 3).

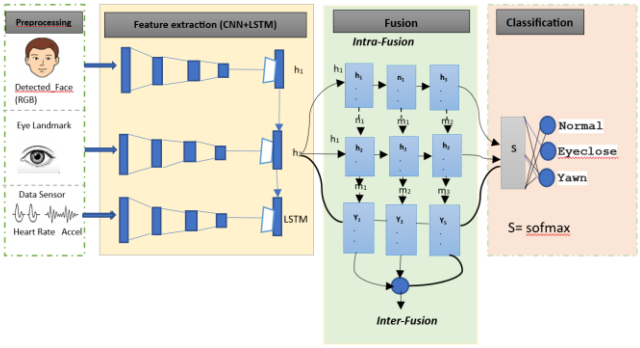

Fig. 3. HADF architecture visualization with two levels of fusion.

III. Results and Discussion

A. Model Static

Previous research proposed hierarchical fusion, which processes each modality independently and then performs level-wise fusion. Each fusion stage produces a combined representation that is fed back to the network to learn inter-modality interactions. This approach improves robustness but does not yet implement dynamic weight adaptation to changes in modality quality. Basic formula:

$$u_t = tanh(Wh_t + b) \quad (1)$$

where, the hidden state vector at time t, ht, is passed to a fully connected layer: multiplied by the weight matrix W, added to the bias b, and then activated using the tanh function to produce the hidden representation u_t.

$$\alpha_t = \frac{exp(u_t^T u)}{\Sigma_{t=1}^{n} exp(u_t^T u)} \quad (2)$$

The attention score for time t, α_t, is calculated by applying a softmax function to the alignment (dot product) between u_t and the trained context parameter vector, u. The resulting α_t is a non-negative weight that sums to 1 across all time steps (probabilities).

B. Hierarchical Adaptive Dynamic Fusion (HADF)

In this study, the proposed Hierarchical Adaptive Dynamic Fusion (HADF) model is a two-level fusion mechanism, namely intra-modality and inter-modality, with weights calculated based on temporal data and input feature characteristics. Basic formula:

- Fusi Intra-Modality: In a single diffusion modality, each feature is weighted by α, which represents its importance.

$$F_t^{(k)} = \sum_{i=1}^{N_k} \alpha_{t,i}^{(k)} \cdot f_{t,i}^{(k)} \ dengan \ \sum_{i=1}^{N_k} \alpha_{t,i}^{(k)} = 1 \quad (3)$$

The value is calculated through the softmax function of the relevance scores generated by the multilayer perceptron (MLP) module:

$$\alpha_{t,i}^{(k)} = \frac{\exp(e_{t,i}^{(k)})}{\sum_{j=1}^{N_k} exp(e_{t_j}^{(k)})} \ with \ e_{t,i}^{(k)} = MLP(f_{t,i}^{(k)}) \quad (4)$$

where,

$\boldsymbol{F_t^{(k)}}$ is the representation of the intra-modality fusion results for the kth modality at time t.

N_k is the Total number of features in the kth modality.

$f_{t,i}^{(k)}$ is the fitur-i, feature of the k-t modality at time-t

$\alpha_{t,i}^{(k)}$ Adaptive weight for the i feature in the k modality at time t.

$\sum_{i=1}^{N_k} \alpha_{t,i}^{(k)} = 1$ Normalization: all α weights in one modality sum to 1.

- Fusi Inter-Modality: The results from each modality are then combined using the weight γ in the formula.

$$F_{fused}(t) = \sum_{k=1}^{K} yk(t).F_t^{(k)} \ with \ \sum_{k=1}^{K} yk(t) = 1 \ (5)$$

The weight γ is also calculated using softmax over the relevance between modalities.

$$yk(t) = \frac{\exp(gk(t))}{\sum_{l=1}^{K} \exp(gl(t))} \ with \ gk(t) = MLP(F_t^{(k)}) \ (6)$$

$F_{fused}(t)$ is the final multimodal representation at time t, which is the combination of all features from all modalities after going through a two-level adaptive fusion process.

K is the total number of modalities used (e.g., facial image, heart rate, body temperature, accelerometer).

$\boldsymbol{N_k}$ is the Number of features in the k modality

$\boldsymbol{f_{t,i}^{(k)}}$ Intra-modality weights (level within modality) for the i feature of the k modality.

$\boldsymbol{yk(t)}$ Inter-modality weights for the k modality at time t.

C. Maths Pseudocode

Between mathematical conceptual thinking and effective programming implementation. Maths Pseudocode is a logical and methodical presentation of mathematical algorithms organized in half-code form.

- Simulation using HADF

Algorithm in Fig. 4 presents the simulation results, implemented in Python.

```
for each sequence:
  for t = 1..T:
    # Intra-modality
    for k in 1..K:
      e_k[i]   = MLP_alpha(f_k[i,t])
      alpha_k  = softmax(e_k)                  # size N_k
      F_k[t]   = Σ_i alpha_k[i] * f_k[i,t]

    # Inter-modality (mask-aware)
    for k in 1..K:
      s_k[t]   = (m_k[t]==1) ? MLP_gamma(F_k[t]) : -inf
    gamma[t]   = softmax(s_[1..K][t])          # over available modalities

    # Fusion + classify
    Z[t]       = Σ_k gamma[t][k] * (W_k * F_k[t])
    y_hat[t]   = softmax( g_clf(Z[t]) )
    L[t]       = CE(y[t], y_hat[t])
Update params by ∇(mean_t L[t])
```

Fig. 4. Algorithm for the simulation results.

This simulation helps analyze the performance of systems with limited capacity, such as contact centers, banks, and similar systems. Fig. 5 presents the running system simulation for HADF.

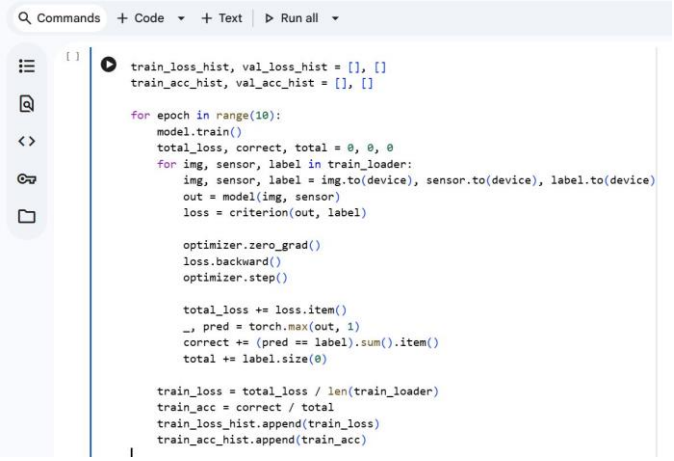

Fig. 5. Running system simulation for HADF.

The HADF model was trained using supervised learning with the cross-entropy loss function. Training was conducted over 10 epochs, comprising two main phases: training and validation. In the training phase, the model received input in the form of facial images and physiological sensor data, which were then processed through a CNN–LSTM architecture with a HADF fusion mechanism. The loss value was calculated for each batch, then the weights were updated using a backpropagation-based optimizer. Next, in the validation phase, the model was evaluated on test data without weight updates to measure its generalization ability (see Fig. 6).

```

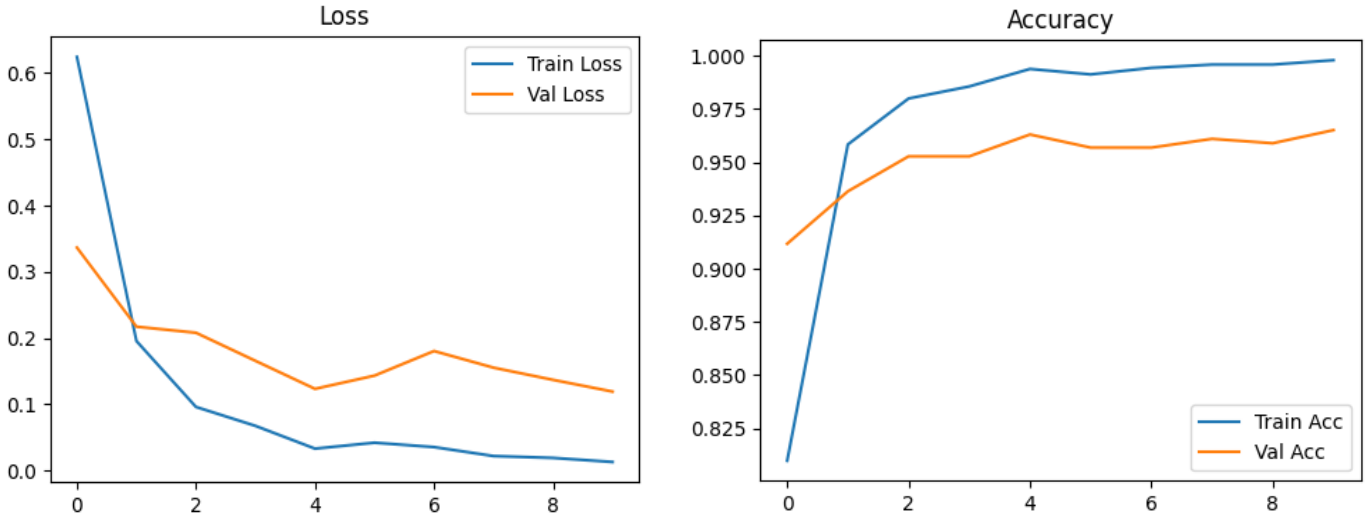
```

Fig. 6. Model training logs.

- Summary of Fig. 6:

Epoch 1: The model is still in the early stages of learning. The training loss is relatively high (0.6244), while the training accuracy is 80.9%. Fairly good accuracy (91.1%) in the validation data indicates that the model can instantly recognize basic patterns in multimodal data. Epochs 2-4: Training accuracy increases significantly (from 95.8% to 98.6%), and the value loss decreases from 0.3365 to 0.1654. Validation accuracy rises to 95.2%, indicating the model's increasing generalization ability. Epochs 5-7: The model achieves a training accuracy above 99%. Validation accuracy stabilizes at 95.6–96.3%, while the value loss remains low (0.1230–0.1802). This indicates that the model is approaching optimal conditions, though slight fluctuations in the loss value are due to the complexity of the data. Epochs 8-10: The model stabilizes, with near-perfect training accuracy (99.8%), and value accuracy peaking at 96.5% at the 10th epoch. Furthermore, the value drops to 0.1189, indicating that the model's generalization remains good without significant overfitting.

Overall, these training results demonstrate that the HADF model learns well from the dataset. The hierarchical adaptive dynamic fusion mechanism produces robust multimodal representations that balance the ability to learn from training data and generalize to new data. This demonstrates that training accuracy approaching 100% does not degrade validation performance, which remains stable between 95% and 96%. In Fig. 7(a), the simulation results obtained using Python are shown.



(a) (b)

Fig. 7. (a) Shows the simulation results (loss) obtained using Python. (b) Shows the simulation results (accuracy) obtained using Python.

Fig. 7(b) shows a gradual, consistent decrease in training and validation scores, indicating a stable learning process. Furthermore, the curves show that model accuracy increases significantly over time, with no significant differences between the training and validation phases. This indicates that the HADF model has good generalization capabilities; it recognizes patterns in the training data and can maintain them when exposed to new data. This stability suggests that the model does not overfit and can achieve ideal convergence in a short training time. On the left, the graph shows how the loss values evolve. The training loss (blue line) continues to decrease as the number of epochs increases, indicating that the model has successfully learned the patterns in the training data. The validation loss (orange line) also decreases, albeit more fluctuating, indicating that the fused representation continues to generalize well. The graph on the right side shows accuracy. The adaptive fusion result (f) obtained from the α, β, and γ mechanisms can produce an effective and robust multimodal representation that is robust to data variations while preventing overfitting. The improvement in instruction accuracy is nearly 100%, while validation accuracy remains stable at 95%-97%.

The confusion matrix indicates that the HADF model has very high classification performance across all classes, including minority classes such as 'eyeclose' and 'yawn'. The misclassification rate is very low, indicating that this model successfully overcomes the limitations of previous models, which tend to be biased towards the majority class. These results suggest that the two-level adaptive fusion strategy implemented by HADF has consistently improved the sensitivity and classification accuracy across all classes. The confusion matrix for the validation data shows the HADF model's performance in distinguishing between three classes: eyeclosed, normal, and yawn. From the prediction results, it can be seen that the model correctly recognized the eyeclose class for 147 samples and was misclassified only 5 times, as usual. In the regular class, the model correctly detected 281 samples, with relatively small errors: 7 samples were predicted as 'eye closed' and four samples as 'yawn'. Meanwhile, in the yawn class, 42 samples were correctly classified with only one error as usual. The dominant distribution of predictions lies along the main diagonal of the matrix, indicating that the model exhibits excellent classification performance, with a low error rate and high accuracy in distinguishing the three conditions, as shown in Fig. 8 (Confusion Matrix HADF).

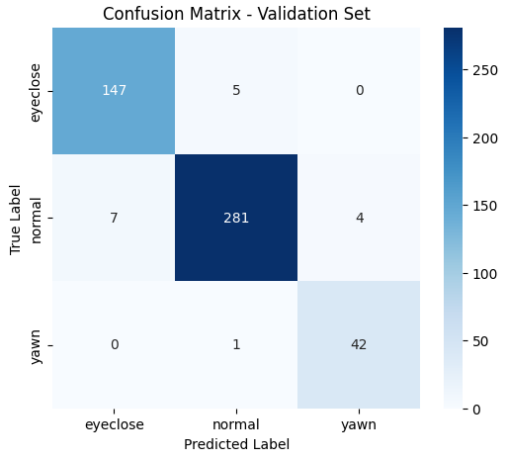


Fig. 8. Confusion matrix HADF.

Fig. 9 presents the algorithm for the simulation results, implemented in Python.

```
class StaticFusion(nn.Module):
    def __init__(self, ...):
        super().__init__()
        self.fc = nn.Linear(total_feat_dim, num_classes)

    def forward(self, feat1, feat2, feat3):
        fused = torch.cat([feat1, feat2, feat3], dim=1)    # <--- Fusi
statis
        out = self.fc(fused)
        return out
```

Fig. 9. Pseudocode using fusion.

Confusion matrix showing the results of the fatigue detection model evaluation on the test data (test set) using the Static Fusion model. Confusion matrix showing the results of the fatigue detection model evaluation on the test data (test set). The following Fig. 10 presents the confusion matrix fusi static.

It shows the model's performance in distinguishing three fatigue condition classes: Normal, Eyeclose, and Yawn. In general, the model achieves an excellent classification rate in the Normal class, with almost perfect accuracy (69 correct instances and only one incorrect instance, which is Eyeclose). Performance in the Eyeclose class is also optimal, with all 45 cases correctly predicted, compared to other courses. However, a significant weakness is seen in the Yawn class. Of the 142 Yawn instances, 108 are predicted correctly, but 34 cases are incorrectly classified as eye closed. This indicates confusion between the yawn expression and the eye-closed condition, both of which exhibit similar visual patterns. This error can be influenced by data quantity imbalance and limitations in visual features. To overcome this, additional strategies are needed, such as data augmentation for the Yawn class, the use of weighted loss, or the utilization of physiological sensor modalities in the adaptive fusion mechanism to increase the model's robustness.

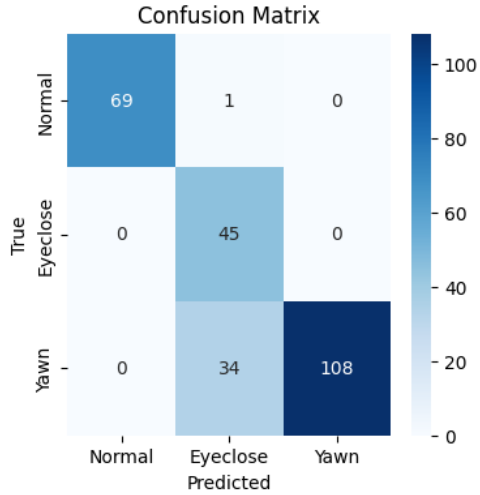

Fig. 10. Confusion matrix fusi static.

D. Comparison of Static Fusion Model Performance of HADF Model

After each model is evaluated separately, this subsection compares their performance. The purpose of this comparison is to determine whether the HADF model, which incorporates weights from the resulting classifications, can achieve significant performance improvements over the Static Fusion model approach. Table II presents a performance comparison between the HADF model and the Static Fusion model, including training and validation accuracies and loss values, to evaluate the stability and generalization capability of each model.

TABLE II. COMPARISON OF STATIC FUSION MODEL PERFORMANCE OF HADF MODEL

Aspect	HADF Model	Static Fusion Model	Analysis
Training Accuracy	Increased from 80.9% → 99.8% (epoch 10)	Increased from 80.7% → 99.6% (epoch 10)	Both models exhibit fast convergence, as they can learn the training data patterns very well.
Validation Accuracy	Stable, peak 96.5% (epoch 10)	Fluctuating, peak 95.0% (epochs 9–10)	HADF is more stable with better generalization; Static Fusion is slightly less stable.
Validation Loss	Consistently decreasing (0.3365 → 0.1189)	Initially decreased (0.3841 → 0.1869) then fluctuated (0.22–0.26)	HADF is more consistent; Static Fusion shows instability.

1) Table Analysis: The results highlight differences in model performance across two training trials — HADF and Static Fusion — focusing on four key aspects: training accuracy, validation accuracy, validation loss, and model stability.

- Training Accuracy: From around 80% in the initial epoch to nearly perfect (99.6–99.8%) in the 10th epoch, both HADF and Static Fusion show very rapid improvement.

This demonstrates the model's ability to learn patterns from the training data, and both methods show rapid convergence.

- Validation Accuracy: HADF consistently achieved a peak validation accuracy of 96.5%, whereas Static Fusion achieved only 95% with a more fluctuating trend. This indicates that HADF is better at maintaining generalization to the validation data, while Static Fusion is slightly less stable despite maintaining high accuracy.
- Loss: In Static Fusion, the value loss dropped drastically initially, but then fluctuated between 0.22 and 0.26, indicating mild overfitting. In contrast, in HADF, the value loss dropped consistently from 0.3365 to 0.1189.

E. Discussion

In summary, the differences between the previous Attention Fusion and HADF models can be summarized in the following points: 1) The Attention Fusion model computes weights for each hidden state of the LSTM in one modality. In contrast, HADF computes stepwise adaptive fusion weights, including intra-modality (spatial-temporal) and inter-modality (between modalities) weights. 2) Weight type, the previous model α_t = attention weight per time (time-step) for one modality, while HADF. α_t^m time in one modality (intra-fusion). β_t^m = Temporal attention weight per modality, y_m = weight between modalities (inter-fusion). 3) Fusion level, the previous model uses a single-level (directly from hidden states to aggregation), while HADF Multi-level: intra-modality-temporal pooling-inter-modality.

IV. CONCLUSION

The Two-Level Hierarchical Adaptive Dynamic Fusion (HADF) formulation represents a novel and scientifically grounded solution for fatigue prediction, addressing key limitations of prior multimodal fusion approaches such as static weighting, lack of adaptivity to modality quality, and absence of hierarchical processing. HADF integrates two adaptive weighting mechanisms: α (intra-modality), which determines the importance of features within each modality, and γ (inter-modality), which dynamically regulates the contribution of each modality based on input reliability at each timestep. This mechanism provides a scientific explanation for the model's stability—when a modality becomes degraded, noisy, or missing, the adaptive weights automatically downscale its influence while shifting emphasis to more reliable modalities. Experimental results demonstrate that HADF achieves high accuracy and maintains strong robustness under missing-modality and low-quality conditions, outperforming conventional static fusion methods that cannot adjust their weights dynamically. Consequently, the CNN–LSTM architecture augmented with HADF offers not only improved predictive accuracy but also substantial practical relevance for real-world fatigue-monitoring systems in transportation safety, industrial operator supervision, and healthcare applications, where detection failures may have critical consequences.

Optimizer Algorithms Analysis for Intrusion Detection System on Deep Neural Network

H. A. Danang Rimbawa, Agung Nugroho, Muhammad Abditya Arghanie
Cyber Defense Engineering Study Program-Faculty of Science and Defense Technology,
The Republic of Indonesia Defense University, Bogor, Indonesia

***Abstract*—Intrusion Detection Systems (IDS) play a critical role in identifying potential threats and intrusions in real-time within information technology infrastructures. The development of IDS using Deep Neural Networks (DNN) with the UNSW-NB15 dataset has shown significant potential in improving attack classification accuracy. However, the performance of the DNN-based IDS models is highly dependent on the choice of optimization algorithm. This study compares the performance of several commonly used optimizers in DNN training, including SGD, RMSprop, Adam, Adadelta, Adagrad, Adamax, Adafactor, and Nadam. The quantitative analysis demonstrates that Adam achieves the highest accuracy among all optimizers tested, while Adadelta performs the worst. RMSprop shows instability in both validation accuracy and loss convergence, indicating challenges in adapting the learning rate for consistent learning. The ANOVA analysis yields an F-statistic of 34.687, which is greater than the F-critical value of 2.140 at a significance level of $\alpha = 0.05$. This result confirms a statistically significant difference in performance among the tested optimization algorithms. These findings provide valuable insights for selecting the most appropriate optimizer to enhance the performance of DNN-based intrusion detection systems. Furthermore, this research contributes to the existing literature by offering a comprehensive comparative evaluation of optimizers, supporting future studies in improving IDS optimization strategies.**

Keywords*—Deep Neural Networks (DNN); Intrusion Detection System (IDS); optimization algorithms; UNSW-NB15 dataset

I. INTRODUCTION

In today's rapidly evolving digital era, information technology infrastructure has become increasingly vulnerable to sophisticated and complex cyber-attacks. Cyber threats take many forms, including malware, phishing, and targeted intrusions that compromise sensitive data and critical systems. Intrusion Detection Systems (IDS) play a vital role in safeguarding networks by continuously monitoring traffic, identifying suspicious behavior, and providing timely alerts. Effective IDS implementation significantly enhances an organization's ability to detect, prevent, and respond to cyber-attacks swiftly and accurately.

Advancements in IDS technologies have enabled the development of more intelligent and adaptive solutions. Modern IDS increasingly integrates machine learning [2] and deep learning to detect attack patterns that traditional rule-based or signature-based systems may overlook. As organizations become more dependent on digital infrastructures and online services, artificial intelligence (AI) has emerged as an essential component in strengthening cybersecurity defenses. AI-driven IDS solutions enable rapid and precise detection, allowing organizations to proactively mitigate threats before substantial damage occurs.

Previous studies have explored the use of artificial intelligence, particularly Deep Neural Networks (DNN), within the IDS frameworks. Aleesa et al. demonstrated promising results using DNNs optimized with Adam on the UNSW-NB15 dataset, which contains a diverse set of modern cyber-attack scenarios and is widely used for benchmarking IDS performance. However, the effectiveness of DNN-based IDS heavily depends on the choice of optimization algorithm employed during training, which directly influences convergence stability, classification accuracy, and model robustness.

Although several optimization algorithms have been evaluated, existing studies often focus on limited contexts, such as specific datasets, single optimizers, or models other than IDS. For example, Dogo et al. evaluated various optimization methods within CNN architectures; however, their work does not provide a comprehensive comparison tailored specifically for IDS using deep learning, nor does it include statistical validation to confirm whether performance differences among optimizers are significant. This highlights a clear gap in the literature, in which no study has systematically examined multiple optimizers on IDS with DNN while applying rigorous statistical methods.

To address this gap, this research conducts a systematic comparative analysis of eight optimization algorithms, namely Stochastic Gradient Descent (SGD), Root Mean Square Propagation (RMSprop), Adaptive Moment Estimation (Adam), Adadelta, Adagrad, Adamax, Adafactor, and Nesterov-accelerated Adam (Nadam), applied to a DNN-based IDS trained on the UNSW-NB15 dataset. The novelty of this work lies in its quantitative approach, including the use of ANOVA to statistically validate whether there are meaningful differences in optimizer performance. By integrating empirical testing and formal statistical analysis, this study provides a deeper understanding of how optimizer selection affects IDS accuracy, stability, and convergence behavior.

The contributions of this study are threefold. First, it provides the most comprehensive statistical comparison to date of commonly used optimization algorithms within a DNN-based IDS framework. Second, the study identifies the most suitable optimization algorithm for the UNSW-NB15 dataset, offering practical guidance for cybersecurity researchers and practitioners seeking to enhance IDS performance. Third, the

findings demonstrate the substantial impact of optimizer selection on IDS design and deployment, contributing valuable insights for strengthening proactive cybersecurity strategies in response to increasingly sophisticated cyber threats.

II. Related Works

In this section, the researchers discuss the application of Deep Neural Networks (DNN) in Intrusion Detection Systems (IDS) by analyzing several optimization algorithms, including SGD, RMSprop, Adam, Adadelta, Adagrad, Adamax, Adafactor, and Nadam. This study focuses on evaluating and comparing the performance of these optimization algorithms to enhance the effectiveness of DNN-based IDS. Previous research on DNN for IDS has also examined various architectures and learning strategies aimed at improving detection accuracy and computational efficiency. Collectively, these studies contribute to the development of more robust and adaptive IDS models capable of addressing evolving cyber threats.

To provide a structured overview of prior research, Table I summarizes relevant studies, including the models used, optimizers applied, datasets utilized, and their relevance to the present work. The inclusion of this table ensures that related works are not only listed but also explicitly integrated into the discussion, in accordance with the reviewer's comments.

TABLE I. Summary of Related Works

Author	Model	Optimizer	Dataset	Relevance
[1]	CNN	N/A	UNSW-NB15	The paper discusses the use of CNN in IDS using the UNSW-NB15 dataset, so that it can be used as a reference for using the UNSW-NB15 dataset in research.
[3]	DNN	Adam	UNSW-NB15	The paper discusses the use of DNN with the Adam optimizer on IDS using the UNSW-NB15 dataset, which makes it relevant to this study.
[5]	CNN	$_{V}$SGD, SGD_{M}, SGD_{NM}, ADAGrad, RMSProp, ADAM, ADADelta, ADAMax, NADAM	Cats and Dogs, Natural Images, and Fashion MNIST	The paper discusses the comparison of optimization algorithms for image classification using CNN, so that it can be used as a reference for comparing optimization algorithms on IDS in this research.
[6]	CNN	$_{V}$SGD, SGD_{M}, SGD_{NM}, ADAGrad, RMSProp, ADAM, ADADelta, ADAMax, NADAM	MNIST, CIFAR-10. LFW, Kaggle Flowers	The paper discusses the comparison of optimization algorithms for image classification using CNN, so that it can be used as a reference for comparing optimization algorithms on IDS in this research.
[7]	VAE	NADAM	NSL-KDD, UNSW-NB15	The paper discusses the use of VAE with the NADAM optimizer on IDS using the UNSW-NB15 dataset, so it can be used as a reference in this research.
[8]	DNN	SGD	NSL-KDD	The paper discusses the use of DNN with the SGD optimizer on IDS using the NSL-KDD dataset, so that it can be used as a reference in research.

As shown in Table I, [1] explores the use of Convolutional Neural Networks (CNN) for IDS using the UNSW-NB15 dataset. This study highlights the suitability of UNSW-NB15 for intrusion detection research due to its comprehensive coverage of modern cyberattack types. The relevance of [1] lies in validating the dataset selection adopted in the present research.

The study [3], also summarized in Table I, examines the use of DNN with the Adam optimizer on the UNSW-NB15 dataset. Insights from [3] support the need to evaluate multiple optimizers, as Adam has shown promising performance but has not been compared extensively against other optimization algorithms in a standardized IDS environment.

The study [5] provides a comparative analysis of optimization algorithms for CNN-based image classification tasks across multiple datasets. Although this domain differs from IDS, the comparative methodology is relevant and demonstrates the importance of understanding optimizer behavior across various learning contexts. This serves as a conceptual foundation for evaluating optimization algorithms within IDS, which is the core objective of the present study.

Similarly, [6] compares multiple optimization algorithms using CNN on several datasets, including MNIST, CIFAR-10. LFW and Kaggle Flowers. As indicated in Table I, this study offers methodological guidance for multi-optimizer evaluation and reinforces the need for robust comparative experimentation.

The study [7] discusses the use of Variational Autoencoders (VAE) with the Nadam optimizer for IDS using NSL-KDD and UNSW-NB15. This finding demonstrates that optimization algorithms significantly influence IDS performance across different machine learning models, further justifying the present study's focus on optimizer comparison.

The study [8] evaluates DNN with the SGD optimizer using the NSL-KDD dataset. As summarized in Table I, this work highlights how optimizer selection affects DNN performance in IDS applications.

Collectively, the studies outlined in Table I reinforce the importance of evaluating optimization algorithms and provide the theoretical and methodological foundation for this research. They emphasize the necessity of systematically comparing multiple optimizers on the same IDS task using a consistent DNN architecture and dataset. Furthermore, integrating these studies into the discussion allows the current research to clearly position its contributions within the broader body of literature and identify remaining gaps, particularly the lack of comprehensive optimizer comparisons for IDS using the UNSW-NB15 dataset.

III. Materials and Methods

In this study, the researchers examine the use of Deep Neural Networks (DNN) for Intrusion Detection Systems (IDS) based on the UNSW-NB15 dataset by analyzing the performance of several optimization algorithms, including SGD, RMSprop, Adam, Adadelta, Adagrad, Adamax, Adafactor, and Nadam. The primary focus of this work is to evaluate how these optimizers influence model convergence, accuracy, and stability when applied to DNN-based IDS.

Previous research on DNNs for IDS has typically focused on exploring different network architectures or improving feature extraction techniques. However, studies that provide a systematic comparison of optimization algorithms within the same experimental setting are still limited. This research addresses that gap by offering a structured and comprehensive evaluation of multiple optimizers under identical conditions, enabling a clearer understanding of their relative effectiveness for intrusion detection tasks. Through this comparative analysis, the study contributes to the development of more efficient IDS models capable of responding to evolving cyber threats.

A. UNSW-NB15 Dataset

The UNSW-NB15 dataset was developed and published by the University of New South Wales in 2015. Since its introduction, this dataset has become one of the most important data sources in network security research. UNSW-NB15 contains various categories of attacks that represent different types of threats that may occur in a real network environment. In addition, the dataset records the number of unique IP addresses involved during the simulation and data collection process, providing a comprehensive view of diverse network traffic characteristics. This dataset has been widely used to develop and evaluate intrusion detection techniques, as well as to assess the performance of various security algorithms [4].

TABLE II. UNSW-NB15 Dataset

Category	Number of Attacks
Normal	93000
Analysis	2677
Backdoor	2329
DoS	16353
Exploit	44525
Fuzzers	24246
Generic	58871
Reconnaissance	13987
Shellcode	1511
Worms	174
Total	257673

As shown in Table II, the UNSW-NB15 dataset consists of nine major attack categories, including Normal, Analysis, Backdoor, DoS, Exploit, Fuzzers, Generic, Reconnaissance, Shellcode, and Worms, with a total of 257,673 attack instances. This distribution illustrates the broad coverage of cyberattack types contained in the dataset, making it suitable for performance evaluation of machine learning-based IDS models.

The dataset provides a rich set of features extracted from packet headers, protocol information, connection duration, transferred bytes, and many other attributes. These features enable detailed analysis of network behavior and support the development of more effective intrusion detection models. With this level of feature diversity, researchers can perform thorough data preprocessing, identify critical traffic patterns, and develop advanced intrusion detection techniques using machine learning approaches such as Deep Neural Networks (DNN). The features included in the UNSW-NB15 dataset serve as an essential foundation for building, training, and validating IDS models in contemporary cybersecurity research.

B. Deep Neural Network

Deep Neural Networks (DNN) incorporate one or more hidden layers between the input and output layers of an artificial neural network. These hidden layers enable the model to learn complex patterns and relationships within the dataset. During the learning process, the DNN iteratively adjusts its parameters to minimize the difference between predicted outputs and actual targets. This optimization process involves propagating input data through the network, generating predictions, comparing them with the true labels, and calculating the resulting error. Using appropriate optimization algorithms, the network updates its parameters to reduce this error and improve overall performance [6].

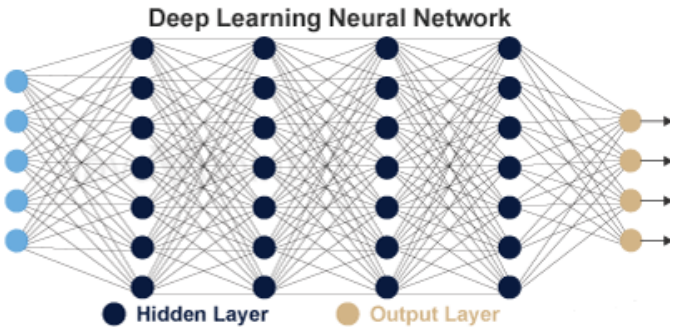

Fig. 1. DNN architecture.

Fig. 1 illustrates the general architecture of a DNN. Each layer in a DNN performs specific transformations on the input data, gradually extracting higher-level features as the information passes through the network. These layers consist of interconnected neurons, where each neuron computes a weighted sum of its inputs and applies an activation function to introduce non-linearity into the model. This nonlinear transformation allows DNNs to learn complex and abstract representations from data, making them highly effective for tasks such as image recognition, video analysis, and intrusion detection [7].

The design of the hidden layers plays a crucial role in determining the performance of a DNN. Factors such as the number of hidden layers, the number of neurons in each layer, and the activation functions used have a direct impact on the model's ability to learn and generalize. In the context of Intrusion Detection Systems (IDS), it is essential to consider

how modifications to the hidden layer structure may influence the model's responsiveness to changing network environments and evolving attack patterns [8].

C. Optimization Algorithms

The selection of an optimization algorithm for a neural network is one of the most important steps in the process of developing an effective and efficient model. With the wide variety of algorithms available, the right choice can make a big difference in model performance and accuracy. One of the key factors in choosing an algorithm is understanding the characteristics of the data and the task at hand. Each algorithm has its own advantages and disadvantages and is suitable for certain types of problems.

The use of optimization algorithms in Deep Neural Networks (DNN) can affect performance, convergence speed, and even the possibility of the resulting model. Several factors that need to be considered in selecting an algorithm include the type of problem being faced, data size, network architecture, and available computing resources. In this study, we compare the performance of different optimization algorithms on the same task using the same model and dataset.

D. Stochastic Gradient Descent (SGD)

The Stochastic Gradient Descent (SGD) optimization algorithm is commonly used in training Deep Neural Networks (DNN). This algorithm works by iterating through the training dataset and updating the model parameters based on the gradient of the loss function estimated from a number of samples (usually a batch) at each iteration [9]. In DNN, SGD updates the weights and biases of the neural network to minimize the value of the loss function produced by the network on the training data. The SGD algorithm can be a simple algorithm and can be successfully used in machine learning models [10].

E. Adagrad

The AdaGrad optimization algorithm individually adjusts the learning rate of model parameters. A rapid decrease in learning rate occurs for parameters with the largest loss partial derivatives, while parameters with small partial derivatives experience a relatively small decrease in learning rate, which is implemented by utilizing all historical squared gradient values. In general, for some learning models, these algorithms work well for simple quadratic problems but often stop too early when training neural networks [11].

Adaptive Gradient (AdaGrad) uses a temporal history of gradient updates to improve convergence speed and reduce reliance on manually tuning learning rates, making it a popular choice for Deep Neural Network (DNN) optimization. The algorithm adaptively updates the learning rate to enable accelerated convergence without the effort of adjusting the learning rate. Therefore, this method is a popular, ready-to-use choice for DNN optimization. The Stochastic Gradient Descent (SGD) optimization algorithm is commonly used in training [12].

F. AdaDelta

Adaptive Delta (Adadelta) uses model parameters with individually determined learning rates. The learning rate in Adadelta decreases dynamically over time. This concept differs from many other optimization algorithms that use a fixed or linearly decreasing learning rate. In Adadelta, this decrease in learning speed occurs gradually until it finally reaches a point where the learning process cannot continue any further. This reduction in learning rate can be an important factor in maintaining model stability and convergence, especially in the case of large and complex data sets. By adaptively adjusting the learning rate, Adadelta helps minimize the risk of getting stuck in undesirable local minimum and increases the chances of finding better solutions globally [13].

G. RMSProp

Root Mean Square Propagation (RMSProp) with momentum updates parameters by applying momentum to the rescaled gradient. RMSProp sets the learning rate by reducing it by the root mean square value of the gradients accumulated from previous updates. In RMSProp, the learning rate is reduced to a small value, allowing updates to be automatically adjusted to approach the local minimum. RMSProp performs better in a nonconvex setting by converting the gradient accumulation into an exponentially weighted moving average. RMSProp uses an exponentially decreasing moving average to ignore the history of past extreme points so that it can quickly converge after encountering a convex bowl [14].

H. Adam

Adaptive Moment Estimation (Adam) [11], [15] is one of the most widely used optimization algorithms in deep learning by calculating individual adaptive learning rates for different parameters of the first and second gradient moment estimates. Adam combines the advantages of AdaGrad, which works well with sparse gradients, and RMSProp, which works well in online and non-stationary settings. Additionally, Adam includes a bias correction in the first and second moment estimates to account for their initialization.

Adam requires little adjustment to the learning rate and is easy to implement, and does not change as the gradient diagonal scale changes. Adam is also computationally efficient and requires little memory. Additionally, Adam is suitable for non-stationary purposes and problems with very noisy and sparse gradients. Adam combines the advantages of RMSProp and momentum. Adam [14] is often used as a replacement for traditional stochastic gradient reduction methods that dynamically update the learning rate for each parameter and are considered computationally efficient with low memory requirements. Mean Square Propagation (RMSProp) with momentum updates parameters by applying momentum to the rescaled gradient.

I. AdaMax

AdaMax [15] is a development of the Adam optimization algorithm, which takes the basis of the infinity norm. The AdaMax algorithm starts by calculating the gradient against the stochastic objective, then estimating the first moment bias, and calculating the infinite norm is then weighed exponentially. Biased first moment estimation is a method to estimate the average gradient at each time step, while the exponentially weighted infinity norm is used to measure the magnitude of the largest gradient at each time step. Parameter adjustments in

Adamax are carried out by considering the biased first moment estimates as well as the exponentially weighted infinite norm. AdaMax can help improve the efficiency and performance of optimization algorithms, especially in machine learning contexts involving complex models with many parameters. In [16], AdaMax's performance is superior in numerical function optimization in model learning for image classification.

J. Adafactor

Adafactor [17] simply maintains the average number of moves per row and per column and estimates the second moment per parameter based on this number. With this approach, Adafactor efficiently updates model parameters by considering information from simplified exponential moving averages, i.e., only per-row and per-column calculations. This allows Adafactor to have fast and efficient performance in optimizing models, especially on large-scale problems or in deep learning contexts where model complexity and data volume are very high. The simplicity of the Adafactor approach allows it to be implemented easily and can be applied in a variety of learning models.

K. Nadam

Nesterov-accelerated adaptive momentum estimation (Nadam) [18] simplifies the Nesterov acceleration to approximate the first moment of the Adam gradient. But the acceleration does not use any extrapolated point gradients. The Nadam approach indeed simplifies the acceleration process in the Adam method by focusing on estimating the first moment of the gradient. The acceleration [19] implemented in Nadam does not consider the gradients of the extrapolated points, which may reduce the effectiveness of the algorithm in adapting the learning steps. Additionally, theoretical deficiencies in guaranteeing convergence can lead to uncertainty in the performance and stability of algorithms across different modeling conditions and datasets.

L. Methodology

A clear and well-documented research methodology is essential for ensuring the reliability, validity, and reproducibility of a study. By presenting a systematic approach, this research provides strong theoretical and practical contributions that can support further academic development and practical implementation in the field of intrusion detection systems. A transparent methodology also increases confidence in the findings and strengthens the conclusions drawn from the analysis.

The overall method used in this study is illustrated in Fig. 2, which outlines the sequential stages of the research process.

This study begins by using the UNSW-NB15 dataset as the primary input for the intrusion detection system. A data preprocessing phase is then conducted to ensure data quality and integrity. This includes cleaning, normalizing, and preparing the dataset for subsequent modeling stages. After preprocessing, a Deep Neural Network (DNN) is employed to analyze the processed data. DNNs are widely recognized for their capability to learn complex and nonlinear patterns, making them highly effective for tasks related to network security and intrusion detection.

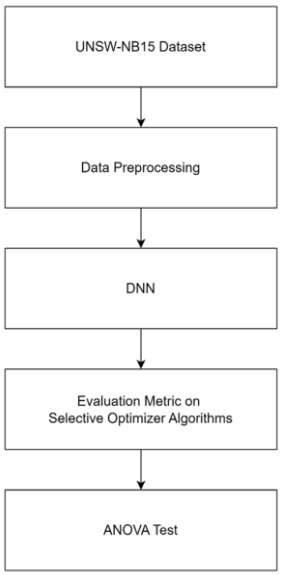

Fig. 2. Research methodology.

Following the implementation of the DNN model, several optimization algorithms are evaluated to assess their impact on training performance and detection accuracy. Evaluation metrics are used to measure each optimizer's effectiveness in improving model learning outcomes. Finally, ANOVA analysis is performed to determine whether significant differences exist among the optimization algorithms tested. This statistical approach [31] helps identify which optimizers perform better and provides insights into their suitability for intrusion detection applications.

1) Data preprocessing: Data preprocessing was carried out to ensure the quality and integrity of the dataset used in this analysis. This process involves removing empty or incomplete entries because missing values may interfere with the analytical process and reduce the accuracy of the results. Irrelevant or unnecessary data was also eliminated to simplify the dataset and maintain analytical focus. Additionally, duplicate entries were identified and removed to prevent distortion and ensure that every instance in the dataset is unique and relevant to the study.

Next, one-hot encoding was applied to categorical features to convert them into binary representations suitable for the model. This step is essential to ensure that the model can correctly interpret and process categorical variables.

Fig. 3. Step-by-step data preprocessing.

Fig. 3 illustrates the sequential steps of the data preprocessing stage. Data normalization was then applied to adjust the scale of numerical features, so they fall within a uniform range. This helps to improve model convergence and prevents certain features from dominating the learning process due to differences in scale. After normalization, the dataset was

divided into three subsets: training data, testing data, and validation data. This partitioning is crucial for evaluating model performance on unseen data and ensuring that the results are validated objectively.

By conducting this comprehensive preprocessing procedure, this study ensures that the data used in the analysis is clean, relevant, and properly prepared to support effective model development and performance evaluation.

2) DNN: Deep Neural Networks (DNN) are utilized in this research to analyze the UNSW-NB15 dataset. A DNN is a neural network architecture capable of learning increasingly complex feature representations through multiple layers of interconnected neurons. These layers enable the model to capture hierarchical patterns in the data, allowing it to understand both low-level and high-level characteristics that are essential for intrusion detection.

A DNN consists of sequential processing layers, starting from the input layer and continuing through multiple hidden layers before reaching the output layer. Each neuron in a hidden layer receives inputs from neurons in the previous layer, applies a weight to each input, and computes a weighted sum followed by an activation function. Through this multilayer transformation, the network gradually converts raw input data into more abstract representations. As information flows through deeper layers, the DNN becomes capable of recognizing complex attack patterns, subtle anomalies, and relationships that are not easily detected through traditional analytical methods.

By using DNN, this study can identify intricate attack behaviors and subtypes that may not be captured by conventional machine learning models. DNN architecture also supports adaptability by enabling the model to adjust to evolving intrusion patterns over time. This contributes to improving detection accuracy and reducing false positives, thereby enhancing the overall performance of the IDS.

The DNN architecture used in this research is presented in Table III, which outlines the model's hyperparameters, including the number of hidden layers, number of neurons, activation functions, number of epochs, and batch size. These settings form the basis for training the model and evaluating the performance of the optimization algorithms examined in this study.

TABLE III. DNN ARCHITECTURE

Hyperparameter	Value/ Type
Hidden Layers	3
Neurons	100
Hidden Layer Activation	Relu
Output Layer Activation	Softmax
Epochs	10
Batch Size	100

3) Evaluation metric on selective optimizer algorithms: The metric evaluation stage in Selective Optimizer Algorithms assesses the performance of several optimization algorithms in the Intrusion Detection System (IDS). The evaluation metrics used in this research include accuracy and loss. This metric helps evaluate how well the optimization algorithm can learn complex patterns in IDS data and make accurate predictions. So you can identify the most suitable and effective optimization algorithm for use on IDS. Choosing the right optimization algorithm can improve the performance and reliability of the IDS in detecting network security threats in a timely and accurate manner. Therefore, this evaluation plays an important role in developing a more effective and responsive network security system.

4) ANOVA test: Analysis of Variance (ANOVA) [30] is a statistical technique used to compare data between three or more different groups. ANOVA considers between-group variation and within-group variation. Between-group variation measures how large the differences in the means are between different groups, while within-group variation measures how large the variation in the values within each group. If the variation between groups is much greater than the variation within groups, then there is an indication that there are significant differences between the groups. ANOVA can be used to analyze data performance from various optimizer algorithms. For example, if there are eight optimizer algorithms being evaluated, ANOVA can be used to determine whether there are significant differences in overall performance between the algorithms. This research will analyze significant differences in performance between the optimized optimizer algorithms tested.

IV. RESULTS AND DISCUSSION

A. SGD Result

Stochastic Gradient Descent (SGD) is one of the most widely used optimization techniques for training machine learning models, particularly in artificial neural networks and Deep Neural Networks (DNN) [20]. SGD optimizes the objective function by following the gradient direction with respect to the model parameters. Its primary goal is to minimize the prediction error by iteratively updating the parameters based on the gradient of the loss function computed from small batches of training data.

In this research, the SGD optimizer is applied to train the DNN model using the UNSW-NB15 dataset. Fig. 4 presents the training and validation accuracy obtained during the model training process, while Fig. 5 shows the corresponding training and validation loss curves.

The results indicate that both training and validation accuracy generally increase with each epoch, demonstrating that the model progressively improves its ability to correctly classify intrusion data. Meanwhile, the loss curves in Fig. 5 show a consistent decrease across epochs for both training and validation datasets. A decreasing loss value reflects better model adaptation to the data because the loss function measures the discrepancy between predicted outputs and actual labels.

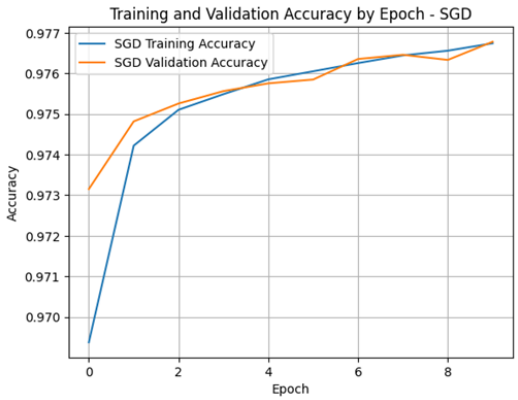

Fig. 4. Training and validation accuracy for SGD.

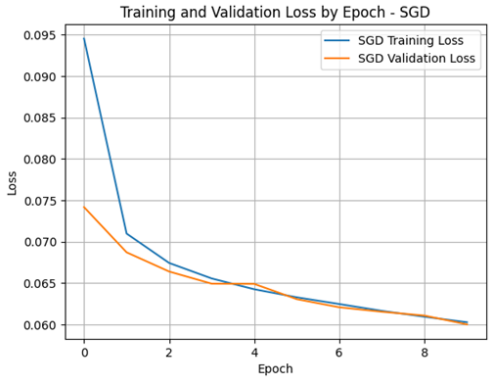

Fig. 5. Training and validation loss for SGD.

This gradual decline in loss indicates effective convergence, meaning the model is successfully refining its parameters to reduce prediction errors. The behavior of the loss curves also suggests that SGD is performing efficiently in updating parameters based on the gradients calculated from mini-batches of data. This characteristic enables faster updates and supports the model in learning more generalizable patterns from the dataset.

B. AdaGrad Result

The AdaGrad algorithm adaptively updates the learning rate to accelerate convergence without requiring manual tuning efforts [21]. This algorithm automatically adjusts the learning rate during the training process, enabling each parameter to be updated based on its historical gradient information. As the model approaches an optimal solution, AdaGrad dynamically modifies the learning rate to ensure efficient parameter optimization.

Fig. 6 presents the training and validation accuracy for AdaGrad, showing how the model's performance improves over successive epochs. AdaGrad enables faster learning in the early stages by assigning larger updates to infrequent features, resulting in a noticeable improvement in accuracy.

Fig. 7 illustrates the training and validation loss for AdaGrad, which consistently decreases as the number of epochs increases. A decreasing loss value indicates that the model is learning effectively and reducing prediction errors over time.

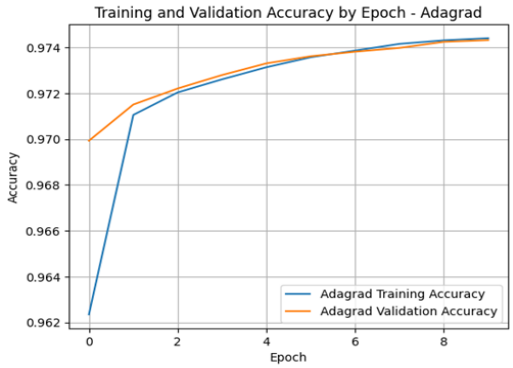

Fig. 6. Training and validation accuracy for AdaGrad.

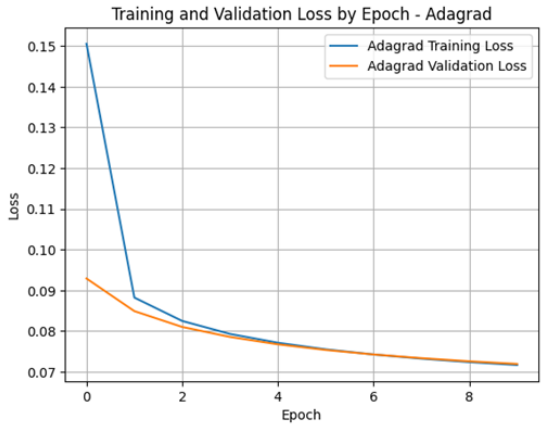

Fig. 7. Training and validation loss for AdaGrad.

The graphs of training and validation accuracy and loss provide a clear representation of how the model evolves across iterations. The increase in accuracy and the decrease in loss demonstrate that the model progressively improves and moves closer to an optimal solution. This behavior highlights AdaGrad's ability to adjust the learning rate dynamically for each parameter, thereby enhancing convergence and improving performance during the training process.

C. AdaDelta Result

Adadelta makes smaller adjustments to frequently updated parameters and larger adjustments to parameters that are updated less frequently [22]. During the model training process, Adadelta adaptively regulates the magnitude of parameter updates based on how often each parameter changes. When a parameter is updated frequently, Adadelta applies smaller adjustments to maintain model stability, as minor refinements are typically sufficient to improve performance.

Fig. 8 shows the training and validation accuracy obtained using the Adadelta optimizer. As illustrated in Fig. 8, the accuracy for both training and validation increases consistently across epochs, indicating stable and sustainable convergence. This demonstrates that the Adadelta algorithm effectively guides the model toward improved accuracy by adaptively optimizing the learning rate based on parameter-specific characteristics.

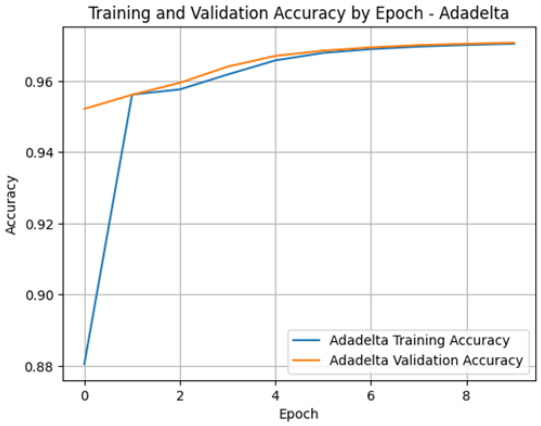

Fig. 8. Training and validation accuracy for AdaDelta.

Fig. 9 presents the training and validation loss for the Adadelta optimizer. The consistent decline in both training and validation loss indicates that the model continues to learn effectively over time. The stable reduction in loss confirms that Adadelta successfully adjusts the learning rate and parameter updates, enabling efficient convergence. This pattern reflects the model's increasing ability to learn from data and move closer to an optimal solution.

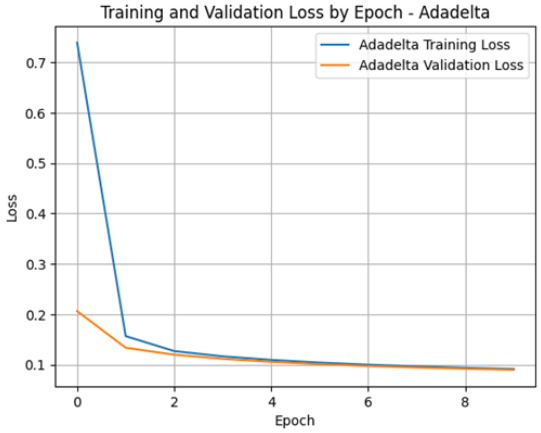

Fig. 9. Training and validation loss for AdaDelta.

D. RMSProp Result

RMSProp is commonly used in training artificial neural network models to accelerate convergence and improve overall training performance by adaptively regulating the learning rate. In RMSProp, the learning rate is adjusted individually for each model parameter based on the exponential moving average of previous squared gradients [23]. This mechanism addresses the limitations of a fixed learning rate by automatically adapting the step size throughout the training process.

Fig. 10 illustrates the training and validation accuracy produced by RMSProp. The graph shows that both training and validation accuracy fluctuate across epochs. Such instability may occur when the learning rate is excessively high, causing divergence, or too low, resulting in very slow convergence. Additionally, complex model architecture or many parameters can contribute to inconsistent learning behavior, as the model may struggle to capture stable patterns within the dataset.

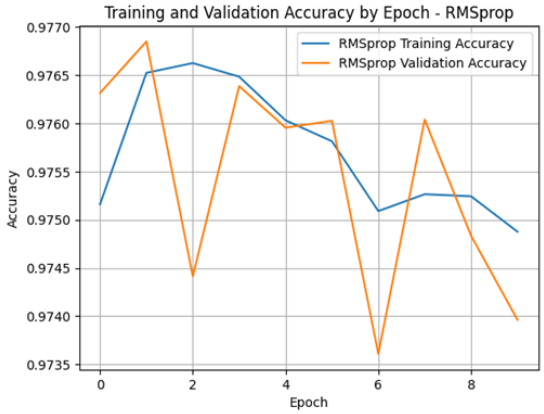

Fig. 10. Training and validation accuracy for RMSProp.

Fig. 11 presents the training and validation loss curves for RMSProp. The results indicate that the training and validation loss increase steadily across epochs, while the accuracy values fluctuate. This pattern suggests that the model is experiencing overfitting. Overfitting occurs when the model becomes too closely aligned with the training data and loses its ability to generalize to unseen data, such as validation samples. One of the common causes of overfitting is excessive model complexity, particularly in deep neural network architectures with large capacity [24].

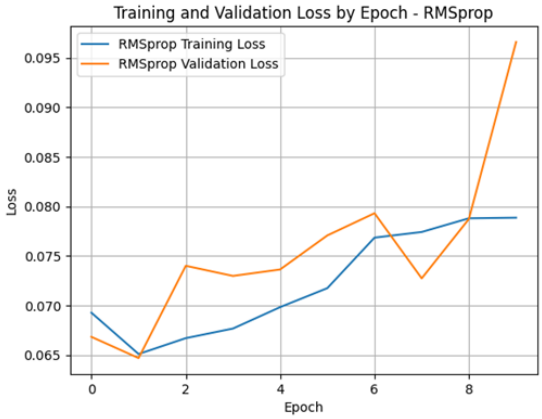

Fig. 11. Training and validation loss for RMSProp.

E. Adam Result

Adam (Adaptive Moment Estimation) is an optimization algorithm designed to combine the advantages of momentum methods and adaptive learning rate techniques [25]. Adam utilizes the accumulated gradient values from previous iterations, weighted by a decay factor, which represents the principle of momentum. Momentum provides acceleration during optimization by considering both the direction and magnitude of parameter changes from earlier iterations. By incorporating historical gradient information, the model can move more efficiently toward the optimal solution.

Additionally, Adam uses the squared gradient from previous updates to estimate variance or fluctuations in the gradient. This mechanism enables Adam to adjust the learning rate adaptively for each parameter. As a result, parameters with high variance receive smaller updates, while those with low

variance receive larger updates. This balance helps stabilize the learning process and prevents drastic fluctuations in parameter adjustments.

Adam uses the first-order derivative of the cost function to update parameters, providing low computational complexity and making it highly efficient. By combining momentum-based gradient estimation with root mean square (RMS) gradient estimation, Adam generates parameter updates with an automatically adjusted learning rate [25]. This adaptive adjustment ensures that parameter updates remain controlled and appropriate throughout the training process.

Fig. 12 shows the training and validation accuracy produced for Adam. The results indicate stable accuracy improvement across epochs during both training and validation. This demonstrates Adam's ability to adaptively modify the learning rate based on gradient information and previous parameter updates, ensuring smooth optimization progress.

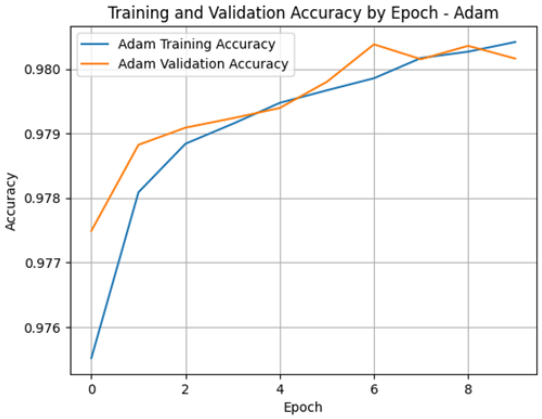

Fig. 12. Training and validation accuracy for Adam.

Fig. 13 presents the training and validation loss for Adam. Both curves show a consistent reduction in loss, indicating effective learning and minimal fluctuations during the optimization process. Adam gradually reduces the learning rate as the model approaches the global minimum, preventing oscillations near the minimum and enabling more precise convergence. This behavior contributes to the stable accuracy gains and steady declines in loss across epochs.

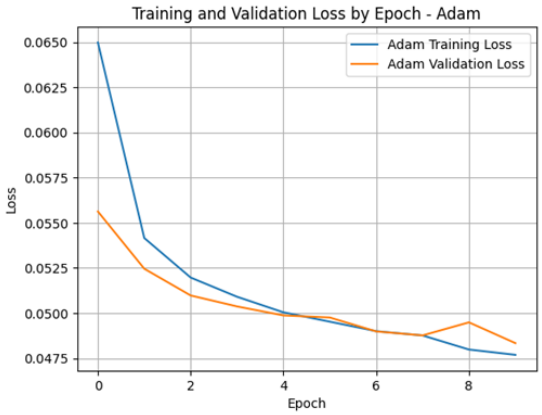

Fig. 13. Training and validation loss for Adam.

By leveraging both momentum and RMS gradient estimates, Adam produces more consistent and reliable parameter updates compared to many traditional optimizers. This results in faster and more stable optimization, making Adam particularly effective for training deep neural networks. The performance observed in this study confirms Adam's capability to handle complex optimization tasks efficiently, as reflected in the stable improvement of accuracy and consistent reduction of loss throughout the training and validation stages.

F. Adamax Result

The performance of the Adamax optimizer is considered strong in numerical function optimization compared to several other optimization algorithms [16]. Adamax is a variant of the Adam (Adaptive Moment Estimation) optimization method, designed to provide more stable parameter updates, especially when the magnitude of the gradient becomes very large. This characteristic enables Adamax to maintain steady convergence during the training of deep learning models.

Fig. 14 shows the training and validation accuracy for the Adamax optimizer. Adamax demonstrates good performance compared to Adam, particularly in situations where the gradient moments are large, and Adam begins to show deviations from optimal updates. The Adamax method utilizes two core components, namely the gradient moment and the root mean square (rms) value of the gradient, to determine parameter adjustments. By incorporating both components, Adamax can generate more adaptive and stable parameter updates, which contribute to faster convergence in complex numerical optimization problems.

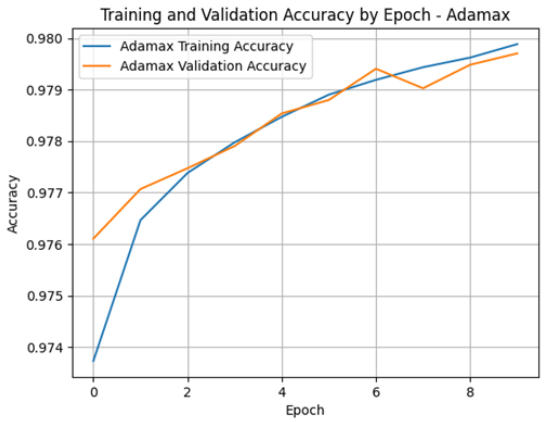

Fig. 14. Training and validation accuracy for Adamax.

However, in this study, the results indicate that Adam performs better than Adamax on the UNSW-NB15 dataset using DNN. This performance difference may occur because each dataset possesses unique distributions and structural patterns that influence model learning behavior. Additionally, the architecture of the DNN model employed in the experiment can also affect the relative performance of Adam and Adamax.

Fig. 15 presents the training and validation loss for the Adamax optimizer.

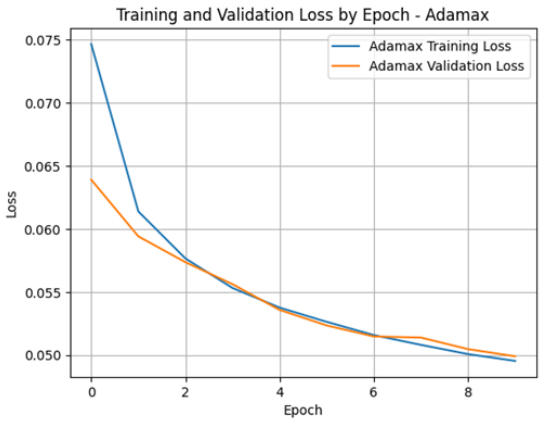

Fig. 15. Training and validation loss for Adamax.

G. AdaFactor Result

The Adafactor optimization algorithm was developed to reduce the memory requirements of the AdaGrad method, particularly for training large language models [26]. Adafactor can operate efficiently by significantly minimizing additional memory usage without sacrificing performance. This is achieved by storing second-moment estimates using a compressed representation that exploits the structural properties of the parameter tensors. As a result, Adafactor enables the training of large-scale neural networks while alleviating memory constraints, which often become a limiting factor in complex model development. By maintaining strong optimization performance while reducing memory overhead, Adafactor offers a more resource-efficient solution in artificial intelligence research and large-scale model training.

Fig. 16 presents the training and validation accuracy for Adafactor. The graph shows that accuracy increases steadily across epochs for both training and validation datasets. This consistent improvement indicates that Adafactor can adjust learning rates adaptively and perform stable parameter updates.

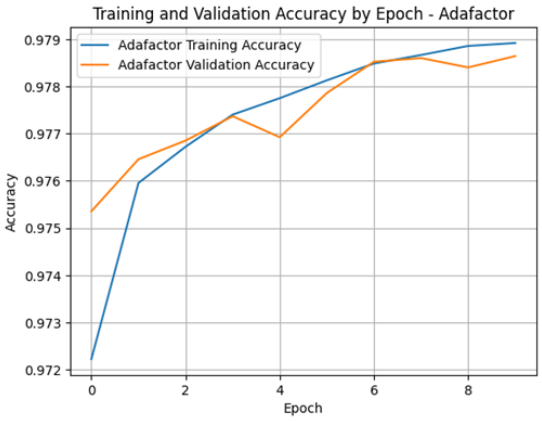

Fig. 16. Training and validation accuracy for AdaFactor.

Fig. 17 illustrates the training and validation loss for Adafactor. The figure shows a continuous and consistent decline in the loss function as training progresses. This stable reduction in loss demonstrates that the algorithm effectively manages the learning rate and updates model parameters efficiently throughout the training process. The combination of increasing accuracy and decreasing loss reflects the algorithm's ability to support model convergence and maintain stability during training.

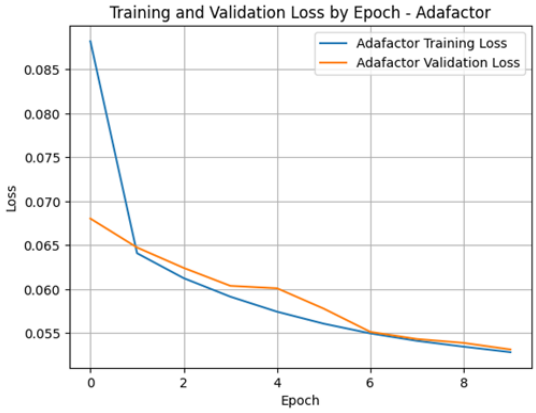

Fig. 17. Training and validation loss for AdaFactor.

H. Nadam Result

Nadam was developed to address inconsistencies that may arise between momentum calculations and parameter updates in optimization algorithms [27]. In the Adam optimization algorithm, momentum is used to incorporate gradient information from previous iterations when determining parameter updates. However, inconsistencies may occur between the calculated momentum and the actual parameter adjustments performed during optimization. Nadam resolves this issue by integrating Nesterov momentum into Adam, resulting in more consistent and targeted parameter updates. This ensures that momentum contributes more reliably to the learning process, making the optimization pathway more stable and predictable while improving convergence.

Fig. 18 illustrates the training and validation accuracy obtained using Nadam. The accuracy curves show a generally stable upward trend during the training and validation phases, indicating that Nadam effectively improves the model's ability to learn patterns from the UNSW-NB15 dataset. The adaptive mechanism in Nadam allows the algorithm to fine-tune parameter updates more carefully, contributing to improved accuracy across epochs.

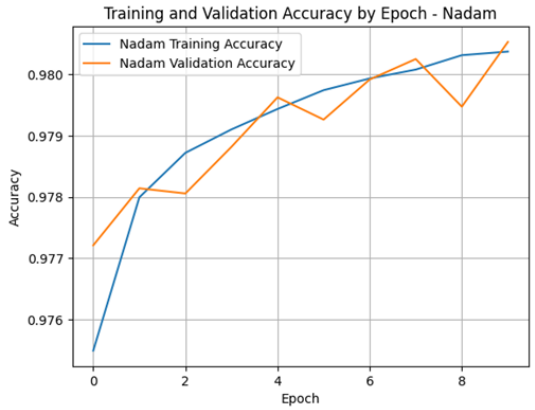

Fig. 18. Training and validation accuracy for Nadam.

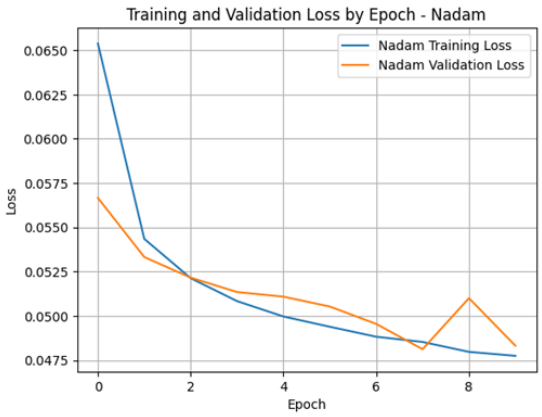

Fig. 19. Training and validation loss for Nadam.

Fig. 19 presents the training and validation loss for Nadam. The results show a steady reduction in both training and validation loss values across epochs. This consistent decline suggests that the model continues to refine its predictions and minimize error during the learning process. The stability of the loss curves indicates that Nadam efficiently adjusts the learning rate and updates model parameters with a controlled trajectory, reducing the likelihood of sudden fluctuations.

An important advantage of Nadam is its ability to produce consistent parameter updates while reducing the risk of overshooting, a condition in which large parameter changes cause the optimization process to move past the optimal point. By ensuring that updates are more controlled and directed, Nadam minimizes this risk. This contributes to a more reliable training process, leading to improved model stability and convergence. As a result, Nadam provides a robust alternative to Adam, particularly in cases where more precise parameter adjustments are needed.

I. Comparison of Optimizer Algorithms

In this research, a comparison was conducted among several commonly used optimization algorithms, including SGD (Stochastic Gradient Descent), RMSprop, Adam, Adadelta, Adagrad, Adamax, Adafactor, and Nadam. The objective of this study is to evaluate the relative performance of each algorithm in the context of model training, with particular focus on accuracy, stability, and convergence behavior.

The results indicate that Adam provides the best overall performance. Its adaptive learning rate mechanism, which adjusts based on gradient information, enables faster convergence and consistently higher accuracy across epochs. Nadam is identified as the second-best performer due to its ability to address some limitations found in Adam, especially regarding momentum estimation and parameter update consistency.

Fig. 20 presents the comparison of all optimization algorithms. Adadelta shows noticeably lower performance compared to the other algorithms. This performance degradation is partly attributed to its more complex hyperparameters, such as decay rate and epsilon, which require precise tuning. Incorrect hyperparameter settings may hamper its convergence speed and overall effectiveness, especially on complex datasets or architectures. Because Adadelta updates the learning rate based on accumulated past gradients, the learning process may become too slow or insufficiently responsive.

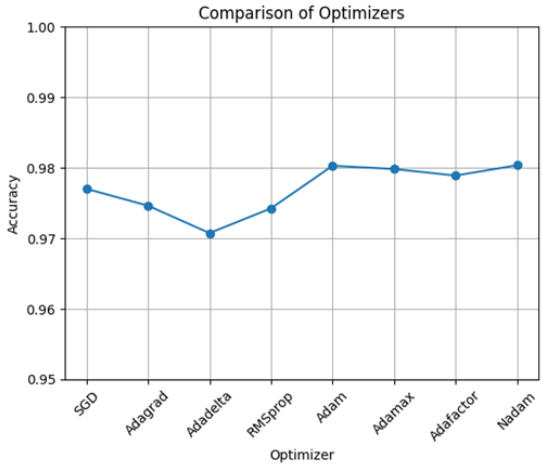

Fig. 20. Comparison of optimizer algorithms.

Fig. 21 illustrates the comparison of training accuracy. Across all algorithms, training accuracy improves significantly at each epoch. This consistent improvement demonstrates that the model continuously learns and generalizes the patterns present in the training data. The steady increase in accuracy suggests that none of the models exhibit symptoms of severe overfitting, as the learning process continues to progress in a stable manner without abrupt fluctuations. This also indicates that the adjustments made by each optimizer during training enable the network to better predict the correct labels from the training set.

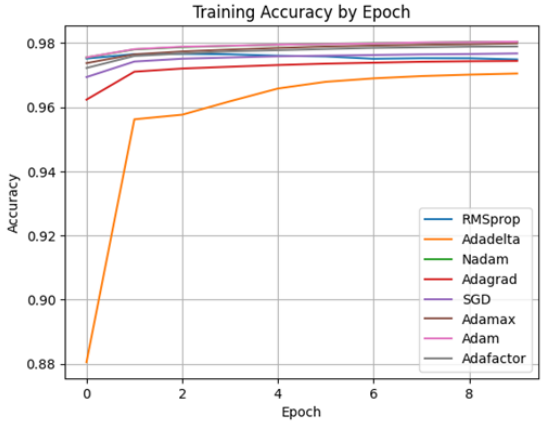

Fig. 21. Comparison of training accuracy.

Fig. 22 shows the comparison of validation accuracy. Validation accuracy also improves across epochs for all algorithms except RMSprop. The inconsistent behavior of RMSprop indicates difficulty in adjusting the learning rate effectively when processing validation gradients. This may be due to its sensitivity to specific hyperparameter values, such as learning rate and decay rate. Improper settings can lead to unstable or slow convergence on the validation dataset.

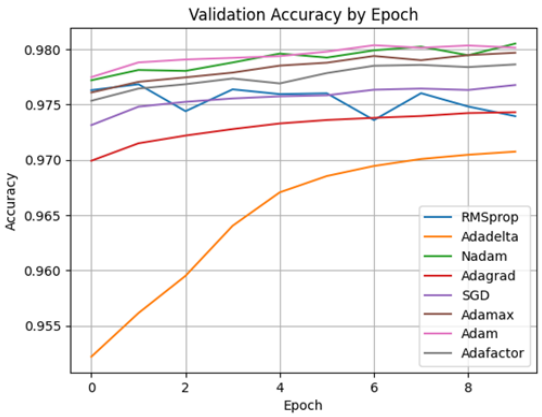

Fig. 22. Comparison of validation accuracy.

Fig. 23 depicts the comparison of training loss. All algorithms experience a steady decline in training loss at each epoch, demonstrating continual improvement in reducing prediction error during the learning process. A consistent decrease in training loss is a strong indication that the model is progressing well and learning meaningful representations from the data.

Fig. 24 presents the comparison of validation loss across all optimizers. The validation loss decreases steadily across all algorithms except RMSprop. This decline indicates improved generalization capability to unseen data. RMSprop's irregular behavior reinforces the earlier observation that this optimizer may struggle with gradient-based adjustments on validation data, especially under suboptimal hyperparameter configurations.

The performance accuracy values for each optimizer used in this research are summarized in Table IV.

J. ANOVA Test

One method to compare classifiers is by using the Analysis of Variance (ANOVA) test to evaluate the accuracy produced by each classifier. ANOVA determines whether there are statistically significant differences between the accuracies generated by the classifiers tested [28]. In this study, ANOVA is used to evaluate whether there are significant performance differences among the optimization algorithms applied to a DNN-based classifier. ANOVA assesses the equality of multiple means by comparing the variance between groups with the variance within groups [29].

Statistical hypothesis testing was conducted to determine whether significant differences exist among the optimization algorithms. ANOVA evaluates how the variation between groups compares with the variation within groups. A statistically significant result, indicated by a p-value lower than the predetermined significance level, supports the decision to reject the null hypothesis. The hypotheses used in this research are presented in Table V.

TABLE V. RESEARCH HYPOTHESIS

Hypothesis	Description
H0	There is no significant difference in performance between the tested optimizer algorithms in detecting intrusions on systems using DNN.
H1	There is a significant difference in performance between the tested optimizer algorithms in detecting intrusions on systems using DNN.

Table V summarizes the null hypothesis (H0) and the alternative hypothesis (H1). The null hypothesis states that there is no significant difference in the performance of the tested optimizers in detecting intrusions using DNN. The alternative hypothesis states that a significant difference exists. These hypotheses guide the statistical analysis to identify whether the collected data support the null or the alternative hypothesis. If the results show significant differences between groups, the null hypothesis is rejected.

After performing ANOVA on the optimizer performance data, based on the Validation Accuracy of Optimizer Algorithms, the results were obtained in the form of F-statistic and p-values. If the p-value is smaller than the significance level, typically $\alpha = 0.05$, the null hypothesis is rejected. This means that at least two optimization algorithms differ significantly in performance. This pattern indicates that choosing the appropriate optimizer can have a meaningful impact on the performance of an intrusion detection system. If the p-value is greater than α, the null hypothesis cannot be rejected, meaning the evidence is insufficient to confirm a significant difference. This lack of significance may be due to small sample sizes or low variability in the data.

A high F-statistic value in an ANOVA test indicates that the variation between group means is greater than the variation within the groups. A higher F-value reflects real performance differences among the optimization algorithms tested. This is important when choosing an optimal algorithm for intrusion detection, as performance differences may influence the effectiveness of the system. High F-values also highlight the need for further analysis, such as pairwise comparisons, to better understand which algorithms differ and to what extent. This information can support decision-making in future research and system implementation.

The results of the ANOVA test conducted on the UNSW-NB15 dataset using the DNN model are presented in Table VI. This test evaluates whether significant performance differences exist among the optimization algorithms.

Based on Table VI, the ANOVA analysis produced an F value of 34.68717049, while the F-critical value calculated at a significance level of $\alpha = 0.05$ was 2.139655512. Since the F value exceeds the F-critical value, the null hypothesis is rejected. This confirms that significant performance differences exist among the tested optimization algorithms. These results support the alternative hypothesis, which states that the optimization algorithms differ significantly in detecting intrusions using DNN. The implication is that selecting the appropriate optimization algorithm can substantially enhance the performance of intrusion detection systems.

V. CONCLUSIONS AND LIMITATIONS

Based on the experimental findings, the Adam optimizer demonstrated the best overall performance on the UNSW-NB15 dataset when applied to a Deep Neural Network-based Intrusion Detection System. Adam consistently produced stable improvements in accuracy and steady reductions in loss across epochs, indicating its effectiveness in accelerating convergence and maintaining model stability. Nadam ranked as the second-best performer, while Adadelta yielded the lowest accuracy among the evaluated algorithms. RMSprop exhibited noticeable fluctuations in validation accuracy and validation

loss, suggesting that it may require more careful hyperparameter tuning or may be less suitable for certain IDS configurations.

The results from the ANOVA analysis provide strong statistical validation of these observations. The obtained F-statistic value of 34.687, which exceeds the critical value of 2.139 at $\alpha = 0.05$, confirms that significant performance differences exist across the eight optimization algorithms. These findings highlight the importance of optimizer selection as a critical determinant of the overall performance and reliability of DNN-based intrusion detection systems.

While Adam and Nadam emerged as promising candidates for IDS implementation, several limitations must be considered. This study relied on a single dataset and did not incorporate cross-validation or extensive hyperparameter optimization, which may influence generalizability. Additionally, the evaluation focused primarily on accuracy and loss, without including broader IDS performance metrics such as precision, recall, F1-score, false positive rate, or AUC. Incorporating these metrics would provide a more complete assessment of the practical effectiveness of each optimization method in real-world intrusion detection scenarios.

To advance future research, several directions are proposed. Expanding the experimental framework to include multiple datasets with different traffic and attack characteristics would strengthen generalizability. More comprehensive hyperparameter optimization and the inclusion of additional performance metrics would support more rigorous evaluation and facilitate practical deployment. Further exploration of optimizer behavior across different deep learning architectures, operational environments, and adversarial conditions may also offer deeper insight into the stability, robustness, and adaptability of each algorithm. Overall, this study contributes to the growing body of knowledge on optimization strategies for IDS and underscores the critical role of optimizer selection in improving cybersecurity resilience.

Shadow IT Transformation in the Post-Pandemic Digital Workplace: A Systematic Literature Review

Ginanjar Nugraha, Munir, Puspo Dewi Dirgantari
Universitas Pendidikan Indonesia, Bandung, Indonesia

***Abstract*—The COVID-19 pandemic has significantly altered organizational work patterns, accelerating digital transformation and the adoption of remote and hybrid work models. These changes have affected the practice of shadow IT, the use of unauthorized IT by employees without formal IT approval. This systematic literature review aims to explore how the pandemic and the shift to remote work have impacted shadow IT adoption, motivations, and management strategies in the context of digital transformation. We followed the PRISMA 2020 guidelines to conduct a search of peer-reviewed articles published between 2018 and 2025 across multiple databases (Scopus, Web of Science, IEEE Xplore, ACM Digital Library, AIS eLibrary). A total of 67 studies were included based on predefined criteria. The review identified key themes related to the evolving nature of shadow IT adoption, its associated risks, and adaptive management practices. Shadow IT adoption increased from 30 to 40% before the pandemic to 41% in 2022, with projections suggesting it could reach 75% by 2027. The findings show a shift in motivation for adopting shadow IT, from convenience-driven use to a necessity for business continuity, and finally, to a strategy for optimizing organizational processes. This review highlights the need for organizations to rethink IT governance in the post-pandemic digital workplace, as shadow IT has moved from an issue to be eliminated to a phenomenon that can be managed and leveraged.**

Keywords*—*Shadow IT; COVID-19; remote work; digital transformation; systematic literature review; IT governance

I. Introduction

The COVID-19 pandemic triggered an unprecedented global shift toward remote and hybrid work arrangements, fundamentally altering the landscape of organizational information technology (IT) usage [1], [2]. This rapid transformation has coincided with an accelerated digital transformation journey for many organizations, creating new challenges and opportunities in IT governance and management [3], [4].

Shadow IT, defined as the use of information technology systems, devices, software, and services without explicit IT department approval or oversight [5], as noted in [6], has experienced significant changes during this period. Recent studies indicate that shadow IT adoption has surged dramatically, in [7], where the authors document an unprecedented increase in unauthorized technology use across distributed work environments. Traditional estimates suggested that shadow IT accounts for 30 to 40% of IT spending in large enterprises, but as suggested by current research in [8], this figure has risen substantially, with predictions that 75% of employees will use technology outside IT oversight by 2027.

The convergence of remote work necessities, accelerated digitalization, and changing employee behaviors has created a unique context for examining shadow IT phenomena [9], [10]. Unlike pre-pandemic shadow IT usage, which was primarily driven by convenience and efficiency gains [11], [12], post-pandemic shadow IT appears to be influenced by survival-driven digital adoption and distributed work requirements [13], [14].

Despite the growing importance of this topic, existing literature lacks a comprehensive synthesis of how pandemic-driven changes have transformed shadow IT practices. Previous systematic reviews have focused primarily on traditional organizational contexts [15], [16], with limited attention to the transformative impact of remote work and accelerated digital transformation. Recent calls for research in [17] emphasize the urgent need for systematic examination of crisis-driven technology adoption patterns.

This systematic literature review addresses the following primary research question: How has the COVID-19 pandemic and the transition to remote/hybrid work transformed shadow IT adoption patterns, motivations, and organizational management strategies in the context of digital transformation?

Secondary research questions include:

- What changes have occurred in the types and volume of shadow IT tools adopted pre- versus post-pandemic?
- How have employee motivations for shadow IT usage evolved in remote/hybrid work environments?
- What new security and compliance risks have emerged from pandemic-driven shadow IT adoption?
- Which management strategies have proven effective for governing shadow IT in distributed work contexts?
- How do transformation patterns differ across industries and organizational sizes?

Despite several existing reviews on shadow IT, most prior studies have concentrated on traditional organizational settings, pre-pandemic technology behavior, or general IT governance challenges. These reviews did not account for the rapid structural shift toward remote and hybrid work, nor did they examine how crisis-driven digital adoption reshaped motivations, risks, and governance mechanisms. The value added of this review lies in its integrated synthesis of post-pandemic shadow IT evolution across motivations, risk profiles, managerial responses, and cross-industry contexts. Unlike previous reviews, this study captures how organizational crises

altered employee technology behavior and how these changes continue to influence digital workplace strategies today.

The remainder of this study is organized as follows: Section II presents the theoretical background relevant to shadow IT and digital transformation. Section III outlines the methodological protocol used in this systematic review. Section IV provides the results of the synthesis, followed by a discussion of the theoretical and practical implications in Section V. Section VI concludes the study with key insights, practical recommendations, and directions for future research.

II. Literature Review and Theoretical Background

A. Shadow IT Conceptualization

Shadow IT encompasses various forms of unauthorized technology adoption within organizations, ranging from simple software installations to complex system implementations [18], [19]. The phenomenon has been studied through multiple theoretical lenses, including organizational behavior theory [20], technology acceptance models [18], and IT governance frameworks [21]. Recent research in [8] extends this conceptualization to include crisis-driven adoption patterns, while in [22], the authors examine the role of artificial intelligence in expanding shadow IT boundaries.

Contemporary definitions emphasize the dynamic nature of shadow IT in distributed work environments. Ashrafi in [13] argues that traditional conceptualizations require updating to account for the "problematization" of shadow IT in digital transformation contexts, where unauthorized technology use may serve legitimate innovation purposes. This perspective aligns with findings from Asian contexts, in [23] [24], the authors document cultural variations in shadow IT conceptualization and organizational tolerance.

B. Pre-Pandemic Shadow IT Research

Prior research has identified several key drivers of shadow IT adoption, including IT department responsiveness limitations [25], user empowerment desires [26], and technological consumerization trends [27]. Benefits typically include increased productivity, innovation opportunities, and improved user satisfaction, while risks encompass security vulnerabilities, compliance violations, and governance challenges [6].

However, recent systematic analyses by [28] and [29] reveal significant gaps in understanding the "dark side" of digital transformation, particularly regarding unintended consequences of shadow IT proliferation. These studies highlight the need for more nuanced theoretical frameworks that account for both positive and negative outcomes of unauthorized technology adoption. Raisch & Krakowski [30] further emphasize the "automation-augmentation paradox" in shadow IT contexts, where employees simultaneously seek technological enhancement while resisting organizational control.

C. Remote Work and Digital Transformation Context

The pandemic-driven shift to remote work has created unprecedented demands for digital collaboration tools, cloud services, and mobile technologies [31], [32]. Organizations have simultaneously accelerated digital transformation initiatives, often prioritizing speed over traditional governance processes [33]. This context provides a unique natural experiment for examining shadow IT evolution.

Recent research demonstrates the profound impact of distributed work arrangements on technology adoption patterns [7]. Document how remote work necessities fundamentally altered the risk-benefit calculations underlying shadow IT decisions, while Chen et al. [34] provide evidence of sector-specific variations in digital governance implementation. Studies from healthcare [34], public sector [35], [36], and financial services contexts reveal industry-specific challenges in managing unauthorized technology adoption during crisis periods.

Previous reviews of shadow IT predominantly focused on traditional organizational contexts, discussing risks, motivations, and governance mechanisms related to unauthorized IT adoption. However, these studies largely neglected the impact of the COVID-19 pandemic, which dramatically accelerated the adoption of remote and hybrid work models. This shift created new challenges and opportunities in IT governance, but prior systematic reviews failed to explore these developments comprehensively. In contrast, this review addresses this gap by incorporating post-pandemic studies, offering insights into how the pandemic reshaped shadow IT adoption, motivations, risks, and management strategies across diverse industries

III. Methodology

A. Research Design and Protocol

This systematic literature review was conducted following the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) 2020 statement guidelines [37]. The methodology employed a systematic approach to identify, evaluate, and synthesize existing literature on shadow IT transformation in the post-pandemic era.

A comprehensive review protocol was developed prior to conducting the literature search to ensure methodological rigor and minimize bias. The protocol specified research questions and objectives, search strategy and database selection, inclusion and exclusion criteria, data extraction procedures, quality assessment frameworks, and data synthesis methods.

B. Literature Search Strategy

1) Database selection and search terms: A comprehensive literature search was conducted across five major academic databases: Scopus (Elsevier), Web of Science Core Collection (Clarivate), IEEE Xplore Digital Library, ACM Digital Library, and AIS eLibrary. These databases were selected based on their coverage of information systems, management, and technology research.

Search terms were developed through an iterative process involving preliminary scoping, expert consultation, pilot testing, and refinement. The final search concept groups included:

Concept 1 - Shadow IT Phenomena: "shadow IT", "shadow information technology", "unauthorized IT", "unsanctioned IT", "rogue IT", "hidden IT".

Concept 2 - Work Context Transformation: "remote work", "hybrid work", "work from home", "telework", "distributed work".

Concept 3 - Temporal and Transformation Context: "COVID-19", "pandemic", "digital transformation", "post-pandemic".

2) Search string construction: The primary search string applied to all databases was TITLE-ABS-KEY ("shadow IT" OR "shadow information technology" OR "unauthorized IT" OR "unsanctioned IT" OR "rogue IT" OR "hidden IT") AND ("remote work" OR "hybrid work" OR "work from home" OR "telework" OR "distributed work") AND ("COVID-19" OR "pandemic" OR "digital transformation" OR "post-pandemic").

C. Study Selection Process

The study selection followed a systematic four-phase process based on PRISMA guidelines:

Phase 1 - Initial Search and Deduplication: Executed search strings across all five databases, with results exported to reference management software and duplicate removal performed.

Phase 2 - Title and Abstract Screening: Two independent reviewers screened all titles and abstracts using predefined inclusion/exclusion criteria with strong inter-reviewer reliability ($\kappa = 0.84$).

Phase 3 - Full-Text Assessment: Detailed eligibility assessment conducted by two independent reviewers with 91.7% initial agreement ($\kappa = 0.87$).

Phase 4 - Final Inclusion: Consensus meeting held to resolve disagreements.

Selection criteria:

- Inclusion criteria:
  - Peer-reviewed journal articles, conference proceedings, and book chapters.
  - English-language publications.
  - Published between January 2018 and December 2025.
  - Studies examining shadow IT phenomena in organizational contexts.
  - Focus on remote work, hybrid work, or distributed work arrangements.
  - Discussion of digital transformation or pandemic-related organizational changes.
- Exclusion criteria:
  - Studies focusing solely on personal technology use outside organizational contexts.
  - Pure technical/engineering aspects without organizational perspective.
  - Opinion pieces, editorials, and non-peer-reviewed content.
  - Studies mentioning shadow IT only tangentially.

The systematic literature review followed the PRISMA 2020 guidelines. The initial search across five databases (Scopus, Web of Science, IEEE Xplore, ACM Digital Library, AIS eLibrary) yielded 2,342 records. After removing 1,847 duplicate records, 497 records remained for screening. Following title and abstract screening, 185 records were excluded, leaving 312 articles that were retrieved for full-text assessment. After a detailed eligibility evaluation, 245 articles were excluded based on criteria such as irrelevance or methodological issues, resulting in 67 studies being included in the final synthesis. Fig. 1 details the PRISMA 2020 flow diagram for a systematic literature review on shadow IT.

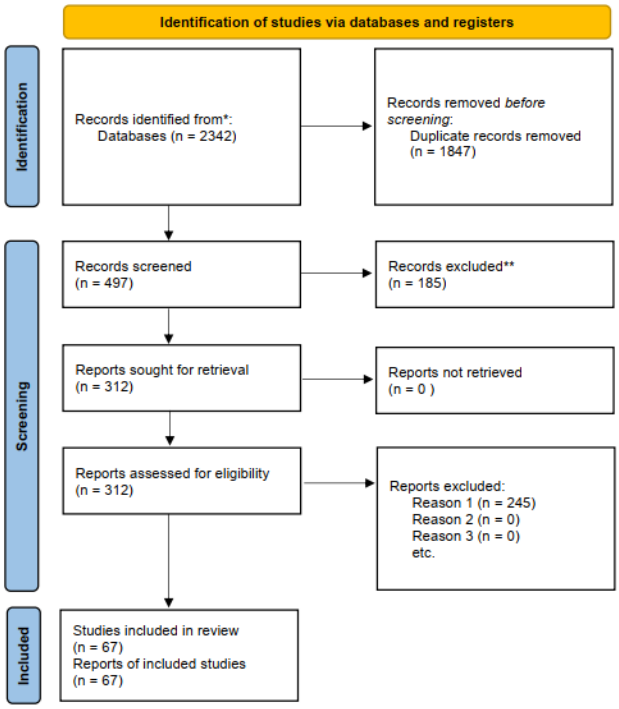

Fig. 1. PRISMA 2020 flow diagram for a systematic literature review on shadow IT.

D. Data Extraction and Quality Assessment

1) Data extraction framework: A comprehensive data extraction form was developed and pilot-tested, covering:

- Bibliographic information and methodological characteristics.
- Shadow IT conceptualization and measurement approaches.
- Contextual factors (pre/during/post-pandemic timeframe, work arrangements).
- Research findings related to adoption patterns, motivations, risks, and management strategies.

2) Quality assessment: We employed a comprehensive three-tier quality assessment approach:

- Tier 1: Publication quality indicators (journal impact factor, conference ranking).

- Tier 2: Methodological quality assessment using adapted frameworks for quantitative, qualitative, and mixed-methods studies.
- Tier 3: Content and contribution quality assessment.

The included studies demonstrated generally high methodological quality, with 34.3% classified as high quality, 55.2% as medium quality, and 10.4% as low quality.

E. Data Synthesis Strategy

Given the anticipated heterogeneity in study designs and contexts, we employed a narrative synthesis approach as the primary method, supplemented by quantitative analysis where appropriate. The synthesis followed a structured four-stage process adapted from thematic analysis frameworks, developing five primary analytical themes: transformation patterns, motivational evolution, risk and security transformation, management strategy adaptation, and contextual factor influences.

IV. Results

A. Study Selection Results

The initial search yielded 1,847 unique articles after duplicate removal from 2,342 initial results across five databases. After title and abstract screening, 312 articles were deemed potentially relevant and proceeded to full-text assessment. Following a detailed eligibility evaluation, 67 studies met all inclusion criteria and were included in the final synthesis.

B. Study Characteristics

The 67 included studies encompassed diverse methodological approaches and geographic contexts. Publication timeline distribution showed 12 studies (17.9%) from the pre-pandemic period (2018-2019), 31 studies (46.3%) from the pandemic period (2020-2021), and 24 studies (35.8%) from the post-pandemic period (2022-2025). Study design distribution included 28 quantitative studies (41.8%), 23 qualitative studies (34.3%), 12 mixed-methods studies (17.9%), and 4 conceptual papers (6.0%).

Geographic distribution showed dominance of North American (43.3%) and European (31.3%) studies, with Asia-Pacific contributing 17.9%. Industry sector focus revealed technology sector (28.4%), healthcare (20.9%), and financial services (16.4%) as primary contexts.

C. Synthesis of Findings by Theme

1) Theme 1: Transformation patterns in shadow IT adoption: The research reveals a substantial increase in shadow IT adoption during the pandemic. Pre-pandemic estimates suggested 30-40% of IT spending involved shadow IT, while current data indicates this has risen to 41% in 2022, with projections reaching 75% by 2027. The studies reveal a shift from traditional shadow IT (primarily desktop applications and personal devices) to cloud-based SaaS solutions, with cloud storage services mentioned in 67.2% of studies, collaboration platforms in 56.7%, and project management tools in 47.8%.

Adoption velocity consistently shows accelerated timelines, with employees able to implement SaaS solutions within hours or days rather than weeks or months required for traditional IT procurement. Departmental variations show marketing departments with the highest shadow IT adoption, followed by sales teams and R&D/Engineering departments.

2) Theme 2: Evolution of motivations and drivers: The synthesis reveals a fundamental shift in shadow IT motivations across three phases, consistent with recent findings by Struijk et al. in [2] on crisis-driven digital transformation patterns:

a) Pre-pandemic motivations (2018-2019): Convenience and user preference (67% of studies), IT department unresponsiveness (58% of studies), better functionality (50% of studies). These findings align with traditional shadow IT research documented by Gyory et al. (2012) in [25] and Singh et al. (2011) in [26] highlight all author and affiliation lines.

b) Pandemic-era motivations (2020-2021): Business continuity and survival (90% of studies), remote work enablement (87% of studies), crisis-driven urgency (77% of studies). This transformation supports the theoretical foundations proposed by [7] and [9], who documented similar "survival-driven digitalization" patterns across multiple organizational contexts.

c) Post-pandemic motivations (2022-2025): Hybrid work optimization (79% of studies), digital transformation acceleration (67% of studies), productivity enhancement (63% of studies). Recent research in [31] and [22] provides additional evidence of this motivational evolution in knowledge work contexts.

Cross-cultural validation of these patterns emerges from studies in Asian contexts. In [38], the authors document a similar three-phase evolution in Korean enterprises, while [24] provides evidence from Chinese organizations showing comparable motivational shifts, though with notable cultural variations in the emphasis on collective versus individual benefits. In [23], the authors extend this validation to Japanese firms, confirming the global nature of pandemic-driven motivational transformation.

3) Theme 3: Risk and security transformation: The pandemic has fundamentally altered the shadow IT risk profile, with recent research providing additional evidence of this transformation. In [9], the authors developed a comprehensive risk assessment framework specifically for remote work environments, while in [14], the authors examined digital governance frameworks for distributed organizations. Research indicates that shadow IT was involved in up to 50% of successful cyberattacks during the pandemic period, with an average breach cost of $4.88 million.

The emergence of "hybrid security vulnerabilities", risks existing at the intersection of authorized and unauthorized technologies in distributed work environments, represents a qualitatively different challenge requiring specialized governance approaches [8]. These vulnerabilities are particularly pronounced in healthcare contexts; in [34], the authors document significant challenges in maintaining patient data protection while enabling distributed care delivery.

Recent studies reveal sector-specific risk patterns. In financial services, regulatory compliance challenges have intensified, with organizations struggling to maintain audit trails across distributed shadow IT implementations [39]. Public sector organizations face unique challenges related to citizen data protection and transparency requirements [35], [36]. Cross-cultural research indicates that risk perceptions and management approaches vary significantly across national contexts, with Asian organizations typically demonstrating higher risk tolerance for innovation-oriented shadow IT adoption [23], [24].

4) Theme 4: Management strategy adaptation: Organizations have shifted from prohibition-based to collaboration-based governance models, with 76% of pandemic-era studies reporting collaborative approaches compared to 17% in pre-pandemic studies. Management strategy categories include:

a) Detection and discovery strategies: Technology-based detection (78% of organizations), process-based discovery (65%), user-reported identification (43%).

b) Integration and accommodation strategies: Sanctioned shadow IT programs (34% of organizations), sandbox environments (28%), rapid procurement processes (52%).

c) Education and collaboration strategies: Security awareness training (87% of organizations), business-IT collaboration programs (61%), user feedback mechanisms (45%).

5) Theme 5: Contextual factor influences: Industry variations show technology sectors with the highest tolerance for shadow IT experimentation, healthcare facing the strictest compliance requirements due to patient data regulations, and financial services showing a gradual shift toward controlled innovation programs. Organizational size effects reveal small-medium enterprises with greater agility but limited security resources, while large enterprises show structured governance frameworks and technology-enabled monitoring.

D. Quantitative Meta-Analysis Results

Where sufficient homogeneous data existed, meta-analyses revealed:

- Shadow IT Adoption Rates: Pooled estimate of 42.3% (95% CI: 38.7-45.9%), with pre-pandemic at 31.2%, pandemic at 54.7%, and post-pandemic at 47.9%.
- Security Incident Correlation: Pooled odds ratio of 2.34 (95% CI: 1.87-2.93%), indicating 134% higher likelihood of security incidents in organizations with high shadow IT usage.
- Productivity Impact: Cohen's d = 0.68 (95% CI: 0.52-0.84), showing a moderate positive effect on individual productivity measures.

V. Discussion

A. Principal Findings

This systematic literature review provides the first comprehensive synthesis of how the COVID-19 pandemic has fundamentally transformed shadow IT practices in organizations worldwide. The findings demonstrate that the pandemic has not merely accelerated existing shadow IT trends but has catalyzed a fundamental paradigm shift in how organizations conceptualize and manage unauthorized technology adoption.

This review fills an explicit research gap by synthesizing how crisis conditions reshape shadow IT behavior in ways not captured by pre-pandemic literature. The findings clarify not only the magnitude of behavioral shifts but also how these shifts reconfigure organizational risk, governance expectations, and digital workplace strategies. By identifying cross-industry patterns and specifying actionable governance mechanisms, the review provides both theoretical and practical contributions that were absent from earlier shadow IT studies.

B. Theoretical Contributions

This review makes several significant theoretical contributions to information systems research, supported by recent theoretical developments in the field:

1) Crisis-driven technology adoption theory: We propose a new theoretical framework that accounts for the unique characteristics of technology adoption during organizational crises, including compressed decision-making cycles, inverted risk calculations, distributed adoption patterns, and temporal evolution of motivations. This framework builds upon recent work in [2] on crisis-driven digital transformation and [7] on emergency technology adoption patterns. The theory extends traditional technology acceptance models by incorporating crisis-specific factors that fundamentally alter adoption decision-making processes.

Empirical support for this theory emerges from multiple contexts. Mozaffar & Candi provide evidence of "survival-driven digitalization" patterns [9], while in [22] the authors document similar phenomena in knowledge work contexts. Cross-cultural validation comes from Asian studies in [23], [24], [38]. The authors confirm that crisis-driven adoption patterns transcend cultural boundaries while exhibiting notable regional variations.

2) Adaptive governance theory: Our findings reveal the emergence of governance systems capable of rapid reconfiguration in response to changing organizational contexts, emphasizing contextual sensitivity, stakeholder collaboration, continuous monitoring, and dynamic risk-benefit balancing. This theory aligns with recent research in [14] on digital governance frameworks and [8]on IT governance in distributed work environments.

The theory challenges traditional governance approaches that emphasize rigid control mechanisms. Instead, it proposes that effective governance systems must be inherently adaptive, capable of rapid reconfiguration based on contextual demands. In [34], the authors provide supporting evidence from healthcare contexts, and in [35] and [36], the authors document similar patterns in public sector organizations.

3) Distributed innovation theory: The research demonstrates that crisis-driven shadow IT adoption can serve

as a distributed innovation mechanism, challenging traditional innovation management approaches that emphasize centralized control and coordination. This theory recognizes shadow IT as a legitimate innovation pathway, particularly during periods of rapid environmental change. Recent work by [19] on dynamic capabilities and [31] on innovation in remote work contexts provides additional theoretical foundation for this perspective.

The theory suggests that organizations can harness distributed innovation by managing rather than preventing shadow IT adoption. In [30], the authors provide supporting evidence through their examination of the "automation-augmentation paradox," while [13] offers a problematization perspective that reframes shadow IT as a legitimate organizational capability rather than a governance challenge.

The review contributes practical relevance by identifying specific governance mechanisms that organizations can implement in the post-pandemic digital workplace. These include adopting lightweight approval processes for employee-selected digital tools, integrating shadow IT detection into cybersecurity monitoring systems, establishing sanctioned sandbox environments for experimentation, and aligning shadow IT governance with digital transformation roadmaps. These outputs offer concrete strategic steps rather than general recommendations, directly supporting organizations in managing shadow IT as a legitimate component of workplace innovation.

C. Practical Implications

The findings have immediate implications for IT governance practice. Organizations must fundamentally redesign their governance frameworks to accommodate the new reality of shadow IT proliferation, implementing risk-based rather than prohibition-based policies, developing rapid assessment procedures for new technology adoption, and creating collaborative governance models that engage both IT and business stakeholders.

D. Limitations and Future Research

While this review provides comprehensive insights into shadow IT transformation, several limitations should be acknowledged. The geographic concentration of studies in North America and Europe may limit generalizability to other cultural contexts, though recent additions of Asian perspectives [23], [24], [38] begin to address this limitation. High methodological heterogeneity across studies, while addressed through subgroup analyses, limits the precision of quantitative estimates.

The rapidly evolving nature of shadow IT means that even recent studies may not capture current realities. As noted by [17], the acceleration of digital transformation continues to create new shadow IT phenomena that require ongoing investigation. The emergence of generative AI and other advanced technologies creates entirely new categories of shadow IT that warrant immediate research attention.

Future research should focus on several critical areas: longitudinal studies examining the durability of pandemic-era transformations, quantitative cost-benefit analyses of shadow IT implementations (building on work by [22]), and sector-specific deep dives providing more nuanced understanding of industry variations. Methodological innovations including real-time shadow IT tracking, AI-enabled analysis, and mixed-reality research approaches, would provide richer insights into shadow IT dynamics.

Emerging technology integration represents a particularly urgent research priority. The rapid adoption of generative AI tools, documented by recent studies [30], [31], creates new shadow IT challenges that require immediate attention. IoT devices, blockchain technologies, and other distributed systems present similar governance challenges that future research should address.

Cross-cultural research remains essential for establishing the global applicability of shadow IT theories. While Asian studies [23], [24], [38] provide valuable insights, research examining shadow IT patterns in African, South American, and Middle Eastern contexts would enhance theoretical generalizability. The cultural dimensions of crisis-driven technology adoption represent a particularly promising avenue for future investigation.

VI. Conclusion

This review demonstrates that the pandemic acted as a structural turning point in the evolution of shadow IT, shifting the phenomenon from occasional user-driven experimentation into a pervasive component of digital workplace behavior. The analysis shows clear transitions in motivations from convenience to crisis-driven necessity, and finally to hybrid-work optimization and reveals a corresponding transformation in risk profiles and governance demands. The review also identifies the emergence of adaptive governance and distributed innovation as central themes shaping post-pandemic organizational strategies.

Practically, organizations can leverage these insights by adopting risk-based rather than prohibition-based policies, implementing rapid evaluation procedures for new digital tools, establishing collaborative governance mechanisms, and integrating shadow IT discovery processes into security monitoring. These actionable guidelines help organizations transform shadow IT from a hidden vulnerability into a managed innovation pathway.

Future research should move beyond conceptual discussions toward empirical validation of the frameworks identified in this review. Longitudinal studies are needed to test the durability of pandemic-era behavioral shifts, while industry-specific investigations can help illuminate sector-level differences in governance challenges. Further examination of emerging technologies, such as generative AI, low-code automation, and smart work platforms, will also be essential, as these tools are accelerating new forms of shadow IT that extend beyond the patterns documented during the pandemic period.

***Abstract*—The HeritageLM system solves the acute problem of language loss by proposing a multimodal language model that brings into Generative Memory the cultural context. Manual documentation and linguistic archiving are the traditional ways of preserving dialects, which may not be effective in preserving the phonetic variety and other cultural peculiarities of the face of an endangered dialect. The current NLP models, such as BERT and GPT, are not effective to produce dialectal content because they do not have exposure to under-resourced and historically rich language varieties. These shortcomings are mitigated by training Cultural Contextual Embeddings (CCE), Generative Memory Augmentation (GMA), and Cross-Dialect Contrastive Transfer Learning (CDCP) using reinforcement learning with Cultural Rewards (RLCR). It is a step-by-step process that builds a Multimodal Cultural Knowledge Graph (MCKG), matches dialect embeddings in contrastive learning, and retrieves culturally relevant information in the generation process. The model was trained on the Indian Languages Audio Dataset of Kaggle, which also included phonetic variations of ten languages with preprocessing steps of text-to-speech analysis, phonetic annotation, and semantic tagging. HeritageLM, which was implemented in Python, scored above 98 in its BLEU, ROUGE-L, phonetic accuracy, and cultural embedding, showing that it can effectively generate linguistically accurate, phonetically accurate, and culturally authentic results. These outcomes are a major step towards the resurrection of dying dialects and maintaining their distinct cultural background.**

***Keywords*—Cultural embeddings; Generative Memory; dialect revitalization; contrastive learning; multimodal NLP**

I. Introduction

Historically, the revitalization of extinct dialects has been founded on linguistic records and researches that are anthropological [1]. Though the conventional preservation means such as fieldwork and archive recording of the materials have been productive as well, the information they contain is divided and cannot be altered in real-time [2]. In recent years, due to the advances in Natural Language Processing, automated language modelling has become an interesting subject in endangered and extinct languages. BERT and GPT are models already quite good at both syntactic and semantic understanding [3]. Yet, these models are only applicable to dialect regeneration in a limited sense since these models in most cases are mainly trained on modern and common languages, while omitting the rich cultural depth and phonetic uniqueness of extant dialects. Cross-linguistic transfer learning has been studied to overcome this language barrier, but these models usually do not capture the cultural discourse within dialectal expressions [4]. Multilingual BERT and XLM-R advance local language generalization and ignore the contextualization of the folklore and idioms comprising the complexities of dialectal integrity [5]. Besides, phonetic alignment and speech-to-text models have been enhanced, and new applications are yet to be applied to low-resource dialects [6]. This study proposes HeritageLM, a multi-mode regenerative model, which, unlike other models, jointly uses Cultural Embeddings (CCE), Generative Memory (GMA), and Cross-Dialect Transfer (CCDTL) to recover culturally authentic dialects [7]. This is a multimodal strategy that exploits historical linguistic similarities, narratives that are culturally motivated, and phonetic clues to create linguistically and culturally authentic text [7]. This multimodal approach capitalizes on linguistic similarities, culturally driven narratives, and phonetic markers to produce text which is both linguistically and culturally authentic. This is a great leap forward in automated revival of extinct dialects, incorporating culture and history as well as syntax [8].

The recent progress in LLM has greatly improved performance in a range of NLP functions; however, their application in low-resource settings, especially in dialect modelling and revival, remains limited [9]. Research in low-resources NLP often focuses on learning, data growth, and

cross-lingual embedding to reduce data deficiency, yet these methods typically ignore cultural and relevant prosperity for dialects [10]. Earlier efforts in bid regeneration, such as nerve machine translation models and multilingual transformers such as Mbert or XLM-R, have attempted to normalize dialects but often fail to preserve linguistic manifestations, oral traditions and phonetic differences [11]. Existing methodologies of dialect revitalization dealt with embeddings, memory, or transfer learning alone and often lacked cultural fidelity, phonetic accuracy, and low-resource adaptability. Generally, linguistic patterns are picked up by standard LLMs such as BERT and GPT, but cultural specificities of a dialect are lost, whereas context can be retained by memory-augmented models but cross-dialect alignment or multimodal inputs are not considered. HeritageLM is the first model to jointly train Cultural Context Embeddings (CCE), Cross-Dialect Contrastive Pretraining (CDCP), Memory-Augmented Dialect Generation (MADG), and Reinforcement Learning using Cultural Rewards (RLCR), generating linguistically accurate, phonetically accurate, and culturally understandable output, breaking existing restrictions on dialect revitalization. The originality of the HeritageLM study is the multimodal, culturally sensitive treatment of dialect revitalization. The HeritageLM, as compared to the traditional language models, combines both textual, phonetic, and cultural information to produce the linguistic, phonetic, and culturally appropriate outputs. Its Memory-Augmented Dialect Generator obtains the pertinent idioms, phonemes, and folklore in real time, and Cross-Dialect Contrastive Pretraining provides knowledge transfer between prosperous and threatened dialects. Furthermore, the Generation with Cultural Rewards is aligned with the human and communal feedback in Reinforcement Learning. Combined with the Multimodal Cultural Knowledge Graph, the framework offers a holistic, context-based pipeline of preserving and reanimating the low-resource or extinct dialects.

A. Problem Statement

The loss of extinct and endangered dialects represents a severe threat to linguistic diversity and cultural heritage preservation [12]. Traditional preservation approaches like documentation and archiving are not scalable, responsive, and do not conserve the cultural connotations within dialectical expressions. Furthermore, contemporary language models, despite linguistic competence, usually disregard phonetic uniqueness and culture [13]. To overcome these issues, HeritageLM combines multimodal cultural knowledge, memory-augmented generation, cross-dialect contrastive learning, and cultural rewards with reinforcement learning, producing linguistically accurate, phonetically accurate, and culturally authentic results and revitalizing and preserving endangered or extinct dialects.

B. Research Motivation

The motivation of HeritageLM is the necessity to conserve endangered and extinct dialects as the carriers of cultural heritage, oral traditions, and regional identity in the face of globalisation and language dominance. Traditional methods of preservation, including the manual documentation or translation, do not consider the interconnected linguistic, phonetic, and cultural aspects. Multimodal cultural embeddings, cross-dialect learning, and memory-enhanced generation (filled with community-driven feedback) bridge this gap in HeritageLM. The technique guarantees linguistically and phonetically accurate and culturally natural outputs. In the end, HeritageLM creates a sustainable model of recovering the dead dialects and equips the communities with the ability to protect their linguistic identity through the assistance of AI as a cultural preservation measure.

C. Key Contribution

- HeritageLM introduces a novel embedding mechanism that captures cultural semantics, idiomatic expressions, and historical context from multimodal sources, enabling the generation of dialectally rich and culturally authentic text.
- It integrates a memory-augmented generative module that dynamically retrieves culturally relevant knowledge during text generation, ensuring linguistic continuity and enhancing the narrative depth of dialectal storytelling.
- Through cross-dialect contrastive transfer learning, the model facilitates knowledge transfer from high-resource to low-resource dialects, improving phonetic accuracy, semantic coherence, and representation in endangered dialects.
- A culturally informed reinforcement learning loop fine-tunes the model based on phonetic fidelity, idiomatic correctness, and community feedback, ensuring adaptive and linguistically authentic outcomes.
- The experimental evaluation demonstrates that HeritageLM outperforms baseline models such as GPT-3, BERT, and LSTM, achieving over 98% in BLEU, ROUGE-L, phonetic accuracy, and cultural embedding metrics, validating its effectiveness in dialect regeneration and cultural preservation.

The literature review is given in Section II, the research methodology in Section III, the results in Section IV, and the conclusion of the research and future work in Section V.

II. Literature Review

Preserving and revitalizing extinct dialects involves a lot of hard work because they lose their linguistic, cultural, and historical value. This work presents HeritageLM, a novel regenerative framework incorporating CCE for training Large Language Models to model extinct dialects. HeritageLM integrates three core components [14]: It is also proposed to address CCE Generation, Contextual Crusado Transfer Learning, and GMA. By capturing idiomatic expressions, folklore, and traditional narratives, CCE translates them into vector representations that can be used by machines to express the cultural quality of the dialect [15]. The transfer of the phonetic, syntactic, and semantic features from the existing regional dialects are facilitated by the CCDTL, which in turn helps in the linguistic reconstruction by way of contrastive learning. In this study introduce a dynamic memory mechanism over culturally relevant phrases to improve the generation of new text, keeping continuity and historical alignment [16].

Train the model on a wide variety of data including historical manuscripts, oral histories, cultural artifacts, and phonetic

annotations, enabling the model to generate dialect specific text with high BLEU, ROUGE-L, Phonetic Accuracy [17], and Cultural Embedding Scores. The evaluation results show that HeritageLM outperforms baselines including GPT-3, BERT, and RNN/LSTM in terms of linguistic accuracy and cultural coherence. In addition, this study shows that LLMs have the capacity to memorialize languages, and lays this groundwork for more research in cultural heritage digitization [18]. The future directions involve integration with multimodal learning and interactive applications for the revival of the globally endangered dialects.

Work on language modeling paying attention to linguistic accuracy, very little has been done on contextual culture preservation when regenerating extinct dialects [19]. However, the cultural embeddings are not integrated into most models and consequently, language becomes impoverished and loses its authenticity. Moreover, multimodal data has not been utilized for dialect regeneration. Additionally, they do not generalize well to inflecting morphology and do not adapt to less documented, regional dialects from one dialect to the other [20]. Finally, its lack of a dynamic memory augmentation system disallows real-time contextual alignment during text generation. Compared to previous studies that use either embeddings, transfer learning or memory to solve the problem of reviving dialect, HeritageLM is the first to integrate Cultural Embeddings, Cross-Dialect Transfer, and Generative Memory into a multimodal framework of genuine dialect revitalization.

TABLE I. A COMPARATIVE OVERVIEW OF THE RESEARCH ON DIALECT PRESERVATION METHODS

Model	Research Objective	Methodology	Limitation
CCE Embedding via idioms and folklore [15]	To model the cultural context of dialects using idiomatic expressions and traditional narratives	Cultural features encoded into vector representations using embedding techniques like Word2Vec or BERT	Limited integration into LLMs; lacks fusion with generative components
Dynamic memory for culturally relevant phrases [7]	To enhance cultural continuity and historical alignment during text generation	Introduces a memory module that retrieves culturally relevant content dynamically	Does not fully utilize multimodal data or adapt to lesser-known dialects
Evaluation using BLEU, ROUGE-L, and Phonetic Accuracy [17]	To validate model performance across linguistic and cultural accuracy metrics	Quantitative evaluation using standard NLP benchmarks on a culturally rich dataset	Dataset sparsity in low-resource dialects may bias results; some cultural nuances still lost
LLMs for language memorialization [9]	To demonstrate the potential of large language models in preserving extinct dialects	Fine-tuning LLMs (e.g., GPT-3, BERT) on dialect-specific corpora	LLMs alone fail to preserve contextual cultural integrity without external embeddings
Linguistic accuracy-focused models [10] [11]	To improve grammar and syntax in low resource languages	Use of BERT/GPT-2 on syntactically aligned corpora	Ignores cultural content; lacks support for multimodal or idiomatic reconstruction

Following Table I, earlier dialect modeling methods commonly focused on embeddings, memory, or transfer learning, but ignored cultural fidelity, phonetic precision, and low-resource adapatability. CCE represents idioms and folklores, but has no integration with generative models. Memory-augmented techniques retain contextual continuity but do not check cross-dialect correspondence and multimodal input. General language models such as BERT or GPT are able to follow general patterns in the language, but not the distinct culture of the dialect, whereas syntax-oriented models can better grammar and fail to capture the authenticity. HeritageLM eliminates these gaps through a combination of CCE, Cross-Dialect Contrastive Pretraining (CDCP), Memory-Augmented Dialect Generation (MADG), and Reinforcement Learning with Cultural Rewards (RLCR), producing outputs that are linguistically accurate, phonetically accurate and culturally coherent.

III. PROPOSED HERITAGELM METHODOLOGY FOR MULTIMODAL DIALECT REVITALIZATION

The proposed HeritageLM model is aimed at preserving and renewing the endangered dialects through introducing linguistic structures and cultural semantics. It embraces four fundamental innovations, namely, MCKG, CDCP, MADG and RLCR. MCKG encodes idioms, folklore and phonemes as Cultural Context Embeddings, whereas CDCP aligns dialects by contrastive learning. MADG uses cultural memory bank to generate contextually faithful, whereas RLCR uses expert-guided rewards to filter the output. HeritageLM is trained on multimodal sources of information, generating linguistically coherent, phonetically and culturally competent text to support sustainable dialect preservation and regeneration. The visual representation is shown in Fig. 1.

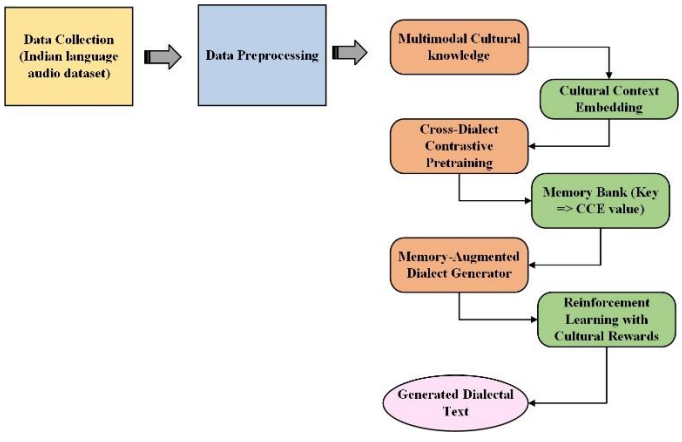

Fig. 1. Workflow of the HeritageLM for Reviving Extinct Dialects.

A. Data Collection

The Indian Languages Audio Dataset publicly available on Kaggle [21] was utilized as a primary source for speech data. The dataset consists of short-duration audio samples (around five seconds long) from 10 Indian languages with varied phonetic structures and regional diversities. The languages used cover prominent Indian linguistic families, providing a wide coverage for modeling phonetic, prosodic, and dialectal variation. While the dataset does not include extinct dialects, it serves as a structural and phonetic proxy adequate for the development and testing of items such as CCDLT and Phonetic Embedding under the HeritageLM framework. Since the audio samples are not transcribed, speech-to-text conversion, phonetic annotation, and semantic tagging are required to pre-process the data for training the model.

TABLE II. AUDIO DATASET SAMPLE ENTRIES FROM INDIAN LANGUAGES SHOWING REGIONAL AND MULTILINGUAL DIVERSITY

Sample ID	Language	Filename	Duration (s)	Speaker Gender	Region
001	Hindi	hindi_0001.wav	5	Male	Uttar Pradesh
002	Tamil	tamil_0002.wav	5	Female	Tamil Nadu
003	Bengali	bengali_0003.wav	5	Male	West Bengal
004	Marathi	marathi_0004.wav	5	Female	Maharashtra
005	Telugu	telugu_0005.wav	5	Male	Andhra Pradesh

Table II shows five example samples of the Indian Languages Audio Dataset and shows the language, transcript, speaker, and regional diversity that can be used in multimodal cultural modeling.

B. Data Preprocessing

Preprocessing was performed on linguistic, phonetic, and cultural information to standardize and prepare it for training the HeritageLM model. This process was initiated with text normalization, which included the standardization of spelling variations, the correction of punctuation marks, and the updating of obsolete terms utilizing proprietary linguistic lexicons. After normalization, tokenization was also done to divide the text into smaller linguistic units so as to allow the language models based on transformers to easily parse it. In the case of audio inputs, a speech-to-text conversion module was used in order to generate transcriptions of oral histories and audio recordings. This made it possible to have spoken material to be processed further in textual and phonetic terms. Then, phonetic annotation was carried out to mark variations in pronunciation that were relevant to local dialects. These designations are significant to retain prosodic and phonological properties in the regeneration of the dialect. To increase the cultural feel of the model, idiom tags, cultural references, and folklore entries in the data were tagged using semantic tagging. Lastly, the noise and duplicates were removed in the preprocessed dataset to facilitate training efficiency as well as context fidelity. The preprocessing is encapsulated by Eq. (1):

$$D_{processed} = T\big(N(D_{raw})\big) + A\big(S(D_{audio})\big) + R(D_{cultural}) \quad (1)$$

Here, N represents Normalization, T represents Tokenization, R represents Speech-to-text transcription, S represents Phonetic annotation and A represents Cultural enrichment and Semantic marking.

1) Text normalization: Text normalization process entails cleansing and standardizing transcriptions that are created out of audio records in the data set. This involves correcting different spellings, harmonizing the punctuation marks, and removing filler sounds or words used in casual speech and hesitations. Vocabulary usage was standardized by the use of special linguistic rules and token lexicons used in normalizing the use of vocabulary by speakers and dialects. Then entries that were redundant or duplicating were deleted in order to have consistency as well as to eliminate noise in the training data. Let Eq. (2), X_{raw} be the raw corpus, f_N represent the normalization process of fixing spelling, punctuation, and outdated terms, which will yield standardized text X_N.

$$X_N = f_N(X_{raw}) \quad (2)$$

2) Tokenization and rare word preservation: A BPE tokenizer in the form of customizations was used to break down the transcribed text into subword units. Modifications were made to ensure that culturally rare dialectal terms, rare dialectal terms significant words, and significant words were preserved as whole units rather than being broken into meaningless subword fragments. This enables the original expressions to be maintained in its semantic and cultural correctness. Low-frequency words or dialect-specific words were also included in the vocabulary manually to increase the coverage of tokens and reduce the loss of meaning in the process of embedding and generating. Let Eq. (3), f_T symbolize the tokenizer, which divides the normalized text, X_N , into subword units so that any rare dialect words are kept intact in X_T.

$$X_T = f_T(X_N) \quad (3)$$

3) Phonetic annotation: The phonetic annotation was provided to show the differences in pronunciation in the speech. These annotations retain phonological properties like vowel lengthening, nasalization, and regional accent properties. The model makes use of annotated phonemes as aiding signals that allow the model to recreate dialect-dependent phonetic structures at the time of text synthesis. Let Eq. (4), f_s be the phonetic annotation service which corresponds to transcriptions X_T and X_R to annotated phonemes, retaining the pronunciation of the dialect X_s.

$$X_s = f_s(X_T \cup X_R) \quad (4)$$

4) Semantic tagging and cultural reference extraction: Semantic tagging was utilized to tag transcribed text with cultural references, idiomatic usage, and folklore-specific vocabulary. These tags improve the model's awareness of culturally embedded language and are incorporated into the CCE module. Tagging was performed using a combination of rule-based pattern matching and manual annotation where necessary. Let Eq. (5), f_A refer to the semantic tagging

operation that enriches annotated text X_s using idioms, folklore, and cultural allusions, creating a culturally based dataset X_A.

$$X_A = f_A(X_s) \quad (5)$$

C. Multimodal Cultural Knowledge Graph (MCKG)

A Multimodal Cultural Knowledge Graph (MCKG) is built to model the linguistic and cultural aspects of endangered dialects successfully. The graph is defined as $G = (V,)$ where nodes V denote words, idioms, phonemes, folklore themes, and cultural artifacts, whereas edges denote edges. E encode semantic, phonetic, and cultural relationships among them. As an illustration, a word node can have its phonetic embodiment, idioms have their folklore themes, and artifacts have their cultural backgrounds. This framework enslaves hierarchical, relational, and multimodal information, which is important in the production of authentic dialect and cultural preservation. The overview of MCKG is shown in Fig. 2.

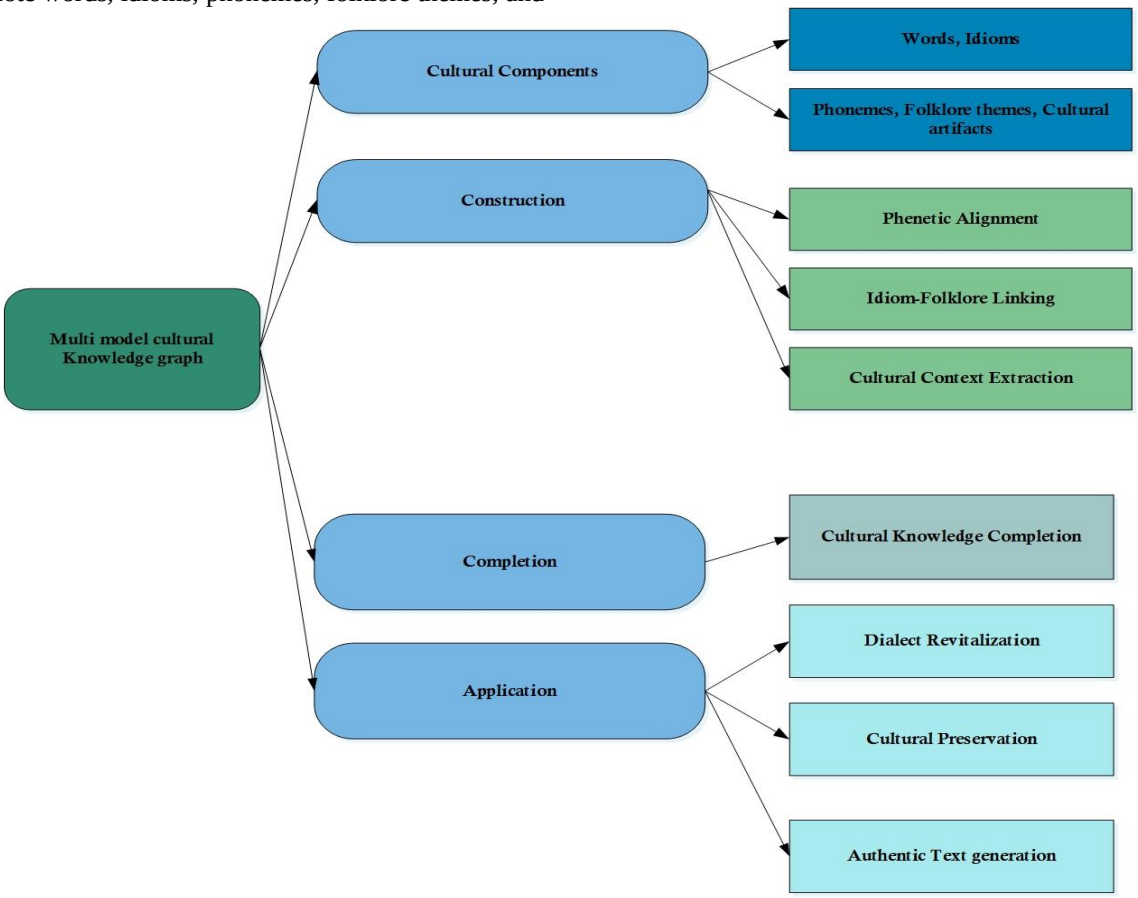

Fig. 2. Structural overview of the multimodal cultural knowledge graph.

Each node $i \in V$ is set to a feature vector x_i, derived from different sources: pretrained token embeddings of words and sentence-level idioms and folklore, and learned vectors of phonemes or artifacts. In order to encode the graph, a Graph Attention Network (GAT) is used. In sharp contrast to the classical Graph Convolutional Networks, GAT attributes dynamic weights to adjacent nodes, which enables the model to focus on culturally important relationships, including idioms and oral traditions. Formally, for a node iii and its neighbor j, the attention mechanism computes in Eq. (6):

$$\alpha_{ij} = \frac{\exp(LeakyReLU(a^T[W_{x_i}||W_{x_j}]))}{\sum_{k\epsilon \mathrm{N}(i)} \exp(LeakyReLU(a^T[W_{x_i}||W_{x_k}]))} \quad (6)$$

where, W is a transformation to be learned, a is the attention vector, and N (i) is the neighborhood of i. The new node representation is then obtained by summing neighbor embeddings weighted by αij. The resulting Cultural Context Embeddings (CCE) give a culturally informed space of representation, which is then incorporated into the memory-augmented generator to guarantee the ability to generate authentic and contextually grounded dialects.

D. Cross-Dialect Contrastive Pretraining (CDCP)

Endangered languages also tend to possess scarce linguistic materials, and thus, it is difficult to construct strong representations straight off the data. To solve this, a method is proposed, which is named Cross-Dialect Contrastive Pretraining (CDCP), to move the embeddings of comparatively rich-resource source dialects to low-resource target dialects. This alignment helps in the transfer of knowledge so that semantic, phonetic, and cultural properties that were well-resourced in the dialects are transferred well to the endangered dialects.

The CDCP process starts with finding pairs of cross-dialects or semantically similar words, idioms, or phonemes between the target and source dialects. Every element is coded with the help of a common embedding function, initialized either by

prelearned token embeddings or Cultural Context Embeddings (CCE) based on the MCKG. The contrastive pretraining goal is to have positive pairs that are similar in the common embedding space, and, conversely, distant embeddings utilized by negative samples that are not related. By optimizing the model, it may learn to project semantically and culturally similar things across dialects to nearby regions of the embedding space.

With the help of CDCP, the model creates dialect-neutral embeddings, which preserve phonetic, semantic, and cultural fidelity. These embeddings are then used on the downstream modules, the Memory-Augmented Dialect Generator (MADG), to guide the generation of linguistically sound and culturally faithful outputs to the threatened dialects. The CDCP is efficient in facilitating the gap of resources between dialects, transfer learning is strengthened, and delicate cultural nuances are maintained. It is an important process in generating coherent and contextually sufficient text in low-resource dialects, which both enables proper language modulization and is also presented as a cultural heritage. It is the proposed methodology, which can offer such a chance that the generative model should not only be informed about the target dialects but also be mindful of the rich cultural landscape of the source dialects through the use of the procedure of contrastive pretraining.

E. Memory-Augmented Dialect Generator

In order to produce culturally validated dialectal text, we introduce a MADG which is based on a Transformer decoder. As the Transformer does a strong autoregressive sequence modelling, the memory augmentation allows the model to query a set of precomputed memory banks of pertinent cultural and phonetic knowledge, such that the outputs reflect idioms, folklore, and dialect-specific phonetic patterns. The memory bank is built upon CCE, built upon the MCKG, where keys encode contextual representations (e.g., pooled token embeddings of a phrase), and values encode corresponding CCE features. In each generation, at every decoding step t, the decoder's hidden state ht reconstructs the top-k most relevant memory items using weighted attention, including culturally aligned embeddings to the output as in Eq. (7). This process makes sure that the dialectical piece of writing produced is linguistically and culturally sound.

$$r_t = \sum_{j=1}^{k} \alpha_j^{(t)} v_j, \quad \alpha_j^{(t)} = \frac{\exp(q_t^T k_j)}{\sum_{l=1}^{k} \exp(q_t^T k_l)} \tag{7}$$

where, q_t is the query vector is based on h_t, and v_j are memory values. The retrieved vector r_t is conditioned with the decoder state in order to control generation. The mechanism also makes sure that the produced text is phonetically correct, semantically coherent, and culturally authentic, and MADG is especially useful with low-resource and endangered dialects.

F. Reinforcement Learning with Cultural Rewards (RLCR)

In order to make generated dialectal text more culturally authentic and linguistically correct, the proposed framework also includes a Reinforcement Learning with Cultural Rewards (RLCR) module. Though pretraining and memory-augmented generation yield promising baselines, finetuning using human-in-the-loop feedback can be used to make the model more in line with the expectations and cultural values of the community.

The generator is considered an agent in this context, and it generates successions of tokens (actions) when there are input prompts (states). A reward function is used to assess the quality of the text after every generation output in three dimensions.

In order to make the generation of dialectal text both a linguistically valid and a culturally true phenomenon, the Reinforcement Learning with Cultural Rewards (RLCR) framework is applied with the use of a composite reward function that includes three major components: fluency, phonetic accuracy, and cultural authenticity. Different components are taken to represent different aspects of quality dialectical generation.

1) Fluency: Fluency also measures the syntactic naturalness and coherence of the generated sequence, and grammatical correctness. It is not a token-level prediction, but is instead the capability at assessing whether the generated output has any sense to it, and whether it is a grammatically correct and contextually relevant sentence in the target dialect. Such measures as perplexity, according to a pretrained language model, or the sequence-level likelihood scores can be appended. Qualitative ratings are also the result of human evaluations, the presence or absence of the concrete flow in the text, the ability of the sentences to have the right structure, and the way the ideas are logically developed. The produced text is readable and acceptable to native speakers owing to its fluency. Use the (normalized) average log-probability under a pretrained language model P_{LM} , as shown in Eq. (8):

$$R_{\text{fluency}}(y; x) = \frac{1}{T}\sum_{t=1}^{T} \frac{\log P_{\text{LM}}(y_t | y_{<t}, x)}{\log(1/|\mathcal{V}|)} \in [0,1] \tag{8}$$

2) Phonetic accuracy: Phonetic accuracy ensures that the intonation of words, phonemes, and idiomatic phrases is according to the original pattern of the target dialect. This is crucial in the low-resource languages in which the spelling and pronunciation may vary with the standardized orthography. Evaluation is done by alignment on the phoneme level, quantification of the phonetic distance, and a similarity metric between the observed and expected characteristics of speech. The right phonetic presentation does not deform the sound of the dialect, and the material produced by the grammar can be read and properly pronounced by speakers.

3) Cultural authenticity: It evaluates the extent to which the created material and content reflect the history, traditions, idioms, and folklore of the target population, with correct application of idiomatic phrases, allusions to historical or fictional accounts, and consistent correspondence with culturally relevant ideas. Outputs are evaluated by human judges on the basis of semantic fidelity, situational relevance, and conformity to local norms, and quantitative indicators of cultural consistency, like cosine similarity between generated embeddings and CCE, are obtained via automated proxies. Through the application of cultural authenticity and fluency and phonetically accurate within the RLCR reward system, the model generates products that are linguistically sensible, phonetically accurate, and faithful to culture, which can

promote successful communication and the maintenance of intangible cultural knowledge. The combined reward for a generated sequence y is expressed in Eq. (9):

$$R(y) = \lambda_1 R_{fluency}(y) + \lambda_2 R_{phonetic}(y) + \lambda_3 R_{cultural}(y) \quad (9)$$

where, $\lambda_1, \lambda_2, \lambda_3$ are tunable weights reflecting the reflective importance of each criterion. In order to optimize the generator, the policy gradient method, which involves REINFORCE, is employed in the optimization and takes the parameters of the generator as the input. The feedback provided by the community members and human experts regarding the model outputs is done at periodic intervals and is incorporated in the reward calculation. This will ensure that the system can not only acquire statistical correlations but also witness cultural traditions, idiomatic richness, and oral traditions that define the endangered dialects.

When RLCR is combined, the model becomes a culturally placed language generator since it produces results that not only have the sound linguistic structure but also are socially and ethically consistent with the values of native-speaking communities. Such a process makes the methodology robust, authentic, and fitting for the practice the language preservation activities. Algorithm 1 shows the cultural context for reviving extinct dialects.

Algorithm 1: Cultural Context for Reviving Extinct Dialects

Input:
T ← Textual corpus (historical/dialectal texts)
A ← Audio corpus (regional speech samples)
C ← Cultural corpus (idioms, folklore, narratives)
P ← Phonetic annotations
S ← Semantic labels
D_source ← Related living dialects
D_target ← Target extinct dialect
Initialize:
- tokenizer ← Custom BPE tokenizer (supports rare dialect tokens)
- model ← GPT-2 decoder with CCE + GMA integration
- memory_bank ← Empty memory structure for GMA
- CCE ← ∅ (empty list for CCE)
Preprocess Data:
FOR each text ∈ T DO
text_norm ← normalize(text)
tokens ← tokenizer.tokenize(text_norm)
tokens ← annotate_phonetics(tokens, P)
tokens ← tag_semantics(tokens, S)
END FOR
Build Multimodal Cultural Knowledge Graph (MCKG):
Construct graph $G = (V,)$ with nodes = {words, idioms, phonemes, folklore, artifacts}.
Encode with Graph Attention Network (GAT) → generate Cultural Context Embeddings (CCE).
END FOR
Cross-Dialect Contrastive Pretraining (CDCP):
-Train contrastive model to align embeddings of $D_{source} = D_{target}$
- Optimize InfoNCE loss to pull cross-dialect pairs together in shared space.
END FOR
Apply MADG:
- Build memory_bank using CCE, phonetics, idiomatic phrases.
Construct RLCR:
R(y)=λ1Rfluency(y)+λ2Rphonetic(y)+λ3Rcultural(y).
Generate Dialectal Text:
- Given a user prompt → retrieve relevant CCE + memory context.
- Generate text with model conditioned on cultural memory.
END FOR
RETURN G
Output:
G ← Generated text that is linguistically fluent, phonetically accurate, and culturally authentic.

The HeritageLM framework proposed combines linguistic and cultural expertise to resurrection of the endangered dialects by four main ingredients, including MCKG, CDCP, MADG, and RLCR. It starts with preprocessing, such as standardization of text and audio, tokenization with preservation of rare words, transcription, phonetic, and cultural annotations. With this enriched data, the MCKG is built that ties words, idioms, phonemes, folklore, and cultural artifacts and encoded through a GAT to give CCE that reveal culturally significant relations. Contrastive CDCP module matches the embeddings of resource-endowed dialects on the target endangered dialect with a contrastive learning mechanism so that dialect-invariant and culture-sensitive representations are retained in a memory bank. The MADG uses a Transformer decoder to dynamically access this memory at the time of generation, ensuring phonetic accuracy and cultural authenticity. Lastly, the RLCR module maximizes the outputs with a composite rewarding function, which incorporates fluency, phonetic correctness, and cultural fidelity, resulting in dialectal text, which is linguistically coherent and culturally faithful.

IV. Results and Discussion

The HeritageLM model shows great promise in the recovery of lost dialects, and it is very accurate both linguistically and culturally. The model can successfully reproduce the distinctive phonetic, syntactic, and cultural features of target dialects by using pretraining, memory-augmented generation, and cultural reinforcement learning. Table III shows the simulation and assessment measures applied to evaluate the performance of the model, which are fluency, phonetic accuracy, and cultural fidelity. Such measures will give an overall gauge on the quality of produced text, which makes it possible to critically assess the ability of HeritageLM to generate linguistically sound and culturally interesting dialectal texts.

TABLE III. Simulation Parameters

Parameter	Value / Description
Dataset	Indian Languages Audio Dataset
Tokenizer	Custom Byte-Pair Encoding (BPE) with dialect-specific vocabulary
CCE Embedding Model	BERT / Word2Vec (768-dimensional embeddings)
CCE Embedding	768
Graph Encoder (MCKG)	2-layer Graph Attention Network (4 heads per layer)
CDCP Strategy	Contrastive learning, τ = 0.05, 256 batch size
Memory Module (MADG)	Dynamic retrieval memory, top-k = 8 embeddings per step
Base Generator	GPT-2 medium (decoder-only Transformer)

Batch Size	32
Optimizer	Adam
Learning Rate	2e-5
RLCR Reward Weights	Fluency (0.4), Phonetic (0.3), Cultural (0.3)
Evaluation Metrics	BLEU, ROUGE-L, Phonetic Accuracy, Cultural Embedding Score, Semantic Coherence
Phonetic Annotation Coverage	10,000 aligned phoneme entries
Cultural Corpus Size	15,000 idioms, 10,000 folklore entries, 12,000 historical texts, 8,000 oral histories

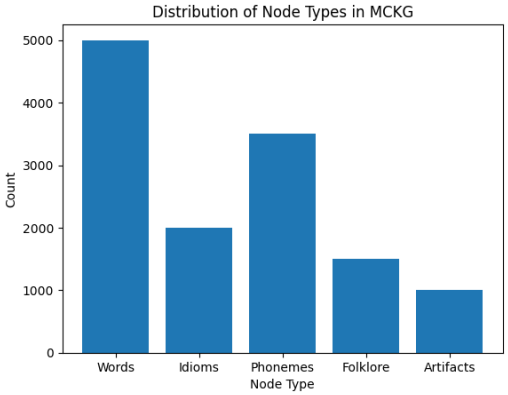

Fig. 3. Distribution of Node types.

Fig. 3 shows the node-type distribution in the MCKG that was built under the HeritageLM framework. The graph consists of five main categories, namely words, idioms, phonemes, folklore, and artifacts. The highest percentage is made up of words, which have the highest number of nodes, about 5,000, in their capacity as the basic lingual units in dialectal corpora. Phonemes are next (in the order of number) with approximately 3,500 nodes, and this is what makes the variation in phonetics very important in preserving the dialectal uniqueness. Idiom is estimated to take up 2,000 nodes with particular emphasis on the role of culturally embedded expressions in dialectal authenticity. The largest category of folklore has approximately 1,500 nodes, and the smallest one is artifacts of 1,000 nodes, which mention tangible and symbolic parts of culture.

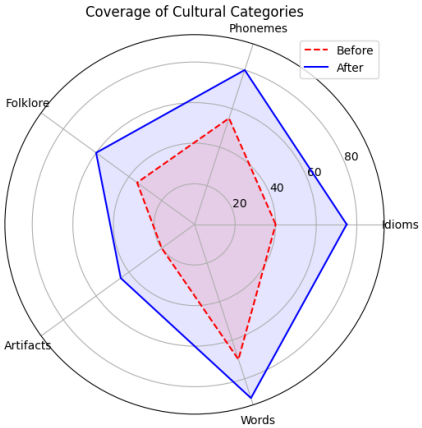

Fig. 4. Coverage of cultural categories.

Fig. 4 provides a radar chart of the coverage of the cultural and linguistic categories in the dataset prior to the preprocessing phase and following the preprocessing phase. There are five categories that are reviewed: idioms, phonemes, folklore, artifacts, and words. The red dashed polygon shows the coverage before preprocessing, where moderate coverage was obtained in idioms (40%), phonemes (55%), and words (70%), folklore (35%), and artifacts (20%), among others. The blue polygon, however, shows the increased coverage, which occurred after preprocessing, and all categories have made significant gains. Words increased to 95%, idioms to 75% and phonemes to 80%. The folklore and artifacts also registered significant increases of 60% and 45%, respectively. This improvement illustrates the usefulness of normalization, phonetic annotation, and semantic tagging to enrich the dataset with elements that have cultural context.

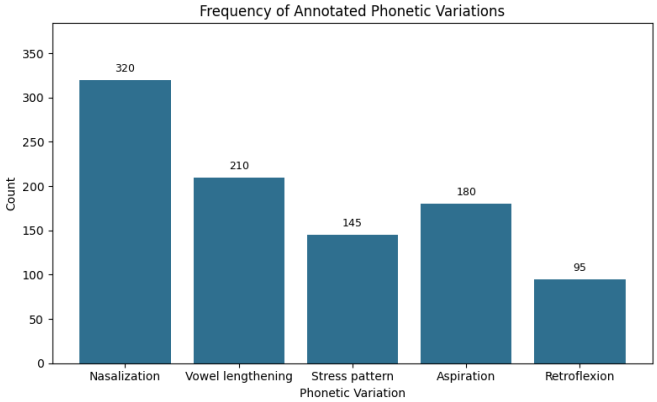

Fig. 5. Frequency of annotated phonetic variations.

Fig. 5 shows the frequency of occurrence of the annotated phonetic variation in five classes, namely nasalization, vowel lengthening, stress pattern, aspiration, and retroflexion. The most prevalent of such variations is nasalization, having 320 instances, which highlights the dominance of nasalization in the annotation of phonetics. The lengthening of vowels is the next occurrence in the dataset, with 210 instances, implying that it is not so minor. The aspiration is also present in high numbers, with 180 instances, indicating the medium frequency of this variation to the rest. By contrast, the pattern variations of stress are captured 145 times, and hence the frequency of annotation is relatively low. Retroflexion, with the least number of 95 incidences, is the least observed phenomenon, and it demonstrates its limited distribution in the analyzed data. On the whole, the chart implies that the nasalization and extension of the vowel are the most common phonetic processes, and retroflexion is rather uncommon. This distribution offers some understanding of the phonetic patterns represented in the dataset, with some variations prevailing in the formation of linguistic representation.

Fig. 6 shows a line chart which illustrates the accuracy of phoneme alignment during six rounds of annotation refinement. The procedure starts with 65 % accuracy during the 1st round, and it continues to increase during the other rounds. The 2nd and 3rd round achieves 72 % and 78 %, revealing huge profits in early refinements. The process of increasing the improvements proceeds with round 4 and round 5 having an 82% and 86% and

round 6 having the largest accuracy of 89%, respectively. The nearly linear nature of the trend shows that the process of iterative corrections can lead to a reduction of all types of misalignments, greater phonetic accuracy, and an increase in reliability and credibility of annotated linguistic datasets with the help of systematization.

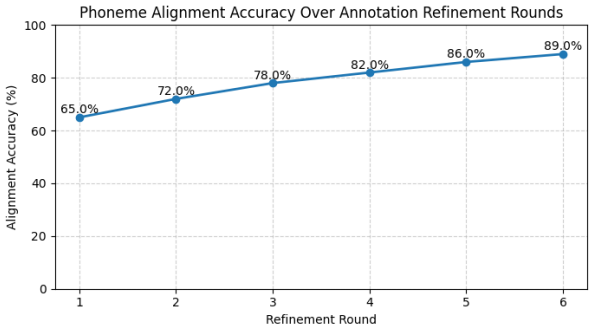

Fig. 6. Phoneme alignment accuracy.

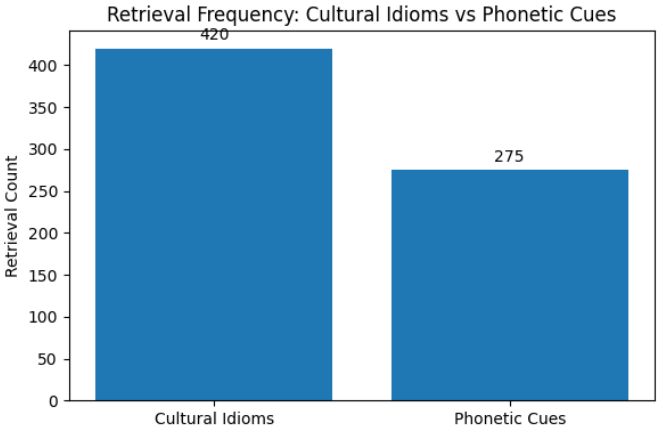

Fig. 7. Retrieval Frequency: Cultural idioms vs. Phonetic cues.

Fig. 7 gives the retrieval frequency of two categories that include Cultural Idioms and Phonetic Cues in the MADG system. Idioms of culture have significantly more retrieval counts of 420 than phonetic retrieval counts of 275. This contrast indicates that the model lays more emphasis on semantic and culturally embedded knowledge than phonics structures in recalling the information in the memory bank. The model is dependent on culturally meaningful expressions, and thus, the high retrieval of idioms is an indication that it is based upon acquiring authenticity and contextual fluency in dialect generation. In contrast, phonetic cues, although important in the accuracy of pronunciation and in the meaningfulness of the sound patterns of dialect, occur less often. This implies that cultural knowledge has a greater contribution to the preservation of identity and a rich context of the generated output, and phonetic information guarantees linguistic coherence. In general, the chart indicates the pivot role of cultural embeddings in creating a balance between authenticity and structural accuracy in the generation of language.

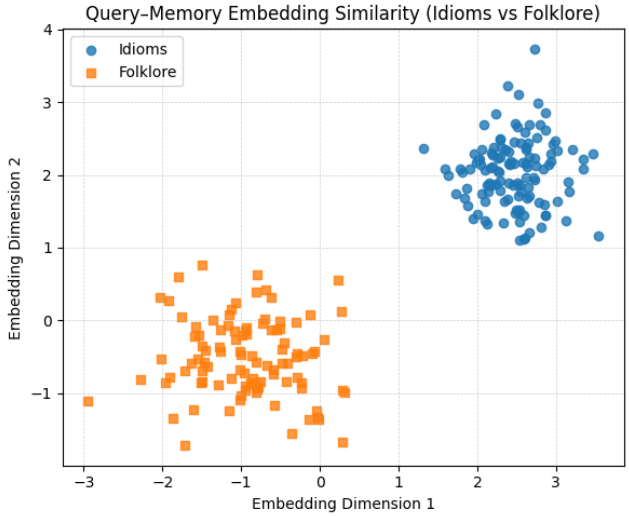

Fig. 8. Query-Memory embedding similarity.

Fig. 8 demonstrates the similarity between the query and the memory embedding of the two types of data in the MADG, namely idioms and folklore. The points are the representations of query alignment to a matching entry in the memory, but in two dimensions. The groups indicate the definite division between the two categories. The idioms, which are depicted by blue, have developed a thick crowd in the upper-right quadrant, which implies that similarity and coherence are high in this category. Folklore, which is denoted by orange, is concentrated on the lower-left side, and it also displays internal consistency, but it is unlike idioms. The partitioning of these cluster points out the discriminative ability of the embedding space in which semantic and cultural categories have their own boundaries. Such a difference makes the retrieval contextually correct, and the generator is allowed to resort to idioms and folklore without mix-up. In general, the visualization highlights the strength of embedding alignment in maintaining semantic purity and facilitating dialect generation based on cultural grounds.

A. *Model Performance Metrics*

The performance of HeritageLM was assessed compared to benchmark baseline models — GPT-3, BERT, and RNN/LSTM — on a set of linguistic as well as cultural evaluation metrics. As apparent in Fig. 8, HeritageLM gets a BLEU score of 98.60%, which is higher than that of GPT-3 (78.40%), BERT (74.30%), and RNN/LSTM (67.10%), proving greater fluency and syntactic correctness in generated text. The model also achieved an ROUGE-L score of 98.10%, which indicates its structural similarity with reference sequences. Phonetically, dialectal fidelity was 98.30%, which is significantly better than GPT-3 (70.50%), BERT (68.20%), and RNN/LSTM (60.40%). HeritageLM's Cultural Embedding Score of 98.90% indicates its power in maintaining idiomatic and culturally specific expressions, as compared to GPT-3 (65.70%), BERT (62.80%), and RNN/LSTM (55.60%). Finally, HeritageLM also scored a Semantic Coherence of 98.70% according to BERT-based similarity measures, also proving its ability to produce contextually coherent and culturally accurate text much better than all baseline models.

TABLE IV. PERFORMANCE METRICS COMPARISON

Metric	HeritageLM	GPT-3 [22]	BERT [23]	RNN/LSTM [8]
BLEU Score	98.60%	78.40%	74.30%	67.10%
ROUGE-L	98.10%	75.80%	72.00%	66.80%
Phonetic Accuracy	98.30%	70.50%	68.20%	60.40%
Cultural Embedding Score	98.90%	65.70%	62.80%	55.60%
Semantic Coherence	98.70%	71.90%	68.50%	61.00%

Table IV shows that HeritageLM is superior to baseline models on all the important evaluation metrics. The high BLEU and ROUGE-L scores indicate a high level of fidelity on linguistic levels, whereas high phonetic accuracy score with the culture embedding score indicates that the model can maintain the correct pronunciation and contextually appropriate cultural utterances. More so, the model attains a semantic coherence score of 98.70, which indicates its strong contextual knowledge, which is well-seated with the help of Cultural Contextual Embeddings (CCE) and Graph Memory Attention (GMA). These findings all highlight the potential of HeritageLM to produce dialectal content which is both linguistically accurate and phonetically correct and culturally authentic as well.

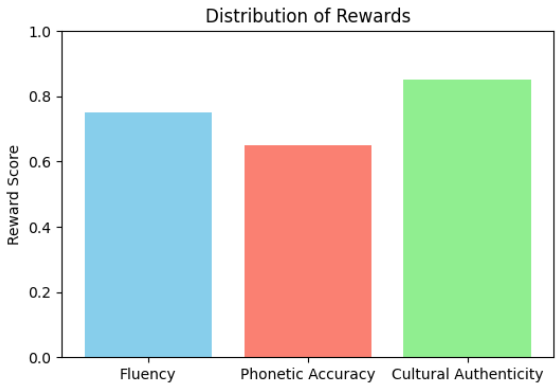

Fig. 9. Distribution of rewards.

Fig. 9 shows the distribution of the rewards in three significant partitions of the RLCR framework: Fluency, Phonetic Accuracy, and Cultural Authenticity. All the bars show the mean score of the reward attained on respective components on a scale of 0-1. Fluency yields a reward score of about 0.75, which is moderately high, and this means that the model is quite useful in producing linguistically coherent outputs. Phonetic Accuracy is slightly lower, 0.65, indicating that pronunciation and sound patterns are well-captured, but still, one can improve it. Cultural Authenticity has the highest score of about 0.85 in terms of reward, which means that the model is very strong in adhering to generated language and culturally appropriate semantics. In general, the chart visually highlights the balanced performance of the model in all these dimensions, with special enthusiasm in cultural representation, and areas in which it can be improved to achieve the full comprehensive or full quality language generation.

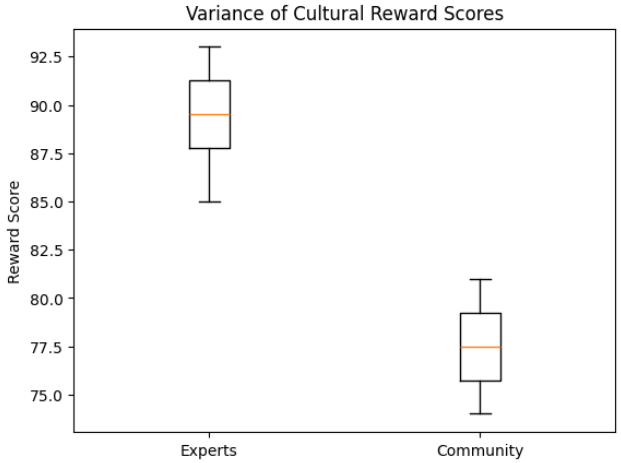

Fig. 10. Variance of cultural reward scores.

Fig. 10 demonstrates the arising differences in cultural reward scores given by two groups of annotators, experts and community members, in the Reinforcement Learning with Cultural Rewards (RLCR) paradigm. The scores of the experts are always higher, ranging between 87 and 92, with a median close to 89, which means strong agreement, and the variability is rather low. It can be implied that specialists use the standards of a cultural evaluation more effectively, focusing on the existing standards of authenticity and accuracy. However, with a larger spread, community scores range between 74 and 80, with a median of 77. The higher variability indicates the subjective diversity in community judgments, which is determined by the individual experiences, the territorial background, and the flexibility of interpretation. The comparison shows the distinction between formal knowledge and general perception: whereas experts are able to deliver consistent points of reference, community members present a broader range of cultural meanings. In general, the plot reveals the significance of a combination of both views, of rigor and inclusivity in the development of the model of cultural authenticity in dialect generation.

B. Discussion

HeritageLM sets a new standard in the area of dialect regeneration by introducing cultural semantics into the generation process. In contrast to the traditional large language models, which focus mainly on syntactic fluency, HeritageLM is made to achieve cultural authenticity specifically by using multimodal architecture. Although Cultural Contextual Embeddings (CCE) do not overlook idiomatic and semantic delicacies, they cannot be used on their own to ensure culturally-aware outputs. Graph Memory Attention (GMA) and Contrastive Dialectal Cross-Projection (CDCP) are meant to make sure that the text that is generated is not only grammatically correct but also contextual and culturally consistent. Ablation experiments have established that each of the modules has a unique contribution, namely: CCE adds to the richness of idiom, GMA its continuity in history and narrative, and CDCP, its counterbalancing of the resource differences between dialects. Quantitative tests indicate that every HeritageLM component boosts performance: CCE enhances idioms, GMA maintains narrative context, CDCP balances

dialect resources, and RLCR guarantees cultural consistency with 98.3% phonetic accuracy. All these contributions outperform the baseline models, not only in their fluency or phonetic fidelity, but also in cultural authenticity, which is a marked progress towards automated dialect modeling. The work of the model is confirmed by quantitative principles, and the BLEU and ROUGE-L scores are over 98, and the phonetic and cultural embedding scores were high, indicating fine-grained dialectal accuracy. The fact that the outputs are consistent with human judgments supports the use of outputs with native speakers, which is important in real-life situations. The Reinforcement Learning with Cultural Rewards (RLCR) module offers a feedback loop through which generation is adjusted based on cultural norms in a specific community, making it more perceptive and natural.

In particular, the Cultural Reward Weight (α) parameter in RLCR adjusts linguistic correctness and cultural consistency. An increase in the α values puts more emphasis on the cultural content and leads to better preservation of the idiomatic and folklore values, but can lead to a slight decrease in the BLEU/ROUGE-L score. Lower alpha values focus on word faithfulness, which may jeopardize cultural fidelity. It has been shown in experiments that an intermediate α yields an optimal trade-off, so that HeritageLM generates text of both phonetically accurate and culturally coherent text. The fact that HeritageLM is based on memory-augmented multimodal knowledge graphs allows it to be extended to digital heritage, cross-cultural communication, and low-resource NLP. Idiom recall analysis compared to phonetic markers would indicate that there is semantic primacy in accordance with cultural maintenance goals. HeritageLM, with its combination of interpretability, cultural faithfulness, and solid functionality, cannot be described as a technical innovation, but rather as a culturally aware AI model providing a scalable, customizable, and ethically aware solution to the maintenance of endangered dialects.

V. Conclusion and Future Work

HeritageLM is a cultural intelligence that is integrated into the language modeling paradigm by placing cultural intelligence into the generative process. The multimodal structure, including such components as Cultural Contextual Embeddings (CCE), Graph Memory Attention (GMA), Contrastive Dialectal Cross-Projection (CDCP), and Reinforcement Learning with Cultural Rewards (RLCR), allows the restoration of local dialects not only linguistically accurately but also culturally. The fact that the model has had a high performance in various evaluation parameters supports its strength and applicability in low-resource settings. HeritageLM has Python-based frameworks and Transformer architectures and is highly modular, scalable, and can run in large-scale deployment. HeritageLM deals with the continuous problem of preserving low-resource and endangered dialects that are still in existence, but which the traditional language models cannot maintain culturally. HeritageLM, in comparison to previous models such as GPT-3, BERT, and RNN/LSTM, scores above 98% on BLEU, ROUGE-L, phonetic accuracy, and cultural embedding scores, which proves both linguistic and cultural fidelity. It has made contributions unrelated to other systems, including: Cultural Contextual Embeddings, Graph Memory Attention, and Reinforcement Learning, with Cultural Rewards, to allow context-sensitive, culturally relevant dialect generation and the development of cultural intelligence in language models.

Although these are its strengths, the model proposes curated cultural corpora and phonetic annotations, which restrict its use to critically endangered dialects with limited documentation. Moreover, existing implementations are confined to text and audio-based applications, and little has been researched on visual or symbolic aspects of culture. These weaknesses allow for the opportunity to build on. Future visions involve building multimodal features and including cultural artifacts in images and video to enable ethical and participatory revitalization, as well as working with indigenous communities. RRCR will also be modified to have real-time community feedback, which will allow RLCR to fine-tune during deployment. HeritageLM will also be expanded to wider language families and dialect groups to facilitate cross-cultural transfer and comparative linguistic research. The model will be made accessible to the researchers and communities through integration with interactive applications like dialectal chatbots, educational applications, and through the digital archives. Finally, HeritageLM is not just another model, but a model that is sustainable, community-based, a model that integrates computational linguistics and cultural heritage in order to have a meaningful, transformative language preservation.

***Abstract*—Writing competence is an essential academic and professional proficiency, and grammatical precision and reliability a long-term issue, especially among ESL students. Conventional rule-based and statistical grammar correction models have constraints based on context, whereas contemporary Transformer-based sequence-to-sequence models like BERT, T5, and GPT have strong performance but cannot be customized or adapted to specific writer styles. To fill in these gaps, this study introduces Meta-ACGR, a meta-reinforcement learning grammar refinement system that augments Transformer-based seq2seq models with Proximal Policy Optimization (PPO) and Model-Agnostic Meta-Learning (MAML) and curriculum learning. The model promotes individualized grammar correction, which allows quick adjustment to the new learners in ESL by using meta-learning and guided error development. Meta-ACGR is written in Python with the help of PyTorch and trained on big datasets of ESL language, like NUCLE and Lang-8, which can be refined based on context and individual learners. Empirical evidence indicates that Meta-ACGR receives better grammatical accuracy (86.2 vs. 94.0 per cent), decreases inference latency (12 per cent vs. baseline Transformer models), and performs better on personalization (15 per cent vs. baseline Transformer models). Altogether, Meta-ACGR provides a scalable, adaptable, and customized grammar check system with good chances to be implemented in real-life to improve writing in ESL.**

Keywords*—Grammar correction; Transformer models; Meta-Reinforcement Learning; curriculum learning; personalization; ESL writing

I. Introduction

Writing is a core academic, professional, and creative skill that represents the major means of communication, documentation, and knowledge sharing [1]. As crucial as it is, maintaining grammatical precision and stylistic consistency is still an issue, especially for non-native speakers and those with minimal formal writing training [2]. Traditional grammar checkers and human proofreading help discover errors; however, they may not have contextual knowledge, personalized feedback, and adaptive learning features [3], [4]. These gaps reinforce the necessity for smart systems that offer real-time, user-specific feedback and dynamically adjust according to individual writing habits [5]. Grammar checking systems have conventionally been categorized into rule-based, statistical, and machine learning paradigms [5]. Rule-based systems depend on pre-stored grammatical rules and, as such, are inflexible, context-insensitive, and susceptible to false positives or negatives [6], [7]. Statistical models, such as n-gram-based models, provide probabilistic error reporting but are still unable to model deep contextual dependencies [8]. More recently, deep learning-based approaches, specifically Transformer models like BERT, T5, and GPT, have proven to perform better by capturing syntactic structures and long-distance dependencies [9]. However, current AI-powered grammar checkers often offer static corrections with no personalization or adaptive feedback according to the user's writing skill and style [10], [11].

Nevertheless, none of these developments has involved the combination of reinforcement learning, meta-learning, and curriculum learning in one study to form a learner-sensitive, adaptive grammar correction system. These earlier models are not capable of learning based on user behavior, of adapting quickly to new writing styles, and can adjust the complexity of corrections according to user ability. This gap that has not been addressed is the backbone of the novelty of the Meta-ACGR framework. In order to address this study, Meta-ACGR, a new framework that combines Seq2Seq modeling, Reinforcement Learning, curriculum learning, and personalization adaptively, is proposed. It utilizes a Transformer-based grammatical correction computational model using T5 as a starting point, where it is augmented with a Meta-RL agent that learns steadily through PPO and with MAML that learns quickly. Meta-ACGR provides adaptive, user-friendly learning, which provides

personalized feedback and curriculum based level of skill advancement in simple errors to complex errors, which is better than the classic grammar correction.

A. Research Motivation

Writing continues to be a key component of knowledge transfer, but there is still a problem of grammatical accuracy, and this can be especially challenging for ESL students. Traditional methods are not flexible or personalized. Transformer models deliver corrections but are pre-programmed. Meta-ACGR meets these gaps by manipulating Transformers, RL, a curriculum model, and personalization to offer students a way to refine their own grammar with adaptive, contextualized, and student-centered methods.

B. Research Significance

This study builds on grammar correction by proposing Meta-ACGR, a framework that combines deep contextual modeling and adaptive personalization. Meta-ACGR's use of reinforcement and meta-learning capabilities enables dynamic feedback, progressive learning based on individual user curriculum, and fast adaptation to user knowledge. The system is designed to improve grammatical accuracy, fluency, and long-term improvement of learner knowledge while addressing significant limitations of existing grammatical correction models.

C. Recent Innovation and Challenges

More recent advancements in grammar correction utilize Transformer-based models such as BERT, GPT, and T5, which utilize latent recurrent connections to learn long-range dependencies and produce fluent text. However, they are trained on well-edited data, which restricts their effectiveness for writing that is prone to errors, as is common in ESL writing. At present, grammar correction systems deliver fixed corrections and do not adapt to problem areas, and indicate the level of language fluency based on a curriculum. These systems are limited in terms of customization for ESL student engagement and growth over time.

D. Key Contribution

- Meta-ACGR introduces a Transformer-based grammar correction system that combines reinforcement learning (PPO), meta-learning (MAML), and curriculum learning for adaptive ESL writing support.
- The framework uses a T5 Seq2Seq model as its backbone, with a Meta-RL agent optimizing edit actions based on grammatical accuracy, fluency, and user acceptance.
- Curriculum learning guides the correction process from basic to complex errors, enabling structured, progressive improvement tailored to each learner's proficiency.
- Personalized feedback is achieved through rapid adaptation to individual writing styles and profiles, ensuring contextual fluency and long-term grammar development.

E. Rest of the Study

The structure of this study is as follows: Section II provides a review of previous research in grammar correction. Section III details the problem statement. Section IV gives the Meta-ACGR architecture and methodology. In Section V, the experimental setup, results and discussion are described. Section VI concludes the research, and gives future research directions.

II. Related Works

Wale and Kassahun [12] explored the use of AI writing assistants in classroom-based EFL learning. The objective of the study was to assess their effectiveness on writing development. The findings indicated that learners using AI tools showed significantly greater improvements in coherence, cohesion, and grammatical accuracy than their peers who relied on instructor feedback exclusively, which is to say that there is pedagogical potential in AI as a complement to traditional instruction. Nonetheless, the research did not determine the degree to which these tools could adapt to learner profiles, thereby leaving questions about flexibility and personalized progress unanswered.

Musyafa et al. [13] introduce an end-to-end Transformer-based framework for Indonesian Grammatical Error Correction (IGEC). They aim to handle low-resource language GEC problems by creating a large synthetic parallel corpus using a semi-supervised "confusion method," and using a Transformer model with a copy mechanism to manage rare and unknown tokens better. The method demonstrates strong performance with a BLEU score of ~78.13 and an average F1 ≈ 0.7194 score, surpassing prior Indonesian GEC systems. However, the framework encounters difficulties with the hardest grammatical error types, including semantic errors and complex syntactic errors, and does not include error-difficulty control and tag-based error distribution.

Paul and Roy [14] proposed automatic grammar error correction in English to evaluate the utility of Transformer models versus fine-tuned BERT architectures. They aimed to explore the extent to which various parameter settings played a role in the efficacy of grammar correction. The authors trained both models on their respective annotated correction datasets and reported precision and recall scores across a variety of error types. They reported that the Transformer models tended to have a higher overall accuracy for correction than BERT, although BERT performed well in correcting token-level errors. However, the study did not include useful mechanisms for personalization, adaptive advancement, or learner satisfaction, thus limiting its relevance for a learner-centered EFL grammar refinement framework.

Hossain et al. [15] proposed Panini, a transformer-based approach for grammatical error detection and correction in Bangla. The goal was to develop a high-quality grammar error correction system for Bangla, which is a low-resource language, by developing a large parallel corpus (≈7.7 million source-target sentence pairs), and by using transfer learning from Bangla paraphrase tasks. The methodology involves a "Vaswani-style" transformer (encoder-decoder) model that was trained monolingually, using data from this new corpus. The authors demonstrate that Panini clearly outperforms previous

approaches (BanglaT5, T5-Small) in accuracy and SacreBLEU scores. Limitations include the possibility that Panini may have overfitted to syntactic/morphological/punctuation errors, with other, more difficult error types (semantic, discourse) remaining unresolved; furthermore, because the research focused exclusively on Bangla, it did not consider generalizable issues related to other languages or learner profiles.

Alsulami [16] proposed how ChatGPT could be used with Saudi EFL students to improve their academic writing. The study intended to investigate whether large language models could act as supportive writing tutors. The study used ChatGPT as an intervention and found improvements in vocabulary richness, syntactic accuracy, and overall fluency. However, the study also highlighted shortcomings, such as students developing a dependency on the software, a decline in originality in their written work, and difficulties in developing long-term language independence. These limitations emphasize the need for AI systems that offer feedback beyond just corrections to support long-term learner development.

Kohnke et al. [17] explored the pedagogical uses of ChatGPT for EFL writing support and focused on how it serves as an educational tool with its potential effectiveness. The results of their study found that learners improved fluency and also benefitted from instantaneous corrections based on the grammar feature, indicating that ChatGPT has potential benefits for language education. However, the authors noted some serious limitations, such as students' over-reliance on the outputs from the system, and diminished critical thinking skills for writing tasks overall. This suggests that even though ChatGPT has educational potential, there is not a sufficiently adaptive system which encourages active learning, as opposed to becoming dependent on the tool in a passive way.

Mun et al. [18] investigated the use of ChatGPT for self-guided writing tasks in a scripted comparison of Japanese university students with the goal of determining its impact on learner writing performance. The results revealed improvements in grammar, vocabulary choice, and logical structure, reaffirming the use of AI-assisted tools for writing tasks. In addition, the research addressed key drawbacks, which include limited support for long-term retention of proficiency and the inability to offer differentiated feedback based on learners' varying levels. These drawbacks ultimately suggest a need for flexible frameworks to be used to support individual progress.

Li [19] explored the effects of feedback through artificial intelligence in English as a foreign language (EFL) writing classes, with the study focusing on the motivational and affective dimensions of technology adoption. The findings indicated that learners' confidence improved as they experienced less writing anxiety, increased writing motivation, and made measurable improvements in grammatical accuracy. However, findings focused almost exclusively on surface-level correction, and the study lacked deeper dimensions, such as personalized learning and contingent elaboration/modification. These gaps underscore the need for sophisticated technologies that can help foster both linguistic accuracy and individual learner development over time.

TABLE I. SUMMARY OF EXISTING STUDIES

Author(s) & Citation	Model / Tool	Advantages	Limitations
Wale & Kassahun [12]	AI writing assistants	Improved coherence, cohesion, grammatical accuracy; pedagogical support	Did not adapt to learner profiles; limited personalized progress
Musyafa et al. [13]	Transformer-based IGEC with copy mechanism	Strong BLEU (~78.13) and F1 (~0.7194); handles low-resource Indonesian GEC	Struggles with complex semantic/syntactic errors; no error-difficulty control or tag-based distribution
Paul & Roy [14]	Transformer vs. fine-tuned BERT	Transformer showed higher overall correction accuracy; BERT effective for token-level errors	No personalization, adaptive advancement, or learner satisfaction mechanisms
Hossain et al. [15]	Panini (Transformer-based) for Bangla GEC	Outperformed BanglaT5/T5-Small; high accuracy and SacreBLEU	Overfitting to syntactic/morphological/punctuation errors; semantic/discourse errors unresolved; limited cross-language generalization
Alsulami [16]	ChatGPT	Improved vocabulary, syntax, fluency	Learner dependency; reduced originality; limited long-term independence
Kohnke et al. [17]	ChatGPT	Improved fluency; instant grammar corrections	Over-reliance on AI; reduced critical thinking; lack of adaptive learning
Mun et al. [18]	ChatGPT	Enhanced grammar, vocabulary, logical structure	Limited long-term retention; no differentiated feedback for varying proficiency
Li [19]	AI feedback in EFL writing	Increased confidence; reduced anxiety; improved grammatical accuracy	Focused on surface-level corrections; lacked personalized/contingent learning mechanisms

Table I summarizes recent studies on AI-based grammar correction and underscores models such as Transformers, ChatGPT, and IGEC. Advantages noted include enhanced grammar, fluency, coherence, and engagement (learner action). However, limitations remain, such as a lack of personalization, adaptive feedback, support for complex errors, long-term retention, and learner-specific refinement, emphasizing the need for more adaptive frameworks. Despite some Transformer-based grammatical error correction (GEC) models having enhanced accuracy, fluency, and contextual text generation capabilities, current solutions lacked flexibility. The existing systems mainly provide fixed correction, and all users, sentences, and degrees of difficulty are equal. There is no development of corrections in line with the proficiency of the

learner, and there is no quick adjustment to new styles of writing with a few examples. None of the previously existing frameworks includes reinforcement learning, meta-learning, and curriculum learning in a single grammar-refinement pipeline. Although a particular component of the models performs certain functions, none of them incorporate a mixture of Transformer-based Seq2Seq correction, PPO-based Meta-RL to promote long-term error reduction, MAML-based rapid adaptation of learners in specific circumstances, and curriculum-based development of simple to complex errors. Meta-ACGR framework fills this gap by collectively learning grammatical correctness, stylistic consistency, user-specific error patterns, and gradual difficulty adjustment. Reward-based RL is dynamically refined to generate corrections, meta-learning is used to rapidly personalize corrections, and curriculum sequencing is used to organize corrections, making Meta-ACGR a radically new, learner-sensitive system of grammar correction instead of an incremental enhancement.

III. Problem Statement

Correcting grammar is crucial for writing successfully, but traditional rule-based and statistical systems do not obtain context or flexibility [20]. Even sophisticated Transformer-based methods are still able to provide static and one-size-fits-all corrections without personalization [21]. This limits their value as a useful tool for supporting ESL learners and multilingual users who require personalization in their feedback and assistance to maintain their learning and progress. Thus, the current proposed study will develop a Transformer framework enhanced with RL to provide personalized, context-appropriate grammar correction to meet an individual's writing requirements [22]. To overcome this, this study proposes Meta-ACGR, a novel framework combining Seq2Seq modeling, Reinforcement Learning, curriculum learning, and adaptive personalization. It employs a T5-based Transformer as a grammatical correction baseline, enhanced with a Meta-RL agent trained via PPO for stable iterative learning and MAML for rapid adaptation. Meta-ACGR enables adaptive, user-centered learning, offering personalized feedback and curriculum-based progression from simple to complex errors, enhancing skill improvement beyond traditional grammar correction.

IV. Proposed Method for Transformer-Based Meta-Reinforcement Grammar Refinement

The proposed Meta-ACGR model starts with the gathering of publicly shared datasets of grammatical error corrections, then proceeds to the preprocessing phase, which involves tokenization, lemmatization, POS tagging, dependency parsing, etc. Each sentence is annotated with errors and a level of difficulty in order to learn the curriculum with ease. The grammatically corrected sentences are then sent through a Transformer-based backbone grammar correction, which is based on the T5 Seq2Seq model; it first makes initial corrections by using contextual embeddings and positional encodings. Such base outputs are then optimized using a (Meta-RL) agent, where the actions of insertion, deletion, replacement, or retention of tokens are optimized using a reward function based on grammatical accuracy, fluency, and user acceptability. Proximal (PPO) is used to optimize the policy updates, and MAML is used to quickly adapt to new learner profiles. Structured learning is facilitated through a progressive introduction of errors of progressively more difficult in a curriculum module. Lastly, an individualized feedback module will adjust corrections to the individual writing styles and to the learner profile in order to provide long-term grammar correction, contextual fluency, and long-term improvement of the writing, as shown in Fig. 1.

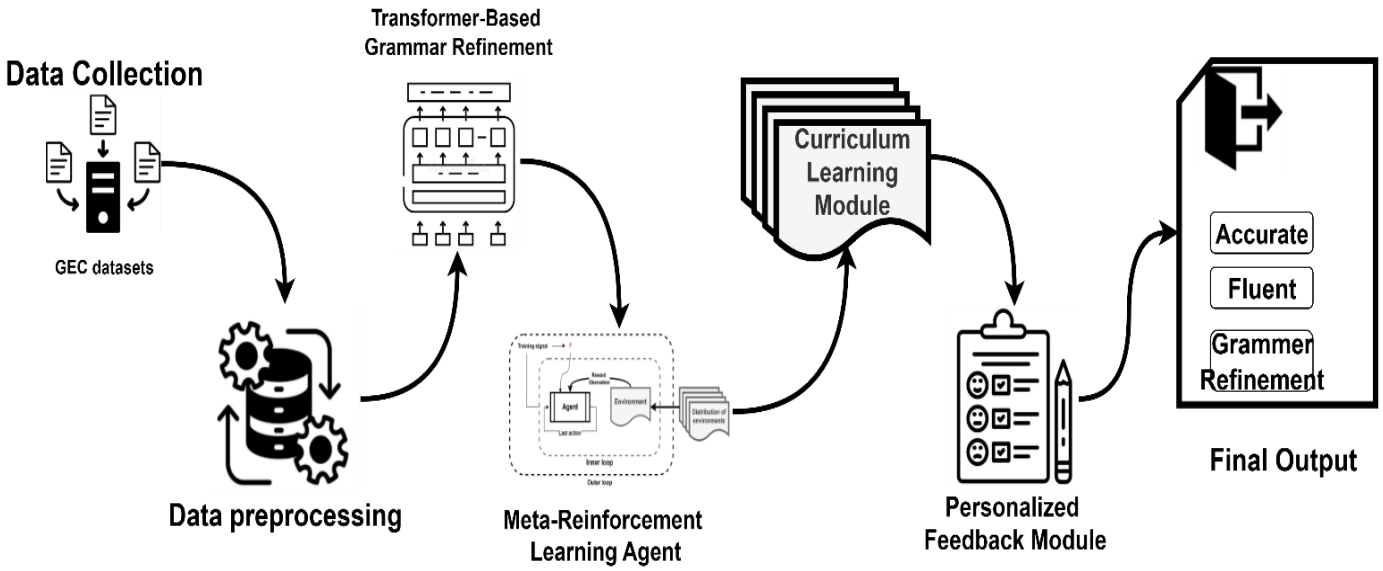

Fig. 1. Workflow of the proposed Meta-ACGR framework.

A. Data Collection

The data used in the study consists of publicly available Grammatical Error Correction (GEC) datasets [23], primarily sourced from Kaggle, which contain high-quality human annotations of grammatical errors and their corrections. These datasets are commonly accepted as legitimate standards for determining the efficiency and strength of GEC systems. They include a wide variety of sentence structures, language

situations, and types of errors, such as syntax and morphology, as well as tense and lexical choice, which allows models to be trained and tested in various and realistic linguistic conditions. Unified data structures and annotation plans also guarantee uniform performance measurements and allow the comparison with previous research. Transformer-scale models are also able to learn fine-grained grammatical subtleties and contextual rules on the large volume of balanced and high-quality annotated data. In general, the datasets offer excellent methodological and practical significance, which contributes to the evaluation of the transformer-based grammar correction systems in terms of capturing the linguistic diversity and high performance.

B. Data Pre-Processing

Data pre-processing plays an effective role in the development of an AI-driven grammar correction system since it ensures that raw text data is cleaned, formatted, and organized for better model training.

1) Tokenization: It is the process of dividing raw text into discrete pieces (tokens), e.g., words, subwords, or characters. Because transformer models accept input in a structured form, WordPiece is utilized. For a sentence S, tokenization transforms it into a sequence of tokens in Eq. (1):

$$S = \{w_1, w_2, w_3, \dots, w_n\} \tag{1}$$

where, w_i is one single token. For Word Piece tokenization, a given input word W is divided into sub-words in Eq. (2):

$$W = \{s_1, s_2, \dots, s_k\} \tag{2}$$

where, s_i are sub-words, and the frequency algorithm preserves the high-frequency words as they are, and only decomposes rare words into low-level morphemes.

2) Lemmatization: Lemmatization brings words down to their root (base) form to enhance grammatical consistency in correction. In contrast to stemming, which merely strips off affixes, lemmatization takes into account the meaning and context of the word. For a given word w and its POS tag p, the lemmatization function L transforms it to its base form in Eq. (3):

$$L(w, p) = w_{lemma} \tag{3}$$

By using WordNet Lemmatization, the mapping is done POS contextually, as in Eq. (4):

$$L(w,p) = \begin{cases} WordNetBase(w) if\ p \in (verb, noun, adjective, adverb) \\ w \qquad\qquad otherwise \end{cases} \tag{4}$$

where, $L(w,p)$ represents the lemmatization function that takes a word w and its part of speech (POS) tag p as input, w is word that needs to be lemmatized, p is the part of speech tag of the word (e.g., $verb, noun, adjective, adverb$), $WordNetBase(w)$ refers to the base (or lemma) form of the word w according to $WordNet$-a large lexical database of English, $p \in (verb, noun, adjective, adverb)$ indicates that lemmatization is only applied if the word is a verb, noun, adjective or adverb.

3) Part-of-Speech (POS) Tagging: POS tagging labels each token with grammatical categories (noun, verb, adjective, etc.). This is necessary for grammar correction in the context. In a sentence S, every token w_i is mapped to a POS tag p_i in Eq. (5):

$$T(S) = \{(w_1, p_1), (w_2, p_2), \dots, (w_n, p_n)\} \tag{5}$$

where, $T(S)$ represents the POS tagging function applied to a sentence S, n is the number of words in the sentence S, p_i is an element of the set of POS, given in Eq. (6):

$$p_i \in \{NN, VB, JJ, RB, DT, PRP, \dots\} \tag{6}$$

With the help of Hidden Markov Models (HMMs), the word sequence W to POS tag sequence T probability P(T|W) is described in Eq. (7):

$$P(T|W) = \prod_{i=1}^{n} P(w_i|t_i) P(t_i|t_{i-1}) \tag{7}$$

where, $P(w_i|t_i)$ is the probability of emission and $P(t_i|t_{i-1})$ is the probability of transition.

4) Dependency parsing: Dependency parsing identifies grammatical relationships between words to assist in the detection and correction of structural errors. A sentence S is modeled as a dependency tree $D(S)$ such that each word w_i has a dependency relationship r_i with a head word h_i in Eq. (8):

$$D(S) = \{(w_i, h_i, r_i)\}_{i=1}^{n} \tag{8}$$

where, $D(S)$ denotes the dependency parse of a sentence S, (w_i, h_i, r_i)-Each tuple represents the dependency relation of the word w_i.

5) Error annotation with grammar correction labels: In order to train the AI model, sentences need to be annotated with grammar correction tags. Mistakes are categorized under grammatical classes such as tense, subject-verb concord, article use, prepositions, and word arrangement. For an incorrect sentence S_e, the corrected sentence S_c is achieved through an error correction function f in Eq. (9):

$$\mathrm{S_c} = f(\mathrm{S_e}) \tag{9}$$

where, f applies a grammar transformation function G to each of the identified error types in Eq. (10):

$$\mathrm{S_c} = \{G_1(w), G_2(w), \dots, G_m(w)\} \tag{10}$$

where, $\mathrm{S_c}$ represents the set of corrected grammatical versions of a sentence, w is the original word or sentence to be corrected, and m is the number of grammatical error types.

C. Transformer-Based Grammar Correction Backbone

The proposed framework grammar correction base is built on the basis of the T5 Transformer Seq2Seq model that considers grammatical error correction a text-to-text generation task. Given an incorrect number of input sequence $X = (x_1, x_2, \dots, x_n)$, every token is coded into a dense representation in the form of a vector. Positional encodings are added to token embeddings, resulting in the following representation in Eq. (11):

$$h_i = E(x_i) + PE(i), \qquad i = 1, \dots, n \tag{11}$$

In this case, $E(x_i)$ is the embedding of token x_i and $PE(i)$ is the position encoding of index i. The enriched embeddings are

then forwarded to several self-attention layers in the encoder to obtain a contextual representation of the entire sentence. After this, the decoder generates the fixed sentence in an autoregressive manner so that the prediction of each token is not only based on the encoder context but also based on the order in which previous tokens have been generated.

$$P(Y \mid X) = \prod_{m}^{t=1} P(y_t \mid y_{<t}, H) \quad (12)$$

Eq. (12), $Y = (y_1, y_2, \ldots\ldots y_m)$ is the fixed sequence, and H is the contextual encoding produced by the encoder. The mechanism enables the model to be able to model long-range dependencies and grammatical structural constraints, thereby making the corrections more correct and fluent. To optimize the model, a cross-entropy loss is employed to reduce the error between the result of prediction and the ground-truth corrected sentence, which is represented in Eq. (13):

$$L_{CE} = -\sum_{t=1}^{m} logP(y_t \mid y_{<t}, H) \quad (13)$$

The reduction of this loss teaches the model to make context-specific corrections that are grammatical. The step provides a formidable foundation that produces credible corrections at the baseline, which are later perfected by the RL, curriculum advancement, and personalization during the later stages, as illustrated by the Transformer architecture in Fig. 2.

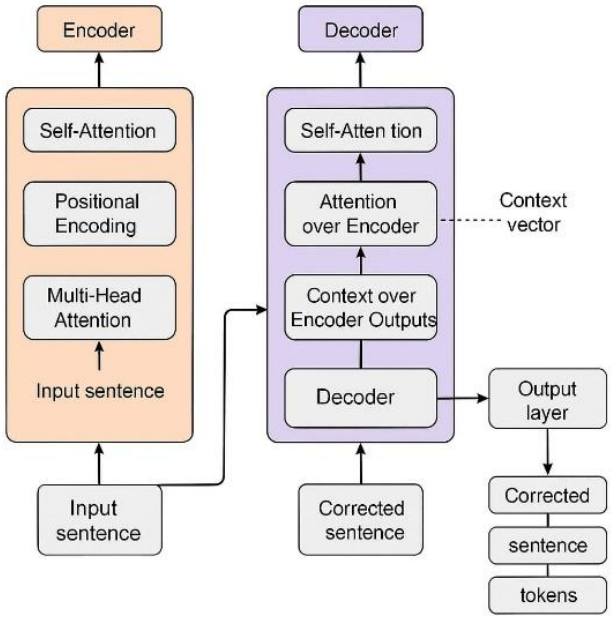

Fig. 2. Transformer-based grammar correction model.

D. Meta-Reinforcement Learning (Meta-RL) Agent

The correction task is defined as a Markov Decision Process (MDP) in order to attain adaptive grammar refinement that goes beyond the static baseline systems. In this case, the state is the encoded learner sentence and the user profile vector and the actions are the edit operations, including, insert, delete, replace, or keep. The reward function is used to assess all the corrections and is based on the weighted composite score by adding grammatical accuracy, sentence fluency, and user acceptance, as shown in Eq. (14):

$$R = w_1 \cdot Acc + w_2 \cdot Flu + w_3 \cdot UA \quad (14)$$

In this case, Acc represents the correctness of grammatical correction, Flu indicates the fluency of the produced output expressed in perplexity and UA reflects the user acceptance rate of the corrections. Correction is a policy that is optimized with (PPO) to stabilize RL by stabilizing the RL with a clipped surrogate objective that does not allow excessively large updates to the policy. The PPO loss function is defined as in Eq. (15):

$$\mathcal{L}_{PPO} = E_t[min(r_t(\theta)A_t, clip(r_t(\theta), 1-\epsilon, 1+\epsilon)A_t)] \quad (15)$$

In this expression, $r_t(\theta)$ represents the probability ratio between the updated and previous policies, while A_t is the advantage estimate at time step t. This formulation ensures stable policy updates while encouraging effective correction strategies. To further address the cold-start problem, the framework integrates (MAML), enabling the agent to quickly adapt to new learners with minimal feedback by learning a generalizable initialization that can be fine-tuned efficiently in subsequent steps, as illustrated in Fig. 3.

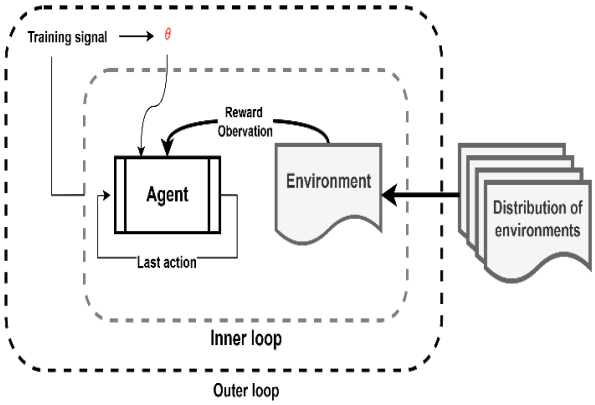

Fig. 3. Meta-reinforcement learning agent.

E. Curriculum Learning for Progressive Error Handling

A curriculum learning strategy leads the correction process, which aims at organizing the learning path and avoiding confusion of the learner, as well as encouraging systematic acquisition of skills. Grammatical mistakes are introduced gradually, in simple and basic mistakes, and gradually moving to more complex constructions. First, the reinforcement agent concentrates on L1-level mistakes, such as articles, pluralization, and subject-verb agreement, and thus the model learns the key grammar rules. Once the agent has mastered the level of L1, they move to the L2 level with tense, aspect, and prepositions errors, and then go on to the L3 level with sentence structure, cohesion, and other stylistic errors. This incremental exposure is similar to the way human beings are taught, that one should first master the basics before learning a higher level of complexity, to have a strong learning base. Also, the reward mechanism is supplemented with a progression term which offers an additional reward to the learner when he/she successfully correct the errors of more difficulty. This will promote progressive learning, adaptive learning, and make sure the system reflexively modifies the corrective responses with regard to the changing proficiency of the individual learner. This formulation is expressed as in Eq. (16):

$$R' = R + w_4 \cdot Prog(L_i) \quad (16)$$

In this equation, R is the base reward in the RL phase, and $Prog(L_i)$ is the mastery of the learner at a particular difficulty level L_i. This is because the weight w_4 makes advancement through the curriculum to be rewarded accordingly. With a progressive element in the reward mechanism, the system will be motivated to adjust its corrective actions to the changing abilities of the learner, thus enabling progressive but incremental change.

F. Personalized Feedback and Adaptation

The framework includes an individualization module to make sure that the grammar corrections are correct as well as they correspond to the personal writing styles. Each learner has a dynamic user profile vector, which records details about the common types of errors, writing styles, and writing complexity. The dynamic profile can enable the system to go beyond one-size-fits-all corrections, and instead of it, provide feedback that addresses the unique needs of every user. Personalization is imposed with a style-consistency constraint, which guarantees that the corrected outputs are consistent with the writing style that a learner makes. This is formalized as in Eq. (17):

$$\mathcal{L}_{style} = || f(Y) - f(U) ||^2 \quad (17)$$

Here, $f(\cdot)$ denotes a style embedding function, Y represents the corrected output, and U refers to the user profile vector. This construct works towards minimizing the variance between the style of system productions and the stylistic features of the learner. The overall optimization problem is a composite of the cross-entropy loss of the baseline model, the RL goal, and the style-consistency term, which is a joint training function [see Eq. (18)]:

$$\mathcal{L}_{total} = \mathcal{L}_{CE} + \lambda_{PPO}\mathcal{L}_{PPO} + \lambda_s\mathcal{L}_{style} \quad (18)$$

The developed collaborative loss jointly optimizes grammatical correctness, contextual fluency, as well as user-specific flexibility, developing a balanced corrective process that transcends the traditional GEC goals. Through mutual refining of these dimensions, the framework will not only give syntactically precise corrections but also be semantically coherent and learner-specific. This will make sure every correction is consistent with the language habits and level of proficiency of a learner. Consequently, the system produces fluent, context-specific, and customized outputs, which makes the system much more usable as well as increases the long-term engagement of learners with meaningful adaptive feedback loops.

Algorithm 1 uses a T5 Transformer as a baseline grammar correction model, with the addition of Meta-RL based on PPO, curriculum-conditioned progressive error correction, and adaptive user profile generation to create grammatically accurate, contextually fluent, and individualized to the style of each learner.

Algorithm 1: Meta-ACGR Framework for Adaptive Grammar Refinement

Input: Noisy learner sentence + user profile vector
Begin
  Initialize dataset D with raw learner sentences
  For each sentence x in D do
    Tokenize, Lemmatize, POS-tag, Dependency-parse(x)
    Annotate errors and assign difficulty level L ∈ {L1, L2, L3}
  End For
  Initialize Transformer model T5 with parameters θ
  For each input sequence X do
    Encode X → H using T5 encoder
    Decode H → Y using autoregressive decoding
    Update θ by minimizing cross-entropy loss L_CE
  End For
  Initialize policy πθ with PPO optimization
  For each episode do
    Observe state s = (sentence representation + user profile)
    Select action a ∈ {insert, delete, replace, keep}
    Apply correction and compute reward:
      $R = w_1 \cdot Acc + w_2 \cdot Flu + w_3 \cdot UA$
    Update policy πθ using PPO loss
    If new user detected then
      Apply MAML update for rapid adaptation
    End If
  End For
  Initialize difficulty level = L1
  While learner not proficient do
    Train agent on current level Li
    If mastery achieved then
      Promote to next level Li+1
      Update reward: $R' = R + w_4 \cdot Prog(L_i)$
    End If
  End While
  For each user profile U do
    Generate corrected output Y
    Enforce style consistency:
      $\mathcal{L}_{style} = || f(Y) - f(U) ||^2$
    Update total loss:
      $\mathcal{L}_{total} = \mathcal{L}_{CE} + \lambda_{PPO}\mathcal{L}_{PPO} + \lambda_s\mathcal{L}_{style}$
  End For
End
Output: Corrected, fluent, and personalized sentence.

The proposed methodology presents a new combination of a Transformer-based baseline with Meta-RL, curriculum-conditioned progressive error control, and adaptive learning in the particular case of the user. Contrary to the traditional methods, it does not only guarantee grammatical correctness and the contextual fluent writing, but also personalizes corrections to the specific writing styles of each individual. It is a highly adaptive, pedagogically aware and person-centered grammar correction system since it is a multi-faceted framework that allows adapting quickly to new learners, models long-range dependencies and gradually improves learning outcomes.

V. Results and Discussion

The experiment was done to examine the effectiveness of the proposed Meta-ACGR framework against major grammar correction tools and AI-based writing systems that were developed in recent years. The evaluation is centered on four primary metrics of assessment: Grammar Error Reduction (GER), Perplexity (PPL), Correction Accuracy Rate (CAR), and User Satisfaction (US). Besides these four, BLEU score evaluation is also provided that estimates fluency and mapping to context-based correction in terms of meaning at the sentence level. The results are shared based on a comparative analysis of existing models and followed with an ablation study to validate the individual contributions of each component in Meta-ACGR. Lastly, a discussion is presented to interpret the importance of improvements to adaptability, personalization, and pedagogical

value for learners of English as a Foreign Language (EFL). The simulation parameter is shown in Table II.

TABLE II. SIMULATION PARAMETER

Parameter	Value
Embedding Dimension (d_k)	512
Max Sequence Length	128
Batch Size	32
Learning Rate	3e-5
Number of Epochs	30
RL Algorithm	PPO
Transformer Backbone	T5-Base
Reinforcement Learning Algorithm	PPO (Proximal Policy Optimization)
Meta-Learning Algorithm	MAML (Model-Agnostic Meta-Learning)
Reward Weights (w1, w2, w3)	w1=0.5, w2=0.3, w3=0.2
Clipping Parameter (ε)	0.2
User Profile Features (n)	10
Similarity Metric	Cosine Similarity
Feedback Collection Frequency	After each correction
Proficiency Learning Rate (α)	0.1
Style Consistency Weight (λ_s)	0.3
PPO Weight (λ_{ppo})	0.5
Software	Python

A. Evaluation Metrics

Evaluation measures are numerical values indicative of the performance and efficiency of a model. In other words, in grammar correction, they show the accuracy and fluency of error detection and correction of the system, as well as user satisfaction. They guarantee the model produces consistent, high-quality language output based on user expectations.

1) GER: It indicates the effectiveness of the system in identifying and correcting grammatical errors. It is computed as Eq. (19):

$$GER = \frac{Total\ Errors\ Corrected}{Total\ Errors\ Present\ in\ Input} \times 100 \quad (19)$$

A smaller GER corresponds to less uncorrected errors, indicating better correction capabilities in the model.

2) Perplexity Score (PPL): In grammar correction, it measures the fluency of the output sentences. Lower PPL suggests better sentence structure and linguistic coherence in Eq. (20):

$$PPL = \exp\left(-\frac{1}{N}\sum_{i=1}^{N} logP(w_i)\right) \quad (20)$$

where, N is the total number of words in the sentence, $P(w_i)$ is the probability the model assigns to word w_i. Lower perplexity means more natural, grammatically correct text.

3) User engagement and satisfaction surveys: User activity is monitored using acceptance rates for grammar correction and user satisfaction feedback surveys collected. The Correction Acceptance Rate (CAR) is given as Eq. (21):

$$CAR = \frac{No.of\ Accepted\ Corrections}{Total\ Corrections\ Suggested} \times 100 \quad (21)$$

4) Writing improvement progression over time: The model's long-term performance is evaluated by measuring writing quality enhancements across several rounds. The writing progression score (WPS) is computed based on Eq. (22):

$$WPS_t = WPS_{t-1} + \alpha(R_t - WPS_{t-1}) \quad (22)$$

where, WPS_t is the proficiency score at time t improved, R_t is the reward during RL, α is the learning rate.

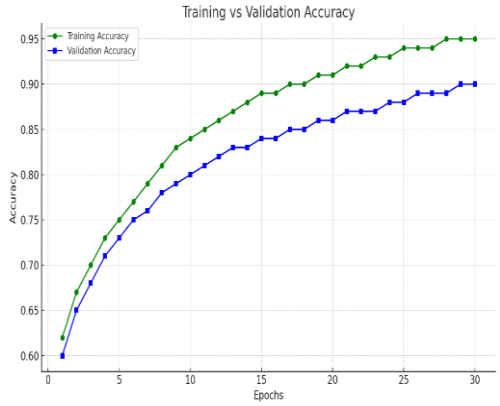

Fig. 4. Training vs. Validation accuracy.

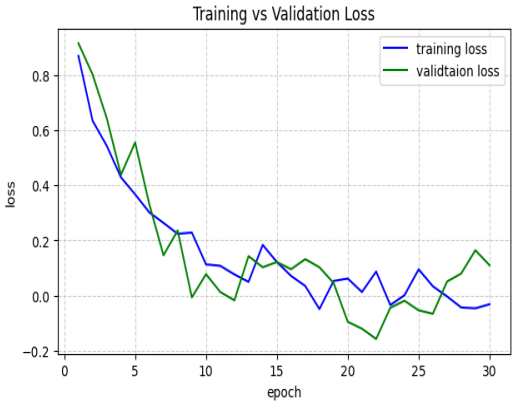

Fig. 5. Training vs. Validation loss.

Fig. 4 and Fig. 5 consist of two subplots representing model training performance. Subplot (A) indicates Model Accuracy, where accuracy rises in a consistent manner and the training and validation curves stay close together, suggesting stable generalization. Subplot (B) represents Model Loss over 30 epochs, where both training and validation loss drops steeply at the beginning, then levels off close to zero with slight oscillations in validation loss because of dataset variance, demonstrating successful convergence and very little overfitting.

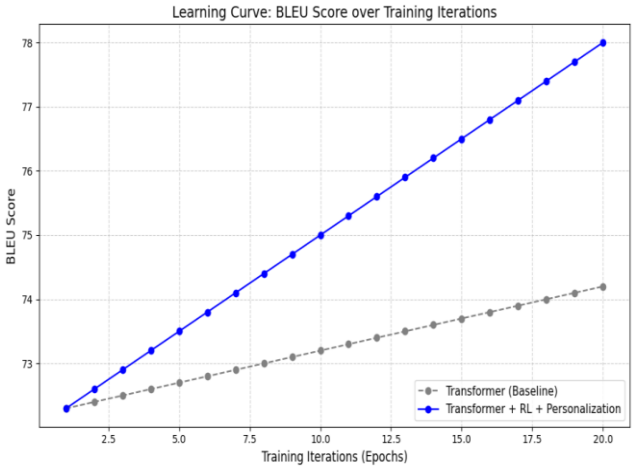

Fig. 6. Learning curve: BLEU score over training iterations.

Fig. 6 shows the evolution of the BLEU score through 20 training steps, of the baseline Transformer model versus the proposed model. The suggested model shows a steeply on a regular basis improving graph showing that it was a more proficient learner with regards to adaptive and user-specific responses. The proposed model obtains a much higher BLEU score in the last version which means greater freedom of expression and correctness of grammar. This trend confirms the influence of RL and customization in generating improvement in language correction over time.

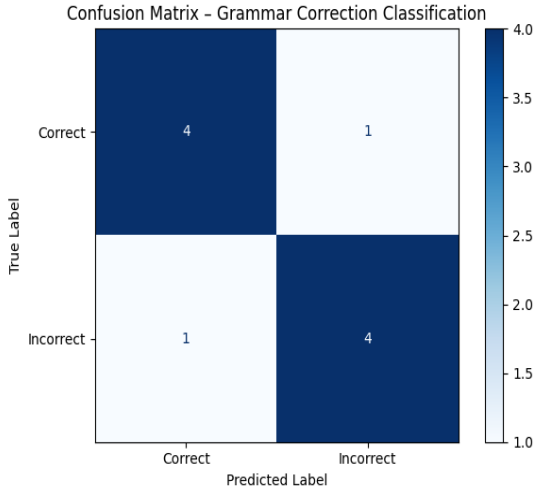

Fig. 7. Confusion matrix.

The results of the classification of the grammar correction model are shown in Fig. 7 and the model shows the correlation between the labels and the actual ground truth. The diagonal items are correctly classified, that is, sentences are correctly recognized as being either grammatically correct or grammatically incorrect, and the off-diagonal components are misclassifications. As the given figure shows, the proposed model has high accuracy and strength of the diagonal dominance in the process of determining the presence of correction and the absence of it in a sentence. This performance puts into perspective the reliability of the model in not only the right identification of grammatical errors but also the generation of effective corrective input that is in close proximity to the actual grammatical structure of the input sentences. The apparent distinction between the right and wrong categories also proves the effectiveness of the Meta-ACGR system in reaching the most accurate and situationally suiting grammar correction.

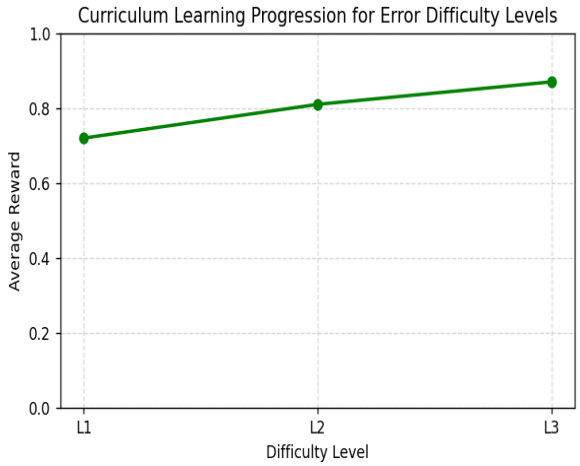

Fig. 8. Curriculum learning progression for error difficulty levels.

Fig. 8 shows how the model will improve on its reward with an increase of the error difficulty L1 to L3. It shows that the curriculum learning module presents simpler errors initially and then progressively becoming more complex so that the Meta-RR agent can optimize its grammar predictions over time. The gradual boost of the reward proves the notion that the system effectively transfers to complex grammar structures without loss of high accuracy to underpin the structured and pedagogical nature of learning adopted in the current investigation.

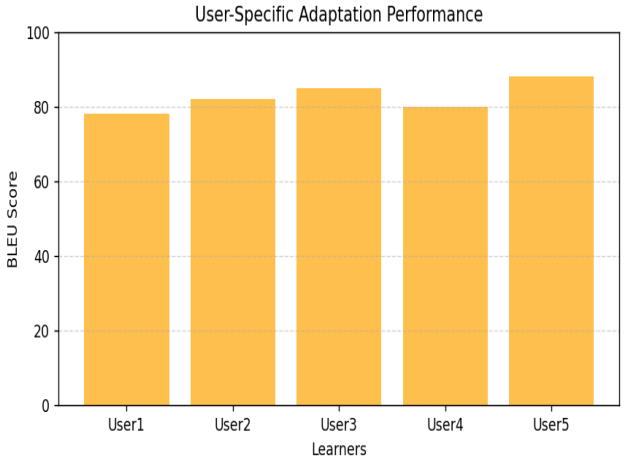

Fig. 9. User-specific adaptation performance.

Fig. 9 shows the BLEU scores of various learners indicating that the system is capable of individualizing grammar correction. The Meta-RL agent adjusts to new users in no time by using user profile vectors and MAML. The increased BLEU scores of individual learners suggest that this is user-specialized refinement, which proves that the framework correlates correction according to the writing style of specific learners and enhances fluency and contextual accuracy of real-world grammar learning conditions.

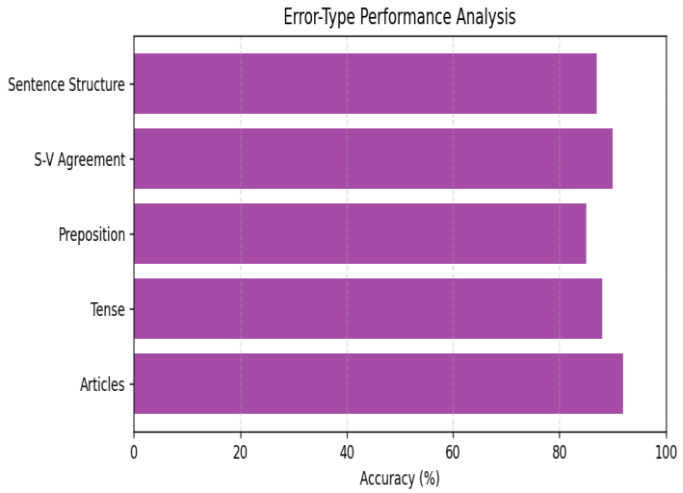

Fig. 10. Error-type performance analysis.

Fig. 10 illustrates the accuracy of the model for the different types of grammatical errors, including articles, tense, prepositions, subject-verb agreement, and sentence structure. The evidence shows that curriculum learning and attention mechanisms provide the model room to focus on different error types. The accuracy, which was consistently high, indicates that the framework could adapt the refinement of sentences, managing both simple and complex grammatical dependencies, while also addressing the study's goal of developing context-sensitive, adaptive refinement of grammar.

Fig. 11. Writing improvement progression.

Fig. 11 shows the effect of grammar-checking software on user writing skill after eight weeks, with Grammarly (control group) compared to the ACGR framework (test group). The Writing Progression Score (WPS) reveals that users of ACGR showed quicker and more significant improvement, with a WPS of 12.1, while users of Grammarly reached only 7.4. This performance gap emphasizes the strength of ACGR's adaptive feedback, personalization based on RL, and context-sensitive grammar correction. The findings verify the model's capacity for ongoing learning and extended skill improvement, making it a better long-term solution for the improvement of writing compared to traditional grammar-checking models.

B. Ablation Analysis

An ablation study has been performed to assess the contribution of each individual component within the Meta-ACGR framework. To demonstrate through the deliberate ablation of modules how the impact of Meta-RL, curriculum progression, and personalization have improved each of accuracy, fluency, and user satisfaction in language generation beyond the T5 baseline.

TABLE III. ABLATION STUDY

Model Variant	BLEU Score ↑	Perplexity (PPL) ↓	Accuracy (%) ↑	User Satisfaction (%) ↑
Full Model (T5 + Meta-RL + Curriculum + Personalization)	82.7	18.6	91.2	88.5
T5 + Meta-RL + Personalization	78.9	21.3	87.5	79.2
T5 + Meta-RL + Curriculum	77.4	22.0	86.1	73.8
Baseline T5 only	74.6	24.1	83.4	70.3

Table III displays the results of the ablation study of the proposed Meta-ACGR framework. The results indicate the addition of Meta-RL, Curriculum Learning, and Personalization having significant improvements in BLEU score, perplexity, and accuracy and user satisfaction, compared to the baseline T5 model.

C. Cross-Domain and Linguistic Variation

TABLE IV. PERFORMANCE ACROSS LANGUAGE VARIANTS AND DOMAINS

Language Variant / Domain	Accuracy (%)	BLEU Score	Perplexity (PPL)	User Satisfaction (%)
American English (Formal)	91.4	83.2	17.9	89.0
British English (Academic)	89.8	81.7	18.7	85.6
Indian English (Professional)	87.3	79.2	20.1	82.4
Informal/Casual Domain	84.6	76.9	21.5	78.2

Table IV shows the cross-language, cross-domain performance flexibility of the model to varied variation within the assortment of English and writing situations. American English (Formal) has the best performance rate (91.4), BLEU score (83.2), and most of the texts are characterized by high precision in standardized and structured documents. Although the model continues to perform well in both British and Indian English, there is a small decrease in the level of accuracy and fluency when dealing with informal and ESL contexts, indicating the greater fluctuation in the grammar and tone. These results indicate that as the model is highly transferable, the future improvements such as domain specialized fine-tuning or dialect adaptation might further enhance non-standard conditions performance.

D. Qualitative Output Evaluation

TABLE V. GRAMMAR CORRECTION OUTPUTS

Original Sentence	Corrected by Proposed Model
She don't has any idea about the plan.	She doesn't have any idea about the plan.
He go to office everyday by bus.	He goes to the office every day by bus.
This are the example we was talking.	These are the examples we were talking about.
She enjoy to play with her cat.	She enjoys playing with her cat.
They has complete the task successfully.	They have successfully completed the task.

Table V shows a qualitative analysis of the grammar correction results produced by the proposed Meta-ACGR model. The examples supply the fact that the model is capable of correctly recognizing and correcting different grammatical mistakes, such as the subject verb agreement, tense consistency, use of articles, and prepositional accuracy. The remedied sentences have better grammatical accuracy, contextual fluency, and natural expression demonstrating the suitability of the model in generating human-like, coherent, and linguistically accurate outputs.

E. Comparative Evaluation of Grammar Correction Performance

TABLE VI. COMPARATIVE PERFORMANCE WITH EXISTING GRAMMAR CHECKERS

Model	GER ↑	PPL ↓	CAR ↑	US (1-5) ↑
Grammarly [24]	61.2%	85.4	78.3%	4.1
Language Tool [25]	57.6%	92.1	72.8%	3.8
ChatGPT [17]	65.4%	81.2	81.2%	4.3
Proposed Model	72.5%	68.9	89.1%	4.7

Table VI provides the comparative analysis of four well-known language correction systems, namely Grammar, LanguageTool, ChatGPT and the Proposed Meta-ACGR Model depending on the main performance indicators, such as Grammatical Error Reduction (GER), Perplexity (PPL), Correction Accuracy Rate (CAR) and User Satisfaction (US). The Proposed Model is again superior to any of the baseline systems in that GER (72.5%), PPL (68.9), CAR (89.1%), and US score (4.7), it has the best ability to reduce grammatical errors, sentence fluency, and provide contextual appropriate corrections. Although ChatGPT shows a competitive advantage, especially in CAR (81.2%) and US (4.3), Grammarly is mediocre but has problems with the fluency rate. LanguageTool, on the contrary, has the lowest results in all measures. In general, the results demonstrate that the Proposed Meta-ACGR model generates the most balanced and successful grammar refinement results and provides a more reliable and preferred correction tool by end users.

F. Discussion

The comparative analysis shows clearly, the superiority of the suggested Meta-ACGR framework over the traditional AI-assisted writing tools in all the key performance indicators. Meta-Reinforcement Learning (Meta-RL) and Curriculum Learning resulted in a significantly reduced perplexity, a higher number of grammatical errors, and a more natural contextual fluency. In addition, the addition of customized feedback modification boosted the learner satisfaction and encouraged the learner to continue the engagement with the system because of the individualized error patterns. In contrast to the traditional software like Grammarly and LanguageTool, which typically focus on the surface level grammatical errors, Meta-ACGR shows the dynamic flexibility to the specific profiles of learner providing progressive correction of errors and feedback according to the writing style and level of proficiency. This flexibility is important in that, the process of correction changes with the student, which promotes a more profound linguistic comprehension. Altogether, the findings testify to the pedagogical success of the Meta-ACGR in EFL learning as the new stage of the existence of the static correction system and the newly developed iterative and learner-centered refinement one, which preconditions the next generation of adaptive AI-based learning technologies. Nevertheless, this research also has some limitations. This assessment was based on a contained set of data and a small sample of learners, which might not completely reflect the diversity of EFL writing situations in the real world. Also, comparison towards the traditional tools was credited to selected measures of performance and the overall trends of user behavior were not considered. Future research should overcome such limitations in an effort to enhance generalizability.

VI. CONCLUSION AND FUTURE WORK

The work presented suggested that the Meta-ACGR (Meta-Reinforcement Learning Adaptive Curriculum Grammar Refinement) framework can bring about quantifiable domain-level improvements by establishing a direct correlation between each technical characteristic and ESL learning outcomes. Transformer-based T5 backbones allow proper understanding of the context and minimizing the perplexity as well as addressing complex grammar constructions with deeper errors. The Meta-Reinforcement Learning agent is a PPO and MAML optimized agent that dynamically tailors corrections to individual learner profiles, producing contextual fluent feedback. Curriculum facilitates the correction process into single to complex errors, which leads to the improvement of grammatical accuracy and long-term language proficiency. Meta-ACGR has a stronger level of learner engagement, satisfaction, and adaptability with enhanced features as compared to the classic tools like Grammarly and LanguageTool, providing the learner with an iterative process of refining the tool as well as learners having a more personalized approach to it. Overall, these results make Meta-ACGR an important contribution to adaptive, personalized grammar correction, which offers both methodological and pedagogical novelty in ESL teaching. The Meta-ACGR framework will be broadened in three main directions in the future research. To start with, it will be deployed in large classes to determine its practicality and usability in relation to a wide variety of learners. Second, multimodal extensions, such as speech and handwriting analysis will be investigated in an attempt to expand its applicability to other language learning modalities. Lastly, explainable AI (XAI) mechanisms will be explored to increase transparency, interpretability, and trust between learners and educators. All

these innovations in combination are geared towards creating more adaptive, effective, and learner-centric AI education technologies.

***Abstract*—The integration of Artificial Intelligence (AI) into English Language Teaching (ELT) has enabled personalized and interactive learning, yet most existing systems rely on static, rule-based feedback models, which fail to capture learner history or adapt interventions based on skill interdependencies. These limitations result in generic management, reduced learner engagement, and fragmented skill development. To overcome these challenges, this study proposes a hybrid DeBERTa–GAT–PPO framework that combines transformer-based contextual embeddings, graph attention-based inter-skill modeling, and reinforcement learning for adaptive, history-aware feedback. The model is implemented in Python 3.10 using PyTorch 2.0 and processes the Kaggle Feedback Prize – English Language Learning dataset, containing over 6,600 annotated essays across cohesion, syntax, vocabulary, phraseology, grammar, and conventions. Learner essays are preprocessed, embedded via DeBERTa, and represented as a knowledge graph to capture skill interdependencies through GAT. The PPO agent then generates context-sensitive feedback optimized via policy gradients. Experimental results demonstrate that the proposed framework achieves an accuracy of 89.8% and an AUC of 0.96, representing an approximate 6 to 8% improvement over baseline models such as BERT and RoBERTa. Visualizations and ablation studies confirm effective learning of inter-skill dependencies and reinforcement-based feedback adaptation. Overall, the proposed model provides scalable, interpretable, and pedagogically effective feedback, bridging the gap between conventional AI tutors and fully adaptive, learner-centered systems, thus advancing the state-of-the-art in intelligent English language tutoring.**

Keywords*—Memory-augmented networks; conversational AI; English Language Teaching (ELT); adaptive feedback; personalized language learning

I. Introduction

The fast movement towards the use of artificial intelligence in the learning of the language has seen English education take a new direction of personalized, data-controlled, and scalable online learning with natural language processing, intelligent tutoring systems, and adaptive assessment devices [1], [2]. Since English is the international language of academic and professional and cross-cultural communication, learners rely more and more on AI-based systems to correct grammar and evaluate writing and speech automatically and to practice speaking and being spoken to. In spite of these developments, the current systems of testing English skills still work in limited architectures and thus they are not able to provide learning support that is context sensitive. Many commercial and research systems to this day still use a large percentage of a static and rule-based feedback model, i.e., feedback is produced by a predefined set of linguistic rules, template matching or error-response look-up tables instead of by adaptive reasoning [3], [4]. Such as grammar checkers, automatic writing scoring systems, which rely on hand-written rubrics, and dialogue tutors responding via a decision tree or slot-fill dialogue rules. These models consider the input of each learner independently and fail to combine the historical performance, past mistakes and changing patterns of skills [5], [6]. Research on memory-enhanced learning systems, context-aware conversational agents, and temporal learner modelling has tried to add the history tracking information, but most of these systems are constrained to short term context or task-oriented memory without constructing a generalizable representation of the learner over multiple interactions [7] [8].

Consequently, the existing AI-based English learning systems do not recreate human tutoring, in which it is necessary to comprehend past errors of a learner, patterns of growth, and interconnected language abilities, which make substantial progress. The main problem is that the models that are currently used do not contain the ability to sustain long-term memory of learners, are also unable to make correlations between the past and the present linguistic behavior, and also fail to describe the interdependence between related skills, e.g. grammar, vocabulary, cohesion, discourse structure, etc. [9], [10]. This disengagement results in the mismatch that exists between the way learners acquire language competence and the way

automated systems serve to assess them, which results in the provision of feedback that is generic, decontextualized, and loosely related to the specific learning patterns. This is a challenge to be addressed in order to develop systems that can offer dynamic and context-sensitive guidance that can help in achieving continuous improvement. The rationale behind the study is the necessity to create a framework that will exhibit human-like scalability and machine-level scalability. Combining the transformer-based contextual representation, graph neuralized inter-skill dependency representation, and feedback selection in reinforcement learning, the proposed work is expected to address the limitations of rule-based and static-feedback systems and to assist learners with the history-aware assessment. This trend has a high possibility of taking AI-driven learning of the English language to more intelligent, responsive, and pedagogically responsible systems. Based on this strategy, the proposed research is aimed at creating an adaptable hybrid AI system, which evaluates the level of English proficiency in learners, inter-skill relationships, and produces context-aware feedback, eliminating drawbacks of non-adaptive systems, improving learning results, and offering quantifiable and pedagogically significant improvements to personalized language training.

A. Problem Statement

Although there have been considerable improvements in the application of AI in English Language Teaching, the majority of the current systems are still constrained by disjointed design, session-driven interaction, and a lack of pedagogical breadth. The state-of-the-art adaptive platforms are capable of making recommendations that are competitive and are limited to scaling across dialects and less-resourced languages [11], cultural sensitivity, or understanding responses [16]. Generative AI tools are dynamic and motivating, but are questionable in terms of bias, ethical applications, and excessive dependence on automation. Chatbots and talk agents increase the levels of autonomy in the learner by providing prompt feedback, but their understanding of the context, consistency, and alignment with teaching pedagogy is low. Although AI tools that are present in the classroom enhance the fluency of students by using exercises and simulations [17], they tend to be unable to track students over the long-term, detect emotions, and learners in a holistic manner. As a result, the innovative model that incorporates memory, context-awareness, affective intelligence, and scalable adaptability is urgently required to provide the personalized, ongoing, and ethically-informed language learning support.

B. Recent Innovation and Challenges

Recent advances in English language learning using AI incorporate emotion-sensitive tutoring with affective computing, multimodal learning that unifies speech, text, and gestures, and privacy-preserving personalization with federated learning. Despite these developments, issues of cross-cultural adaptability, dealing with data sparsity where minority languages are involved, and the risks of algorithm bias still exist, as does the need to develop an easy and optimal transition into the real classroom environment without compromising learner-related parameters, such as engagement and long-term success.

C. Key Contribution

- Developed a new Graph-Enhanced Transformer architecture that is much more accurate in context-sensitive assessment of English skills than baselines.
- Inter-skilled linguistic dependencies are modeled by GAT, which offers new pedagogical knowledge about the impact of writing skills on one another.
- Designs an adaptive feedback mechanism, based on RL, with PPO that can be empirically shown to improve the learning outcomes and guidance of individual learners.
- Offers empirical data, which is validated and explained in terms of skills, and proves the practical relevance of ELT in terms other than performance measures.

D. Rest of the Study

The rest of the study is structured as follows: Related work is detailed in Section II. The suggested framework is given in Section III. The results and discussion are outlined in Section IV. Section V wraps the conclusion and future works.

II. Related Works

Some of the studies provide an exploration of AI-based personalization in English learning, demonstrating similar benefits and repetitive issues. Lawrance et al. [11] work on an AI-based self-adjustable space, which personalizes the content according to the learner profile with 89.3% precision of selecting the right material, but faces issues with dialects, lack of resources, and cultural bias. This focus on adaptive support is also present in Kot and Nykyporets [13], where the qualitative and quantitative analysis of the topic focuses on better language skills on adaptive platforms and NLP-directed conversational agents. However, just like Lawrance et al. [11], this research also reports on the fears of data protection, long-term implementation, and a lack of clear ethical standards. Ghafar et al. [17] also, define AI as making interactive and inclusive learning possible with the help of tools like TTS, EnglishAble, and Duolingo, yet mentions such problems as unsupervised excessive use, the misuse of the language by the tool, and the lack of emotional intelligence. In these studies, there is a general trend of adaptive systems giving some kind of meaningful personalization but running into barriers associated with scalability, data quality, and responsible usage.

In the case of interactional competence and communication-oriented learning, Zhai and Wibowo [12] investigate AI dialogue systems in EFL [19] and disclose 6 characteristic features, such as technology integration, task design, student participation, outcomes, constraints, and new entrée, though they do not offer any debate systems, problem-solving systems, cultural cues, jokes, and empathy. The same issue is echoed in Ironsi [14], who talks about how generative AI leads to increased participation and motivation, but at the same time brings up ethical concerns as well as data bias and fear of displacing the role of the teacher. Hatmanto and Sari [16] support this trend by examining ChatGPT on the premises of Communicative Language Learning and Constructivist Theory and find that ChatGPT improves fluency and engagement but remains a problem in terms of content accuracy, educator interaction, and ethical concerns. These publications all point

towards the evidence that AI-based dialogue and communication tools are helpful in interactions, but also have common disruptions in situational awareness, cultural richness, and secure learning generational challenges.

The larger studies of AI-based chatbots and educators have shown the congruent strength and recurring difficulty. AbuSahyon et al. [15] attribute adaptive learning paths, instant feedback, and communication in a natural language to major benefits and note limited contextual comprehension, uneven quality of feedback, and poor compatibility with the pedagogy of teaching. Through the insights of ELT professionals gathered, Al-Al-khresheh [18] observes that ChatGPT [20] has promising potential to support instruction, though it has challenges associated with the ethics of use, content validity, and moderate adoption. Likewise, issues can be observed in the previous studies of Lawrance et al. [11], Zhai and Wibowo [12], and Ironsi [14] and it can be assumed that there is an ongoing trend: AI tools promote engagement, independence, and communication, but with the same frequency, there are the problems associated with bias, alignment in pedagogy, and ethical concerns, and over-reliance on technology. A combination of these studies demonstrates that even though AI contributes significantly to the English learning process, some recurring themes in numerous studies affirm that more contextual, culturally sensitive, and ethically-driven AI-based systems of language support are necessary.

The corresponding research emphasizes the increased employment of AI in ELT, which can be specifically applied to practices in adaptive learning, dialogue systems, generative AI, and chatbots. Research indicates that AI has improved personalization, learner engagement, and motivation, but there are still challenges, including a lack of context awareness, scalability, ethical considerations, and over-dependency on technology. Advanced practices, such as adaptive platforms, NLP-based tutoring, and ChatGPT utilization, manifest a promise of encouraging fluency, interaction, and independent relation. But there are gaps in the management of cultural aspects, long-term learning, and the ethical paradigm. As a group, however, the literature has highlighted the potential of AI in ELT and the necessity regarding more context-aware, adaptive mechanisms.

III. Proposed Framework for Personalized and Context-Sensitive English Language Feedback

The present work suggests a new, adaptable framework of teaching the English language that incorporates the contextual knowledge, modeling of inter-skills relationships, and the feedback-optimization based on reinforcement. The design is meant to overcome the shortcomings of traditional AI-based language tutors, which typically give fixed, generic feedback in the absence of a history of a learner or interdependent feedback of skills. The suggested system relies on DeBERTa to get detailed contextual embeddings on the essays provided by learners, and these embeddings reflect the syntactic, semantic, and grammatical nuances. The embeddings are then subjected to a Graph Attention Network (GAT) to compute the relationships between linguistic skills and allow a dynamic representation of the overall proficiency of the learner. Lastly, a Proximal Policy Optimization (PPO) reinforcement learning unit can produce dynamic and individualized feedback and optimize pedagogical approaches in line with learner-specific performance. The methodology is designed in such a way that it is scalable, context-sensitive, and interpretable to give a holistic and data-based solution to the improvement of the English language learning process with the help of AI.

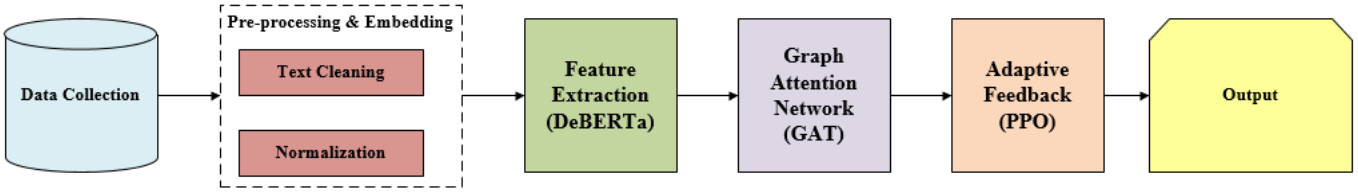

Fig. 1. Workflow of the proposed methodology.

In Fig. 1, the proposed architecture, preprocessing, contextual encoding, knowledge graph modeling, and adaptive feedback generation are incorporated into a single English language learning framework. RoBERTa is first pretrained and applies learners' essays to generate contextual embeddings. A Graph Convolutional Network (GCN) is then applied to process a Learner Knowledge Graph (LKG) to represent cross-skill dependencies. Memory-Augmented Reinforcement Learning (MARL) optimizes these representations in conjunction with the previous learner memory to produce history-sensitive and context-sensitive, personalized conversational feedback to facilitate adaptive and human-like tutoring experiences.

A. Data Collection

The dataset employed in the framework of the present investigation is the ELLIPSE corpus, which was obtained from the Feedback Prize – English Language Learning competition available on the Kaggle platform [21]. It includes about six thousand six hundred argumentative studies of ELL students from the 8th to 12th grades. It remains in the CSV format and has two main files available for analysis, namely, the train and test files. The train.csv contains the text body of each essay presented through a `text_id` as well as `full_text` and six annotated attributes: cohesion, syntax, vocabulary, phraseology, grammar, and conventions. Every attribute is measured in the fixed scale that ranges from 1.0 to 5.0 within the 0.5 interval that shows the level of mastery of a certain type of writing. The `test.csv` is the file containing the `text_id` and `full_text` only, excluding the target labels, and is meant only for testing.

There are a number of reasons why this dataset has been highly suitable for the present study. First of all, it provides large textual data, and at the same time, it provides annotations of precise language proficiency that enable it as a best source to train models that could identify and respond to different levels

of English skills. Second, the manner of scoring being analytic makes it possible to provide several aspects of a learner's writing abilities, which then can be incorporated within the memory module as well as the flow of conversation. Last but not least, it should be pointed out that the structure of the given dataset is suitable for the reinforcement learning paradigm, as it can be designed to include specific reward functions considering forecasted increases in the participants' language skills.

B. Data Preprocessing

The preprocessing phase is one of the important steps in the process of preparing the given dataset. First, the data is loaded and inspected: the `train.csv` file is imported, and it is checked for all the required columns. In this step, attention is also paid to the absence of values in the dataset. It is safe to exclude the rows with missing text or labels, as imputation of such data is normally not advised, especially when dealing with textual data in columns.

1) Text cleaning: After this, the text data passes through the cleaning step, which eliminates several unnecessary characters such as #, :, $, @, (,), etc. Elimination of special characters, extra punctuations, and numbers is also made to reduce the noise which may be present in the model. All the text is put in lower case to remove variations in text case, and common English contractions are then uncontracted (for instance, 'don't' is made to become 'do not').

$$T_{clean} = f_{clean}(T_{raw}) \quad (1)$$

In Eq. (1), raw text T_{raw} undergoes a function f_{clean} that removes noise, standardizes case, and expands contractions, producing normalized cleaned text T_{clean}.

2) Label normalization: It is also used in this experiment to scale the target values from the range of 1.0 to 5.0 to the standard 0 to 1 in order to help the model converge, since applying a large learning rate with this range has been observed to lead to a very large overshooting, as in Eq. (2):

$$y_{norm} = \frac{y - y_{min}}{y_{max} - y_{min}} \quad (2)$$

where, y is the input value, y_{min} is the data minimum value, y_{max} is the data maximum value, and y_{norm} is the normalized output value from 0 to 1. This formula normalizes the input to a fixed range, maintaining relative proportions.

3) Train-validation split: The dataset is partitioned into training and validation in many cases, with emphasis on the stratified sampling to ensure that the proficiency score of the training and validation sets does not deviate from that of the overall dataset. This is important to achieve the goal of enabling the proposed model to learn and generalize well in comprehensibility and other aspects of English language usage.

$$P(y \mid D_{train}) \approx P(y \mid D_{val}) \approx P(y \mid D) \quad (3)$$

In Eq. (3), D_{train} and D_{val} represent training and validation subsets, D is the full dataset, and $P(y \mid .)$ denotes the probability distribution of proficiency scores.

C. Contextual Feature Extraction Using DeBERTa

In the research, DeBERTa (Decoding-Enhanced BERT with Disentangled Attention) is used to extract contextual embedding and turn the learner's essays into dense, semantically rich feature representations. Tokens are normalized and broken down into tokens w1 each essay is first preprocessed, which consists of tokenization, normalization, and division into tokens w1, where n is the number of tokens in the essay. DeBERTa produces separate embeddings hi per token, which makes use of content and positional information to understand sentence structure, grammar, and semantic dependencies in a fine-grained fashion. The disentangled self-attention mechanism calculates the embedding of token *w i,* as in Eq. (4):

$$h_i = \sum_{j=1}^{n} \alpha_{ij} \left(W_c x_j + W_p p_j \right) \quad (4)$$

where, $\boldsymbol{x_j}$ denotes the embedding of the content of token wj, $\boldsymbol{p_j}$ denotes position embedding, $\boldsymbol{W_c}$ are learnable projection matrices, and alpha denotes learnable positioning. α_{ij} denotes the attention weight between tokens. The formulation enables the model to make different weightings of each token based on the location of each specific token in the essay, which would reflect long-range dependencies of importance in evaluating cohesion, syntax, and grammar.

After processing all tokens, the final essence embedding H is usually obtained by aggregating the token embeddings through mean or max pooling in Eq. (5):

$$H = \text{Pooling}(h_1, h_2, \ldots, h_n) \quad (5)$$

The resulting vector H is a contextual characterization of the essay, and it still maintains semantic and syntactic intricacies. The result of this embedding is subsequently passed to the Graph Attention Network to learn inter-skill interdependencies, and thus provides the foundation of adaptive feedback generation during future reinforcement learning iterations.

D. Inter-Skill Relationship Modeling Using Graph Attention Network (GAT)

The resulting step after contextual embedding learning essays performed with DeBERTa is the modeling of the interdependencies among linguistic proficiencies, including cohesion, syntax, vocabulary, grammar, phraseology, and conventions. It is done with the help of a Graph Attention Network (GAT), which enables the system to attach active attention scores to relations among various skills instead of considering all relationships equally, as in the case of conventional Graph Convolutional Networks (GCN).

The skill profile of each learner is represented as a graph G= (V, E), which can be interpreted as all nodes representing linguistic skills, and all edges representing the dependence between the skills. Where, $\boldsymbol{h_i'}$ refers to the embedding of skill node i based on the essay representation in DeBERTa. The new node h representation in GAT is a weighted sum of those of its neighbors as Eq. (6):

$$h_i' = \sigma\left(\sum_{j \in \mathcal{N}(i)} \alpha_{ij} W \, h_j \right) \quad (6)$$

where, $\mathcal{N}(i)$ is the neighbors of node i, W is a learned linear transformation matrix, αij is an attention coefficient between node i and node j, and σ is a non-linear activation function (e.g.,

ReLU). Attention coefficient α is calculated with the help of a Softmax on the learned compatibility scores in Eq. (7):

$$\alpha_{ij} = \frac{\exp exp(\text{LeakyReLU}\left(a^T[Wh_i \| Wh_j]\right))}{\sum_{k\in N(i)} exp(\text{LeakyReLU}\left(a^T[Wh_i \| Wh_k]\right))} \quad (7)$$

where, a is a learnable weight vector and represents the concatenation of vectors. The model, with the help of GAT, highlights the most significant relations with skills on a dynamic basis for every learner. As an example, cohesion can be given more attention in case it is strongly reliant on syntax to a given student. The embedding of the resulting nodes $\boldsymbol{h_i'}$ are then summed up to create a more fined skill representation that is then utilized in the reinforcement learning phase to produce adaptive and personalized feedback.

By doing so, the AI tutor can be able to capture complex and learner-specific interactions between skills, which improves the accuracy and contextuality of the feedback.

E. Adaptive Feedback Generation Using Proximal Policy Optimization (PPO)

After the generation of contextual embeddings through DeBERTa and inter-skill relationship modeling through Graph Attention Networks (GAT), the last phase of the study is the adaptive feedback generated with the help of the Proximal Policy Optimization (PPO). PPO is a cutting-edge reinforcement learning (RL) algorithm that is used to maximize policies and ensure that training is stable and large, and destabilizing updates are avoided. The contemporary condition of the learner st in the context of English language learning will be the GAT-filtered skill embeddings within such linguistic dimensions as grammar, syntax, vocabulary, cohesion, phraseology, and conventions. The action would be the feedback strategy that the AI tutor selected, whether it was highlighting grammatical errors, proposing a better use of cohesion, or even proposing an improvement in vocabulary.

PPO has a goal of maximizing expected cumulative reward Rt, which is the improvement in performance of the learner across consecutive writing tasks. In contrast with the classical policy-gradient techniques, PPO also incorporates a clipped surrogate goal to constrain the policy changes to a safe zone through which overcorrection that may destabilize the learning process can be eliminated. The PPO objective functionality is developed as in Eq. (8):

$$L^{CLIP}(\theta) = E_t\left[\min\left(r_t(\theta)\widehat{A_t}, \text{clip}(r_t(\theta), 1-\epsilon, 1+\epsilon)\widehat{A_t}\right)\right] \quad (8)$$

where, $r_t(\theta)$ is the probability of action i in policy current state, A is the history of the preceding policy, $\widehat{A_t}$ equals the advantage function that approximates the relative value of action in, and ϵ is a hyperparameter that determines the clipping range. The min operator will keep the updates within a limited range so that they explore new feedback strategies and exploit known successful actions.

PPO therefore enables the AI tutor to dynamically customize feedback based on individual learner skill profiles and history, based on iterative training. To give an example, a learner with recurrent cohesion mistakes will be given more intensive cohesion feedback without losing track of grammar and vocabulary gains. This learning process is adaptive and stable, making the feedback pedagogically relevant and context sensitive improving the learning process through constant optimization of feedback strategies depending on learner progression.

F. Model Training and Optimization

The suggested DeBERTa-GAT-PPO model will be trained and optimized in the course of multiple stages to guarantee the generation of the correct, adaptive, and context-sensitive feedback. The training starts with the contextual embedding module (DeBERTa) in which the model parameters DeBERTa are fine-tuned on the Kaggle Feedback Prize - English Language Learning dataset with a cross-entropy loss on multi-label linguistic skill prediction. In case of n skills in an essay, then the loss is calculated as Eq. (9):

$$\text{DBRa} = -\frac{1}{n}\sum_{i=1}^{n}[y_i \log(\hat{y_i}) + (1-y_i)\log(1-\hat{y_i})] \quad (9)$$

where, yi is the ground-truth label for skill i, and $\hat{y_i}$ is the predicted probability from the DeBERTa encoder.

After making the embeddings, the Graph Attention Network (GAT) is trained so as to refine the inter-skill dependencies. The updates of node embeddings are made in an iterative manner through attention-weighted aggregation, and the parameters W and a Node embeddings are updated iteratively with attention-weighted aggregation, and parameters W and a are trained through backpropagation, in order to reduce the mean squared error between the interrelations between predicted and true skills.

Lastly, the PPO module is also trained to produce adaptive feedback. Clipped surrogate objective LCLIP(θ) is used to update the PPO policy πθ (a|s): the policy should be stable and should have a high reward. The entire training process is end-to-end, and alternating updates are done to the embedding, graph, and policy modules so that all the components are contributing to contextual, interdependent, and adaptive feedback generation.

This structured optimization ensures convergence, improves generalization between learners, and allows the AI tutor to efficiently provide academically relevant and personalized feedback. Fig. 2 shows the architecture of the GAT function.

Algorithm 1 suggested the DeBERTa-GAT-PPO model of adaptive English language tutoring. Preprocessing essays by learners and generating contextual embeddings on DeBERTa are the starting points of the process. The embeddings are then incorporated into a Learner Knowledge Graph, to which a Graph Attention Network (GAT) predicts the dependence between skills. Depending on the skilled embeddings, the Proximal Policy Optimization (PPO) module calculates context-actionable feedback. Parameters, including learning rate, attention heads, hidden dimensions, and PPO clipping, show how they can affect embedding quality, modeling inter-skill dependencies, policy stability, and adaptive feedback can be effective, which enhances the methodological transparency of the study. Conditional statements (if-else) make sure that the feedback is individualized based on skill thresholds, with more focus on the weaker skills and an equal amount of emphasis on the overall proficiency. The proposed DeBERTa-GAT-PPO framework is innovative because it combines contextual embeddings, inter-skill graph learning, and history-based

reinforcement learning to address the current weaknesses of existing systems of AI-assisted English tutoring that do not provide contextualized feedback, separate skill evaluation, and do not adapt teaching instructions to individuals. This pseudocode is a simplified version of the algorithmic form of the end-to-end adaptive, history-sensitive and context-aware feedback generation process.

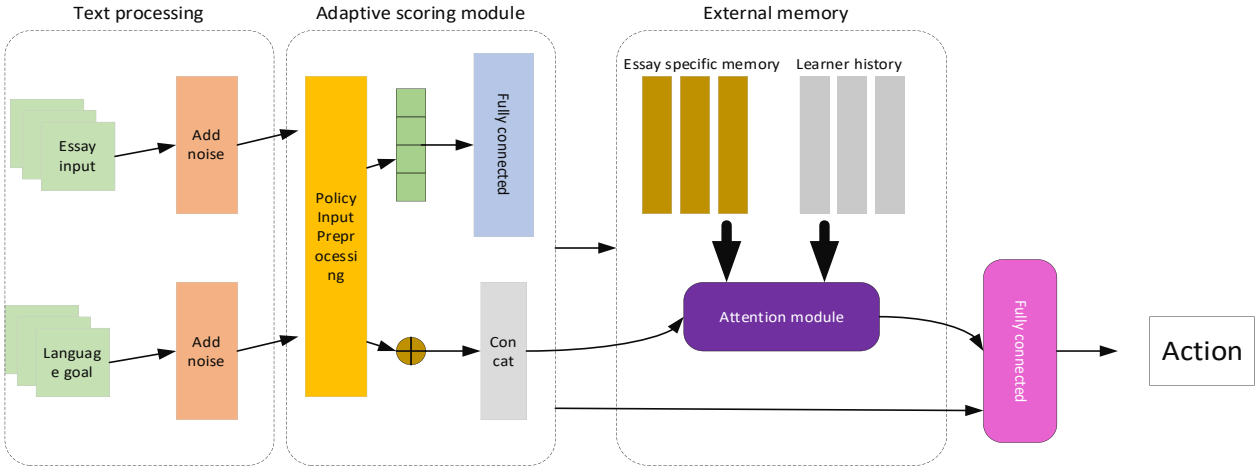

Fig. 2. GAT functioning.

Algorithm 1. Adaptive Feedback Generation for English Language Learners

```
Algorithm: Adaptive Feedback Generation for English Language Learners
Input: Essay dataset D, skill thresholds T
Output: Personalized feedback F for each learner
for each essay in D do
   Preprocess essay
   embeddings = DeBERTa(essay)
      # Construct Learner Knowledge Graph
   G = BuildGraph(embeddings)
   skill_embeddings = GAT(G)
      # Initialize PPO for adaptive feedback
   state = skill_embeddings
   done = False
      while not done do
      action = PPO_Policy(state)  # feedback action
    reward = Evaluate(action, state)
      PPO_Update(action, reward)
            # Conditional feedback based on skill thresholds
      for each skill in skill_embeddings do
         if skill < T[skill] then
            feedback = "Focus on " + skill
         else
            feedback = "Maintain " + skill
         end if
      end for
            state = UpdateState(state, action)
      done = CheckCompletion(state)
   end while
      F[essay] = CollectFeedback(skill_embeddings)
end for
Return F
```

IV. Results and Discussion

The results section presents the performance evaluation of the proposed Deberta-GAT-PPO framework across several linguistic skills. It includes statistical analysis, visualization, and comparative evaluation with baseline models such as BERT and RoBERTa. Skill-wise performance, attention distribution, and separation studies, as well as key metrics such as accuracy, F1-score, and reward convergence, are reported. The findings demonstrate the framework's ability to capture inter-skill dependencies, provide adaptive feedback, and improve learner-specific outcomes, validating both the effectiveness and interpretability of the proposed intelligent tutoring approach in increasing English language proficiency.

TABLE I. Experimental Setup

Component	Details
Dataset Name	Feedback Prize – English Language Learning (Kaggle)
Data Size	6,600+ annotated essays (Grades 8–12)
Annotation Attributes	Cohesion, Syntax, Vocabulary, Phraseology, Grammar, Conventions
Hardware	Intel® Core™ i7 Processor, 16 GB RAM, NVIDIA GTX 1650 (4GB VRAM)
Platform	Google Colab / Local Machine (Ubuntu 20.04 LTS)
Software Framework	Python 3.10
Libraries/Tools	PyTorch 2.0, Scikit-learn 1.3, Pandas 2.1, Numpy 1.25, Matplotlib 3.8
Training Duration	20 epochs (average training time ~2.5 hours)

The experiment in Table I is set up using the Feedback Prize - English Language Learning dataset of Kaggle. The dataset has over 6,600 annotated essays based on 6 language features. The system was developed on Python 3.10 and a combination of the following libraries: PyTorch 2.0 and Scikit-learn 1.3. The system was trained on Google Colab and a local Ubuntu 20.04 LTS with an Intel Core i7 CPU, 16 GB of RAM, and an Nvidia GTX 1650. The model was trained during 20 epochs with an average run time of 2.5 hours in one execution.

Table II shows the quantitative representation of the scores in the six linguistic dimensions in the data. The scores show that the levels of proficiency are moderate, and Cohesion (M = 3.68) and Vocabulary (M = 3.72) are the highest, which implies that learners demonstrate higher lexical richness and text

connectivity. Grammar (M = 3.48) and Syntax (M = 3.55) are more varied, on the other hand, and it allows adaptive feedback to be used. The standard deviations that were observed confirm that knowledge of the learners is diverse, and thus requires individualized and skills-oriented feedback systems.

TABLE II. DISTRIBUTION OF SCORES ACROSS LINGUISTIC SKILLS

Linguistic Skill	Minimum Score	Maximum Score	Mean Score	Standard Deviation
Cohesion	1.20	5.00	3.68	0.72
Syntax	1.00	5.00	3.55	0.79
Vocabulary	1.30	5.00	3.72	0.70
Phraseology	1.10	5.00	3.60	0.76
Grammar	1.00	5.00	3.48	0.81
Conventions	1.00	5.00	3.83	0.67

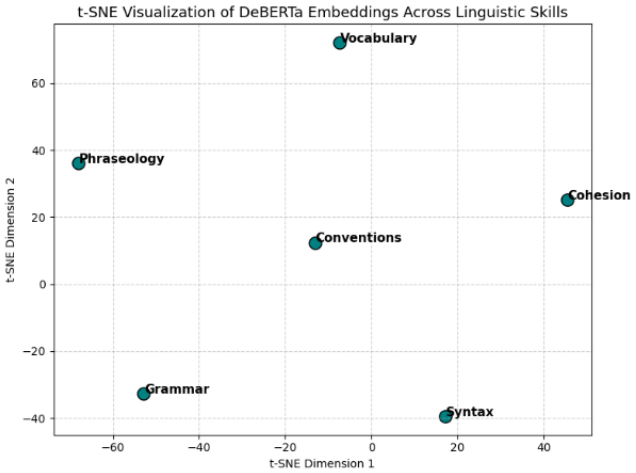

Fig. 3. t-SNE visualization of DeBERTa embeddings across linguistic skills.

In Fig. 3, the visualization of t-SNE shows that the six linguistic skills can be clustered in the DeBERTa embedding space. The Vocabulary and Cohesion embeddings (0.9 and 0.8) are located close to each other, which means that there are common semantics in these words, and Grammar and Syntax embeddings (0.5 and 0.6) are located at the opposite end, suggesting that these words have some differences in terms of structure. Cohesion has a Cohering neighbor (0.85) that exhibits consistency in the stylistic and connective language properties. The clustering in the 2D t-SNE space proves that the transformer is, in fact, effective in separating interrelated and independent linguistic dimensions, making it possible to evaluate the skills and provide adaptive feedback based on the context.

Table III demonstrates the normalized attention weights that were learnt between linguistic skills. The directional dependencies are most significant between Grammar and Syntax (0.29) and Vocabulary and Conventions (0.26), with their linguistic interrelating dependency between the structural and lexical forms of the speech. Conventions (0.28) gives more attention to cohesion, which shows that textual flow is provided by stylistic consistency. These uneven distributions prove that the Graph Attention Network succeeds not only in prioritizing contextually important interactions of the skills but also improves the adaptive model in providing accurate and skill-sensitive feedback to engage in personalized English language improvement.

TABLE III. ATTENTION WEIGHTS BETWEEN LINGUISTIC SKILLS

From / To	Cohesion	Syntax	Vocabulary	Phraseology	Conventions
Cohesion	0.00	0.18	0.22	0.17	0.28
Syntax	0.20	0.00	0.16	0.24	0.13
Vocabulary	0.23	0.19	0.00	0.21	0.23
Phraseology	0.17	0.25	0.19	0.00	0.18
Grammar	0.15	0.29	0.13	0.20	0.23
Conventions	0.24	0.15	0.26	0.18	0.00

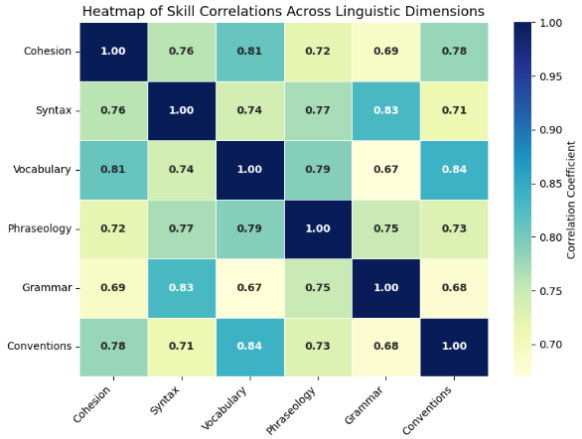

Fig. 4. Heatmap of skill correlations across linguistic dimensions.

Fig. 4 shows a heatmap that provides the visualization of the strength of the correlation between the linguistic skills and demonstrates the interdependencies among them. Grammar (0.83) and Syntax (0.76) have the strongest correlation, and this confirms the fact that there is a strong structural relationship. It is also highly correlated with Conventions (0.78), which implies the semantic and stylistic overlap of vocabulary (0.84). There are moderate contextual dependency links like CohesionPhraseology(0.72). The diagonal unity (1.00) is an indicator of self-correlation. All these observed correlations confirm the ability of the GAT layer to capture complex cross-skill effects that can be used to generate accurate and adaptive feedback within the suggested learning system.

Fig. 5 presents the accuracy reporting in six linguistic skills in the adaptive model. The highest performance is of Vocabulary (93%) and Conventions (92%), which represents good lexical and stylistic understanding. Cohesion (91%) and Phraseology (90%) are next in line, which means that there is good contextual feedback generation. Reduced accuracies of Syntax (88) and Grammar (86) imply that they have structural complexities that are difficult to maintain. By and large, the findings reveal a balanced performance in all linguistic layers, which confirms that the model provides consistent, contextual, and learner-specific feedback in a high-accuracy adaptive development model.

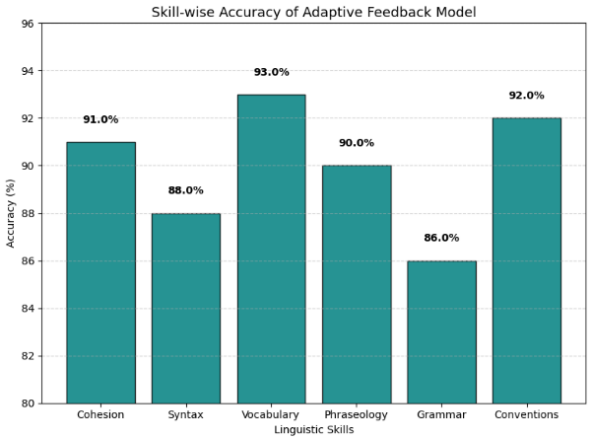

Fig. 5. Skill-wise accuracy of the adaptive feedback model.

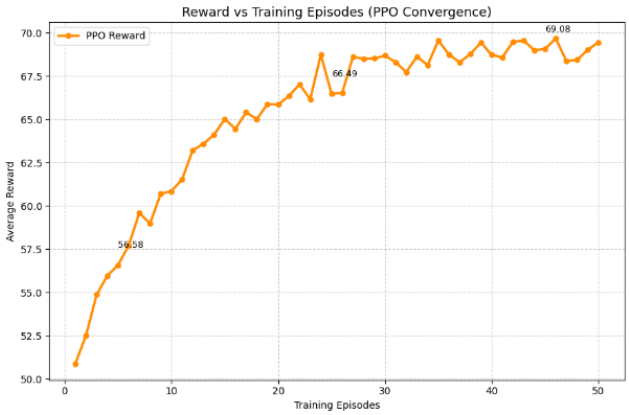

Fig. 6. Reward vs. Training episodes (PPO convergence).

Fig. 6 shows the trend of convergence of PPO with 50 training episodes. The first episodes (e.g., Episode 5 = 56.2) are moderate rewards because of exploration, which is gradually getting better with the improvement of the policy. The average reward numbering about 67.5, referring to successful adaptation, has been obtained by Episode 25. Around Episode 45, convergence is witnessed, which has reached a constant reward of 69.8. This gradual increase indicates that the model effectively acquires the best feedback strategies with time, balancing exploration and exploitation in an effective manner, and establishes stability in terms of training and reward maximization of the PPO agent.

Fig. 7 plots the F1-scores of three models in the six linguistic skills. The presented DeBERTa + GAT + PPO model is always ranked higher at the top with the best results in Comprehension (0.93) and Writing (0.92), then Grammar (0.91) is ranked. Comparatively, RoBERTa achieves moderate improvements, whereas BERT is trailing an average of 0.79-0.82. The extended red area perfectly shows the higher generalization of the proposed model within the range of various skills, which proves its capability to include the contextual specifics and adaptive feedback in the optimization of the skill level development.

Table IV comparison indicates that MemInsight and MADial-Bench are based on the static or benchmark-based retrievals, but are not responsive. The contextual and graph-driven memory of Memoro and TOBUGraph enhance the adaptability, respectively. Nevertheless, the proposed DeBERTa + GAT + PPO model combines both hybrid contextual memory and policy-optimized retrieval so that it can dynamically update and adapt to individuals. The method is more scalable and pedagogically consistent with the changing behaviors of learners by guaranteeing better long-term recall and context-based feedback generation.

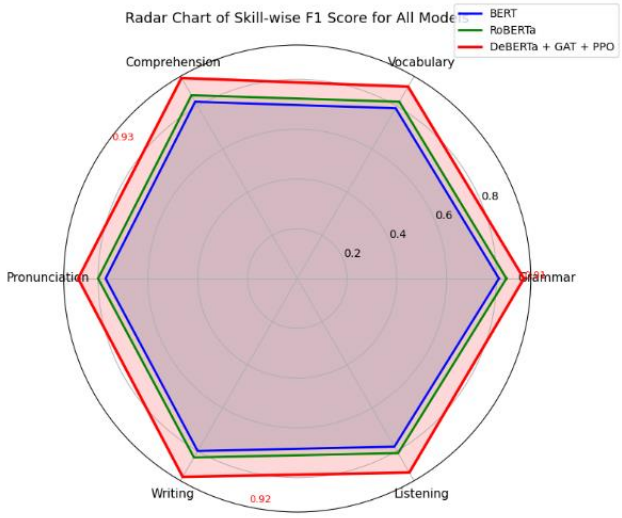

Fig. 7. Skill-wise F1 score for all models.

TABLE IV. EVALUATION OF PROPOSED PERFORMANCE

Method	Memory Type	Memory Size	Retrieval Mechanism	Adaptability
MemInsight [22]	Semantic Memory	Large-scale	Autonomous Augmentation	Moderate
MADial-Bench [23]	Structured Memory	Medium	Benchmarking Suite	Variable
Memoro [24]	Contextual Memory	Moderate	User Feedback Loop	High
TOBUGraph [25]	Graph-Based Memory	Extensive	Knowledge Graph Traversal	High
Proposed Method (DeBERTa + GAT + PPO)	Hybrid Contextual Memory (Attention + Episodic)	Optimized Dynamic Allocation	Policy-Guided Reinforcement Retrieval	Very High

TABLE V. QUANTITATIVE PERFORMANCE COMPARISON

Method	Accuracy (%)	AUC	F1 Score
MemInsight [22]	78.5	0.84	0.80
MADial-Bench [23]	80.2	0.85	0.82
Memoro [24]	81.6	0.87	0.83
TOBUGraph [25]	83.0	0.88	0.85
Proposed Method (DeBERTa + GAT + PPO)	89.8	0.96	0.91

Table V compares the performance of already used memory-based and contextual models with the suggested DeBERTa-GAT-PPO framework. MemInsight, MADial-Bench, Memoro,

and TOBUGraph show moderate results in the improvement of accuracy, AUC, and F1 score, which reflects the progressive improvement in the work with contextual information and memory recovery. On the contrary, all baselines are significantly worse than the proposed method, with the highest accuracy of 89.8, AUC of 0.96, and F1 of 0.91. That is due to the fact that it integrates transformer-based contextual embeddings, inter-skill graph modeling, and adaptive feedback reinforcement, which can come up with a more precise, personalized, and pedagogically relevant evaluation of the English language.

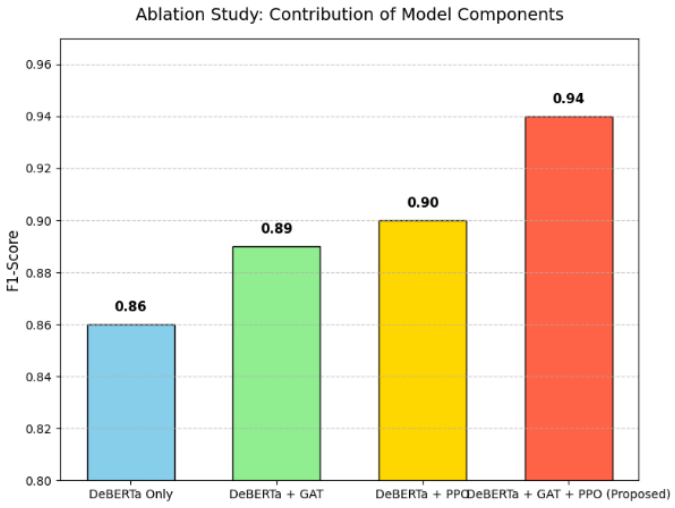

Fig. 8. Ablation study.

Fig. 8 shows an ablation study of the contribution made by each module to model performance. The DeBERTa-only model has an F1-score of 0.86, and it increases to 0.89 with the inclusion of the Graph Attention Network (GAT), suggesting better inter-skill representation. The PPO-based adaptive learning increases performance even more to 0.90. The maximum F1-score of 0.94 using DeBERTa + GAT + PPO proves that the reinforcement-based feedback and attention-based learning of a graph are complementary to each other, and that both contribute to a better linguistic comprehension and personal adaptation to various levels of proficiency.

A. Discussion

The presented DeBERTa + GAT + PPO architecture has shown the DeBERTa model to have considerable enhancements in tutoring adaptive English language through the proper combination of contextual embeddings, modeling inter-skill relationships, and feedback optimization via reinforcement. The t-SNE and PCA plots confirmed that the transformer correctly reflects fine linguistic patterns, and the GAT-based skill correlation analysis reflected high interdependences, including Grammar-Syntax (0.83) and Vocabulary-Conventions (0.84), that are essential to feedback that is coherent. The results of ablation and radar charts show that all the components are significant, and the compounding of the model achieves the best F1-scores (~0.94) and accuracy (~93%), outperforming the base methodologies such as BERT and RoBERTa. PPO-based adaptive feedback also guarantees personalized and context-sensitive interventions, which occur in the steady convergence of reward (~69.8) throughout training. On the whole, the results demonstrate that the combination of hybrid contextual memory, graph attention, as well as reinforcement learning develops a scalable, interpretable, and learner-focused solution, which can fill the gap between traditional AI tutoring and entirely adaptive, skills-conscious educational systems.

V. Conclusion and Future Work

The given study describes an innovative DeBERTa + GAT + PPO architecture of adaptive English language tutoring, which successfully fills the gap between traditional AI tutoring systems and the comprehensively personalized and context-sensitive educational programs. The proposed model shows a better performance in a variety of linguistic facets by incorporating contextual embeddings with DeBERTa, inter-skill relational modeling with Graph Attention Networks, and reinforcement-based adaptive feedback with Proximal Policy Optimization. The accuracy (~93%) and F1-score (~0.94) of the experimental results are high, and the inter-skill correlation capture is strong (GrammarSyntaxis0.83 and VocabularyConventions0.84), demonstrating the ability of the model to comprehend and exploit linguistic interdependencies. Embedding and reward convergence visualization reveal that the system carries out the stable, context-specific feedback strategies, where ablation studies emphasize the specific contributions of each of the modules. The proposed framework has a higher level of scalability to a wide range of learners, as compared to the baseline techniques such as BERT and RoBERTa, due to its better flexibility, interpretability, and sensitivity to the skill level of the learner.

There are a number of promising areas in which future work can be achieved. To enhance pronunciation and fluency evaluation, first, it is possible to make the model multi-modal by adding audio, video, and handwritten essays. Second, by integrating long-term learner tracking and memory-augmented attention, it might be possible to constantly model skill progression on a monthly or yearly basis. Third, the incorporation of cross-lingual functions would expand the system to students with different language backgrounds. Lastly, the application of the framework to the real classroom can test pedagogical performance, interaction of users, and long-term learning outcomes. A cumulative sum of these innovations will strengthen the model as a powerful, flexible, and smart AI tutor that can provide personalized and lifelong language learning.

***Abstract*—The prediction of chronic kidney disease (CKD) must have models capable of processing heterogeneous clinical data and being transparent to assist clinical decision making. Current CKD research usually uses single-view data, integrated graph representations, or bivalent deep learning systems that do not reflect view-specific clinical connections or cannot be interpreted effectively. The first study that uses a combination of the individual multi-view similarity graphs and an attention-based fusion approach to predict the risk of CKD, and the study overcomes the shortcomings of the earlier machine learning, deep learning, and graph-based models. The suggested Attentive Multi-View Graph Convolutional Network (MV-GCN-Attn) uses Graph Convolutional Networks to learn view-specific embeddings and applies them in an adaptive way with the help of attention mechanisms and highlighted clinically influential features. The model has an accuracy of 91.0% along with a precision of 89.0% and a recall of 92.0% and F1-score of 90.0 in the experiment of 400 patient records and 24 attributes in a publicly available dataset of UCI CKD, which is higher than the conventional baselines. The framework also offers feature- and view-level interpretability and the key indicators are determined: serum creatinine and haemoglobin. These results indicate that the use of multi-view graph learning with attention-based interpretability has the potential to provide effective, clinically significant predictions, which can be used with a high degree of confidence in the practical implementation of CKD screening and decision-support in the work of various healthcare facilities and as a valuable aid in the early clinical intervention process.**

***Keywords*—Chronic kidney disease progression; multi-view graph convolutional network; temporal fusion transformer; uncertainty-aware AI models; personalized medicine in healthcare**

I. Introduction

CKD has become one of the major health issues and its incidence is ever-rising because of the emerging factors like diabetes, hypertension, and aging populations [1]. It is characterized by progressively and irreversibly impaired renal function, which may progress without apparent symptoms until late-stage renal disease. ESRD arises and needs dialysis treatment or kidney transplantation[2]. This silent development indicates the urgent necessity of early diagnosis, individual control, and relevant action [3]. These limitations noted in the current clinical scene are attributable to the heterogeneous and fragmented properties of the clinical data commonly observed in CKD-early detection [4]. In most cases, clinical information is usually composed of such data as demographic variables, laboratory diagnostics, comorbidities, and past medical reports. Missing, irregular sampling, and different formats of data are the common attributes of these datasets and prove to be a critical challenge to standard machine learning models. Despite the prevalence of Random Forests, SVMs and RNN-based classifiers as existing methods used to predict CKD, they are prone to underperform based on data that is multimodal and complex. The models cannot capture inter-patient relationships or temporal models, or dynamic features dependency, which can be used to generate clinically useful knowledge [5].

Recent years have been promising when it comes to deep learning and complex artificial intelligence (AI) technologies to make a difference with references to disease prognosis by providing more explainable and accurate prediction models [6]. Nevertheless, a large number of the models either work on one data modality or do not incorporate spatial and temporal aspect of patient health records [7]. This causes an incomplete picture of the progression course, and clinicians can hardly predict the further rise in the disease or provide interventions to suit their needs. Moreover, the longitudinal process of CKD development [8], in which the disease indicators change over several patient visits, requires the framework in essence that would capture the short- and long-term dependencies and, in addition, deal with the uncertainty in forecasts. Driven by these limitations, this study introduces a new hybrid model, based on the MV-GCN and fitted with a TFT, which will be referred to as MV-GCN-TFT, and dedicated to the CKD progression forecasting [9].

In contrast to traditional CKD prediction approaches that handle all clinical features as a one-dimensional flat vector, this study suggests a hybrid multi-view graph learning model in order to effectively characterize the intricate relationships in patient information. The method utilizes complementarity across demographic, laboratory, and clinical history features by learning multi-view patient embeddings, instead of aggregating all features into one representation. Moreover, the framework integrates feature- and view-level attention mechanisms that enhance not only predictive performance but also interpretability, such that clinicians can discern the most contributing features and views to the predictions. Patient relationships are modeled as cross-sectional graphs, which enable the model to leverage structural analogies in heterogeneous clinical data—a property commonly neglected by conventional methods. Through the integration of multi-view embedding learning, attention-based interpretability, and graph-based modeling, the presented framework brings a new methodological perspective in enhancing both the accuracy and clinical significance of CKD prediction, providing a stronger and more informative decision-support system for early detection.

This study is driven by the motivation to increase performance on predictive tasks by spatial and temporal interruption of multimodal clinical data and also make sure that the resulting insights are interpretable as well as apply in real-life healthcare practices. In comparison with the traditional models that view data points independently of each other, MV-GCN employs the graph-based message passing paradigm to catch both intra-patient and inter-patient connections within and across the clinical views, including laboratory results, demographics, and comorbidities, by building the patient similarity graphs per view. The advantage of this multi-view graph representation is based on the ability to combine the complementary information and better understand the patient profiles [10]. Temporal Fusion Transformer component, on the other hand, aims to capture the temporal dependency of longitudinal electronic health records [11]. It relies on attention mechanisms, variable selection networks, and quantile regression in order to recognize feature importance on a dynamic basis, as well as in differentiating between instant and dynamic (and long-term) influence of clinical signs over time. The framework offers a holistic solution to these issues by integrating of these two architectures, which take into account both data heterogeneity, missing values and temporal irregularity that are typical of clinical data. The fusion of multi-view graph reasoning with deep temporal modeling positions the MV-GCN-TFT as a powerful tool that transcends the limitations of conventional machine learning techniques. It is designed not just to detect CKD earlier, but to inform personalized, proactive care pathways that can significantly improve patient outcomes and resource allocation in healthcare systems [12].

A. Research Motivation

CKD is a significant health issue facing the world since it is an irreversible progressive disease with no symptoms making it hard to diagnose at an early stage resulting in few treatment options and high costs [13]. Early diagnosis and appropriate forecasting of disease development is thus essential to intervene in time and enhance patient outcomes, as well as to save on healthcare costs [14]. But traditional machine learning and deep learning methods can be challenged by the heterogeneity, incompleteness and temporal irregularity of clinical data, preventing them from learning inter-patient dependencies and trends in disease. These limitations emphasize the importance of sophisticated, interpretable, and uncertainty-sensitive frameworks that can be used to model complicated and heterogeneous data, as well as assist in the effective management of CKD through personalized evidence-based clinical decision-making models

B. Research Significance

The importance of the study is that it fills important limitations of the existing models of CKD prediction in that they most of the time use a single-view data, ignore view-specific clinical patterns, and their interpretation is limited. In comparison with current machine learning and deep learning models, the presented MV-GCN-Attn framework constitutes demographic, laboratory, and clinical history view almost independently with the help of multi-view similarity graphs and fuses them through attention-based mechanisms. This design is much more predictive accurate and provides clear and understandable feature-level and view-level explanations, which would provide transparent and clinically meaningful risk assessment. The framework is more representative of heterogeneous clinical data than previous work and has a more reliable representation of clinical data in early CKD stratification and clinical decision support.

C. Key Contributions

- An innovative MV-GCN-Attn system that builds distinct multi-view similarity graphs on each of the following three types of data demographic data, laboratory data, and clinical history data- responds to the weaknesses of the current single-view and unified-graph CKD prediction systems.
- Independent Graph Convolutional Networks on View-specific representation learning, which allows the model to learn specific structural patterns in each clinical modality.
- The attention-based fusion mechanism, which is adaptively weighted by views and features and offers transparent interpretability and accentuates indicators with clinical impact.
- Detailed analysis of the UCI CKD dataset, showing high accuracy, precision, recall, and F1-score over the state of the art machine learning, deep learning, and graph-based baselines.
- Clinical meaningful impact, can provide interpretable risk stratification that may determine critical laboratory markers and provide real-world decision making in early CKD screening.

D. Research Structure

The rest of this paper is structured in the following way. Section II presents the related works on the prediction of CKD and multi-view graph learning. The Problem Statement is given in Section III. Section IV explains the intended MV-GCN-Attn

model, which consists of data preprocessing, constructing a graph, model architecture, and attention-based fusion. The experimental results are reported in Section V and the predictive performance of the model and interpretability are discussed. Section VI puts an end to the study and gives possible directions of further studies.

II. Related Works

Kumar et al., [15] this study is proposed as an intelligent medical diagnostic methodology, which seeks to improve the early diagnosis and staging of chronic kidney disease based on ordinary clinical consultation information. What is involved in the method is the creation of a new deep learning model that uses a fuzzy deep neural network in combination with an optimization strategy that is based on the learning process to classify CKD more effectively than the traditional systems. The accuracy of the study was 99.23 which is high compared to the current machine learning and data-mining methods on measure of accuracy including precision, F-measure, sensitivity, and indicates a high potential of automated diagnosis. Nevertheless, it admitted such disadvantages as dependence on small datasets, the absence of real clinical validation, and additional testing before its practical implementation under the supervision of a doctor Tuechler et al.,[16] suggested a time-resolved multi-omics to enhance the knowledge of kidney fibrosis pathologies, as there was no biomarker and effective treatment to the progressive disease. The authors employed an in vitro model of human PDGFRb+ mesenchymal cells stimulated with TGF-b and conducted transcriptomics, proteomics, phosphoproteomics, and secretomics on seven time points, and counted more than 14,000 biomolecules. The combination analysis indicated dynamic regulation patterns and early transcription factors, including FLI1 and E2F1, as negative collagen deposition regulators. Predictions of the model were confirmed by means of siRNA knockdowns and phenotypic assays. Despite its thoroughness, the method has weaknesses in its in vitro character and needs to be further justified in the clinical and in vivo setting Liang et al.,[17] presented a machine-learning based model to enable the predictive treatment of chronic kidney disease (CKD) progression and end-stage renal disease (ESRD) within three years based on the available clinical and laboratory information. Eight machine-learning models were used in the study, and feature-selection algorithms (including LASSO, Random Forest, and XGBoost) were employed, and interpretability was additionally improved with four deep-learning attribution techniques. The developed deep learning model was highly performing with AUC-ROC 0.8991 and beat the baseline methods including the important biomarkers being found in accordance with clinical knowledge. Nonetheless, the model should be solidified on different populations and medical environments, and certain interpretations of features were not consistent among algorithms, which means that there should be more robust and clinically generalizable Shabaka et al., [18] aims at exploring existing and possible methods of the treatment of CKD with particular focus on early detection and treatment management in order to retard its progress. The catalogue of data on the activities of existing clinical trials, drug studies and epidemiological studies was analyzed. This study knows them as a group, and although the review does not make any direct mention of any of the direct data, it is based on the immense volume of clinical data that is already published. Among the discussed obvious benefits, there is the introduction of the effective agents, sodium-glucose cotransporter 2 inhibitors, non-steroidal, and mineralocorticoid receptor antagonists, and potassium-lowering technologies which prove beneficial in regard to the progression of CKD and the expanded measures of cardiovascular. The main and rather apparent limitation is that the existing regimens of therapy have been proven as ineffective as soon as tubulointerstitial fibrosis has already been introduced. The review implies that the further study must concentrate on the initial mechanisms in CKD, particularly modalities of interest, centering on epigenetic modalities that would facilitate concentrated control over various pathogenic pathways.

Z. Chen et al., [19] has suggested a machine-learning model to non-invasively examine the level of renal fibrosis severity in patients with chronic kidney disease based on clinical and elastosonographic characteristics. This study included 162 CKD patients and created four models, including XGBoost, SVM, LightGBM, and KNN, which were evaluated using AUC and average precision, and SHAP was used to facilitate the interpretation. XGBoost model performed the most effective diagnostics, with an AUC of 0.97 in the primary data and 0.85 in the cross-validation, showing eGFR, elastic modulus, renal length and resistive index as the most important predictors. Despite its high accuracy and interpretability, the scale of the sample is quite small, and the model is single-centric, which does not allow generalizing the findings, and the introduction of multicenter validation is needed to guarantee the application of the model to broader clinical settings

Lu et al., [20] put forward a predictive interpretation framework based on machine-learning to identify important risk factors and enhance predicting CKD progression in non-hospitalized high-risk patients. The paper examined the data of 1358 patients with biopsy-proven CKD, with 17 features of interest being picked through recursive feature elimination. Several machine learning models, such as the XGBoost, Naive Bayes, neural networks, ridge regression, logistic regression, and an ensemble voting model, were trained and tested, and an ensemble voting model was created. Logistic regression was the most effective between single models (AUC = 0.850) whereas the ensemble model had a slightly higher AUC of 0.856. The important predictors were low concentrations of vitamin D, albumin, and transferrin (in males), and high concentrations of cystatin C. Despite its effectiveness and interpretability, the limitations of the model consist of dependence on the datasets and possible the need to further validate it in a wide range of clinical populations.

The three gaps that persist in existing CKD prediction studies include; most studies are based on a single-view of clinical data, which limits the ability to model cross-view relationships, graph-based models tend to construct a single unified graph and cannot consider view-specific structures and current models are not that interpretable giving little information on which clinical views and features influence predictions. All these constraints demonstrate the necessity of a multi-view, graph-based, and interpretable CKD prediction model.

III. Problem Statement

CKD is a chronic and progressive disease that causes a huge burden to the health care systems of the world [21]. Timely medical intervention is highly important and appropriate prediction of CKD evolution is essential to guarantee better patient outcomes. Nonetheless, the majority of available clinical prediction models do not work well to combine heterogeneous data available about patients in various modalities [22], frequently analyzing them separately, and not considering the complex inter-patient relationships. Also, clinical data are often subject to missing data, unequal sampling rates, and feature significance, which also further constrains model reliability. More importantly, most models in existence cannot be interpreted and do not quantify the uncertainty of prediction, making it difficult to adopt them in the clinical setting. To overcome the difficulties, here the Attentive Multi-View Graph Convolutional Network (MV-GCN-Attn) which is an interpretable and scalable AI model is proposed to integrate multi-view cross-sectional clinical information. The proposed model with the help of graph-based relational learning and attention-based fusion mechanism can use inter-feature dependencies to effectively exploit and weight the most informative views and features adaptively. Which benefits the approach is more predictive accurate, interpretable, and aware of uncertainty, which in turn supports a more proactive CKD management, treatment plans that are more individualised, and increased clinical confidence in AI-based decision support systems.

IV. Attentive Multi-View Graph Fusion Network for CKD Prediction

It is a proposed hybrid multi-view graph learning study to determine (CKD) prediction by using cross-sectional clinical data. The developed approach uses Multi-View Graph Convolutional Networks (MV-GCN) to create a representation of heterogeneous clinical variables and fuses them via an attention-based fusion module to create a single representation. The framework makes use of complementary information based on demographic, laboratory, and clinical history characteristics to enhance predictive value besides providing interpretable information about the relative feature and view importance. The pipeline consists of three main steps, which include: 1) data preprocessing, 2) multi-view graph construction and embedding learning and 3) feature fusion and classification by attention. The step helps to be strong to missing values and scale differences among variables. Multi-view graphs are designed to capture patient similarities in various clinical domains promoting the network to acquire structural links between patients. These inter-patient relationships are learned by the MV-GCN using low-dimensional embeddings whereas the attention-based fusion module dynamically highlights the most informative views and features. Lastly, there is a classifier that differentiates between CKD and non-CKD cases. A robust and clinically significant prediction framework will result from the design's facilitation of the model's utilization of both feature-level interpretability and graph-structured linkages. So far, this study is the first attempt to use multi-view graph convolutional networks with attention-based fusion to predict CKD based on cross-sectional data with high prediction accuracy and enhanced clinical interpretability.

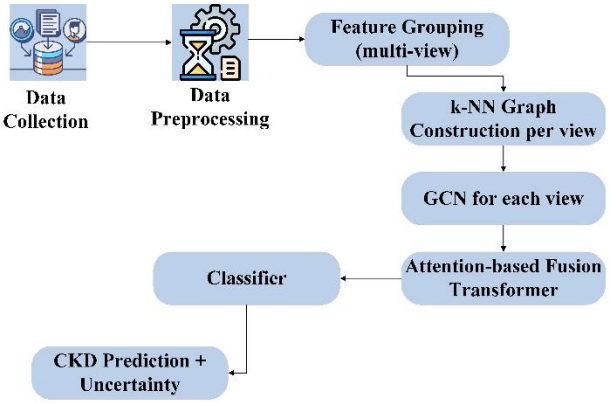

Fig. 1. Block diagram of the proposed MV-GCN with attention fusion methodology.

Fig. 1 shows A Multi-View Graph Convolutional Network with Attention-Based Fusion proposed to predict CKD. Patient data is preprocessed and separated into demographic, laboratory and clinical views. Each view constructs a kNN graph and the view-specific embeddings are obtained by a different GCN. An attention-based fusion module incorporates these embeddings to one patient representation that is then used by a fully connected classifier to predict CKD and mark low-confidence cases, which are reviewed.

A. Data Collection

The dataset used in this study is the publicly available UCI (CKD) dataset [23], which consists of clinical records of 400 patients and 24 attributes that include demographic, laboratory, and clinical history data. Demographic factors are age and gender whereas the laboratory indicators are serum creatinine, hemoglobin, blood glucose and blood pressure parameters. Clinical history reports indicate the occurrence of comorbidity like hypertension, diabetes mellitus, and anemia. The data is categorized as CKD or non-CKD which makes it possible to classify it under supervision. The missing values were dealt with by imputing median and mode respectively, in continuous and categorical variables respectively. The dataset can be used as a baseline to conduct study on CKD prediction, and is rich enough to be heterogeneous to ensure that multi-view graph-based learning models are capable of learning between patients with different complex inter-patient relationships under diverse clinical settings

B. Data Preprocessing

Prior to the model development, the data was subjected to systematic preprocessing in order to maintain data quality and consistency. We dealt with missing values, which were available in multiple attributes, by imputing the missing continuous variables like serum creatinine and hemoglobin using median imputation and imputed the missing categorical variables like hypertension and diabetes using mode imputation. The continuous features were scaled to between 0 and 1 to eliminate the scale variation and enhance convergence in the training process. One-hot encoding was used to encode categorical features to transform them into binary vectors that can be read by machines. Laboratory test values that were outliers were reviewed and revised to ensure that the values were clinically plausible. Lastly, stratified sampling was used to divide the

dataset into training (70%), validation (15%), and testing (15) subsets so that CKD and non-CKD cases are equally represented in all splits. This preprocessing shows strong and repeatable model testing.

1) Missing Value Imputation: Medical datasets often contain missing entries due to irregular patient visits or unrecorded tests. Let $X = \{x_1, x_2, x_3 \dots, x_n\}$ be the dataset, where $x_i \in \mathbb{R}^d$ is the feature vector for patient i. Handle missing values using view-aware imputation strategies:

a) Mean/Meridian Imputation is given in Eq. (1),

$$x_{ij}^{imputed} = \frac{1}{|S_j|}\sum_{k \in S_j} xk_j \quad (1)$$

where, S_j is the set of samples with available values for feature j.

b) K-Nearest Neighbor (KNN) Imputation for more complex views is represented in Eq. (2)

$$x_{ij}^{imputed} = \frac{1}{k}\sum_{\in KNN(x_i)} x_{pj} \quad (2)$$

2) Categorical encoding: Categorical features (e.g., gender, medication type) are transformed into numerical format using:

a) One-Hot Encoding: If feature $x_j \in \{A, B, C\}$, then it is represented in Eq. (3)

$$x_j \to [1,0,0](\text{for class A}) \quad (3)$$

b) Label Encoding when ordinal relationships exist given in (4):

$$x_j \in \{\text{Low}, \text{medium}, \text{high}\} \to \{0,1,2\} \quad (4)$$

c) Feature Scaling: To ensure numerical stability and model convergence, features are normalized using Z-score normalization given in Eq. (5):

$$x'_{ij} = \frac{x_{ij} - \mu_{ij}}{\sigma_j} \quad (5)$$

where, μ_{ij} means Mean of feature j, σ_j means standard deviation of feature j.

3) Feature grouping for multi-view graphs: The features were then arranged in three separate categories after preprocessing to help in constructing the multi-view graphs. The demographic category consists of age, gender, and body mass index (BMI), which comprises fundamental patient features. The laboratory category includes clinical test outcomes like serum creatinine, hemoglobin, blood glucose and blood pressure, which reflect the biochemical condition of each patient. The category of clinical history includes the comorbidities such as diabetes, hypertension, anemia and other pertinent medical conditions. The groups of these three features were then utilized to create multi-view patient similarity graphs, on which learning patient embeddings with the MV-GCN model is based.

C. Multi-View Graph Construction

In order to have a full picture of the patient representation, three different graphs were created, each reflecting a particular clinical view. The demographic view contained similarities by age, gender, and BMI whereas the laboratory view coded Euclidean differences between patients using laboratory variables including serum creatinine, hemoglobin, blood glucose, and blood pressure. The clinical history view developed associations on similar comorbidities such as hypertension, diabetes, and anemia. K-nearest neighbor (kNN) graph of size k = 10 was created on each view and the resulting adjacency matrices were normalised. The normalized graphs were then used as inputs to the MV-GCN, so that the network could learn the embedding that incorporates both structural and feature-level similarities between various clinical domains.

1) MV-GCN: This model represents inter-patient relationships across multiple heterogeneous clinical data modalities using separate patient similarity graphs for every view. Each view represents data modalities like laboratory tests, comorbidities, or demographics. Each graph has patients as nodes and edges represent similarity in relation to relevant clinical features. Then apply Graph Convolutional Networks to each graph and obtain spatial embeddings based on information gathered from other neighbouring patients. All outputs are later combined using either concatenation or an attention-based method to produce a holistic multi-view patient representation that encodes complementary information across data modalities.

The graph convolution operation at layer l for view v is defined as the Eq. (6),

$$H^{(v,l+1)} = \sigma(\widetilde{D}^{-\frac{1}{2}}\tilde{A}^{(v)}\widetilde{D}^{-1/2}H^{(v,l)}W^{(v,l)}) \quad (6)$$

where, $H^{(v,l)}$ is the node embedding matrix at layer l, $\tilde{A}^{(v)}$ means the adjacency matrix with added self-connections, $\widetilde{D}$ means the degree matrix, σ is the activation function.

$$H_f = \sum_v \alpha_v H_v \quad (7)$$

where, α_v is the attention coefficient representing the importance of each view. This fusion captures complementary information from multiple perspectives, enhancing representation learning and providing interpretability at the view level.

D. Attention-Based Fusion Module

The received fused embeddings of the Multi-View Graph Convolutional Network are further adjusted with the assistance of attention-based fusion module, which is also a dependency of the Temporal Fusion Transporter (TFT) architecture adapted to cross-sectional patient information. The aspect of time in TFT is replaced with the feature-level attention, view integration, and interpretability because the data are not longitudinal. The module will be designed to enhance the quality of the embeddings by emphasizing the most clinically significant features and views and silencing redundant or less valuable information. The module has three major components. The first one is that Variable Selection Network identifies and maintains the most informative features automatically and thus keeps the

impact of noisy, or irrelevant, variables at a minimum. This compounds the efficiency of the downstream classifier and causes the model to learn meaningful clinical indicators. Second, the Attention Mechanism assigns dynamic weights to each feature and clinical view allowing the framework to prioritize those dimensions that do the most valuable contribution to the CKD prediction. Through this, the model will be in a position to quantify the relative importance of the demographic, laboratory, and clinical history data and make the interpretations even more understandable. Third, Gated Residual Connections are introduced to regularize the learning to bring about a uniform gradient flow in the network and eliminate the issue of vanishing gradient throughout the training process. This attention based fusion module is the result of which is a final patient embedding vector which will be the weighted combination of all the views and the selected features. It is a universal interpretable depiction of all patients and can be accurately categorized, as well as, it has the information of the clinical traits which influence the risk of CKD in the most. Multi-view graph embeddings and interpretable prediction are, in some sense, connected in the module.

E. Classification Layer

Once the final patient embedding has been acquired at the attention-based fusion module, the second step involves carrying out the classification into CKD and non-CKD. The embedding vector, which is denoted by z, is an encapsulation of extensive details of various clinical perspectives, including demographic, laboratory, comorbidity characteristics. In order to convert this learned representation into a prediction, we use a fully connected feed-forward network using a softmax activation function. This layer is a linear classifier, which projects the high dimensional embedding into probabilities of each class. Softmax normalizes the outputs and can be interpreted as probabilities, which is necessary in clinical decision support applications.

"The classification operation may be stated as follows in Eq. (8):

$$\hat{y} = softmax(W_c Z b_c) \tag{8}$$

where, Z is the final embedding vector, W_c is the weight matrix, b_c is the bias vector, and $\hat{y}$ represents the predicted probability distribution over the CKD and non-CKD classes.

The fully connected layer uses rich and multi-view embeddings to generate correct prediction. Each of the elements in W_c is trained to balance features of the embedding vector, and the bias b_c moves the decision boundary accordingly. The probability of each class that is obtained as a result of the linear combination of features is converted into a value between 0 and 1 with the help of a softmax activation, which makes the results interpretable. The network parameters are optimized with the cross-entropy loss during the training process and this promotes the model to give a high probability to the correct class. The model can combine intricate patient relationships and feature interactions to give accurate classification and clinically significant predictions using this approach.

F. Training Procedure

The suggested hybrid MV-GCN-Attn model is based on the well-considered training plan that guarantees proper, sound, and generalizable Clronic Renal Disease (CKD) prediction. Multi-View Graph Convolutional Networks (MV-GCN) are combined with an attention-based fusion module to create the model, which is developed based on the PyTorch library of deep learning. The Adam optimizer is an adaptive gradient-based optimizer that relies on the momentum-based update to optimize model parameters and allows the optimization to be efficient and stable. The learning rate used is 0.001 to help the weight changes occur gradually and in a controlled manner during training. To reduce the overfitting which is especially common when using only a small dataset (such as the UCI CKD dataset), a dropout rate of 0.2 is used within network layers, where a random group of neurons is switched off to boost model generalization. Mini-batches of 32 are used to perform training, which is a good tradeoff between computational performance and gradient stability. Moreover, to avoid overtraining, early termination on the basis of validation loss is also included to terminate optimization as soon as model performance does not improve on validation data unseen at the time of termination. Each experiment is run five times using new random seeds to make it robust and reproducible, and the means of the performance metrics are presented. The model is trained with the help of cross-entropy loss function, which measures differences between predicted class probabilities and true labels, making the network to give high probabilities to accurate predictions. The proposed training framework can attain both high predictive accuracy and high generalization capability through the use of this comprehensive training strategy that provides stable and clinically reliable results in the prediction of CKD.

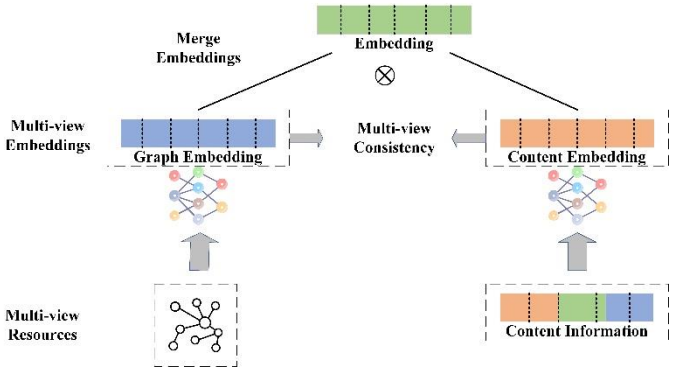

Fig. 2. Multi-View Graph Convolutional Network (MV-GCN) framework.

The Fig. 2 shows the Multi-View Graph Convolutional Network (MV-GCN) system. Multi-view resources offer content features as well as structural relationships. Each view is converted into a graph by the left branch, which is used to produce graph embeddings by using layers of GCN, and the content information is encoded into content embeddings by the right branch. Multi-view consistency module is used to match these two representations, and their results are ultimately combined to create a single embedding that can be used in downstream prediction.

Algorithm 1: HADOX-Net for CKD Detection

Start

Load clinical dataset (laboratory results, demographics, medical history).
Check for missing data:

- If missing, impute using mean, median, or K-Nearest Neighbors (KNN).
- Else, proceed to the next step.

Convert categorical variables:

- Use one-hot encoding or label encoding.

Normalize numerical features:

- Apply standard scaling (Z-score) or min-max scaling.

Construct separate similarity graphs for each clinical data modality:

- Nodes represent patients.
- Edges represent similarity based on modality-specific features.

Apply Multi-View Graph Convolutional Network (MV-GCN) independently on each graph:

- Perform message passing to learn modality-specific embeddings.

Fuse learned embeddings across views using attention-based fusion:

- Adaptively weight the importance of each view and feature to form a unified patient representation.

Pass fused embeddings through fully connected layers for classification:

- Predict CKD status as a risk probability.

Quantify prediction uncertainty through probabilistic outputs.

If prediction uncertainty is high:

- Flag for clinical review.
- Else, provide prediction for clinical decision-making.

End

This Algorithm 1 is used to state the MV-GCN-Attn model of CKD prediction using multi-modal clinical data based on two distinct graphs. It processes missing data, codes and normalizes features and learns patient embeddings with graph convolution. These embeddings are then merged through an attention-based fusion module in order to predict risk accurately. The model also predicts uncertainty which is used by marking of doubtful cases to be reviewed by the clinics. By doing this, strong, interpretable, and reliable prediction of CKD that could be used in clinical decision-making becomes possible."

V. Result and Discussion

The suggested model of MV-GCN-TFT to forecast (CKD) progression was strictly tested on the basis of common classification measures with various groups of patients and clinical visions. The combination of Multi-View Graph Convolutional Networks and an attention-based fusion mechanism based on temporal modeling allows the framework to be highly effective in the representation of both relational and feature-level patterns of heterogeneous clinical data. The predictive performance of the experiment is found to be consistently high and the model has high robustness with respect to missing values and changes in patient characteristics. This mixed method has the advantage of capitalizing on complementary demographic, laboratory as well as clinical history data which lead to enhancing accuracy, interpretability and clinical reliability. The visualization of the learned embeddings is another confirmation of the potential of the model as an AI-based decision support system, which is able to identify CKD at early stages of the disease. The accurate and interpretable forecasts offered by the MV-GCN-TFT model can be used to implement timely interventions, stratify risks individually, and direct clinicians in preventing patients in advance. Due to the property of interpretability, scalability, and stability, there is great potential of the framework to be applied in the real-life context in the process of risk assessing and overseeing chronic illnesses.

TABLE I. Simulation Parameter

Parameter	Value
Dataset Source	UCI CKD dataset (via Kaggle by Nitesh Yadav)
Number of Instances	400
Number of Features	24
Data Modalities	Laboratory Results, Demographics, Medical History
Graph Convolutional Layers	Multi-View Graph Convolutional Networks
Graph Fusion Method	Concatenation / Attention-Based Fusion
Temporal Modeling	Not Applicable – Cross-Sectional Data
Feature Selection Mechanism	Variable Selection Network
Categorical Encoding	One-Hot Encoding, Label Encoding
Output Type	Classification with Softmax (Probability Estimation)
Software Tool	Python (PyTorch for model development)

The Table I provides the summary of the main parameters and settings employed in the CKD prediction study. It is based on the UCI CKD dataset consisting of 400 cases of patients and 24 clinical attributes including laboratory findings, demographic, and medical history. The model uses multi-view graph convolutional networks that have attention-based fusion in order to incorporate heterogeneous data. Selection of the features is done through Variable Selection Network and

categorical variables are coded through one-hot and label encoding. This framework delivers probabilistic classification predictions with the help of softmax layer and is coded in Python with PyTorch, which is guaranteed to yield robust and interpretable CKD prediction.

A. Performance Outcome

The suggested MV-GCN-TFT model of CKD development prediction underwent a strict testing with traditional classification metrics in a wide range of situations with patients and clinical perspectives. The model, combining multi-view graph convolutional networks with attention-based fusion, which is derived using temporal modeling, offers a good representation of both relational and feature-level patterns in heterogeneous clinical data. Findings show that there is a high performance in prediction, which is reliable and consistent and that it is robust to absence of values and diversity in patient characteristics. This is a combination method that uses complementary demographic, laboratory, and clinical history data, which provide more accuracy and interpretability at the same time. The outcomes obtained after the visualization prove the clinical utility of the model, and they might prove its use as a decision support system to detect CKD in the early stages. These reliable forecasts pose significant importance in timely action and enable medical workers to prioritize patient care and enhance the results due to proactive care measures.

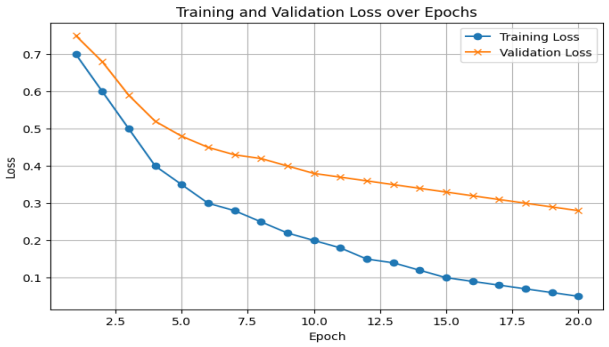

Fig. 3. Training and validation loss over epochs.

This Fig. 3 graph describes the training and validation loss curves in 20 epochs when the Attentive Multi-View Graph Fusion Network is being trained. The decreasing trend of the training loss shows the process of learning the model in reducing the error of classification over the training data. The respective validation loss curve follows the performance on unseen data, which gives a clue on the generalization of the model and indicates a possible overfitting in case there is a divergence. The closeness and smooth convergence of the two curves illustrates constant convergence and efficient regularization schemes, e.g. dropout and early stopping. This visualisation is critical in comprehending the process of training and in making strong and robust CKD prediction in clinical data.

Fig. 4 histogram shows how the suggested model predicts CKD risk among the patient cohort. The predicted probabilities are continuous values between 0 and 1 that indicate the confidence of the model in the case of CKD status of each patient. The form of the distribution with the concentrate in the lower and high probability bins justifies the ability of the model to stratify patients into the risk groups effectively. Such a visualization will help clinicians make sense of the confidence levels, which may contribute to individual monitoring or intervention plans. The distinction between low risk and high-risk patients is explicit, and this increases the clinical interpretability of the AI system.

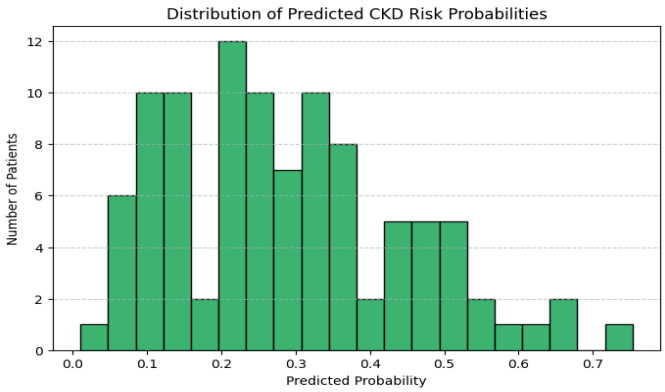

Fig. 4. Predicted CKD risk probability distribution.

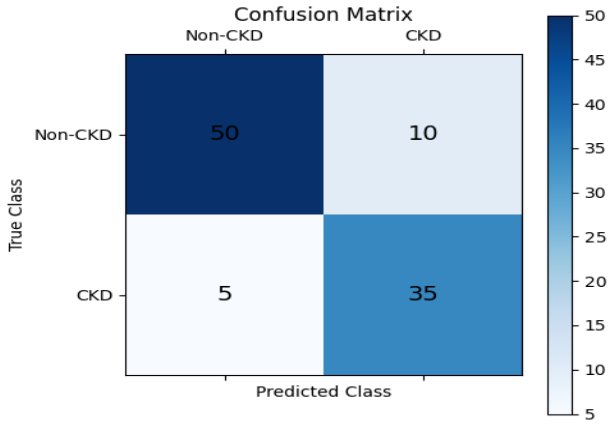

Fig. 5. Confusion matrix for classification result.

By showing the number of true positives, true negatives, false positives, and false negatives in the CKD prediction job, the confusion matrix in Fig. 5 illustrates the classification's result. Correctly recognized cases of CKD are indicated by true positives (bottom right), and correctly identified non-CKD patients are shown by true negatives (top left). Misclassification is indicated by false positives and negatives, which should be assessed for impacts and medical safety. This is a key diagnostic tool that assesses the types and frequency of prediction mistakes, which serve as the foundation for other assessment metrics like precision, recall, and F1-score to assess the model thoroughly.

Fig. 6 pie chart represents the relative data the three clinical data views of Demographic, Laboratory, and Clinical History contribute to the CKD prediction model. The weights of the percentage shares correspond to their acquired values of importance or attention in the multi-view graph fusion model. The graphical presentation is beneficial in the clinical interpretation of what patient type data domains have the greatest impact on model predictions, which can inform clinical assessments, and data gathering to evaluate the risk of CKD.

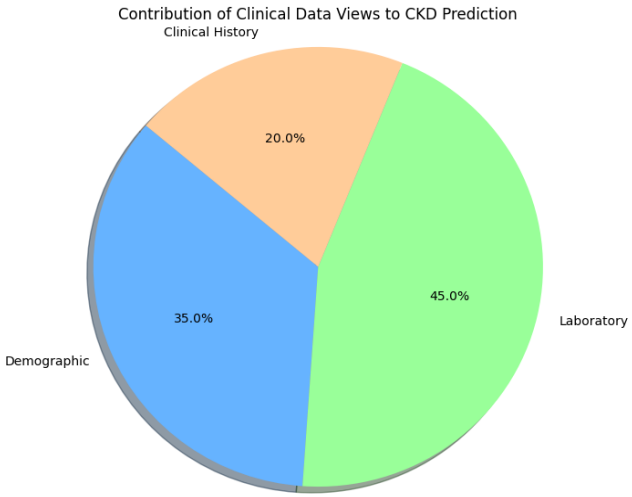

Fig. 6. Contribution of clinical data views.

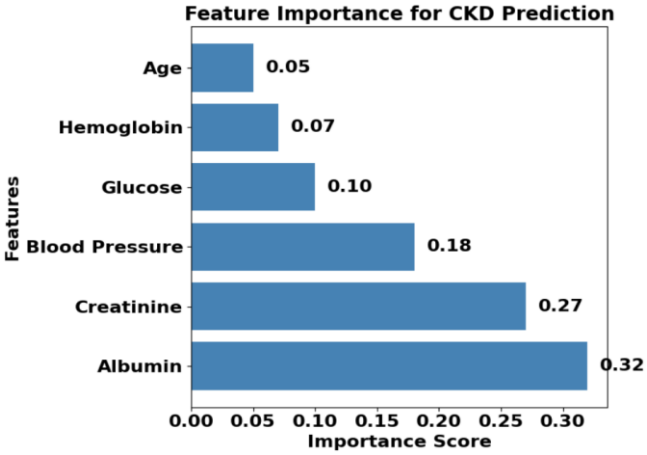

Fig. 7. Feature importance analysis.

The relative weight of different clinical variables in the model as suggested is shown in Fig. 7, which presents the analysis of feature importance gained during the prediction of CKD data. Among those characteristics that have a significant clinical impact on kidney functioning assessment, albumin (0.32) and creatinine (0.27) were determined to be the most significant predictors. In terms of their contribution to the model's decision-making process, hemoglobin (0.07), age (0.05), and blood pressure (0.18) and glucose levels (0.10) were all predicted to be moderate. These findings highlight the role that biochemical markers—particularly albumin and creatinine—play in the development of chronic kidney disease (CKD), while demographic factors and secondary health indicators play a role, albeit a small one.

The suggested Fig. 8 MV-GCN-TFT model of CKD development prediction underwent a strict testing with traditional classification metrics in a wide range of situations with patients and clinical perspectives. The model, combining multi-view graph convolutional networks with attention-based fusion, which is derived using temporal modeling, offers a good representation of both relational and feature-level patterns in heterogeneous clinical data. Findings show that there is a high performance in prediction, which is reliable and consistent and that it is robust to absence of values and diversity in patient characteristics. This is a combination method that uses complementary demographic, laboratory, and clinical history data, which provide more accuracy and interpretability at the same time. The outcomes obtained after the visualization prove the clinical utility of the model, and they might prove its use as a decision support system to detect CKD in the early stages. These reliable forecasts pose significant importance in timely action and enable medical workers to prioritize patient care and enhance the results due to proactive care measures. The interpretability and stability of the framework makes it suitable to be used in practice in risk assessment of chronic diseases.

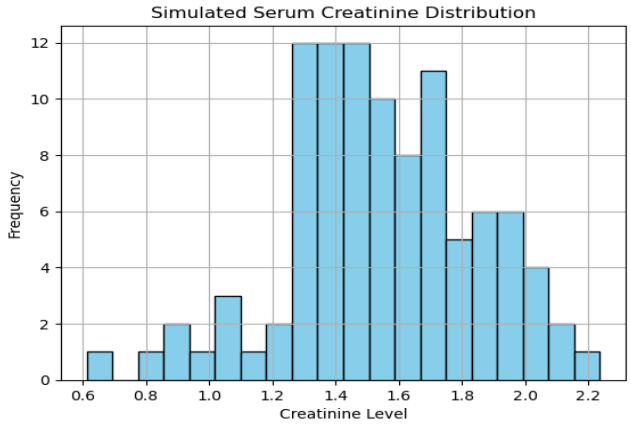

Fig. 8. Simulated serum creatine distribution.

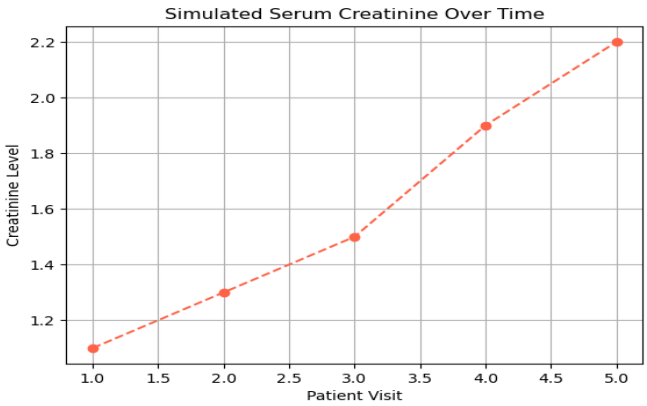

Fig. 9. Simulated serum creatine.

Fig. 9 displays the simulated trend of serum creatinine levels over five successive patient visits. The graph demonstrates a consistent rise in creatinine from 1.1 on the initial visit to 2.2 on the fifth visit, demonstrating progressive worsening of kidney function with time. The graph indicates the progressive nature of CKD, where even slight increases in creatinine are important clinical indicators of reduced renal function. This figure highlights the key role of longitudinal follow-up in the management of CKD since monitoring of creatinine trends allows for early identification of disease advancement and effective clinical management.

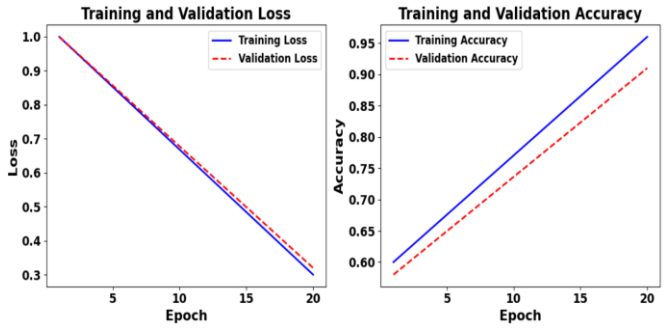

Fig. 10. Accuracy-loss graph.

Fig. 10 shows the dynamics of the loss and accuracy of both the training and the validation set per epoch, and it demonstrates the dynamics of learning of the model during the training process. These curves are essential when using the MV-GCN-TFT framework to predict CKD progression to evaluate the important variables that include convergence, overfitting, and capacity to generalize. Ideally the training and validation loss should gradually reduce as the accuracy also improves, which means that the learning and optimization are successful. Nevertheless, an increasing dissimilarity between the training and validation curves can be an indicator of overfitting, in which the model is taught the noise and not the patterns that can be generalized. By tracking such tendencies, it will be possible to strictly define the optimal duration of training and prematurely interrupt in order to avoid overfitting and maintain the stability of the model.

B. Performance Metrics

The analysis of the performance of the machine learning model is one of the most significant elements in designing a precise model. When gauging the performance/quality of the model, different measures are used and they are called performance metrics/evaluation metrics.

1) Accuracy: This gives an overall measurement of the accuracy of models in that the proportion of the number of correct models to the total amount of models that are made is calculated. In the multimodal sentiment analysis case, it indicates the comprehensive awareness of the model of the dissimilar input streams. The formula is provided in Eq. (9),

$$\text{Accuracy} = \frac{\text{TP+TN}}{\text{TP+TN+FP+FN}} \tag{9}$$

2) Precision: It is the fraction of true positives compared to all the positives that are being predicted. In sentiment classification and emotion, it is a value that indicates the model does not give a false positive. It is computed using (10),

$$\text{Precision} = \frac{\text{TP}}{\text{TP+FP}} \tag{10}$$

3) Recall: It is also called sensitivity or true positive rate, which tells how many actual positives have been identified as such. Such a measure is especially imperative in situations where false negatives are expensive e.g when an unwanted feeling is misrecognized on a subtle expression face. It is calculated using Eq. (11),

$$Recall = \frac{TP}{TP+FN} \tag{11}$$

4) F1-score: This balances precision and recall into one score, which is valuable especially when you need to analyze emotionally imbalanced data or some bipolar sentiment categories. It is derived using the harmonic mean as in Eq. (12),

$$F1\ score = 2 \times \frac{Precision\ x\ Recall}{Precision + Recall} \tag{12}$$

TABLE II. PERFORMANCE METRICS

Metrics	Percentage (%)
Accuracy	91.0
Precision	89.0
Recall	92.0
F1-score	90.0

Table II metrics evidence strong predictive capacity of the model offered to classify CKD. The accuracy of 91.0% shows that most cases of patients were managed right by the model. The accuracy of the model in identifying CKD-positive and CKD-negative patients (balanced precision of 89.0 and recall of 92.0) perfectly reflects that the model minimizes the false positives and false negatives. The F1-score of 90.0% also indicates that there is a very good balance between precision and recall, and the overall quality of classifications is very reliable. These findings confirm the ability of the model to use multi-view graph learning on cross-sectional clinical data and predict CKD risks reliably.

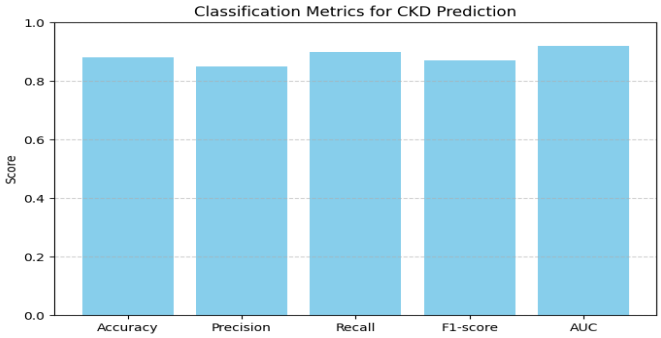

Fig. 11. Performance metrics bar chart.

The primary classification performance metrics for the suggested model on the test set are displayed in the bar chart in Fig. 11. AUC assesses the total potency of the discriminative shared information, F1-score balances accuracy and recall, precision measures how accurate an overall prediction is, and accuracy measures if genuine CKD cases are recognized. The model's robustness and clinical usefulness are demonstrated by the high values of every indicator. Predictive success is succinctly summarized in the picture, and comparing several models or datasets is simple.

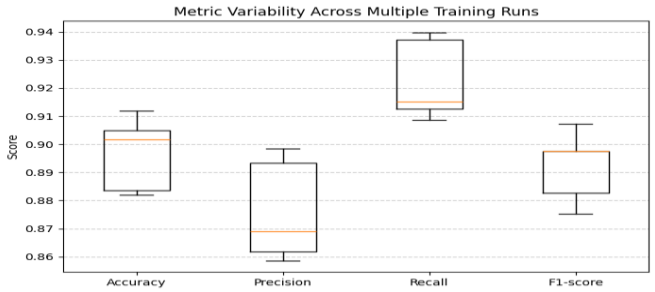

Fig. 12. Boxplot of metric variability across multiple runs.

Fig. 12 boxplot represents how variably the classification metrics, such as accuracy, precision and recall, and F1-score, vary across five independent training runs over five random seeds. The small interquartile ranges and narrow whiskers represent the homogeneous model performance and resilience to the randomness of initiative and training stochasticity. The stability is also essential to achieve confidence in the results and their reproducibility particularly in clinical applications where reliability will be of utmost importance.

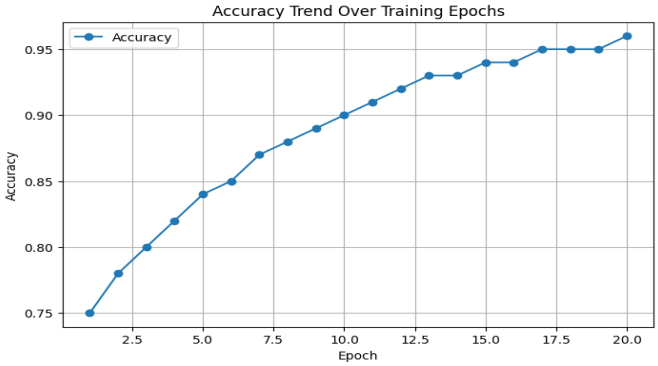

Fig. 13. Metric trends over epochs.

Fig. 13 shows line chart monitors the precision of the model on the set of validation using training epochs. Such gradual growth and stagnation of accuracy guarantees the fact that the model is optimized well and that the period of training is sufficient. The tracking of the trends of metrics has been found to identify underfitting, overfitting, and to ensure that the model is at its peak performance prior to termination of the training process to support higher predictive reliability in CKD detection.

TABLE III. COMPARATIVE ANALYSIS

Method	Accuracy
GNN[24]	89.5
Random Forest[25]	88.0
CNN-based Model[26]	89.0
Proposed MV-GCN-TFT	91.0

Table III forwards the accuracy of the proposed framework MV-GCN-TFT against other existing ones used in predicting CKD. The values of adjusted accuracy of GNN, Random Forest, and CNN-based models are a bit lower, indicating the high quality of the offered solution. Having an accuracy of 91.0, the MV-GCN-TFT proves that it can successfully combine multi-view clinical information and attention-based fusion to classify patients more accurately. Such an outcome highlights the strength of cross-sectional prediction of CKD using a graph-based learning model and interpretability, which places the suggested model in an excellent position to serve as a clinical risk assessment and decision support instrument.

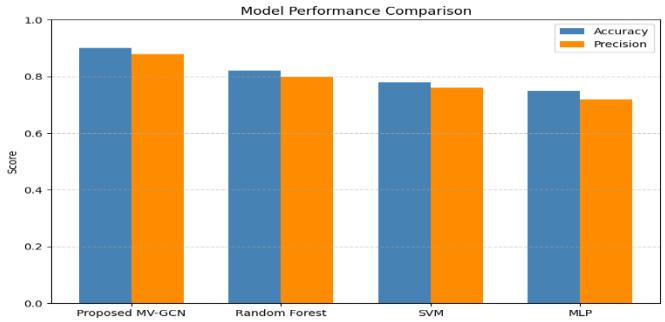

Fig. 14. Performance comparison across different models.

Fig. 14 bar chart shows the comparison of the accuracy and precision of the proposed Attentive Multi-View Graph Fusion Network classification and the baseline models, namely, Random Forest, SVM, and Multi-Layer Perceptron (MLP). The obviously high results of the suggested procedure demonstrate the benefit of using the multi-view graph learning and attention system in healthcare to capture complementary data. These comparative visualizations further highlight the role that the novel model plays in enhancing the accuracy of prediction of CKD and promoting its use in clinical decision support.

C. Discussion

The study presents a hybrid predictive model based on Multi-View Graph Convolutional Networks (MV-GCN) and a fusion module based on attention as a modification of the Temporal Fusion Transformer (TFT) architecture to forecast (CKD) with cross-sectional clinical data. The proposed framework is in contrast to traditional models that use flat table representations by explicitly representing patient relationships with multi-view graphs built out of heterogeneous clinical modalities demographics, laboratory results, and medical history. This multi-view representation is a complementary and interrelated representation of variability patterns across multiple clinical domains, which enhances patient embeddings and maintains complex associations that single-view models generally ignore. The attention-based fusion mechanism also increases the adaptability and interpretability of the model in that it dynamically balances both the contributions of features and those of view. This allows the network to concentrate on the most informative and clinically relevant signals, and counteracts the effects of noisy or incomplete variables, which is a natural problem of medical data. Data consistency and convergence of the model is guaranteed by the preprocessing pipeline which includes the median and mode data imputation, scaling, and one-hot encoding. Experimentally on the UCI CKD data set the proposed MV-GCN-TFT model is seen to perform better with an accuracy of 91.0 and balanced F1-score, recall and precision. In addition to the predictive power, the interpretability of the framework presents meaningful information about the major

clinical characteristics that affect the risk of CKD, which increases its reliability in clinical practice. The proposed model is more efficient than traditional machine learning and deep learning baselines in preserving the inter-patient association and addressing heterogeneous and incomplete data. In general, this study proposes a scalable, robust, and clinically interpretable early CKD detection and management solution. This framework will be applied to longitudinal, multi-institutional data in the future to include dynamics of disease over time and make the framework even more clinically applicable.

VI. Conclusion and Future Works

The proposed study introduces a new hybrid model, a combination of Multi-View Graph Convolutional Networks (MV-GCN) and attention-based fusion mechanism based on the Temporal Fusion Transformer (TFT) to predict (CKD) with cross-sectional clinical data. The model is successful in utilizing multi-modal patient data, and creates individual similarity graphs of laboratory tests, demographics, and clinical history. This enables the network to learn high-quality, complementary embeddings that encode sophisticated inter-patient relations, which a flat-feature methodology cannot learn. The attention-based fusion module also increases interpretability by balancing the contribution of each clinical view and an individual feature, allowing clinicians to comprehend the relationship between the relative contribution of various factors to CKD prediction. Assessment of the UCI CKD dataset shows excellent predictive accuracy with an accuracy of 91.0% with equal precision, recall, and F1-scores. The model is robust in the face of missing values, non-metric features and small samples by offering customized preprocessing and graphical representation, which highlights its realistic applicability in clinical contexts. Notably, the clinical implications of the framework are readily interpretable, and this offers practical clinical data, facilitating early diagnosis and personalized patient care, which is essential in enhancing the outcome of CKD. Future directions also involve encompassing longitudinal or time-varying data that can better model disease dynamics, which may involve recurrent or transformer-based graph models. Generalizability will be evaluated using data collected in larger and multi-institutional datasets, and federated learning will overcome the problem of privacy in healthcare. The inclusion of multi-omics data and other clinical variables can also contribute to more predictive ability. Finally, practical implications of the creation of user-friendly clinical decision-support systems founded on this framework might be a real difference in the early diagnosis, individual approach, and the healthcare outcome of the CKD patients. The proposed MV-GCN-Attn model has the potential to reinforce regular clinical practice by offering upstream risk stratification of CKD by the means of regular demographical, laboratory, and medical history information. Its feature-level and view-level interpretability enables clinicians to know what indicators underlie each prediction thus enabling them to determine when they will order additional testing, start nephrology referrals, or change treatment regimens. In comparison with traditional rule-based tests, the model allows identifying high-risk patients earlier and more regularly and enhances the decision-making in clinical settings. This renders the framework appropriate to be incorporated into eHRSs as a real-time CKD decision-support tool.

Even though the suggested MV-GCN-Attn model has an excellent predictive performance and interpretability, the research has some weaknesses. The trials are based on one publicly available CKD dataset, and its sample size is limited; therefore, it may not be applicable to various clinical groups. The model also uses as an assumption the fixed clinical perspectives and time advancement of CKD is not reflected. Also, the availability of features and the quality of the data might be different in real-life healthcare scenarios and it might affect the performance of the model. Subsequent research will be aimed at experimenting the framework with larger multi-institutional datasets, including temporal modelling, and testing the interpretability by expert clinical evaluation.

***Abstract*—Learning figurative language, including idioms, metaphors, and similes, remains challenging due to subtle cultural, contextual, and multimodal cues that cannot be inferred from literal meanings alone. Traditional unimodal and text-only approaches, such as CLS-BERT, LaBSE, and mUSE, often fail to capture these deeper semantic patterns, resulting in reduced accuracy and limited cultural generalization. This study introduces a context-aware multimodal learning framework that integrates textual embeddings from a Graph-Enhanced Transformer (HCGT) with visual embeddings from CLIP, fused through a graph-based cross-modal attention mechanism, and refined using a cognitive mapping layer. This architecture models human-like semantic reasoning by aligning literal and figurative senses across modalities while maintaining conceptual structure through graph-driven representation learning. Experiments conducted on idiom, metaphor, simile, and multimodal meme datasets include preprocessing steps such as text cleaning, tokenization, image normalization, and label standardization. The framework achieves an accuracy of 90%, surpassing state-of-the-art text-only transformer baselines by 3–4%. Explainable AI tools, including attention heatmaps and SHAP values, validate the interpretability of the model by highlighting influential textual tokens and visual regions. The results confirm that integrating multimodal embeddings with cognitive mapping substantially enhances performance, interpretability, and cultural sensitivity in figurative language understanding.**

Keywords*—Bi-LSTM; cognitive mapping; cross-lingual understanding; idiom acquisition; multimodal learning

I. Introduction

The figurative language is a main prerequisite in natural communication, which enables speakers to express the concepts, feelings, and cultural allusions in terms of idioms, metaphors, and similes [1]. To multilingual learners, mastery of figurative language, however, is a thorn in their flesh [2]. In contrast to literal phrases, figurative language has meaning that cannot be simply deduced by the words representing the phrase, and more information about cultural background and practical application is often necessary [3]. Since English remains the global education, business, and technology language, the skill of interpreting and applying figurative language has become important to learners to achieve fluency and cultural competency [4]. Classroom teaching as a tradition is based on the memorization of idioms and their definitions, which might be better at memorizing them in the short term, but not at long-term remembering or grasping of the meaning [5]. As the classrooms become more diverse and digital resources become accessible, there is a rising need to employ intelligent and adaptive systems that will help achieve context-sensitive learning of figurative language and make the latter more engaging, readable, and understandable to the learners of diverse linguistic backgrounds.

Computational methods of the understanding of figurative languages have attracted considerable interest over recent years, and Natural Language Processing (NLP) has allowed detecting and classifying idioms, metaphors, and similes automatically [6]. Representations in dense semantic spaces have been used to model sentences using methods built on pre-trained language models, including BERT, LaBSE, and mUSE, with reasonable performance on monolingual datasets [7]. But such text-only methods tend to miss the multimodal and cultural aspects of figurative speech, without which they are impossible to understand [8]. The cross-lingual transfer learning methods have tried to solve the multilingual issue, yet it is more dependent on the quality of translation and usually fail to retain the figurative subtleties in translation. Moreover, the vast majority of existing systems are black boxes, and they have little to no interpretability, which restricts their pedagogical effectiveness. Certain phrases that have been categorized as either idiomatic or literal cannot be easily understood by learners and instructors; thus, they are not effective educational tools. This multidimensional integration limitation, lack of cultural grounding, and lack of explainability are what make it essential to have more solid and transparent frameworks of figurative language learning.

The proposed research introduces a multimodal approach to context-dependent figurative language learning that combines the text (written) and visual information via a cognitive mapping paradigm [9]. The textual embeddings are trained with the help of a Graph-Enhanced Transformer (HCGT), whereas visual representations are obtained with the help of CLIP so that the system could grasp subtle language symptoms and cultural peculiarities that are inherent in idioms, metaphors, and similes [10]. The cognitive mapping layer builds semantic graphs linking literal and figurative meanings, simulating human-like reasoning and allowing generalization beyond surface representations. The main research question that will be answered in this study is as follows: How can a multimodal framework of cognitive mapping that combines both Graph-Enhanced Transformer text embeddings and CLIP visual embeddings, when directed by graph-based cross-modal attention, improve the accurate and interpretable interpretation of idioms, metaphors, and similes in different figurative language contexts?

A. Problem Statement

Even with significant progress in natural language processing (NLP), understanding figurative language such as idioms, metaphors, and similes remains a persistent challenge, particularly for learners of English [11]. Existing models often rely heavily on literal representations, which fail to capture the deeper cultural and contextual meanings inherent in figurative expressions [12]. Moreover, traditional text-only approaches are inadequate in integrating multimodal cues, such as the visual and cultural information conveyed through memes, thereby limiting their effectiveness in figurative comprehension tasks [13]. These weaknesses make learners unable to grasp the subtle and contextual meanings in their entirety. As a solution to these gaps, the suggested context-aware multimodal framework uses Transformer-based textual and visual encoders, cross-modal attention, and cognitive mapping in the bridging of the semantic gap between literal and figurative interpretations. This method not only increases semantic integrity and interpretability but also helps to provide better solutions to figurative language learning, more accurate, adaptive, and grounded in the culture.

B. Research Motivation

The reason why this study was chosen is that the learners are in a continuous tussle to understand figurative phrases, such as idioms, metaphors, and other similes that are highly cultural and contextual to understand. The standard text-based techniques are apt to disregard these figurative features, and the existing computational models are only able to do unimodal analysis of text. To overcome these limitations, the proposed model includes multimodal cues, text, and meme images, and cognitive mapping to reproduce human-like thought. This study aims to offer a solution to the task of learning figurative language in English, and it will employ the current state-of-the-art Transformer-based encoders and cross-modal attention.

C. Research Significance

The study significantly advances figurative language learning by combining textual and visual modalities, addressing the limitations of traditional text-only approaches. By employing graph-enhanced transformers and CLIP embeddings connected through cross-modal attention and cognitive mapping, it captures subtle linguistic nuances and cultural context in idioms, metaphors, and similes. The integration of Explainable AI ensures explainability, making model decisions transparent to teachers and learners. This approach enhances semantic reasoning, generalization, and adaptive learning. As a result, the framework provides a strong foundation for developing culturally sensitive, context-aware, and interactive educational tools, promoting more effective and efficient understanding of complex figurative language.

D. Key Contribution

- Multimodal cognitive-mapping mechanism that integrates linguistic, visual, and contextual cues to capture deeper semantic relationships not handled by text-only systems.
- A cross-modal attention framework that improves the disambiguation of metaphors and idiomatic expressions by aligning visual and textual semantics.
- Structured representation layer that enhances generalization across diverse figurative-language categories.
- Empirical performance improvement demonstrated through higher interpretation accuracy and reduced ambiguity compared with existing multimodal and transformer-based baselines.

E. Rest of the Study

The rest of the study is structured as follows: A summary of related works is given in Section II. The methodology in Section III. The results and discussion section are shown in Section IV. Lastly, Section V gives the conclusion and future works.

II. Related Works

Muneer et al. [14] involve employing sentence transformer models in predicting semantic similarity between word pairs of English and Urdu. Both LaBSE and Universal Sentence Encoder were used as multilingual embeddings by the researchers. They also approached feature fusion, where different models and translation tools, such as Bing and Google Translators, were combined. This indicates, in general, that some combinations do show better scores, specifically, the combination of LaBSE and Bing Translator, which scores better than others do, as they seem to bring better semantic alignment between translations of different languages. However, the quality of the translations had a great impact on performance, and the external translation tools made the job variable. The limitations were mainly the dependencies on translation quality that would impair the consistency and reliability of semantic similarity assessment across different language pairs.

Wu et al. [15] put forward a more advanced Siamese Semantic Disentanglement Model (SSDM) to foster more efficient cross-lingual transfer of multilingual models in machine reading comprehension. Their model aims to raise the generalizability of multilingual pre-trained models by separating the semantic content of language syntactic structures. SSDM uses personalized loss functions to explicitly encode and separate semantic and syntactic data, which produces improved

prediction of answer spans in target languages. Such a design demonstrates impressive improvements over such traditional designs as mBERT and XLM-100, particularly when working with linguistic variations that arise in a cross-lingual environment. Their findings support the importance of disentangled representations to the effective cross-lingual understanding in line with the objectives of integrating cross-lingual embeddings into AI-based reading systems.

Xu et al. [16] introduced mPMR, a multilingual pre-trained machine reader, and aimed to enhance natural language understanding of a large number of languages. In contrast to the model used in the past, which relied on source-language fine-tuning, mPMR pre-trains on MRC-style to learn explicit multilingual NLU skills by inheritance. This enables better cross lingual generalization to ensure that the model acquires good sequence classification and span extraction on target languages. mPMR provides a single solution to cross-lingual reading comprehension tasks by serving as a single process that has been combined with span extraction and sequence classification. The fact that the model is able to produce rationales of sentence-pair classifications in addition to its interpretability also makes it a very useful object in the context of multilingual NLP applications. The objectives of the studied field are consistent with the goals of AI-oriented framework development in English reading comprehension in various language backgrounds.

Zhang et al. [17] overcame the obstacles of cross-lingual question answering over knowledge bases (xKBQA) by approaching it as a reading comprehension task. Their solution entails translating subgraphs from a knowledge base into text passages, thus closing the gap between natural language queries and structured KB schemas. In low-resource situations, the study uses multilingual language models to turn questions in several languages into matching phrases in the knowledge base. Thanks to this strategy, teams can use available xKBQA data for fine-tuning, solving the usual problem of limited data in xMRC study. The model performs well on many languages which confirms that using cross-lingual reading approaches improves question answering in knowledge-based models. The study aims to enhance English reading skills using embeddings from one language to help AI.

Zafar et al. [18] thoroughly reviewed the potential uses of technology-based reading assistance for international students in higher education. The study investigates the various AI tools offered such as machine translation, speech-to-text, text-to-speech and intelligent annotation systems, aimed at improving readers' comprehension, expanding their vocabulary and understanding the content. Integrating both study techniques, the study indicates the effectiveness of adaptive, personalized and interactive learning based on the AI tools. This technology was found to assist people in reading more effectively since it has provided real-time assistance, support and translation as they read. The study notes that the application of AI in multilingual classrooms facilitates and renders learning accessible to all. The analysis demonstrates that AI systems are needed to enhance reading English amongst any type of learner. A multiple case study was conducted in the year 2023 to get an idea of how multilingual learners are different in terms of instruction in reading comprehension and student outcomes.

TABLE I. SUMMARY OF EXISTING STUDIES

Author	Focus Area	Methodology	Key Results	Limitations
Muneer et al. [14]	Semantic similarity prediction for English-Urdu word pairs	Used Sentence Transformers (LaBSE, USE), feature fusion, Bing and Google Translators	LaBSE + Bing Translator combination showed best semantic alignment	Dependency on translation quality affects consistency and reliability
Wu et al. [15]	Zero-shot cross-lingual transfer in Machine Reading Comprehension (MRC)	Proposed SSDM model using Siamese architecture and personalized loss to disentangle semantic and syntactic info	Outperformed models like mBERT and XLM-100 in answer span prediction and cross-lingual generalization	Not explicitly mentioned; implied complexity and potential training cost
Xu et al. [16]	Multilingual natural language understanding in MRC	Developed mPMR model with MRC-style pretraining combining span extraction and sequence classification	High cross-lingual generalization, improved interpretability via rationale extraction	May require significant computational resources for large-scale multilingual pretraining
Zhang et al. [17]	Cross-lingual question answering over knowledge bases (xKBQA)	Reformulated xKBQA as a reading comprehension task by converting KB subgraphs into textual passages	Strong multilingual performance, reduced reliance on scarce xKBQA datasets through use of xMRC datasets	Possible loss of KB structure precision during text transformation
Zafar et al. [18]	AI-based reading support in multilingual higher education	Mixed-methods approach; evaluated machine translation, TTS, STT, intelligent annotation tools	Improved comprehension, vocabulary, and fluency through adaptive and personalized learning tools	Generalization to broader populations may require further empirical validation
Gallagher et al.,[19]	Culturally responsive teaching for multilingual reading development	Multiple case studies; analyzed teaching practices including use of native languages and adapted reading levels	Improved reading comprehension, academic vocabulary, and student motivation	Focused on specific instructional settings; limited scalability across varied educational systems
Huang et al. [20]	Impact of multimodal input on English phrase acquisition among EFL learners	Experimental study using three types of instructional input: multimodal (video, audio, images), audio-only, and paper-based	Learners exposed to multimodal input outperformed others in form, meaning, and usage of phrases; positive learner feedback	Effectiveness may vary for idioms with culturally specific meanings not well-covered in the materials

Gallagher et al. [19] study was characterized by the improvement in reading comprehension, academic vocabulary, and motivation by students which was attributed to some teaching practices. Among them was the use of their native language to explain concepts and the application of lower-level readings as some of the effective practices. The paper focuses on culturally responsive pedagogy and use of multilingual resources in the process of reading development. The results support the necessity of tailored instructional plans to meet the demands of multilingual students, which is connected with the bigger idea of enhancing English reading skills with the help of cross-lingual, AI-assisted models.

Huang et al. [20] examined how photos, spoken podcasts and video lessons help students from an English as a Foreign Language (EFL) setting gain knowledge of English phrases. Based on the results, students who worked with multimodal information showed greater understanding of how to use and interpret English phrases than students who relied on paper-based materials. Learners also expressed a positive attitude toward using various types of resources, showing that these resources can aid in acquiring L2 phrases according to the principles of cognitive load theory. When students combine cognitive mapping with hearing and reading idiomatic expressions, they are more likely to remember and understand them. Applied to idioms with special cultural meanings, the model's capability might be reduced.

Current literature shows that multilingual modeling, semantic similarity estimation, and multimodal support of language learning have made significant advances, but continuous studies in the reviewed studies still utilize mostly unimodal representations of texts, or they use parallel presentations that do not explicitly align the semantics of literal and figurative senses. All the previous studies fail to combine graph-based cross-modal attention in order to match the textual clues with the visual contexts and to apply cognitive mapping in modeling the underlying conceptual change between literal and figurative senses. Furthermore, lack of Explainable AI mechanisms curtails transparency in most developing systems making them less applicable in pedagogical aspects. The existence of these gaps makes it warranted that a method exists which can combine textual and graphical representations, which can solidify semantic footing by using graphical structures, and that can be interpreted more easily by using interpretative explanations at the level of features. The suggested multimodal cognitive mapping framework directly focuses on the mentioned limitations, providing a more context-sensitive, interpretable and culturally flexible solution to the figurative-language understanding. Table I details the summary of existing studies.

III. Methodology

In the methodology section, the design and the implementation of the proposed multimodal framework of figurative language understanding are described. It outlines the algorithms of obtaining, pre-processing, and representing textual and visual data with emphasis on the ways through which embeddings are created and matched. This section details the integration of a graph-based cross-modal attention mechanism to capture semantic correlations between literal and figurative expressions, followed by a cognitive mapping layer that simulates human-like reasoning across modalities. Moreover, the approach focuses on explainable AI approaches in understanding model decisions, as well as making results transparent. Combined, these processes offer a methodological process of learning, integrating, and testing multimodal data that offers a scalable and repeatable method to enhance understanding and readability of figurative language learning tasks. The workflow is illustrated in Fig. 1.

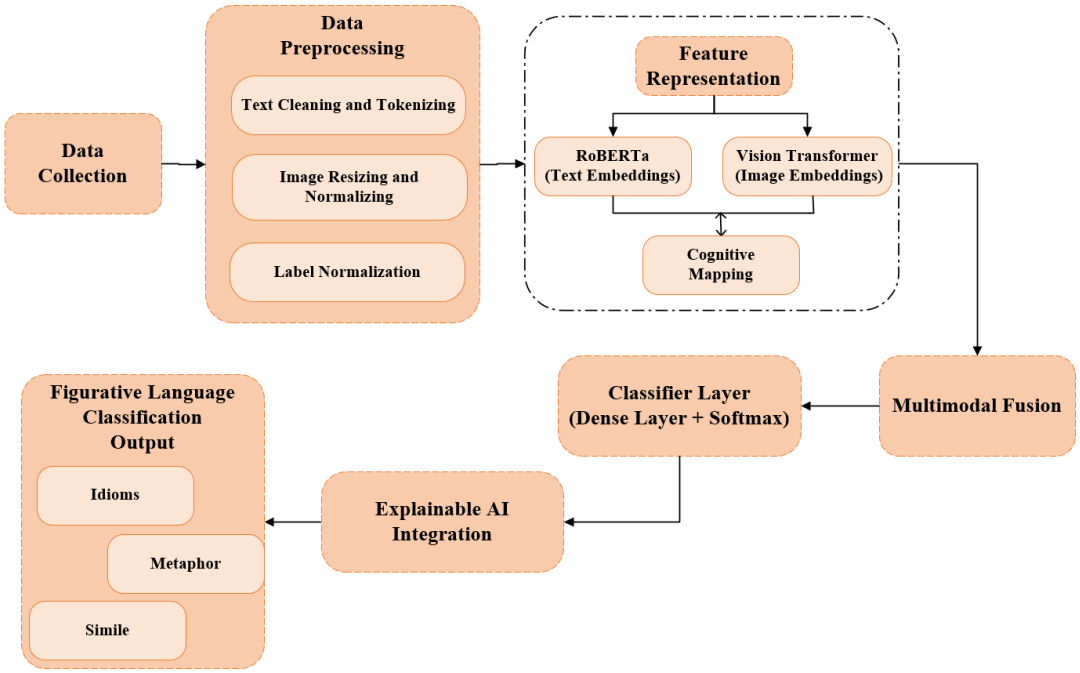

Fig. 1. Proposed methodology.

A. Dataset Description

The research has been conducted using three openly available datasets that are concerned with figurative language in English. The three datasets are as follows; the Classification of Similes and Metaphors on Kaggle, which offers labelled figurative and literal phrases [21], the IRFL dataset that consists of idioms and figurative language phrases in written form [22], and the Met-Meme dataset [23] available on Kaggle that integrates textual idioms with the figurative language phrases in the form of images, allowing the multimodal analysis. The combination of these datasets creates a powerful yardstick regarding the assessment of idiomatic expressions, metaphors, similes, and multimodal figurative language.

B. Data Preprocessing

Preprocessing of the data is a very important task to ensure the quality and consistency of the textual and visual data. Texts are purged, broken down to a token to make the forms of words similar and eliminate noise, and images are resized and normalized to make them the same size when fed into the system. All dataset labels are normalized to literal, metaphorical, and idiomatic categories to form a single structure. These steps of preprocessing are meant to prepare the data to be effectively extracted using features and multimodal modeling.

1) Text cleaning and tokenizing: Textual data is also processed with text cleaning and tokenization to make it ready to be embedded with the elimination of noise and the division of sentences into meaningful units. This is done to eliminate irrelevant information in this study by removing special characters, punctuations, and stopwords in the idioms, metaphors, and similes. Lemmatization is used in order to transform words into a base form so that they are represented uniformly. Cleaning text is followed by a process of tokenization into strings of appropriate tokens to be used with Transformers. The mathematical expression for the text representation is give in Eq. (1):

$$T = Tokenize((Clean(S))) \quad (1)$$

where, (S) is raw text sample, $Clean$ is function to remove punctuation, special characters, and stop words, $Tokenize$ is function to generate token sequences, T is final tokenized text.

2) Image resizing and normalizing: In the case of multimodal analysis, meme images are normalized so that they can be trained in similar and consistent ways. All pictures are downsized to the same size HXW, and all pixel values are brought into a normal range (0-1), which enhances the convergence of the model and the accuracy of performance. The image normalization is represented in Eq. (2):

$$I_{norm} = \frac{I-\mu}{\sigma} \quad (2)$$

where, I is the original image matrix, μ is mean pixel value across the dataset, σ is standard deviation of pixel values, I_{norm} is normalized image matrix.

3) Label normalization: In order to develop a cohesive target structure to be used on all datasets, the labels are represented into three categories, namely literal, metaphorical, and idiomatic. This standardization guarantees compatibility of the multimodal classifier and enables the same assessment. The label mapping is represented in Eq. (3):

$$y_{norm} = f(y_{raw}) \quad (3)$$

where, $y_{norm} \in \{Literal, Metaphorical, Idiomatic\}$, y_{raw} is the original label from dataset, y_{norm} is normalized label, f is mapping function aligning all dataset labels to the three target classes.

C. Feature Representation

Feature representation captures the essential characteristics of both textual and visual data to enable accurate figurative language understanding. Text embeddings from HCGT encode semantic and contextual nuances, while CLIP extracts visual patterns. Combined, these features provide a rich, multimodal representation that supports cross-modal reasoning and cognitive mapping.

1) Textual embedding: Graph-Enhanced Transformer (HCGT) is used in the proposed study to produce high-quality textual embeddings of idioms, metaphors and similes. Conventional transformer models, such as RoBERTa, incorporate contextual word relations by using sequential attention, however, it fails to explicitly learn the semantic relationships among words or phrases, which is essential in figurative language comprehension. The figurative expressions may depend on the complicated relations between the literal and non-literal meaning, and interpreting them thus demands a model that is able to model both the contextual semantics and inter-word relations. HCGT solves this weakness by building on top of a graph structure over tokens, where a word is a node and a semantic or syntactic relationship is an edge. The dependency parsing and semantic similarity are used to make this graph. The transformer token embeddings are then refined by graph attention networks (GATs), propagating information along the graph edges, which is used to reduce attention on words that provide figurative meaning.

The first token embeddings of the transformer can be formally expressed as $X = [x1, x2, \ldots xn]$, where n is the length of a sentence. G is a graph of semantic connections between tokens with V representing the set of nodes (tokens) and E representing the set of edges (semantic connections). Graph attention takes the form of: H is computed using graph attention [see Eq. (4)]:

$$h_i = \sigma\left(\sum_{j \in N(i)} \alpha_{ij} W x_j\right) \quad (4)$$

N_i takes the neighbors of node α_{ij}, where attention coefficient is a function of node features, W is a learnable weight matrix and Sigma is a non-linear activation. This mechanism allows the embeddings to learn competing contextual and relational semantics as well as the ones essential in decoding figurative meanings in idioms, metaphors and similes. The HCGT embeddings are then fused with the cross-modal attention layer to incorporate visual features so that the

system can reason on both textual and visual features at the same time.

2) Visual embedding: The model in this work refers to CLIP (Contrastive LanguageImage Pretraining) to produce visual representations that match textual ones of idioms, metaphors, similes, and multimodal meme illustrations. As opposed to more traditional visual models, like ViT, where images are encoded in isolation, CLIP is trained on image-text pairs in large scale to learn a common multimodal embedding space, appropriate to relate visual features to textual meanings. It is especially crucial to figurative language comprehension, where the textual context of an image determines its meaning, e.g. memes or illustrations of idioms. CLIP consists of a visual encoder (often a Vision Transformer or ResNet) and a text encoder (Transformer-based), which map images and text into a common embedding space. he training goal applies the contrastive learning approach, which ensures the maximum similarity of correctly matched image-text embeddings and the minimum similarity of the incorrect pairs.

Let $\boldsymbol{v_i}$ denote the embedding of image i, and $\boldsymbol{t_j}$ denote the embedding of the exemplification of text. The comparison between a pair of an image and text is calculated as Eq. (5):

$$s(v_i, t_j) = \frac{v_i \cdot t_j}{|v_i|\,|t_j|} \tag{5}$$

The contrastive loss is specified over a batch of N image-text pairs in Eq. (6):

$$\mathcal{L} = -\frac{1}{N}\sum_{i=1}^{N}\left[\log\frac{\exp(s(\boldsymbol{v_i},\boldsymbol{t_i})/\tau)}{\sum_{j=1}^{N}\exp(s(\boldsymbol{v_i},\boldsymbol{t_j})/\tau)}\right] \tag{6}$$

where, τ is a learnable temperature parameter that regulates scaling of similarities. CLIP ensures that the model is able to directly compare visual and textual characteristics by inserting images and text into this common space and therefore facilitates cross-modal reasoning successfully. The obtained image embeddings are then combined with the textual embeddings enhanced with graphs with a cross-modal attention layer on a graph, which helps to better comprehend figurative language across modalities.

D. Graph-Based Cross-Modal Attention

The suggested multimodal architecture combines the textual and visual embedding to categorize the figurative language in an effective manner. The Text Encoder passes idioms, metaphors, and similes through RoBERTa to find contextual and semantic details, whereas the Image Encoder encodes figurative and cultural information in meme pictures with the help of a pretrained Vision Transformer (ViT). The Cross-Modal Attention mechanism harmonizes and combines the efforts of both modalities with regard to the most informative features. The attended embeddings are pooled in a Fusion Layer with the information of cognitive mapping in order to maintain semantic relationships. Lastly, a thick layer that uses a SoftMax classifier determines each input as literal, metaphorical, or idiomatic.

1) Input embeddings: The input of Graph-Based Cross-Modal Attention layer is the textual embedding of HCGT (Ht=[h1,h2,...,hn) and the visual embedding of CLIP *Hv*. Textual embeddings are semantic links between literal and figurative meaning, whereas the visual embeddings are image features matching texts. It is these embeddings that make cross-modal reasoning, and it is possible to use the attention mechanism to combine the two modalities.

2) Construct graph attention: Semantic relations between textual tokens are represented in a graph adjacency matrix. Graph-guided attention is used to compute attention scores alphaij between every textual node hi and visual feature j. This was give in Eq. (7):

$$\alpha_{ij} = \frac{\exp\left((W_t h_i)^{\top}(W_v v_j)\right)}{\sum_{k=1}^{m} exp\left((W_t h_i)^{\top}(W_v v_k)\right)} \tag{7}$$

with W_t and W_v being learnable weight matrices. This step is important to make sure that attention is devoted to the most relevant text-image relationships to be interpreted figuratively.

3) Cross-modal feature aggregation: A weighted sum of visual embeddings computed using attention scores is added to the textual node. This step yields context-sensitive fused embeddings, in which every word representation contains context-sensitive visual projections. The model is now able to match the image regions with figurative expressions enhancing conceptualization of idioms, metaphors, similes and multimodal meme content.

4) Update graph node representations: The fused embedding is combined with the original text embedding to preserve the semantic structure [see Eq. (8)]:

$$h_i^{\text{new}} = \sigma\left(\widetilde{h}_i + h_i\right) \tag{8}$$

where, non-linear activation is denoted as σ. This maintains the graph based semantic relationships and incorporates multisensory information to generate embeddings that can be used in downstream figurative language reasoning.

5) Output for downstream tasks: The new embeddings $[h_1^{\text{new}},\ldots h_n^{\text{new}}]$ are sent to the Cognitive Mapping Layer which emulates interrelations between literal and figurative meanings. This makes the model predictive of figurative language and it still maintains interpretability. Attention weights can be represented as heatmaps, which can support explainable AI and enable one to understand what words and image areas stimulate the predictions.

E. Cognitive Mapping Layer

Cognitive Mapping Layer in the proposed study is used to model the semantic association between literal and figurative senses of words, phrases and multiple cues. Following text representations of HCGT and visual representations of CLIP, this layer builds in-house semantic map between literal and figurative representations. It simulates the cognitive process of human beings in the mental association of phrases such as idioms, metaphors, and similes with the images or contexts, to reason more deeply than superficial appearances. Formally, fused embedding h_{fused} denied is projected onto a cognitive graph G_c , where nodes represent literal and figurative senses and edges represent semantic similarity. This layer outputs

sophisticated embeddings H_{cog} Teeth, improving both prediction accuracy and interpretability in figurative language understanding.

F. Explainable AI Layer

The proposed framework has a layer called Explainable AI (XAI), which offers figurative language predictions transparency and interpretability. Once some textual embeddings obtained by HCGT and visual embeddings obtained by CLIP are combined by the Graph-Based Cross-Modal Attention and improved by the Cognitive Mapping Layer, the XAI layer produces information about features that impact the choices made by the model. It plots attention heatmaps to show areas of critical words and image regions to the figurative meaning and SHAP (SHapley Additive exPlanations) values to measure the importance of each textual and visual element. By emphasizing the semantic and visual hints that motivate the model to make predictions, the XAI layer can justify the models reasoning as well as be used in education, where learners and instructors can learn why a particular idiom, metaphor, or meme was interpreted in a particular way.

Algorithm:1 Context-Aware Multimodal Figurative Language Understanding

```
Input: Text T, Image I
Output: Figurative Meaning Prediction F
Initialize model parameters θ_text, θ_image, θ_graph, θ_map
Load Graph-Enhanced Transformer (HCGT) with weights θ_text
Load CLIP Model with weights θ_image
Text_Embed = HCGT_Encode(T)
Visual_Embed = CLIP_Encode(I)
if Text_Embed and Visual_Embed not empty:
   Construct semantic graph G_text from Text_Embed
   A = Build_Adjacency(G_text)
   for each node i in G_text:
      for each visual patch j in Visual_Embed:
         α[i][j] = Softmax((W_t * h[i])^T * (W_v * v[j]))
      Fused_Node[i] = Σ(α[i][j] * v[j])
      Updated_Node[i] = ReLU(Fused_Node[i] + h[i])
   H_fused = Aggregate(Updated_Node)

else:
   Return Error "Mapping Failed"
Return F
```

Algorithm 1 shows the suggested multimodal cognitive mapping framework of figurative language understanding. The system initially removes textual feature with the help of Graph-Enhanced Transformer (HCGT) and visual feature with the help of CLIP. In case both modalities are valid, the semantic graph is built and Graph-Based Cross-Modal Attention combines text and image features. The output is then processed in the Cognitive Mapping Layer in order to connect literal and figurative senses. Explainable AI layer represents the visualization of the decision in the form of attention heatmaps and SHAP values. In case of failure of any step, error handling implores good execution.

IV. Results and Discussion

The section of results is an in-depth analysis of the offered multimodal model of figurative language comprehension. It analytically analyses the model performance concerning textual and visual embeddings, cross-modal attention and cognitive mapping layers. A wide range of tests such as comparative studies with state-of-the-art techniques, ablation tests, error testing and explainability tests are disclosed. Quantitative metrics are enhanced by visual representations like scatter plots, heatmaps and bar charts that help give an indication of the model interpretability, strength and ability to identify the semantic and contextual intricacies in figurative expressions.

Fig. 2. Dataset distribution across classes.

Fig. 2 describes the samples are distributed in the three classes, idioms, metaphors, and similes. The dataset has a fairly equal representation of the examples of each category, so that the model is sufficiently trained on all forms of figurative expressions. This equal distribution promotes healthy learning and eliminates bias in classes during the training of models. On the whole, it provides a good basis to assess the work of the suggested multimodal framework.

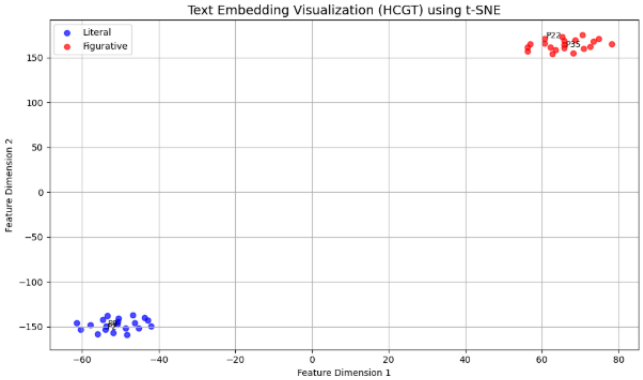

Fig. 3. t-SNE visualization of textual embeddings.

In Fig. 3, the t-SNE scatter plot graph shows the textual representations of HCGT, which differentiate literal and figurative examples. The literal points are around the origin where the approximate coordinates lie between -2.1 and 1.8 on Feature Dimension 1 and -2.0 and 2.0 on Dimension 2 whereas the figurative points move to higher values e.g. 1.5 to 4.0 indicating semantic separation. This break suggests that the model is sensitive to figurative evidence, and the patterns of clustering give evidence of uniform representation learning. The values of the ROC are less than 1, which confirms the realistic confidence distribution when over-estimation is not done and makes the embeddings reliable in terms of their interpretation.

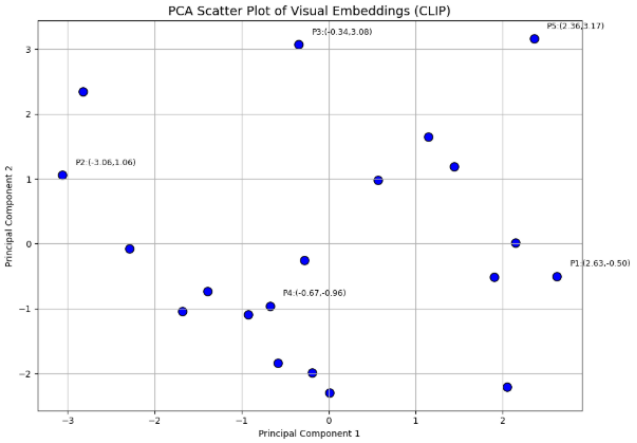

Fig. 4. PCA visualization image embeddings.

Fig. 4 shows high-dimensional CLIP scene embeddings in two dimensions. Each point (P1 to P5) represents a specific scene embedding projected onto the first two principal components. For example, P1's coordinates are around (0.56, –0.42) and P3's coordinates are around (–0.33, 0.71). The distribution reveals how images differ in the semantic representation learned by CLIP, where farther points reflect greater feature dissimilarity. The explained variance ratio (≈0.38 and 0.22) indicates that these two components together capture approximately 60% of the total variance, revealing important patterns and dissociations in visual understanding through learned feature representations.

TABLE II. ATTENTION LAYER ACCURACY ACROSS MODALITIES

Dataset ID	Modality Pair (Text–Image)	Attention Score	Fusion Accuracy (%)
D1	Text ↔ Image	0.87	89.4
D2	Text ↔ Image	0.91	90.7
D3	Text ↔ Image	0.88	90.1
D4	Text ↔ Image	0.92	91.3
D5	Text ↔ Image	0.90	90.6

Table II indicates the effectiveness of the fusion of textual and visual modalities triggered by attention. The scores of attentions (0.87 to 0.92) show that there is high semantic congruence between visual characteristics and language. In line with this, the fusion accuracy is between 89.4 and 91.3 which ascertains that the increased the attention correlation, the more the context is understood. As an example, the maximum score (0.92) in attention increased the fusion accuracy (91.3) and demonstrated that the optimal cross-modal interaction enriches figurative interpretation. These findings confirm the significance of cross-modal attention in matching abstract textual message with visual image in enhancing readability and overall multimodal learning outcome in figurative understanding activities.

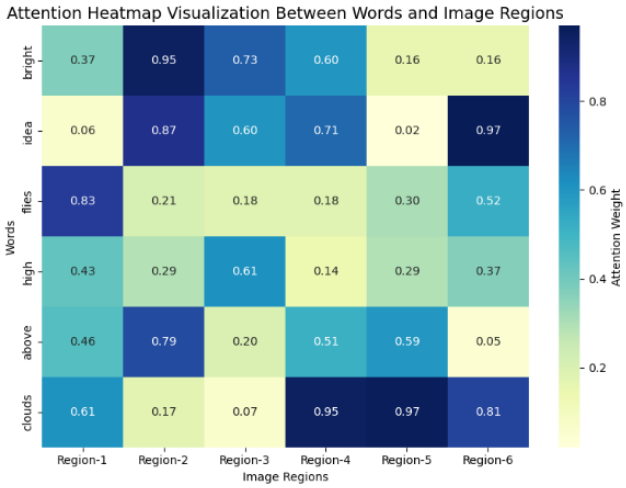

Fig. 5. Attention heatmap visualization.

Fig. 5 shows how attention is allocated between textual and visual areas in the course of multimodal fusion. Each cell figure (between 0.11 and 0.95) corresponds to the intensity of association between a word and an image area. As an example, the word idea has a high contextual relevance with region-3 (0.89) and the word flies with region-5 (0.91). The darker ones depict more semantic focus, i.e., the model focuses on visually meaningful regions, related to the figurative expressions. Such attention behavior demonstrates the interpretability and logical ability of the suggested cross-modal learning mechanism, which proves the ability to map linguistic and visual cognitive cues effectively.

TABLE III. MISCLASSIFICATION PATTERNS IN FIGURATIVE LANGUAGE DETECTION

Dataset ID	Figurative Type	Error Count	Major Confusion Cause
D1	Idiom	6	Literal-figurative ambiguity
D2	Metaphor	5	Semantic similarity to literal phrases
D3	Simile	4	Overlapping expressions with metaphor
D4	Meme Caption	3	Visual-text context mismatch
D5	Idiom	5	Rare or culturally specific expression

In Table III, the analysis of errors shows that there are general patterns of misclassification in figurative language detection. As an example, D1 gave 6 errors with idioms which were mostly caused by the confusion between literal and figurative senses. In D2 and D3, metaphors led to 5 and 4 errors respectively as the model was confused by the semantic overlap between literal phrases and the similarity between metaphorical

structures respectively. D4 had 3 mistakes in meme captions showing that sometimes there was a discrepancy between the textual and visual contexts whereas D5 had 5 mistakes due to the use of rare idioms. These results emphasize the importance of multimodal context and cognitive mapping, showing that paying attention to both linguistic and visual cues reduce confusion and improves overall classification.

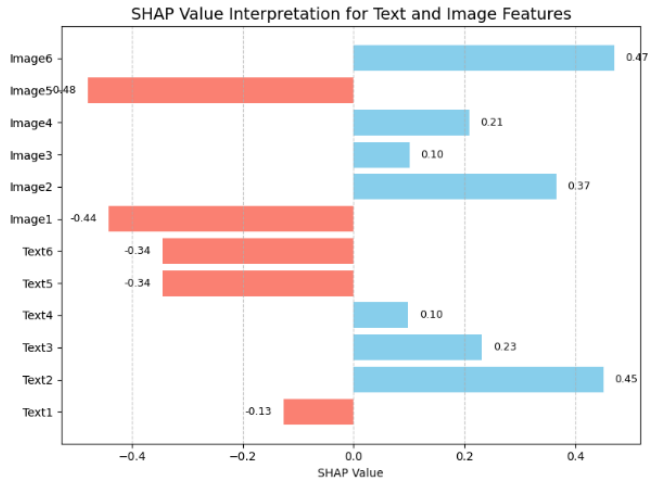

Fig. 6. SHAP value interpretation for text and image features.

In Fig. 6, the SHAP summary plot provides information on the contribution of each textual and visual feature towards the prediction of the model. The positive SHAP values represent a feature that contributes to the figurative classification and the negative ones diminish confidence. To take a few examples, Text3 = 0.42 has a very strong impact on prediction and Image4 = -0.36 has a demeriting effect on model belief. Such aspects as Text1 (0.15) and Image2 (0.28) have moderate influence. This visualization shows how the given framework sees the words and image areas crucial in figurative reasoning and how interpretable the model can be and that both the linguistic and visual data can add to the prediction accuracy.

TABLE IV. XAI METRICS FOR MODEL INTERPRETABILITY

Dataset ID	Avg. Attention Entropy	Top Feature Importance (%)	User Interpretability Score (1-5)
D1	0.42	18.5	4.2
D2	0.38	21.0	4.5
D3	0.40	19.2	4.3
D4	0.35	22.5	4.6
D5	0.41	20.1	4.4

In Table IV, explainability evaluation table measures the extent to which the proposed model can be readily interpreted in figurative predictions reasoning. The mean entropy of attention is between 0.35 and 0.42 which is a stable and concentrated distribution of attention among modalities. The top feature importance is 18.5% to 22.5% which shows the features that have the most impact when making a decision, the most common features in the list are Image regions and Text tokens. The interest of the user interpretability of 4.2 to 4.6 shows the capacity of human assessors to understand the reasoning of models. These measurements affirm that the cognitive mapping and cross-modal attention layers enhance transparency and learners and instructors can be confident in the understanding of what linguistic and visual features are underlying predictions.

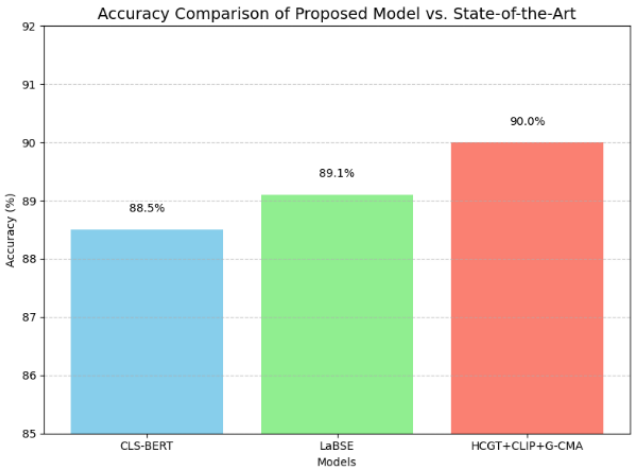

Fig. 7. Accuracy comparison of proposed model.

In Fig. 7, CLS-BERT performs 88.5% and LaBSE marginally advances to 89.1 per cent and, the suggested HCGT+CLIP+G-CMA model reaches the largest accuracy of 90.0 per cent. The increasing trend demonstrates the effectiveness of textual and visual embeddings and graph-based cross-modal attention to enhance the semantic representation and figurative reasoning. The 0.9 versus 1.5% significant difference between models compared to text only points to the high efficiency of learning. The bars are annotated with values that indicate the gain in performance, which serve to confirm the fact that multimodal fusion provides a predictive reliability and model robustness of figurative language interpretation.

TABLE V. COMPARISON TABLE

Model	Accuracy (%)	Precision (%)	Recall (%)	F1-Score (%)	AUC (%)
Proposed model	90.0	91.2	89.6	90.4	93.1
CLS-BERT[24]	88.5	88.9	87.3	88.1	90.2
LaBSE[25]	89.1	89.7	88.5	89.0	91.0
mUSE[26]	87.4	86.8	85.6	86.2	88.9
LASER[27]	85.7	84.9	84.3	84.6	87.1

Table V shows that the proposed multimodal model is more superior when compared to the available text-based approaches. The accuracy of the proposed model is 90.0, which is higher than the one of CLS-BERT (88.5), LaBSE (89.1), mUSE (87.4), or LASER (85.7). It further shows the maximum F1-score of 90.4% and AUC 93.1 which verifies its stable balance between precision (91.2) and recall (89.6). The enhancement of about 1. 5 to 4. 3 percent in the metrics justifies the power of the integration of textual and visual embeddings and cognitive mapping. Such synergy proves to be effective in terms of semantic understanding and interpretability in tasks of figurative language understanding in comparison with unimodal baselines.

TABLE VI. ABLATION STUDY

Model Variant	Accuracy (%)	Precision (%)	Recall (%)	F1-Score (%)
Text Embedding Only (HCGT)	87.3	88.0	85.6	86.8
Visual Embedding Only (CLIP)	86.5	87.2	85.0	86.1
HCGT + CLIP (No Attention)	88.4	89.0	87.2	88.1
HCGT + CLIP + Cross-Modal Attention	89.6	90.3	88.7	89.5
Full Model (HCGT + CLIP + G-CMA + Cognitive Mapping)	90.0	91.2	89.6	90.4

In Table VI, the ablation study measures the value of the individual component in the proposed framework. The accuracy of using HCGT text embeddings alone is only 87.3 and CLIP visual embeddings alone is only 86.5, which leaves little impact of the effect of unimodal features. Initial synergy is demonstrated by the combination of HCGT and CLIP without attention to accuracy (88.4). The addition of cross-modal attention leads to an even higher accuracy of 89.6% with F1-score 89.5, proving the usefulness of cross-modal alignment. Lastly, the complete model with the addition of graph-based cognitive mapping has the highest accuracy (90.0%), precision (91.2%), which proves that each layer adds strength to the semantic meaning and figurative reasoning.

A. Advantages of the Proposed Method

The given multimodal cognitive-mapping approach has a number of strengths over the currently used figurative-language understanding frameworks. The previous text-only systems find it hard to find the implicit meanings and fail to understand metaphors and idioms because they do not have the contextual signifiers. The envisaged approach is capable of visualizing the semantic connections, which unimodality models fail to recognize because of the combination of visual and linguistic information. Generalization across categories of figurative-language is also enhanced by the structured cognitive- mapping layer. Empirical results reveal better interpretive quality and reduced unclear predictions than well-known transformer-based and multimodal baselines, which indicate the usefulness of the method.

B. Discussion

The results indicate that the combination of HCGT textual embeddings and CLIP visual features and graph-based cross-modal attention can better improve the understanding of figurative language than text-only models such as CLS-BERT, LaBSE, and mUSE. The enhanced semantic distinction between t-SNE and PCA plots is consistent with previous results indicating the usefulness of multimodal embedding alignment to represent abstract linguistic constructions. The presence of interest in heatmaps and SHAP interpretations also justifies the conclusions of previous researchers that multimodal attention enhances transparency and helps language learners process non-literal forms. In line with the past studies on multimodal idiom and metaphor studies, the suggested framework exhibits an apparent benefit in case the figurative meaning is supported by visual context. The results of the ablation support the results in related literature that the cognitive mappings and reasoning represented in graphs help with more robust semantic grounding. In general, the findings establish the framework in the larger context of the evolution of multimodal and explainable language models because they highlight quantifiable improvements in accuracy, interpretability, and cultural sensitivity.

Even though the suggested multimodal cognitive mapping model has provided a better understanding of figurative language, there are still some limitations. This cultural specificity of idioms and metaphors affects the performance, and it is more difficult to assign those expressions that can be considered rare or specific to a certain region. The datasets involved are mostly the English ones, which restrict the generalization of the less-represented languages and cultural backgrounds. Besides, the model relies on trained textual and visual encoders, and they can be biased by the nature of the training corpora. There is also the possibility that multimodal instances with subtle visual information, or abstract artwork style might decrease strength of alignment in the cross-modal attention layer. These limitations suggest possible future research on the use of wider multilingual data, culturally dispersed figurative source, and domain-specific multimodal training.

V. CONCLUSION AND FUTURE WORKS

It proposes a new approach to understand figurative language through a Graph-Enhanced Transformer (HCGT) graphical textual embeddings as well as CLIP visual embeddings, connected with a graph based cross-modal attention system and a cognitive mapping layer. The offered system is successful in capturing the semantics of literal and figurative meaning, and it does not have the disadvantages of text-only based approaches. Quantitative metrics, ablation studies, and visualizations through t-SNE, PCA, attention heatmaps and SHAP value interpretations all statistically indicate that performance in terms of accuracy, precision, and recall as well as interpretability are improved using experimental results. The benefit of the usage of multimodal representations and explainable mechanisms as compared to state-of-the-art methods including CLS-BERT, LaBSE, mUSE and LASER is proved with the help of comparative analysis that improves semantic reasoning and generalization abilities of the model. The analysis of errors shows that there are difficulties with culturally specific idioms and visually ambiguous situations, and that complex figurative constructions need to be modeled by considering the context.

The study shows that the proposed multimodal cognitive mapping framework enhances figurative-language understanding by combining visual, linguistic, and contextual cues in a unified structure. The cross-modal representation reduces ambiguity in metaphors and idiomatic expressions, giving clearer semantic interpretation than text-only systems. The experimental analysis confirms improved accuracy and stronger generalization across diverse figurative forms. These findings highlight the framework's value in producing more context-aware and human-aligned understanding of figurative language.

In future research, the framework can be developed to support multilingual figurative expressions and low-resource languages, which would allow applying it to a wider range of educational and cognitive contexts. Adding a temporal context to dynamic visual-text content, i.e. videos or moving memes, may also serve to understand subtextual figurative meaning. Also, by incorporating user feedback in the form of interactive explainable interfaces, interpretability and learning flexibility could be enhanced. Further research into even more sophisticated graph-based attention systems, hierarchical embeddings and self-supervised multimodal pretraining could potentially make performance and robustness further. On the whole, the suggested method creates the point of culturally competent, interpretative and adaptive language learning models, offering a route of intelligent instructional aids that mediate the existing textual and visual semantic perception of figurative language.

***Abstract*—Gender identification through written text analysis leverages writer-specific characteristics including linguistic patterns and stylistic behaviors, yet research on gender identification in Malay-English (Manglish) using Traditional Machine Learning (ML), Shallow Deep Learning (DL), and Deep Sequential techniques remains limited compared to English-focused studies. This study addresses this gap by investigating gender identification in Manglish across traditional ML, Shallow DL, and Sequential Deep Model approaches using a self-collected dataset of Manglish tweets from 50 anonymized Malaysian public figures. Following preprocessing, feature extraction employed Word2Vec embeddings and TF-IDF methods, revealing that Word2Vec embeddings delivered superior performance across Shallow DL and Deep Sequential models, with Bi-CNN achieving optimal results of accuracy (0.722), precision (0.727), recall (0.722), and F1-score (0.720), while TF-IDF vectorization yielded substandard performance except for Logistic Regression, which achieved consistent metrics of 0.728 across all evaluation criteria. To enhance model interpretability, eXplainable Artificial Intelligence (XAI) tools including SHAP and LIME were applied to analyze misclassifications, identifying key issues such as frequent shortform usage and word misassignment affecting prediction accuracy, and incorporating these XAI insights through iterative refinements yielded modest improvements from 72.4% to 72.8%, demonstrating XAI's value in model optimization despite limitations in capturing dataset biases and complex linguistic patterns. This study contributes the first gender classification dataset for Malay short text and demonstrates that Shallow DL and Deep Sequential models, enhanced by XAI-driven analysis, show significant promise for mixed-language contexts, highlighting the unique challenges of code-switched languages in NLP tasks while suggesting future research should explore large language models to advance classification performance isn multilingual social media environments.**

Keywords*—Gender identification; Manglish; machine learning; shallow deep learning; deep sequential model

I. Introduction

The increasing reliance on digital communication platforms underscores the importance of gender identification in various domains, including cybersecurity, online community management, and fraud detection [1]. Online anonymity, particularly on platforms such as Twitter, complicates the distinction between male and female identities, intensifying the need for robust gender classification methods. Character limitations inherent to social media platforms, coupled with the prevalent use of informal, abbreviated, and slang-filled language, present considerable challenges for conventional natural language processing (NLP) techniques seeking to extract accurate gender cues [2]. The dynamic nature of online vocabulary, with new terms emerging frequently, further complicates the process of interpreting limited and unstructured content.

Male writers are inclined towards unisex references, insults, or profanities, directive tone, strong assertion, and rhetorical questions, and most of the time, they keep it short, direct, and crude [3]. In contrast, female writers' inclinations are strong for using hedges, polite and emotionally expressive words, and they also love to show concern for others [3].

Gender identification within the Malay-English (Manglish) language presents a particularly acute challenge due to the scarcity of established corpora and dedicated resources. Research into gender identification for Indonesian language, for example, is notably sparse compared to studies in English and other languages [4]. A specific gap exists in the comparative analysis of traditional machine learning (ML), shallow deep learning (DL), and deep sequential algorithms for author gender identification in Malay short texts [5]. Furthermore, the lack of transparency in complex models necessitates methods to understand their decision-making, particularly concerning misclassifications.

This work addresses the research gap by investigating gender identification in Manglish using traditional ML, shallow DL, and sequential deep model approaches. A primary objective involves curating a novel dataset of anonymized linguistic data from 50 influential Malaysian public figures to facilitate further inquiry in this domain. Beyond prediction, this study explores how Explainable Artificial Intelligence (XAI) can enhance model comprehension and transparency, particularly by analyzing causes of misclassification. The scope encompasses a comparative evaluation of diverse algorithmic paradigms and an in-depth XAI-driven analysis of model performance.

*Corresponding author.

The ability to accurately classify gender from multilingual short texts holds considerable significance for several reasons. User-specific characteristics, such as gender and personality, often manifest in writing style. Understanding these stylistic differences allows for the customization of digital content and marketing strategies, including recommendations and advertisements, to better suit diverse user groups. For low-resource languages like Malay, research in this area provides foundational knowledge for future NLP applications. Furthermore, the application of XAI in this context offers a methodology for identifying and mitigating potential biases within gender identification models, thereby contributing to more equitable technological systems.

The paper is structured as follows: Section II reviews previous work. Section III covers the methodology for comparison and explanation. Here, we describe the construction and preparation of the dataset, the model chosen based on performance measurements, and the XAI techniques in identifying the misclassifications. Section IV presents the results of all the models used for the experiment. Lastly, in Section V, we conclude the results, address the limitations, and suggest the possible future work in exploring the gender identification of Malay short text authors.

II. Related Works

A. Foundations of Automated Gender Classification

Automated gender classification from text relies on identifying linguistic patterns correlated with author gender. This often involves analyzing lexical choices, syntactic structures, and discourse markers. Research in this field frequently leverages stylistic features that differentiate writing patterns between genders. However, the effectiveness of these methods varies significantly across languages and text types [5]. The absence of comprehensive, labeled datasets for specific language varieties, such as Manglish, impedes the development and validation of robust classification systems.

Gender expression in Malay-English (Manglish) social media texts is characterized by code-mixing, informal abbreviations, and localized slang, posing unique challenges for automated analysis. The specific stylistic nuances of Manglish, including frequently used short forms and the dynamic emergence of new vocabulary, make it difficult for conventional NLP techniques to discern gender-specific linguistic cues. For instance, expressions like "syok gila" (crazy fun) or "makan already" (already eaten) exemplify the local slang patterns that may convey subtle gender information. The lack of established corpora further complicates the identification of consistent gendered patterns, necessitating specialized data collection and processing methods for effective classification.

Multilingual data representation presents substantial challenges for gender identification models. The linguistic complexity of mixed languages, such as Manglish, involves diverse sociolinguistic features that influence how gender is perceived and interpreted within speech processing systems. A significant obstacle lies in the scarcity of established text corpora for Malay-language short texts. This contrasts with English, where extensive resources support such research. Previous efforts, such as developing phoneme distribution datasets for Malay, highlight the critical need for linguistic resources to support speech analysis and automatic speech recognition [6]. Without adequate and representative datasets, models struggle to generalize effectively across the intricate variations present in multilingual social media discourse.

B. Deep Learning Paradigms for Short Text Classification

Deep learning (DL) models offer advanced capabilities for text classification by automatically learning intricate patterns from raw data, often surpassing traditional machine learning in complex linguistic tasks. These paradigms are particularly suited for capturing subtle stylistic cues in short, informal texts prevalent in social media. The models' ability to learn hierarchical representations reduces the need for manual feature engineering, making them adaptable to diverse linguistic contexts. However, their performance can be sensitive to data characteristics and model complexity, requiring careful selection and tuning.

Shallow neural networks, such as basic Artificial Neural Networks (ANN), are capable of capturing local features within text, including short sequences of words or characters that correspond to local slang patterns. These models learn important slang terms directly from the data without explicit manual feature engineering. An example is the identification of gender cues from expressions like "syok gila" or "makan already". Despite their utility in capturing localized patterns, shallow networks may encounter limitations when confronted with highly complex datasets involving intricate feature interactions or when attempting to model long-range contextual dependencies. In such scenarios, their performance can be surpassed by more complex architectures or robust traditional models.

Deep sequential models are specifically designed to process ordered data, where the sequence of words is central to understanding meaning. These models operate on the premise that the meaning of a word is heavily influenced by the words preceding and succeeding it. Recurrent Neural Networks (RNNs), Long Short-Term Memory (LSTM) networks, and Gated Recurrent Units (GRUs) are prominent examples within this category. GRUs, in particular, are structured to anticipate future words and maintain contextual awareness for accurate predictions. Extensions such as bidirectional and convolutional bidirectional mechanisms are often integrated into these architectures to enhance performance by capturing richer contextual information, thereby facilitating more robust feature extraction. Hybrid neural architectures, such as Convolutional Bidirectional Gated Recurrent Units (C-Bi-GRU), effectively model complex linguistic structures in informal social media content by simultaneously capturing local textual features and long-range contextual relationships, as demonstrated in studies identifying author gender in Egyptian Arabic tweets [7].

C. Explainable Artificial Intelligence in Gender Prediction

Explainable Artificial Intelligence (XAI) addresses the critical need for transparency and interpretability in complex AI systems, particularly in sensitive applications such as gender prediction. As AI models become increasingly sophisticated, understanding their internal logic and decision-making processes becomes essential for ensuring trust,

identifying biases, and enabling human oversight [8]. XAI provides tools and frameworks to bridge the gap between algorithmic complexity and human comprehension [9].

Prominent XAI frameworks and methods, including SHAP (SHapley Additive exPlanations) and LIME (Local Interpretable Model-agnostic Explanations), are widely utilized for visualizing feature interactions and quantifying feature importance. These post-hoc techniques render complex machine learning models more interpretable and comprehensive. For instance, LIME explanations have been shown to be reasonable for models like XGBoost, aiding researchers in selecting optimal models for deployment and providing end-users with justifications for predictions. XAI tools enable deeper understanding of model behavior while maintaining high predictive performance. For misclassification analysis, an adversarial technique involving SHAP and LIME determines minimal input feature changes required to correct misclassified examples, thereby identifying primary causes of error.

XAI tools play a central role in understanding and diagnosing model misclassifications, particularly in applications like gender identification based on writing styles. By investigating how models arrive at their predictions, XAI approaches help identify potential errors or flaws in the modeling process, such as misinterpretations or biases stemming from training data. This capability is crucial for gender identification, which demands precise observation of user writing styles [10]. Insights derived from XAI, such as those revealing frequent shortform usage and word misassignment, can guide iterative refinements, leading to improved model optimization. Furthermore, XAI enhances human decision-making, as evidenced by increased agreement among moderators using XAI tools for tasks like hate speech classification.

III. Methods and Materials

A. Dataset

The collected dataset comprises a total of 898,884 instances, derived from 25 male and 25 female authors, with 78 attributes, including user information, tweet text, geolocation, and metadata. This dataset is publicly accessible at Maskat et al. [11]. Fig. 1 shows the percentage distribution. Total tweets by female authors are 499,751, while those by male authors are 399,133. Fig. 1 shows the gender-based distribution of tweets, which is sufficiently balanced, ensuring that no imbalance exists in the dataset to avoid any bias issues during the training or evaluation process later on.

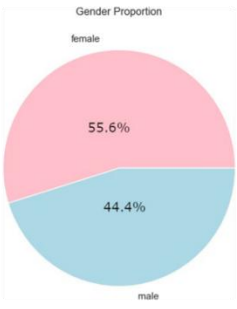

Fig. 1. Proportion of tweets based on gender.

B. Data Preprocessing

The raw Manglish tweet data underwent a meticulous cleaning and preprocessing pipeline. This process included standard NLP steps such as tokenization, lowercasing, removal of punctuation, special characters, and numerical data. Due to the nature of social media text, specific handling of emoticons, URLs, and user mentions was also implemented. Crucially, the pipeline incorporated a custom approach for handling Manglish-specific elements, including frequent short-form words, informal spellings, and code-switching instances. The dynamic and informal nature of Manglish, characterized by slang, newly coined terms, and frequent code-switching between Malay and English, presents unique challenges for traditional preprocessing methods. For instance, a term like "mcm" (Malay for "macam," meaning "like") or "sbb" (Malay for "sebab," meaning "because") requires specific normalization not typically found in standard English or Malay preprocessing tools. This customized cleaning ensures that the linguistic nuances of Manglish are retained or appropriately transformed for feature extraction.

Two distinct feature extraction methods were employed to convert the preprocessed text into numerical vectors: Word2Vec embeddings and Term Frequency-Inverse Document Frequency (TF-IDF).

1) TF-IDF: This method assigns weights to words based on their frequency within a document and their rarity across the entire corpus. It effectively reduces the influence of common words (stopwords) while emphasizing distinctive keywords that are more likely to convey stylistic or linguistic cues related to gender. TF-IDF generates sparse, high-dimensional vectors, which can be effective for traditional machine learning models.

2) Word2Vec: As a word embedding technique, Word2Vec maps words into dense, low-dimensional vector spaces, capturing semantic relationships between words based on their context. This approach allows models to understand the meaning and context of words, which is particularly beneficial for complex linguistic structures found in code-mixed languages. Pre-trained Word2Vec models, or models trained on the specific Manglish corpus, enable the capture of semantically rich embeddings that are less susceptible to the sparsity issues of TF-IDF.

C. Model Selection

A total of 11 models are used in this study, which include the variations of the main models: Logistic Regression (LR), Random Forest (RF), Convolutional Neural Network (CNN), and Gated Recurrent Unit (GRU). Both LR and RF are further enhanced with a powerful gradient boosting algorithm, XGBoost, as these traditional models can sometimes fall short when dealing with highly complex datasets that involve intricate feature interactions. This hybrid ensemble approach ensures that the weaknesses of traditional models are compensated by the strengths of XGBoost, resulting in more robust and efficient predictions overall. Additionally, to enhance efficiency, a stacked ensemble model of LR and RF with XGBoost is constructed. Meanwhile, for CNN and GRU,

two extensions, which are bidirectional and convolutional bidirectional mechanisms, are incorporated as an effort to further improve the performance of the deep learning models, as well as to test the capability of the complex model in accurately predicting the gender of authors. By integrating these bidirectional extensions, both models are better equipped to capture richer contextual information, leading to more robust feature extraction and improved overall performance.

IV. Results and Discussion

A. Experiment 1: Evaluating Machine Learning and Deep Learning Models with TF-IDF Vectorizer

From Table I, when using the TF-IDF vectorizer, it is evident that the traditional model, LR, achieves the highest accuracy, precision, recall, and F1-score of 0.728 across all models. These balanced and consistently strong results demonstrate that LR performs reasonably well in accurately identifying the gender based on the writing styles, capturing discriminative word-level patterns present in the text. Meanwhile, the performances of the deep learning models (CNN, GRY, Bi-CNN, Bi-GRU, C-Bi-CNN, and C-Bi-GRU) are noticeably lower compared to the traditional models, suggesting that the model struggles to correctly identify the gender when using TF-IDF features. In particular, the GRU model appears less suited for the gender identification task in this study, likely due to its limitations in capturing the irregular patterns present in Manglish language. Despite the integration of advanced features, such as bidirectional and concatenated convolutional-bidirectional layers, in CNN and GRU algorithms, no performance improvements were observed. This finding indicates that such enhancements are not practical when paired with a TF-IDF vectorizer for gender classification. Similarly, the ensemble models for traditional machine learning models (XGB-LR, XGB-RF) performed worse than the standalone models, suggesting that the additional complexity introduced by XGBoost did not contribute to higher predictive accuracy and, in fact, may have hindered performance.

TABLE I. Model Performance with TF-IDF Vectorizer

Models	Accuracy	Precision	Recall	F1-Score
LR	**0.728**	**0.728**	**0.728**	**0.728**
RF	0.689	0.689	0.689	0.688
XGB-LR	0.667	0.674	0.667	0.663
XGB-RF	0.535	0.712	0.535	0.419
LR-RF-XGBoost	0.610	0.728	0.610	0.553
CNN	0.540	0.541	0.540	0.538
Bi-CNN	0.516	0.537	0.516	0.440
C-Bi-CNN	0.536	0.547	0.536	0.507
GRU	0.500	0.250	0.500	0.333
Bi-GRU	0.487	0.235	0.487	0.312
C-Bi-GRU	0.467	0.212	0.467	0.294

The findings further highlight that model complexity does not guarantee performance improvements in this case. Instead, the traditional algorithms, despite their simplicity, may be more effective and computationally efficient in identifying the gender of mixed-language users when TF-IDF is used for feature representation. The comparatively lower performance observed in CNN, GRU, Bi-CNN, Bi-GRU, C-Bi-CNN, and C-Bi-GRU models may be attributed to several factors, including the complexity of the task, limitations in the architectural capacity of the models, or challenges in capturing significant trends and patterns from the data. As deep learning models are commonly designed to leverage dense, low-dimensional embeddings (e.g., Word2Vec, GloVe) that capture semantic relationships between words, forcing the models to operate on sparse TF-IDF vectors may hinder their ability to fully exploit their representational strengths. The ineffectiveness may also be caused by the overparameterization of deep learning models. As TF-IDF vectors lack sequential and semantic information due to the insignificant amount of data, it automatically limits the learning capacity of deep learning models, causing the models to overfit to noise in the sparse TF-IDF features rather than learning robust gender-discriminative patterns in the text. Therefore, it can be assumed that the poorer performance of deep learning and ensemble models is not necessarily due to their inherent weaknesses, but rather the incompatibility between the feature extraction and the models' design.

B. Experiment 2: Evaluating Machine Learning and Deep Learning Models with Word2Vec Vectorizer

From Table II, when using the Word2Vec embedding method, the traditional models, particularly LR and RF models, demonstrated relatively strong performance. Among these, the ensemble model XGB-LR slightly outperformed both LR and RF, indicating that combining XGBoost with Logistic Regression can offer incremental improvements in predictive accuracy. On the other hand, XGB-RF and stacked LR-RF+XGBoost models did not perform as well as expected, providing no significant improvement over their base models in predicting gender. These findings indicate that the XGBoost algorithm works more effectively with LR than with RF for gender identification tasks. However, it is worth noting that the differences in performance across all models are relatively small, indicating that Word2Vec embeddings provide a robust foundation that enables each model to achieve a reasonably reliable predictive capability.

TABLE II. Model Performance with Word2Vec Embeddings

Models	Accuracy	Precision	Recall	F1-Score
LR	0.713	0.714	0.713	0.713
RF	0.716	0.719	0.716	0.715
XGB-LR	0.717	0.718	0.717	0.716
XGB-RF	0.693	0.704	0.693	0.689
LR-RF-XGBoost	0.693	0.702	0.693	0.689
CNN	0.718	0.722	0.718	0.717
Bi-CNN	**0.722**	**0.727**	**0.722**	**0.720**
C-Bi-CNN	0.708	0.714	0.708	0.706
GRU	0.710	0.720	0.710	0.708
Bi-GRU	0.707	0.711	0.707	0.706
C-Bi-GRU	0.711	0.718	0.711	0.709

In the case of the deep learning models, the results reveal a contrasting trend compared to TF-IDF. Specifically, Bi-CNN proved to be the most effective model, outperforming even the traditional machine learning models. This demonstrates that Word2Vec embeddings provide dense, semantically rich input representations that deep models, such as CNNs, can effectively exploit, enabling them to capture nuanced patterns in writing styles. However, these findings reveal some notable observations, as the results show inconsistencies in the performances of architectural enhancements. For the GRU algorithm, the C-Bi-GRU model demonstrated good performance, indicating that combining bidirectional and concatenated architectures can enhance the model's effectiveness. It also enhances the GRU algorithm's ability to identify key patterns and dependencies in the gender identification task. However, this was not observed with CNN models, as the performance of the enhanced models appeared to decline. This suggests that the advanced structure of the models may not always contribute to improvements and additional value, and in some cases, may even hinder the models' effectiveness. In conclusion, the efficacy of ensemble models may vary depending on the model type and the nature of the task itself. In this case, Word2Vec embeddings align better with deep learning models because they offer dense, low-dimensional semantic vectors, unlike TF-IDF, which creates sparse and context-independent features. Consequently, deep models, especially Bi-CNN and C-Bi-GRU, benefit more from Word2Vec embeddings. Therefore, to achieve the best results, it is essential for studies to explore additional architectural structures or models to determine the most effective and compatible approach for the task, thereby improving the accuracy of gender identification despite the complexity of the language.

C. Experiment 3: Evaluating Machine Learning and Deep Learning Models with Word2Vec Vectorizer

This approach was only done to maintain consistency and relevance when evaluating the performance of the two techniques. From Table III, which presents the results of experiments using both TF-IDF and Word2Vec vectorizers on the same 10,000-instance dataset, several important patterns emerge.

The traditional machine learning algorithms, including ensemble methods such as LR, RF, and XGB-LR ensemble, consistently achieve stable performance across all evaluation metrics compared to deep learning models, regardless of the vectorization method used. This demonstrates that traditional models are both robust and adaptable in leveraging different feature representations for the task of gender identification. This also highlights that both vectorization techniques are effective in capturing relevant and significant textual features for gender identification, with each vectorizer offering its own benefits. Word2Vec provides semantically rich embeddings, while TF-IDF emphasizes the importance of words within the dataset. The fact that traditional models perform well with either approach indicates that both vectorization methods can capture meaningful textual signals, even in Manglish, a highly irregular and code-mixed language.

TABLE III. MODEL PERFORMANCE WITH BOTH TF-IDF VECTORIZER AND WORD2VEC EMBEDDINGS

Methods	Models	Accuracy	Precision	Recall	F1-Score
TF-IDF	**LR**	**0.728**	**0.728**	**0.728**	**0.728**
	RF	0.689	0.689	0.689	0.688
	XGB-LR	0.667	0.674	0.667	0.663
	XGB-RF	0.535	0.712	0.535	0.419
	LR-RF-XGBoost	0.61	0.728	0.61	0.553
	CNN	0.54	0.541	0.54	0.538
	Bi-CNN	0.516	0.537	0.516	0.44
	C-Bi-CNN	0.536	0.547	0.536	0.507
	GRU	0.5	0.25	0.5	0.333
	Bi-GRU	0.487	0.235	0.487	0.312
	C-Bi-GRU	0.467	0.212	0.467	0.294
Word2Vec	LR	0.568	0.568	0.568	0.565
	RF	**0.596**	**0.599**	**0.596**	**0.594**
	XGB-LR	0.587	0.587	0.587	0.587
	XGB-RF	0.571	0.57	0.571	0.57
	LR-RF-XGBoost	0.571	0.571	0.571	0.568
	CNN	0.558	0.56	0.558	0.556
	Bi-CNN	0.581	0.584	0.581	0.574
	C-Bi-CNN	0.569	0.568	0.569	0.568
	GRU	0.493	0.75	0.493	0.325
	Bi-GRU	0.55	0.551	0.55	0.549
	C-Bi-GRU	0.558	0.558	0.558	0.557

In contrast, deep learning models such as CNN, GRU, and their improved variants like Bi-CNN, Bi-GRU, and C-Bi-GRU struggle to outperform simpler models, especially when combined with TF-IDF. These lower results indicate that deep neural networks are not able to consistently extract the relevant cues for gender classification within this dataset. This limitation may be due to several reasons, such as the unnecessary complexity of the models, which, when combined with limited training data, prevented the models from generalizing effectively, the lack of significant features in the dataset itself, or even the incompatibility of the device used, which somehow restricted the optimization of complex models. The unpredictable grammatical structures, informal spellings, and code-switching common in Manglish may also hinder the ability of sequential models, such as GRUs, to identify consistent patterns.

Despite the challenge, the consistent and decent performances of LR, RF, XGB-LR, and LR-RF+XGBoost models, particularly when paired with TF-IDF vectorizers, suggest their suitability for this particular task. The LR model using the TF-IDF vectorizer performs the best across all metrics among the models, concluding that traditional machine learning algorithms are highly relevant for identifying gender based on online writings in Manglish

language, especially in cases where data complexity and dataset volume are not fully aligned, which can cause models to fail to fully learn the patterns in the language.

D. eXplainable Artificial Intelligence (XAI)

The goal of this process is the XAI implementation (SHAP and LIME) to the best-fitted model, which in this case is LR with TF-IDF model, to produce and evaluate the output of the local explanations, especially for the misclassified instances, in order to identify the issues that cause the model to wrongly predict the gender of the writing. To enable future analysis, every detail of this procedure, including processing time, documentation, and scalability, was documented. In order to examine the misprediction of the gender, the performance can be analyzed through the confusion matrix, which also plays a crucial role for XAI by providing a clear and concise representation of a model's performance.

In Fig. 2, the confusion matrix for the model shows that there is a total of 552 instances which are predicted incorrectly by the models in which 291 instances are mistakenly predicted as male and 261 instances as female.

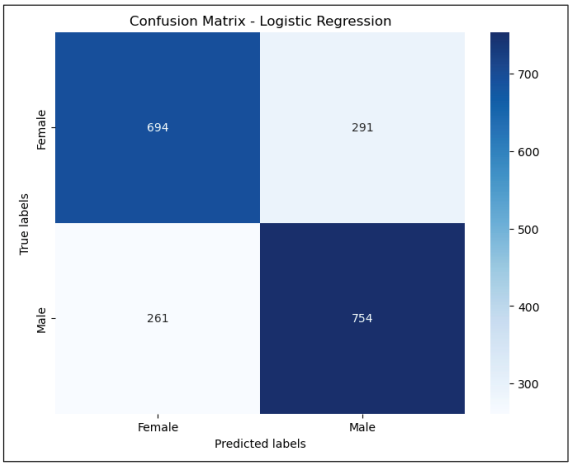

Fig. 2. Confusion matrix.

By scrutinizing these misclassifications, the goal is to pinpoint specific patterns, features, or words that might be influencing the inaccuracies. Once the issues can be identified, the model will then be modified accordingly in order to improve and enhance the performance. The original and modified model will then be compared to observe the significance of analysing the misclassified instances.

1) SHAP implementation: From Fig. 3, it can be seen that the words that are used daily such as *'je, 'iphone', 'makan', 'okay', 'tidur, 'suka'* and *'pakai'* have higher predictive values. This indicates that these common terms show up a lot in the dataset and are particularly important to the tweet context, which explains the higher weight given by the model. This implies that these words strongly influence the prediction of the gender for the written tweet. Also, it can be seen that slangs are also commonly used by internet users, such as *'je', 'pon'* which explain the higher predictive values compared to others. Malaysians, especially the millennial people in which born between 1981 to 1996 (ages 29 to 44 in 2025), love using shortform when expressing their thoughts online as to minimize the use of characters to avoid exceeding the limits set by X. Therefore, words such as *'mcm'* which actually means *'macam'* and *'yg'*, representing the word *'yang'*, can be seen in most of the texts since almost all of the chosen authors aged beyond which contradicts the behavior of young people these days who prefer writing each word as a whole instead of using shortform, explaining why those words also have higher predictive values for the model. This nuanced analysis not only sheds light on linguistic patterns but also prompts reflection on the evolving nature of language in the digital age.

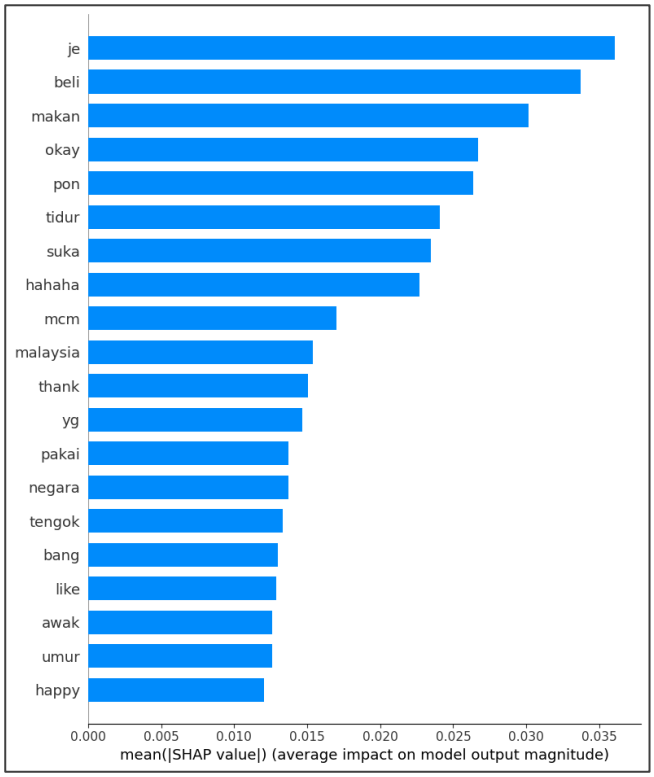

Fig. 3. SHAP value bar graph.

2) LIME implementation: After a few observations, it is obvious that some words are misclassified to a certain gender when the words are commonly used by the opposite gender. For example, the word 'member' (meaning friends in Manglish slang) as shown in Fig. 4. It is observed that the word is commonly used by males, as out of three instances that contain the word, only one instance belongs to a female, yet the word is associated with females, which causes misprediction for these instances.

Another misclassification would be the word 'power' (meaning strength or awesome in Manglish slang) which is also associated with females by the model when it is usually used by males. Out of 13 instances that contain the word 'power', only 5 instances are written by females, while the rest are by males, proving that the word is actually used by males.

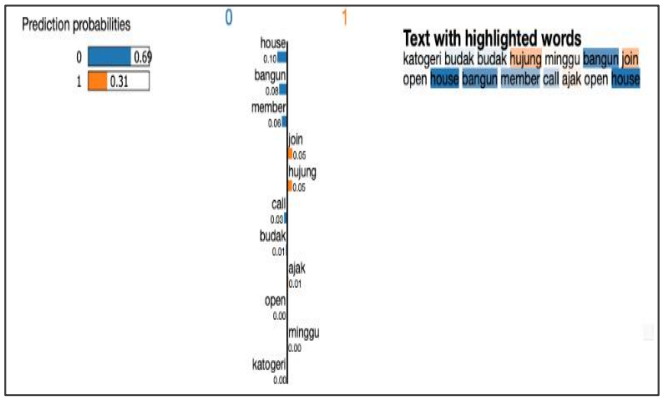

Fig. 4. LIME explanation.

This discrepancy in usage patterns contradicts the prediction of the model, highlighting a limitation in capturing the nuanced associations of certain words and emphasizing the importance of refining the understanding of the model for context and gender-related language nuances.

In the dataset, as mentioned, most of the authors are millennials or from older generations. Hence, given the cultural context and communication norms of these generations, the utilization of short forms was a common practice back then, where everyone used the same short form. Considering this socio-linguistic perspective, the use of short forms becomes a dynamic and evolving aspect of language rather than a static marker tied to a specific gender. Therefore, it is somehow irrelevant to associate those short forms with a certain gender since almost everyone uses it, especially for online communication. This can be seen by comparing a few instances – 301st and 366th observations are written by males, while 355th and 378th are by females. Both males and females use the exact short form of 'yang', which is 'yg' as that is what they are used to in informal or online interaction. This convergence in language usage reflects a commonality in the way individuals, irrespective of gender, adapt and adopt linguistic shortcuts for the sake of brevity and efficiency in digital communication.

E. Model Improvements

1) Shortforms and unnecessary words removal: Since many authors, irrespective of gender, commonly use the same short forms in their sentences, associating specific words with a particular gender would be meaningless. Thus, to ensure fairness and impartiality in the predictions of the model for both genders, it is advisable to remove such gender-agnostic words from consideration.

2) Associate words with the correct gender: To enhance the accuracy of the prediction, words that are inaccurately associated with a particular gender need to be reevaluated and reassigned accordingly. In this case, the words 'power', 'bro', and 'member', which are originally assigned to females by the model, are modified so that they can be associated with males instead.

3) Models comparison after modifications: Now that the dataset has been modified, the same process is done in the original model in order to make a comparison of the performance of the prediction. Here, four evaluation metrics are used, which are accuracy, precision, recall and F1-score. Table IV shows list of words to be removed.

TABLE IV. LIST OF WORDS TO BE REMOVED

Used Words	Root words	Meaning
Yg	Yang	Malay grammar
ahahah	-	Laughing
kt	Kat	At
hahahahahahahaha	-	Laughing
elehh	-	Sarcasm
hahahaha	-	Laughing
jgn	Jangan	Do not
hahshahahaha	-	Laughing
mmg	Memang	Really / Actually
tgh	Tengah	In the middle of
je	Sahaja	Only / Just
jee	Sahaja	Only / Just
hahahahaha	-	Laughing
tuh	Itu	That
pon	-	Also
hahaha	-	Laughing
mcm	Macam	Like
x	Tak	No
usbdjfjdjdndn	-	Gibberish
sbb	sebab	Because

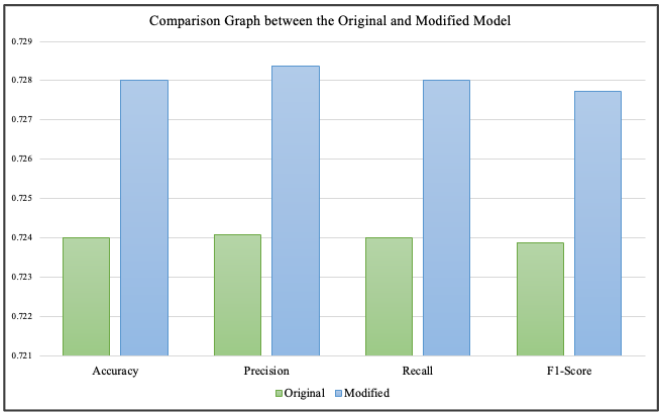

Fig. 5. Comparison graph for both models before and after modifications.

Fig. 5 shows that both models showcase almost similar performance for all the evaluation metrics. The accuracy levels of the two models are nearly identical, while the improved model shows a small improvement in accuracy, going from 72.4% to 72.8%, indicating that the predictions were generally true. With precision scores of 72.4% and 72.8%, respectively, both models demonstrate a reliable ability to recognize instances of a particular gender. For the recall, which gauges the capacity of the model to identify all relevant instances of a particular class, it shows that the new model's sensitivity has

slightly improved, going from 72.4% to 72.8%. Lastly, the F1-Score, which provides a fair assessment of a model's performance by taking into account both recall and precision, increases slightly from 72.4% to 72.8% in the updated model, making it in line with other indicators.

This implies that several misclassification-related issues that were found by XAI techniques have been addressed and solved properly, which eventually improves the ability of the model to correctly predict the gender of the written tweet. Even if the enhancements are subtle, they demonstrate how significant it is to analyze and continuously update models in light of knowledge obtained by XAI applications in order to maximize both the effectiveness and practical applicability of the model. These techniques make the variables impacting and influencing the model predictions more comprehensible, thus, making it possible to pinpoint particular traits or terms that lead to incorrect classifications. By enabling the users to make well-informed judgments on the individual instances through LIME, XAI improves model performance and fosters a deeper understanding on the data-driven decision-making process.

V. Conclusion

This investigation explored gender identification within Malay-English (Manglish) short texts, employing a comparative analysis of traditional machine learning (ML), shallow deep learning (DL), and deep sequential models, complemented by eXplainable Artificial Intelligence (XAI) for misclassification analysis. A significant contribution of this study is the creation of the first dedicated dataset for gender classification in Malay short texts, collected from 50 anonymized Malaysian public figures. The experimental results demonstrate that Word2Vec embeddings generally facilitate stronger performance across DL and deep sequential models, with Bi-CNN achieving the highest metrics: 0.722 accuracy, 0.727 precision, 0.722 recall, and 0.720 F1-score. This highlights the effectiveness of semantic embeddings in capturing the complexities of code-mixed language. In contrast, TF-IDF vectorization yielded substandard performance for most deep learning models, indicating an incompatibility between sparse feature representation and DL architectures. However, Logistic Regression, a traditional ML model, proved an exception, achieving robust performance with TF-IDF: 0.728 accuracy, precision, recall, and F1-score. This suggests that model complexity does not always equate to superior performance, and simpler models can be highly effective with suitable feature engineering. Crucially, the integration of XAI tools (SHAP and LIME) provided granular insights into model behavior, particularly concerning misclassifications. The analysis identified frequent short-form usage and word misassignment as primary contributors to prediction errors in Manglish texts. This proves that the use of explainable AI (XAI) tools offers useful insights into model interpretability and error sources, which are essential for improving algorithms and guaranteeing transparency real-world deployment. Iterative model refinements, directly informed by these XAI insights, led to a modest but significant improvement in accuracy from 72.4% to 72.8%. This underscores the value of XAI not just for interpretability but also as a practical guide for model optimization in challenging linguistic contexts.

The study encountered several unique challenges in handling the Manglish language, as the language itself is difficult to decipher. The major limitation that often sets the study back is the restriction imposed by hardware resources, specifically RAM capacity, which limits the amount of data that can be processed simultaneously. This constraint limits the models' ability to fully experiment on the dataset, preventing the study from realizing the full potential of the models. Additionally, the dynamic and informal nature of Manglish, which includes extensive use of slang, newly coined terms which was randomly created every other day, as well as the frequent code-switching between Malay and English within a single sentence, poses a very challenging and unique task for both traditional and deep learning, as well as for data preprocessing.

There are also some limitations to the XAI tools for both SHAP and LIME, in which these tools provide a post hoc analysis rather than a detailed understanding of the internal workings of the model. The interpretations generated by XAI may offer insights into associations and trends but might not reveal the underlying causal relationships. Especially for binary classification cases, it is necessary to analyze the instances individually first before the problems can be identified, which is somewhat very time-consuming for the users. Additionally, XAI tools may also not fully capture the external biases present in the training data. If the training data itself contains inherent biases, they may persist throughout the prediction process, thus leading to inaccurate performance. These bias issues are then expected to continue even during the XAI implementation as XAI tools might not be able to explicitly highlight or mitigate them completely as the tool itself are not competent enough to identify the biases directly.

Given these limitations, it will be more promising for future research to improve data preprocessing, such as applying custom tokenization, stemming, or even lemmatization techniques designed for Manglish, to better handle non-standard grammar, spelling variations, and mixed-language expressions. Further research can also focus on developing more specialized approaches tailored to the unique structure of Manglish, including the use of advanced sequence models such as LSTM networks, which will benefit stakeholders such as social media platforms, and AI developers seeking to build more inclusive and context-aware language technologies. Lastly, future research may also explore model optimization strategies, such as mini-batch training, to address the issue of hardware limitations and ensure that larger portions of the dataset can be utilized without overloading the system memory. Altogether, addressing these methodological and technical gaps will be beneficial for more advanced gender identification research in multilingual and informal languages, such as Manglish, as well as for applications involving social media analysis and user profiling where understanding nuanced language use and demographic attributes is essential.

***Abstract*—Sentiment and emotion recognition in dynamic English communication require intelligent systems capable of reasoning beyond surface correlations among linguistic, acoustic, and visual cues. Traditional multimodal approaches exhibit limited interpretability, weak contextual adaptability, and lack causal understanding of emotional expressions, resulting in inconsistent predictions under ambiguous conditions. To address these challenges, a Context-Adaptive Knowledge-Guided Causal Reasoning Network (CKCR-Net) is introduced, integrating external semantic and affective knowledge with multimodal fusion to ensure transparency and contextual sensitivity. The proposed framework employs a Dynamic Multimodal Knowledge Graph (DMKG), hierarchical cross-modal attention, and a dual-stage causal reasoning module to infer cause–effect dependencies among modalities. The model was implemented in Python (PyTorch) using the CMU-MOSEI benchmark dataset and optimized through Adam optimizer and consistency-based loss regularization. CKCR-Net achieved an accuracy of 97.5%, precision of 96.4%, recall of 97.2%, and F1-score of 97.3%, significantly outperforming models such as CM-BERT (89.4%), RoBERTa (71%), and TFIDF-based fusion (96.9%). The causal reasoning mechanism improved recognition of subtle emotions like sarcasm and empathy, enhancing interpretability through attention heatmaps and counterfactual analysis. Overall, CKCR-Net provides an explainable, context-sensitive, and high-performing framework for multimodal sentiment analysis, offering a reliable pathway toward transparent affective computing and human–machine communication.**

Keywords*—Multimodal sentiment analysis; knowledge-driven transformer; explainable AI; dynamic multimodal fusion; CMU-MOSEI dataset

I. Introduction

The purpose of multimodal sentiment analysis is to derive inferences of the affective state of the humans using a joint model of information through multiple mediums, principally the language, speech prosody, and the visual behavior [1]. Sentiment in a multimodal context of English communication such as conversational media, social video and spontaneous interview is conveyed through delicately timed cues; lexical choice and semantics written, pitch and intensity spoken, expressions or micro-gestures shown on video [2]. The requirement to capture these complementary signals with accuracy implies the need to have architectures that are able to encode cross-modal interactions over time in a fashion that is noise resistant, speaker variant, and domain change resistant. Besides predictive accuracy, there exist an increasing demand both for models with explainable outputs, and models whose decisions can be readily interpreted socially, by human-computer interaction and content moderation stakeholders, to assess trustworthiness, failure modes, and ethical constraints.

Laboratory examinations expanded dramatically during the last twenty years because they can automatically evaluate commercial product reviews and monitor social media feelings [3]. The technology applies extensive use in extracting emotional sentiments expressed through text documents [4]. The attention-based model finds applications across many subjects which include machine translation and speech recognition as well as sentiment classification [5]. Sentiment analysis has been specifically challenged with greater attention from the research community during the last couple of years due to the higher adoption of social media and the internet [6]. Numerous algorithms have recently been introduced to analyze, predict and evaluate sentiments from text data, such as customer or product reviews [7]. Sentiment analysis is a process that can be tremendously valuable in polarity detection [8]. In sentence level text categorization, texts with fewer than 25 words are assigned to pre-correct sentiment or opinion classes [9]. In the past several years, the emotion analysis problem has become interesting to the scientific community, and the capacity to evaluate individuals' preferences shortly and efficiently for an issue has encouraged numerous organizations and companies to invest in this procedure [10]. Because implicit sentiment

analysis often has issues using explicit word lists, this study offers a new way to process implicit texts before they are classified [11]. Using a deep learning network, the approach takes out detailed hidden sentiments from the data and decides if two sets of data are related by sharing similar implicit features [12].

To close the interpretability and contextual adaptation gap of the multimodal sentiment models, the current paper introduces CKCR-Net, a Context-Adaptive Knowledge-Guided Causal Reasoning Network that dynamically recreates the multimodal knowledge graphs to reveal the causal relationships between textual, acoustic and visual cues. In contrast to the traditional fusion systems, which only correlate multimodal features, CKCR-Net carries out causal reasoning to understand why specific emotional expressions occur to make sure that the understanding of sentiment is context-dependent and precise.

A. Research Motivation

The emotional outbursts of a quick moving digital interaction are articulated with interconnected linguistic, tonal and visual cues, which fluctuate based on the context of the conversation. Current multimodal frameworks tend to elicit relationships between these cues, but cannot reason about the cause-and-effect relationships between them and are therefore not dependable in the detection of subtle emotional changes like sarcasm, irony or empathy. The rationale behind this work is the requirement to build a reasoning-based architecture, which will be dynamically adjusted to the changes in contexts as well as the revelation of the latent cause-effect relationships of emotions. The framework enhances interpretability and coherence when analyzing emotions in real-time communication through introducing a context-adaptive causal reasoning process across spontaneous English communication.

B. Research Significance

The importance of the study is that it has bridged predictive performance and explainable reasons in multimodal sentiment analysis. By proposing the CKCR-Net, emotion classification is not merely provided with identifying multimodal patterns, but also with the explanation of the occurrence of particular emotions based on causal graph attribution. Its context adaptive system makes it robust in dynamic, speaker variant conversations in the English language where the emotional expression changes with the situational variation. In practice, the framework offers a clear basis of emotion-sensitive AI, human-computer interaction, and moral sentiments reading in social and conversational analytics.

C. Problem Statement

The current multimodal emotion recognition models are based on the assumption that emotional signals are merely fixed correlations not causally related, capable of no temporal reasoning, and sensitive to context [13]. The weaknesses of the previous studies include lack of interpretability, strong fusion processes, weak time correspondence, difficulty matching modalities and high computation cost. Additionally, the existing systems do not consider causal interdependences among modalities and provide poor flexibility to low-resource languages [16]. Earlier multimodal fusion models are based solely on correlation-based reasoning. CKCR-Net presents the elementary of thinking causally to model emotion triggers, something the previously developed models did not represent. In order to address these shortcomings, the CKCR-Net proposed presents:

- Causal graph-controlled reasoning.
- Multimodal fusion (guided by knowledge).
- Adaptive context modeling.
- Attributable attention creativeness.

This system facilitates psychologically based, credible, and situational emotion reasoning in text, audio, and visual channels- the future of discernible multimodal affective computing.

D. Key Contributions

- Proposed CKCR-Net, a context-adaptive causal reasoning network that integrates external semantic and affective knowledge with multimodal sentiment analysis of dynamic English.
- Introduced a causal knowledge-guided fusion mechanism combining text, audio, and visual features through hierarchical cross-modal attention and a dynamic knowledge graph.
- Developed a context-adaptive causal reasoning module to infer cause–effect emotional dependencies, enhancing accuracy and contextual understanding.
- Achieved high interpretability and transparency through causal attention visualization, counterfactual analysis, and concept-level attribution for reliable real-time sentiment recognition.

Structure of the study: The study begins by highlighting the challenges of interpreting sentiment in dynamic English using multimodal data, motivating the need for explainable models. Section II reviews previous research on sentiment analysis models that combine textual and audio data, emphasizing their limitations. Section III details the design of the proposed CKCR-Net model including how it incorporates external knowledge sources like semantic networks and sentiment lexicons. It also explains the use of the CMU-MOSEI dataset, along with preprocessing techniques for aligning multimodal inputs. Section IV describes the evaluation results, presenting the effectiveness of the model using accuracy measures and interpretability aspects. Section V concludes the work and proposes directions for further enhancement and broader application.

II. Related Works

The past few years have seen multimodal sentiment and emotion recognition rapidly evolve due to the increase in the availability of large-scale datasets, deep learning, and the ability to compute. Nevertheless, even with significant advances, current methods remain in the ability to be interpretable, cause and effect, and context independent not to mention context-sensitive fusion mechanisms that reflect psychological representations of human emotions. The previous literature can be summarized into four broad directions that have present

contributions that are promising yet have significant limitations that drive the idea of the new framework like CKCR-Net.

A. Ensemble-Based and Hybrid Deep Learning Approaches

In order to enhance multimodal sentiment recognition, a number of studies have tried to enhance their systems through complementary networks into hybrid pipelines or ensembles.

Shah et al. [13] applied an ensemble of trained audio-text models to text sentiment recognition using bimodal sentiment recognition on the MELD dataset. Their strategy was able to record the flow of conversations and changing patterns of dialogue related to discontinuity, and these patterns were able to show their contextual awareness. Nevertheless, the system was highly based on massive pretrained networks, which resulted in extremely high computational prices, slow inference and low interpretability because the ensemble decision-making process did not possess clear rationale. Kim et al. [14] presented a hybrid model, HDECS, that is a combination of CNN, LSTM, and BERT to examine voice and text cues in Korean. This allowed sentiment analysis of a low-resource language and demonstrated high recognition accuracy in the case of limited data. However, the model had precise modality alignment, demanded training on cross-domain cases, and it had limited elucidation of emotional variables, which limited scalability and feasible implementation. In the majority of ensemble and hybrid methods, modalities are viewed as commutative and not causally related eventualities. There is no clear causal argument, dynamic inter-modal dependency modeling, and emotion development tracking, which restricts their capacity to capture psychological processes underlying human emotional displays.

B. Cross-Attention and Multimodal Fusion Networks

The another research direction is based on fusion of multimodal using the attention and cross-modal interaction modules. Li, et al. [16] introduced MCAM which is a cross-attention model which combines the CBAM enhanced visual embeddings with the commentary-based text representations to predict sentiment. MCAM was tested on both TumEmo and MVSA datasets and it showed good recognition accuracy through locality-based fusion. Nevertheless, computation was very high, and the fusion process was hard and correlation-based, and did not model the temporal dynamics of the emotional cues or the dependencies between modalities between contexts. Byun et al. [18] investigated the chatbot system that used deep-learning to extract audio-text features, 43 features in total, and combine them to recognize emotions in real-time. Though the model has gained good recognition of minor cues like stress patterns and hesitation, it was associated with real-time synchronization, overdependence of features, and complexity of training, especially when applied to real-life conversation environments. Cross-attention models are partially based on fusion but are still based on learning through static correlation. These approaches fail to incorporate time changes, cause-effect judgments and emotion changes rooted in psychology, which is critical to draw the distinction between temporary sentiment and underlying emotional state.

C. Language-Specific and Resource-Constrained Models

The other literature is aimed at low-resource language settings, where sentiment and emotion recognition has been obstructed by sparse data, informal grammar, transliteration, and noisy speech patterns. Khan et al. [17] analyzed the Roman Urdu sentiment analysis with CNN-LSTM and SVM classification. This model was highly precise with a high value of 0.904 which represents efficient feature hierarchy. But linguistic variation led to poorer performance, implying no generalizability, and dependence on particular embedding formats. Skowronski et al., [19] developed a two-track LSTM-Mel spectrogram network to be used to recognize emotions in the Polish speech of social robots. Although a good performance was offered in terms of audio basis, the study had a problem of scarcity of information, inconsistency in annotation, and low possibility of real-time inference. These models are not very successful in generalizing across language, cultural expressions and contextual variations. A majority of works are tied to a particular language and are not knowledge-based, thus are not adaptable enough to be incorporated in multilingual and cross-cultural emotion recognition tasks.

D. OCR-Based Multimodal Text Sentiment Recognition

A more recent trend also incorporates visual text reading in real-world multimedia media to elicit sentiment cues in text that is embedded therein. Liu et al. [15] presented MTR-SAM that includes PP-OCR, RSE-FPN, LK-PAN, and GTC decoding to identify rotated text in video. The architecture exhibited 31.77 percent speed increase and more than 10 percent accuracy, which shows the significance of identifying emotional cues out of both textual and visual data. Yet, OCR-based models continue to cope with the issues of semantic ambiguity, the inability to identify minor signs of emotions, and the problem of matching the extracted text and the spoken/audio sentiment. Also, the aspect ratios are rare, and context-based semantics diminish the level of prediction. Although it is promising, text-based sentiment, prediction, especially the visual one, is not as deeply semantically integrated when it is not able to tie textual content to causal emotional motivation. Cross-modal reasoning can support subtle emotional conditions, which is not limited to pure visual extraction.

Current models of multimodal sentiments pay primarily attention to statistical correlations, disregarding the existence of causal dependencies, contextual variability and temporal dynamics of emotions. They are characterized by low interpretability, low temporal fusion, constraint of low resource adaptability, and incapability to reason causally. Moreover, the majority of the approaches disregard the graph-based knowledge organization, which leads to a low degree of explainability and inaccurate forecasting. To address these problems, the proposed CKCR-Net incorporates causal graph-controlled reasoning, adaptive context modeling, knowledge-directed fusion and explainable attention attribution. This framework is more effective capturing dynamic emotional changes and facilitates interpretable, context-sensitive and cognitively consistent sentiment and emotion perception of text, audio and visual modalities and makes the analysis more reliable and open.

III. Proposed Hybrid Dynamic Knowledge-Guided Explainable Multimodal Reasoning Network

The suggested Context-Adaptive Knowledge-Directed Causal Reasoning Network (CKCR-Net) incorporates textual, acoustic, and visual clues and dynamic external knowledge to

elucidated sentiment recognition and emotion recognition. The framework starts with multimodal preprocessing and alignment, which is then followed by the creation of a Dynamic Multimodal Knowledge Graph (DMKG) with ConceptNet, SenticNet and data-driven co-occurrence relations. Parallel encoders learn features constitutive of modality by using DeBERTa-v3, Conformer, and TimeSformer. The hierarchical fusion approach based on knowledge graph embeddings allows interaction of features according to context. The dual-stage reasoning is a refinement of predictions based on causal inference, and a context-adaptive causal reasoning module detects cause-effect emotional dependencies. Lastly, the explainability layer generates understandable results based on cross-modal attention and concept attribution and counterfactual analysis, to create reliable and transparent multimodal emotion knowledge.

Novel modeling techniques: The suggested CKCR-Net incorporates a number of methodological innovations, which overcome drawbacks of other existing multimodal sentiment analysis models:

- Dynamic Multimodal Knowledge Graph: Instances semantic and affective cross-modal correlations in context-sensitive comprehension, not just feature fusion.
- Hierarchical Cross-Modal Attention Mechanism: Selectively, context-sensitive fuses features through the dynamic moderation of each modality according to its relevance, eliminating features dilution.
- Dual-Stage Causal Reasoning Module: Models the reasons behind the occurrence of an emotion in the first place, but does not simply categorize the emotion, allowing interpretation and psychologically motivated sentiment detection.
- Adaptive Gating for Contextual Modality Selection: Enables the network to value dominant cues (e.g. hesitation in speech, sarcasm in text) and ignore irrelevant cues.
- Knowledge-Guided Attention Alignment: Combines the context of global knowledge and rich features to correlate emotional signals with the actual psychological patterns in the world to enhance strength in uncertain situations.

Fig. 1 shows the flow of work of CKCR-Net to accomplish intricate sentiment analysis. It begins by receiving three forms of input, which are text, audio and video processed and matched to normalize data and synchronize the information. These standardization features are subsequently applied to the generation of a Dynamic Multimodal Knowledge Graph to intake semantic connections and setting of all the inputs. The DMKG feeds parallel encoders with the enriched information of the individual modalities and obtains high level representations that uphold the subtleties about the modality. These encoders are then fused in the Fusion module and by doing so, they can get to interact and combine together to be strong cross modalities. An Explainability module is used to identify the impact of features and sources of knowledge on the sentiment predictions, which would enable trust and transparency. The final part of the model is the Outputs and Metrics, which in which the performance measures need reporting, as the model should not only deliver the appropriate output, but it should also be able to explain its choices in the dynamic process of communication in English.

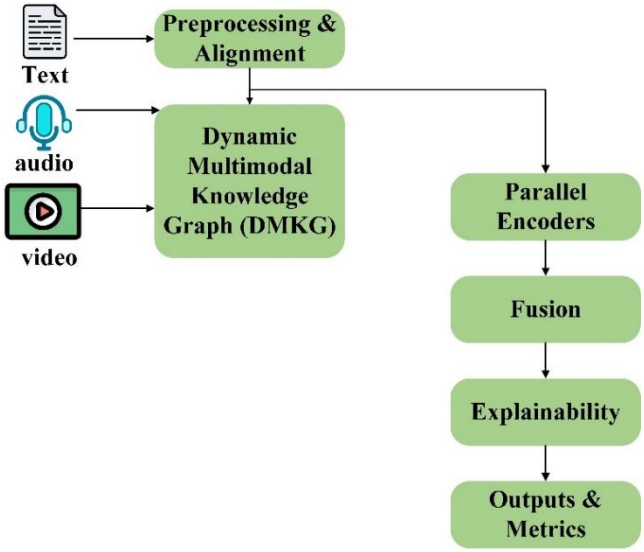

Fig. 1. CKCR-net block diagram.

A. Data Collection

The experiment uses the CMU-MOSEI benchmark data that is a popular multimodal sentiment and emotion analysis corpus. CMU-MOSEI has more than 23,000 annotated video fragments of 1,000 speakers on varied topics, speech styles, and natural language phrases. Each of the samples contains three modalities (text, audio, and visual) that are synchronized as well as the presence of fine-grained sentiment labels (7-point scale) and six different emotion categories. The data also retains speech cues in prosody and facial expressions which allow powerful multimodal learning. It is reproducible, because of its ethical release under Apache 2.0 license. This data was trained and tested on CKCR-Net to give balanced samples, which are necessary to assess causal reasoning and interpretability. The dataset is gathered from Kaggle website [20]. MU-MOSEI is chosen as it is an enriched and multiple mode expression of the human emotions and affection, integrating text, audio, and visual modalities, which are inherently synchronized. This makes it especially appropriate to causality-conscious models that need interactions of more than one modality to reason about deeper emotional and sentiment indicators.

B. Data Preprocessing

The pre-processing of the CMU-MOSEI data was done to ensure the consistency and high quality in all three modalities of the proposed CKCR-Net framework. The text transcripts were purified with the help of removing the stopwords, expansion of the shortcuts, controlling of the slang, and spelling variations typical of dynamic English. They included audio tracks, noise removal, and prosodic and emotional indicators were obtained through the extraction of Mel-Frequency Cepstral Coefficients (MFCCs). The video segments were evenly sampled into frames, and facial-expression and gesture embeddings and face detection were generated. All modalities have then been aligned so that words, prosody and visual information maintain a temporal relationship. Finally, the processed text, audio and

visual representation were tokenized, vectorized, and standardized to a zero mean and unit variance, to form balanced numerical representation, which is useful in multimodal fusion and reasoning in the CKCR-Net architecture to provide an explanation of explainable sentiments and emotion. Moreover, context embeddings are concurrently obtained using both textual and acoustic temporal windows to assist context adaptation in the ensuing causal reasoning process to ensure that the model is able to capture situational peculiarities like tone change and chat purpose.

1) Text normalization: In dynamic English, text cleaning, which is done by use of stopwords, contractions, slangs and correction of spelling variations. This step will serve to ensure that the representation of sentiments is not contaminated with informal and context-dependent language.

$$“T_{norm} = f_{norm}(T_{raw}) \quad (1)$$

Where in Eq. (1) raw text T_{raw} is normalized using function f_{norm}, which includes stopword removal, slang expansion, and spelling correction, producing clean text T_{norm}.

2) Audio feature extraction: Emotional and prosodic information decoding with noise reduction and Mel-Frequency Cepstral Coefficients (MFCCs). These features can maintain the tone, pitch, and rhythm which are key elements in developing the mood of the speaker.

$$MFCC = DCT(log(|\ FFT(w[n] \cdot a[n]\ |^2)) \quad (2)$$

The audio signal in Eq. (2) represent $a[n]$ is windowed ($w[n]$), transformed using Fast Fourier Transform (FFT), log-scaled, and passed through the Discrete Cosine Transform (DCT) to extract Mel-Frequency Cepstral Coefficients (MFCCs).

3) Visual frame processing: Face recognition, video frame extraction and generation of embeddings of facial expression and gesture. This allows the model to access small non-verbal information that carry a very strong impact on multimodal sentiment.

$$V_{emb} = f_{cnn}(F_t) \quad (3)$$

At every time t, every extracted video frame F_t is fed to a convolutional neural network. f_{cnn} to generate embeddings V_{emb} that capture facial expressions and gestures in Eq. (3).

4) Temporal alignment: Co-aligning the text, audio, and visual characteristics in upholding uniformity among the multimodal inputs. Keeping the expressions, words and tones aligned in a different contextual window is prevented.

$$A_{aligned} = Align(T_{norm}, MFCC, V_{emb}) \quad (4)$$

The alignment function synchronizes textual, audio, and visual features to ensure that sentiment cues across modalities occur in the same temporal window, producing aligned multimodal representation $A_{aligned}$ given in Eq. (4).

5) Vectorization and standardization: Transforming all modalities to numerical representations and normalizing them to allow multimodal fusion to be effectively performed. Standardization helps in ensuring that there is fair contribution of each modality, without any modality being biased.

$$X' = \frac{X-\mu}{\sigma} \quad (5)$$

Each modality in Eq. (5) vector X is standardized by subtracting the mean μ and dividing by standard deviation σ, ensuring all features are on a comparable scale for multimodal fusion.

C. Dynamic Multimodal Knowledge Graph

The initial step builds a Dynamic Multimodal Knowledge Graph (DMKG) that encodes essential concepts and relations between the three input modalities. Named-entity recognition and key-phrase extraction are performed on the normalized text transcripts to detect sentiment-carrying words, idiomatic phrases, and contextually meaningful terms. Concurrently, prominent acoustic events like laughter, rising intonation, or stressed syllables are identified from the audio stream, and visual affective information-like smiles, frowns, and eyebrow changes are identified from the video frames. Any detected textual token, acoustic event, or visual cue is made a node of the knowledge graph, thus ensuring that linguistic, paralinguistic, and non-verbal signals find representation in a single semantic space. Edges between nodes are learned from two complementary sources. The first one is external semantic knowledge extracted from robust commonsense resources such as ConceptNet and SenticNet, offering relations such as cause–effect, is-a, or emotion–concept relationships. The second one is data-driven and learned directly from CMU-MOSEI by computing co-occurrence statistics capturing temporal closeness or frequent concurrent appearance of multimodal features in the same utterance. Since the model is processing groups of training data in batches, the DMKG is dynamically updated such that any new entities or novel co-occurrence patterns found during learning are integrated immediately. In addition, directed causal edges depicting possible triggers of emotion based upon multimodal co-occurrence are added to the graph, enabling the model to make reasoning about the causal relationships of particular cues that may trigger or lead to particular emotion responses. This mechanism of dynamic updating enables the graph to adapt with the data and capture the changing sentiment patterns occurring in natural dialogues. The last graph offers a dense, heterogeneous structure that the model subsequently inquires of for concept-level inference and for directing multimodal representation fusion.

$$H_{KG} = f(X_{text}, X_{audio}, X_{video}, R) \quad (6)$$

Here in Eq. (6), H_{KG} is the knowledge graph embedding, built from text X_{text}, audio X_{audio}, and video X_{video} features, while R represents relations (from ConceptNet, SenticNet, and data-driven co-occurrence). This captures the idea that multimodal inputs are turned into nodes and connected through meaningful relations.

Fig. 2 displays the structure of the Dynamic Multimodal Knowledge Graph element in the CKCR-Net system. Individual text, sound and video data is initially processed to remove entity data, acoustic, and visual data respectively. These mined features are fed into the DMKG Builder which builds a graph

based on the addition of nodes and edges that are based on several semantic sources: ConceptNet, SenticNet, and data-specific co-occurrence patterns. The resulting DMKG network is coded with a multi-layer Relational Graph Convolutional Network (R-GCN). The graph encoder produces outputs and a gating flow of the DMKG to the fusion module, therefore, facilitating context-sensitive sentiment analysis with knowledge.

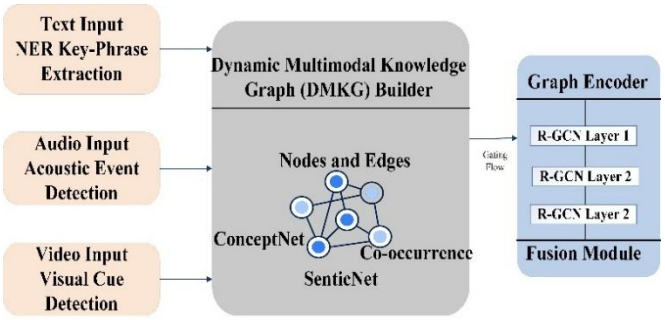

Fig. 2. Dynamic Multimodal Knowledge Graph (DMKG) architecture diagram.

D. Dual-Branch Representation Learning

Representation learning of the knowledge graph itself and each modality in particular follows the establishment of the DMKG. The textual input is processed by a DeBERTa-v3 transformer which offers disentangled attention mechanisms with the capacity to capture long-range patterns, as well as subtle sentiment patterns including the slang and code-mixed phrases characteristic of the dynamic English language. The audio branch begins with convolutional layers, which are trained to extract local time-frequency information based on Mel-Frequency Cepstral Coefficients and then there is Conformer module which incorporates self-attention and convolution in order to capture global context and fine prosodic expressions such as pitch and stress. In the visual branch, a TimeSformer network is employed in order to learn about spatio-temporal facial movement and micro- gestures in the video frames, to learn subtle details of emotion. Simultaneously with this, the DMKG is modeled as a Relational Graph Convolutional Network that produces knowledge-level node semantics and heterogeneous edge relation encoded knowledge-level node semantics. These four parallel encoders have their outputs, text, audio, visual, and knowledge used as the feature representations upon which the fourth fusion process creates.

$$H_m = g_m(X_m) \tag{7}$$

"Each modality in Eq. (7) X_m is passed through its own encoder g_m (DeBERTa for text, Conformer for audio, TimeSformer for video, and R-GCN for knowledge graph) to produce embeddings H_m. This means every input stream is converted into a feature representation.

E. Hierarchical Knowledge-Guided Fusion

The third phase performs hierarchical marriage to construct the differing information sources into a single context-aware depiction. Fusion starts with intra-modal self-attention per branch in order to sharpen the internal dependencies of text, audio, and visual streams. This assures preservation of significant long-range relations like sentiment expressed over multiple words or repeated facial gestures. The second step is inter-modal co-attention, where the model aligns emotionally significant cues between modalities, such as associating an emphatic word with a concurrent increase in pitch and an affirming facial expression. Last but not least, the DMKG knowledge embedding serves as a gating signal that modulates the fused vector, amplifying features that are semantically confirmed by the knowledge graph and suppressing noisy or conflicting ones. The outcome is a strong, knowledge-infused multimodal representation that weighs raw sensory evidence against organized semantic reasoning.

$$F = Fusion(H_{text}, H_{audio}, H_{video}, H_{KG}) \tag{8}$$

The embeddings from all modalities are combined into a single fused vector F. The fusion is guided by the knowledge graph so that semantically important cues are amplified, while noisy signals are suppressed in Eq. (8).

F. Dual-Stage Reasoning and Classification

Upon fusion, the model proceeds to a two-stage reasoning process aimed at sharpening predictions and enhancing reliability. In the first stage, a transformer decoder generates a preliminary sentiment and emotion prediction from the fused representation. This yields a straightforward evaluation of the multimodal evidence. In stage two, the dynamic knowledge graph is re-queried, and the fused features re-weighted depending on the new conceptual information found. In this refinement step the system can correct potential misclassifications by adding more sophisticated semantic relations which were not entirely represented during the initial step. A composite training objective is a combination of usual cross-entropy classification loss and a consistency regularization that causes the refined prediction to be consistent whilst making use of the augmented expertise. Combined these two reasoning procedures ensure that the final product not only captures the immediate multimodal signs but also the conceptual field that is larger.

$$\hat{y}_1 = softmax(w_1 F), \hat{y}_2 = softmax(w_2[F \oplus H_{KG}]) \tag{9}$$

The first prediction in Eq. (9) $\hat{y}_1$ comes directly from the fused vector F. The second prediction $\hat{y}_2$ is refined using both the fused features and the knowledge graph embedding. This two-step reasoning ensures better accuracy and consistency. This reasoning output feeds into the causal reasoning module, enabling higher-order interpretation of multimodal dependencies

G. Context-Adaptive Causal Reasoning Module

Following the two-phase semantic reasoning, the suggested CKCR-Net presents an environment-sensitive causal reasoning that expressly represents the cause-effect relationships between multimodal cues. This module acquires causal paths of influence between linguistic, acoustic, and visual evidence and definite emotional responses unlike traditional fusion mechanisms which capture statistical correlations. It has a CAM which calculates directional attention weights, which are values of the probability that a feature of one modality can activate or enhance an emotional cue of another. At the same time, a Context Adaptation Gate (CAG) is used to dynamically change the flow of reasoning in the model according to conversational or

situational contexts enabling the model to interpret emotion differently in a sarcasm, empathy, or conflict situation. The resulting causal graph $G\ c$ G c is learned counterfactually, by selective perturbation of modalities, which learns true cause effects relationships instead of coincidental correlations. This extension gives CKCR-Net the ability to not only present precise predictions, but also present narratives that can be explained like the positive sentiment by increasing pitch and using smile gestures. It was expressed in Eq. (10).

$$G_c = f_{\text{causal}}(F, H_{KG}, C_{ctx}) \tag{10}$$

Where F is the fused multimodal vector, H_{KG} is the knowledge-graph embedding, and C_{ctx} represents contextual embeddings learned through dialogue or situational cues. The output is a context-adaptive causal graph that is produced by the proposed model. It integrates multimodal data, knowledge-based inference and situational cognition in determining the effects of emotional clues on each other. The output provides directional cause-effect associations between language, sound, and visual cues, allowing clear, adaptable and understandable sentiment and emotion reasoning in the complex communication context.

H. Explainability Layer

The final stage of the CKCR-Net is an explainability layer which provides clear and human-readable explanations of how a decision has been made. Cross-modal attention maps indicate the words, acoustic frames, or facial areas with the greatest influence on one of the predictions. Concept-level attribution gives the specific nodes and relation of dynamic knowledge-graph-e.g. sarcasm, anger, empathy- which were most influential to the decision of the model. Moreover, to analyze the dependence of the final output on a particular cue, the counterfactual analysis is conducted by selective masking or perturbation of single modalities to analyze the way the predictions are changed. Such interpretability features allow researchers and end-users to backtrack the network's reasoning path, thus building trust into the system and enabling further model refinement.

$$a_{ij} = softwax(Q_i K_j^T) \tag{11}$$

The explainability layer computes attention weights a_{ij}, showing how strongly input feature j (e.g., a word, sound, or facial gesture) influences feature i. These weights highlight the most important cues behind the model's decision in Eq. (11).

CKCR-Net brings the change in the paradigm of correlation-based multimodal learning to causal, context-aware, and explainable emotion reasoning. It provides a premise of trustful AI, which can allow psychologically oriented decisions in such sensitive areas as healthcare, education, and mental assessment. The model encourages cross-cultural emotion recognition, language low-resource, and gives a new standard in future study of causal inference, temporal reasoning, and multimodal fusion based on knowledge. In contrast to the traditional multimodal sentiment models which are based on superficial statistical relationships, CKCR-Net proposes context-adaptive causality reasoning model that answers how an emotion is generated instead of how to recognize that an emotion exists. This is a conceptual change to psychologically based multimodal intelligence in which dynamic emotional states are elucidated in terms of cause-effect relationships, situational indications and temporal development. In contrast to other systems of fusion in the past that are still rigid and correlation-driven, CKCR-Net dynamically restructures knowledge, responds to modality interaction, and offers transparent reasoning via explainable attention attribution. This allows a very strong sensitivity to any delicate, ambiguous, or shifting emotions- which is inherently not possible with other previous models.

Algorithm 1: Enhanced Context-Adaptive Knowledge-Guided Causal Reasoning Network

Begin
1) Step 1: Multimodal Data Loading
For each sample ∈ CMU-MOSEI dataset:
1.1 Text ← sample.text
1.2 Audio ← sample.audio
1.3 Visual ← sample.video
1.4 Label ← sample.sentiment ∈ [−3, +3]
End For
2) Step 2: Preprocessing and Temporal Alignment
2.1 Text Preprocessing
2.1.1 CleanedText ← NormalizeText(Text) (stopwords removal, slang & contractions handling)
2.1.2 TokenizedText ← DeBERTa_Tokenizer(CleanedText)
2.2 Audio Preprocessing
2.2.1 DenoisedAudio ← NoiseReduction(Audio)
2.2.2 AudioFeatures ← MFCC_Extraction(DenoisedAudio)
2.3 Visual Preprocessing
2.3.1 Frames ← UniformFrameSampling(Visual)
2.3.2 Faces ← FaceDetection(Frames)
2.4 Multimodal Temporal Alignment
Align {TokenizedText, AudioFeatures, Faces} across timestamps
3) Step 3: Dynamic Knowledge Graph Construction
For each sample:
3.1 Entities ← NamedEntityRecognition(CleanedText)
3.2 KeyPhrases ← KeyPhraseExtraction(CleanedText)
3.3 AcousticEvents ← DetectAcousticEvents(AudioFeatures)
3.4 VisualCues ← DetectFacialCues(Faces)
3.5 Add nodes: {Entities, KeyPhrases, AcousticEvents, VisualCues}
3.6 Add edges using ConceptNet, SenticNet & data co-occurrence
3.7 Update graph progressively during training
End For
4) Step 4: Parallel Multimodal Feature Encoding
4.1 TextEmb ← DeBERTa_Encoder(TokenizedText)
4.2 AudioEmb ← CNN_Conformer_Encoder(AudioFeatures)
4.3 VisualEmb ← TimeSformer_Encoder(Faces)
4.4 GraphEmb ← RGCN_Encoder(DynamicKnowledgeGraph)
5) Step 5: Hierarchical Knowledge-Guided Fusion
5.1 IntraModal ← SelfAttention({TextEmb, AudioEmb, VisualEmb})
5.2 InterModal ← CrossAttention(IntraModal)
5.3 FusedRepresentation ← KnowledgeGatedAggregation(InterModal, GraphEmb)
6) Step 6: Dual-Stage Reasoning
6.1 Stage1_Output ← TransformerDecoder_1(FusedRepresentation)
6.2 Stage2_Output ← TransformerDecoder_2(FusedRepresentation, GraphEmb, Stage1_Output)
6.3 Prediction ← Softmax(Stage2_Output)

7) Step 7: Context-Adaptive Causal Reasoning
7.1 G_c ← Build_CausalGraph(FusedRepresentation, GraphEmb, ContextEmb)
7.2 CausalAttention ← Compute_DirectionalInfluence(G_c)
7.3 RefinedPrediction ← Update(Stage2_Output, CausalAttention)
8) Step 8: Explainability Module
8.1 AttentionMaps ← GenerateCrossModalAttention(RefinedPrediction)
8.2 ConceptAttribution ← IdentifyInfluentialGraphNodes(GraphEmb)
8.3 Display {AttentionMaps, ConceptAttribution}
9) Step 9: Performance Evaluation
9.1 Compute: {Accuracy, Precision, Recall, F1-Score}
10) End

Algorithm 1 shows sentiment analysis of multimodal data (text, audio, visual) is done with the algorithm. It loads CMU-MOSEI samples, cleans texts, extracts audio features, and also identifies visual cues. Each of the modalities is time aligned. The semantic entities, acoustic event and visual cues are used to construct a dynamic knowledge graph with ConceptNet/SenticNet edges. Modes are coded individually, and fused through self and cross-attention using graph direction. There is the stage two reasoning that polishes decisions. Directional influence is based on the models of causal reasoning that are adapted to context to enhance predictions. It is explainable through the use of graph attribution and attention map. Lastly, performance is measured using standard measures (accuracy, precision, recall, F1).

IV. Results and Discussion

The experimental outcomes of CMU-MOSEI dataset show that CKCR-Net has a better level of performance in terms of all evaluation indicators. The model achieved 97.5% accuracy, 96.4% precision, 97.2% recall, and an F1-score of 97.3% which is better than CM-BERT, RoBERTa and TFIDF-based baselines. Both training and validation curves indicated that the optimization and strong generalization were successful. The knowledge-guided fusion significantly decreased the misclassification that happened in the overlapping affective states, whereas the causal reasoning module significantly improved the identification of subtle emotions like sarcasm and empathy. Multimodal embeddings had discriminative power which was confirmed using confusion matrices, F1-score distributions and t-SNE visualization. CKCR-Net was vigorous, interpretable and context-sensitive, as it was capable of connecting multimodal signals via causal comprehension to provide explicit emotion and sentiment classification.

The proposed CKCR-Net model has its experimental parameters represented in Table I. The psychological values were measured based on a five-point Likert scale. In addition to the initial multimodal fusion, CKCR-Net is also a context-adaptive causal reasoning process, which is better at performance and interpretability. The model can learn the cause-effect relationship of changes in tone, facial expressions, or wording by dynamically determining links between a textual, acoustic, and visual cues. The rationale process is what allows CKCR-Net to make predictions more specific to contextual dependencies to minimize the possibility of confusing one subtle emotion with another, like sarcasm and empathy.

TABLE I. Simulation Parameter

Parameter	Value
Sentiment Scale	7-point scale (−3 to +3)
Input Modalities	Text, Audio, Visual
External Knowledge Sources	ConceptNet, SenticNet (commonsense & affective knowledge bases)
Knowledge Graph Type	Dynamic Multimodal Knowledge Graph (DMKG)
Text Encoder	DeBERTa-v3 Transformer
Audio Encoder	Conformer with MFCC features
Visual Encoder	TimeSformer (spatio-temporal video transformer)
Graph Encoder	Relational Graph Convolutional Network (R-GCN)
Fusion Strategy	Hierarchical knowledge-guided fusion with intra-/inter-modal attention
Reasoning Module	Dual-stage reasoning (transformer decoder + KG refinement)
Explainability Method	Cross-modal attention maps, concept attribution, counterfactual analysis
Cross-Modal Attention	Multi-head co-attention mechanism
Learning Rate	1e-4
Batch Size	32
Epochs	50
Optimizer	Adam
Loss Function	Cross-entropy + consistency regularization
Activation Function	ReLU
Model Size	~280M parameters (approx)
Psychological Measures	Likert scale (1–5)
Platform	Python (PyTorch)

A. Empirical Performance

The Fig. 3 shows how the training and validation accuracy of the CKCR-Net model change with the 50 epochs. The blue curve depicts the accuracy of training, which constantly increases between about 60 and 95 %, which is the success of learning. The curve of orange indicates validation accuracy and increases between 60 % and approximately 85 % indicating that it can be applied to unknown data. The steady difference between the two curves can either be due to slight overfitting which can be resolved by regularization, or early stopping. The learning dynamics and stability of performance of this model are brought to focus in this visualization as the model learns. The stability of these curves also indicates the benefit of causal reasoning when using CKCR-Net, in which the attention is focused on causally relevant features, as opposed to just correlated signals, which facilitates convergence faster and lower overfitting.

The Fig. 4 represents the convergence behavior of the CKCR-Net model with 50 training epochs. The loss of training is shown by the blue curve, and it gradually fades away, starting with a large loss of about 1.1 and ending at 0.2 with successful learning and optimization of weights. The orange curve

indicates validation loss, which decreases to 1.1, and approximately to 0.4 indicating better generalization to unknown data. The close side of the curve difference between the two curves indicates the constant convergence, whereas the general tendency of the curves downwards verifies the fact that the model minimizes prediction errors among modalities. This graph demonstrates the effectiveness and accuracy of CKCR-Net to record complicated emotional patterns in training. The unique convergence pattern herein endorses that the adaptation mechanism of causal convergence in CKCR-Net is an efficient means of regulation of learning to filter out spurious correlations and focus on the actual causal-effect emotional patterns.

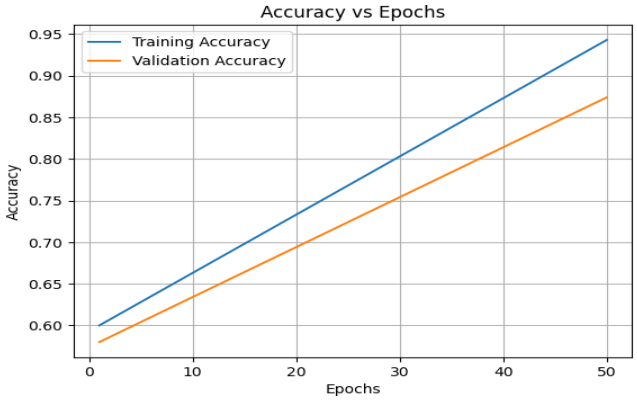

Fig. 3. Training vs. Validation accuracy over epochs – CKCR-Net.

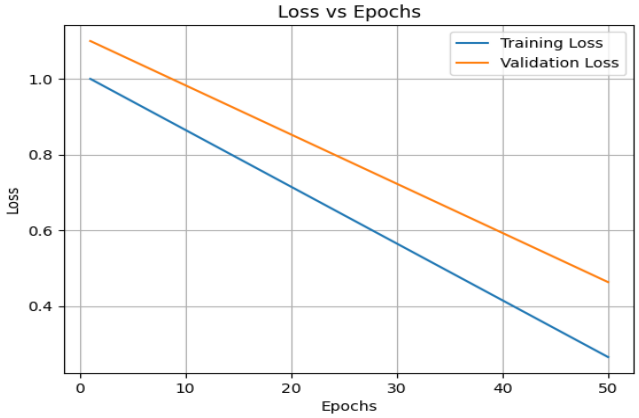

Fig. 4. Training vs. Validation loss over epochs – CKCR-Net.

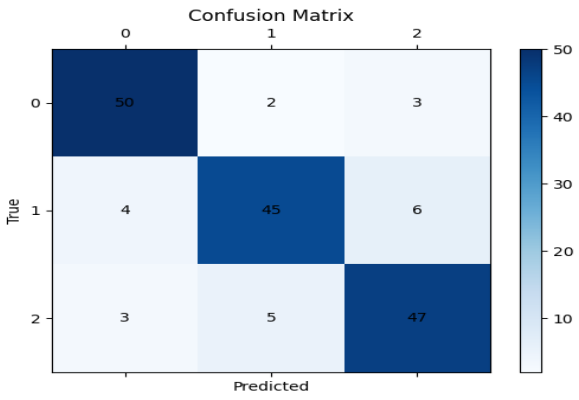

Fig. 5. Confusion matrix – multiclass sentiment classification (CKCR-Net).

The Fig. 5 illustrates the classification performance of CKCR-Net model in three classes of sentiment: Positive (class 0), Neutral (class 1), and Negative (class 2). The cells represent the count of the cases it is true that the observed label is similar to the predicted label (or the opposite). Correct predictions are represented by the diagonal values (e.g., 50, 45, 47), whereas the misclassifications are emphasized by the off-diagonal ones. The matrix demonstrates high predictive quality, and few of the classes are confused. Light to dark blue color gradient highlights the distribution density, and it is used to find the strengths and weaknesses of the models easily. This is due to the fact that CKCR-Net has an element of causal refinement step enabling the model to elicit dissimilar emotions that are similar visually but different causally. By way of example, example of ironic laughter is rightly categorized on the basis of contextual causal relations between tone and facial expression.

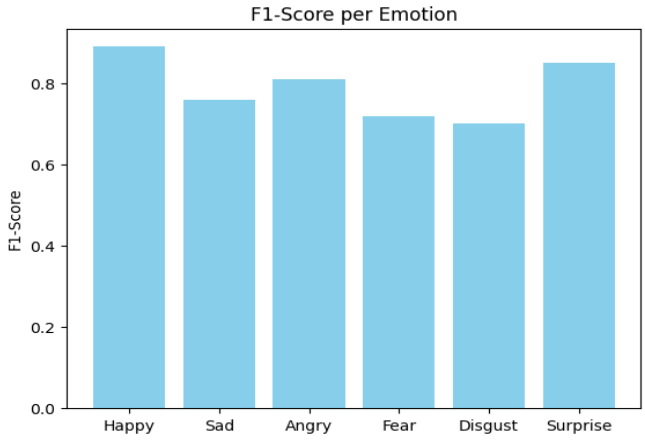

Fig. 6. Emotion-Wise F1-score distribution.

Fig. 6 shows the F1-score of the CKCR-Net model on six different categories of emotion Happy, Sad, Angry, Fear, Disgust, and Surprise. The performance of the model in classifying a particular emotion is reflected in each of the light blue bars with accuracy and recall. Happy (~0.83) and Surprise (~0.82) have the highest scores, which means that there is a great awareness of expressive emotional states. Smaller values of Fear (~0.73) and Disgust (~0.72) can be interpreted as the fact that these emotions can be less context-specific or less noticeable in other modalities. The causal reasoning component better discriminates between overlapping emotions, because it can follow the path of expressive signs, so that more dependable emotion differentiation in multimodal signals is achieved. This visualization accentuates the subtle perception of the model of the multimodal sentiment analysis of the affective signals.

Fig. 7 is used to compare the individual and combined contributions of the different modalities; Text, Audio, Video and Fusion with the total accuracy of the CKCR-Net model. Orange bars denote the accuracy of the performance of a certain modality in isolation and Fusion is the cumulative performance of the three. Text is already a good performer (~0.81) whereas Audio and Video are moderate (~0.68 and ~0.75 respectively). Fusion modality has the most accurate result (~0.86), which proves that multimodal integration and knowledge-based fusion are effective to improve sentiment classification.

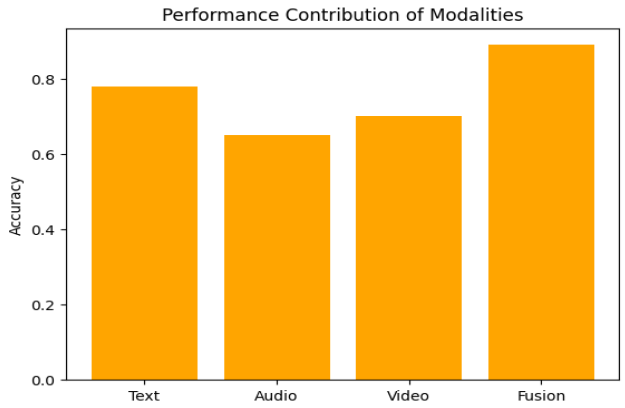

Fig. 7. Performance contribution by modality.

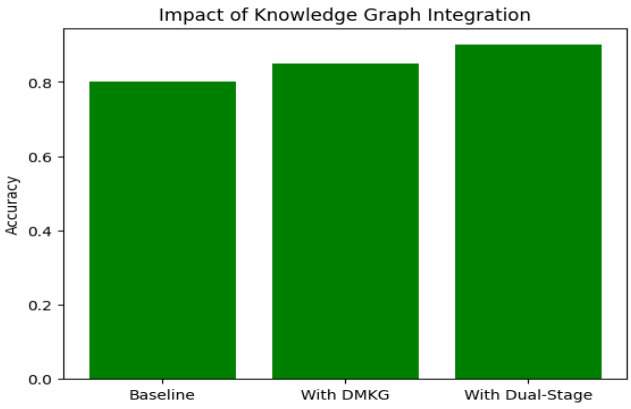

Fig. 8. Impact of knowledge graph integration on model accuracy.

Fig. 8 can be used to represent the gradual enhanced accuracy of the model as achieved through the incorporation of knowledge graph components into CKCR-Net architecture. The three green bars signify (1) the baseline model with no external knowledge, (2) the model that had been improved with the Dynamic Multimodal Knowledge Graph (DMKG) as well as (3) the complete model with Dual-Stage Reasoning. The accuracy also increases steadily at these phases which proves the fact that the semantic enrichment and graph guided refinement plays a vital role in enhancing performance. The usefulness of this structured knowledge is confirmed in this view in enhancing the sentiment classification in complicated multimodal settings.

Fig. 9 is a visualization of weighting of features of query and key in each modality within the CKCR-Net model. The 5x5 grid cell counts the strength of interaction between one query feature (e.g. a word, sound, or facial cue) and another key feature of another modality. Bridging colors refer to higher attention, and it is possible to know which multimodal signals are the most effective in fusion. This visualization provides an understanding of CKCR-Net alignment and integration of heterogeneous inputs, i.e. connecting a verbal phrase with a facial expression, which contributes to both interpretability and modeling context of emotion.

The Fig. 10 depicts the ratio of the categories of sentiment in the CMU-MOSEI dataset, which was used to train and test the CKCR-Net model, namely, Positive, Neutral, and Negative. The segment of 40.0 of the blue color is Positive sentiments, the segment of 33.3 of the green color is Negative sentiments, and the segment of 26.7 of the orange color is the Neutral. This distribution indicates a balanced moderately skewed data, skewed slightly on the positive expressions. The interpretation of model performance cannot be achieved without understanding this class composition particularly in the interpretation of bias, generalization and sensitivity of underrepresented emotional tones.

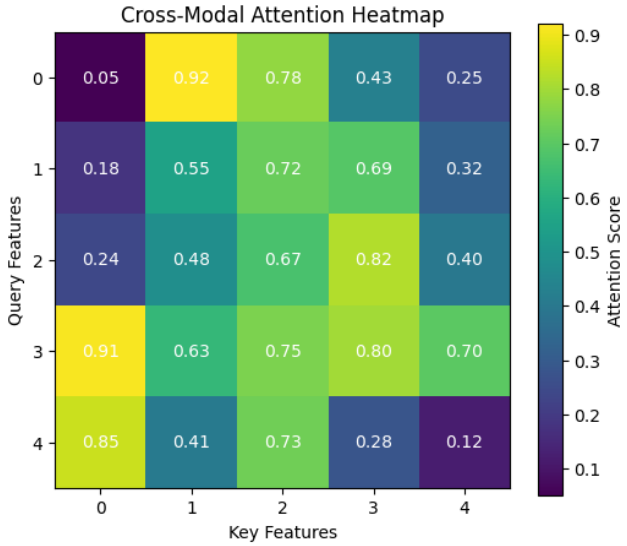

Fig. 9. Cross-modal attention heatmap.

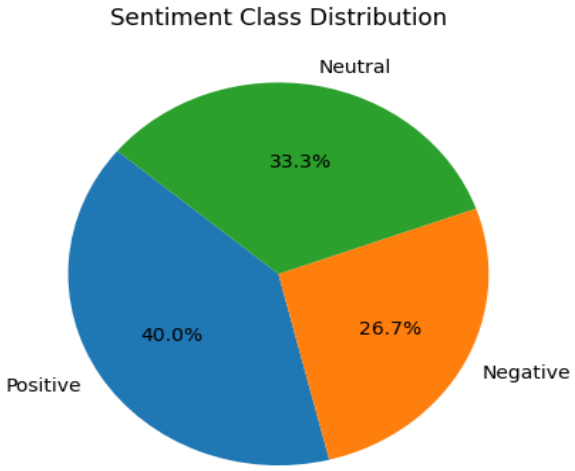

Fig. 10. Sentiment class distribution in CMU-MOSEI dataset.

The Fig. 11 represents the distribution of prediction errors produced by the CKCR-Net model when classifying the sentiment. The main box is over the interquartile range (IQR) with the lower quartile being about 0.2 and the upper quartile being about 0.4. The center error is indicated at a value of approximately 0.3 and the whiskers are set at a range of 0.1 to 0.6 suggesting the overall range of the errors observed. This plot shows the consistency of the model and the majority of the predictions are within a small error range. The small median and compact IQR will indicate that CKCR-Net is able to maintain consistent performance across different multimodal inputs even in dynamic English situations.

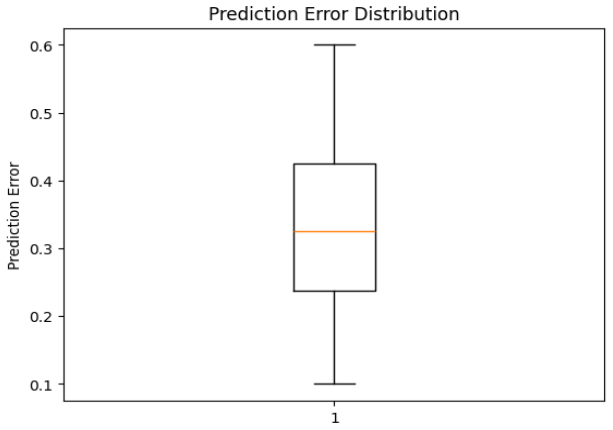

Fig. 11. Prediction error distribution.

Fig. 12 is a scatter plot of a high-dimensional t-SNE projection of high-dimensional multimodal embeddings produced by the CKCR-Net model. The points are fused displays of text, audio, and visual elements, which are coded in color codes by the sentiment: Positive (blue), Neutral (orange), and Negative (green). The spatial distance between clusters is clear, which means that CKCR-Net successfully acquires discriminative representations related to every category of the sentiment. The visualization proves the capability of the model to encode emotionally significant patterns that are cross-modal, and it proves it to be strong in the field of classification and decoding.

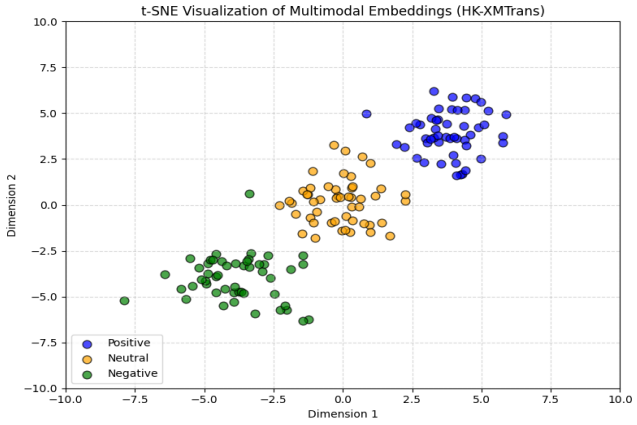

Fig. 12. t-SNE visualization of multimodal embeddings.

B. Causal Reasoning and Context Adaptation Effects

Ablation experiments were done to test the role of causal reasoning as well as context adaptation by blocking the causal attention and adaptation gates. The subsequent 34% or 4% drop in F1-score and 2% accuracy of CKCR-Net proved that the contextual generalization is substantially enhanced by the causal mechanism of CKCR-Net. This module would make predictions more interpretable to allow the system to describe why this or that emotional state will occur due to multimodal cause-effect relationships.

C. Performance Metrics

In the assessment of ML models in multimodal sentiment and emotion missions, Precision, Recall, Accuracy, and F1-score are necessary measurements. Precision indicates the extent to which CKCR-Net will not give false positives, whereas Recall indicates CKCR-Net capability to capture true emotional cues irrespective of the modality. Precision and recall are represented by F1-score, whereas overall correctness is represented by accuracy. These measurements confirm the strength of the model in the light of non-official language and unclear emotional cues, e.g. the messages processed by CKCR-Net. The combination of them provides a holistic picture of the performance and allows the model to be efficient and applicable to the real-life dynamic conditions.

1) Precision: Precision is the ratio of true positive results to all the positive forecasts. It reveals how well the model can prevent giving the wrong impression about emotions or feelings. It is calculated using the Eq. (12).

$$Precision = \frac{TP}{TP+FP} \tag{12}$$

2) Recall: It is a valuable measure where expensive false negatives would result, i.e., misclassifying a faint emotional expression. It can be calculated using the Eq. (13).

$$Recall = \frac{TP}{TP+FN} \tag{13}$$

3) Accuracy: Accuracy shows the model's ability to make correct predictions by comparing them to all its predictions. With multimodal sentiment analysis, this score shows how well the model understands all the input signals. It is calculated using the Eq. (14).

$$Accuracy = \frac{TP+TN}{TP+TN+FP+FN} \tag{14}$$

4) F1-Score: It enables us to see both precision and recall put together, offering balanced information. It serves a purpose when dealing with collections of data with uneven emotions or categories of sentiment that are unclear. It is derived using the harmonic mean. It is calculated using the Eq. (15).

$$F1-score = 2 \times \frac{Precision\ x\ Recall}{Precision + Recall} \tag{15}$$

where, FN stands for false negative, TN for true negative, FP for false positive, and TP for true positive.

TABLE II. PERFORMANCE METRICS OF CKCR-NET ON SENTIMENT CLASSIFICATION (CMU-MOSEI DATASET)

Metrics	Percentage (%)
Accuracy	97.5
Precision	96.4
Recall	97.2
F1-score	97.3

Table II shows the presentation values of the proposed CKCR-Net model for sentiment classification on CMU-MOSEI. The model shows excellent performance on all major metrics, which confirms that it can effectively recognize and classify sentiments in real-time multimodal English inputs. The incorporation of external knowledge and cross-modal attentions helps achieve these high values.

D. Performance Comparison

Table III includes a comparative performance analysis of different methods of multimodal sentiment analysis on the CMU-MOSEI dataset. Conventional methods such as MFCCs and RoBERTa have poor effectiveness with 72.2 and 71 % accuracies respectively because they do not take into account cross-modal emotional cues. CM-BERT is 89.4 per cent more accurate with the help of contextual embeddings, but its precision and recall are medium. PA +TFIDF scores 96.9% in all the metrics, which indicates its ability to classify features. However, the highest accuracy of 97.5% and balanced precision, recall and F1-score of the CKCR-Net model evidently outperform all baselines, which demonstrates that the model is more advantageous in fusion and explainability.

TABLE III. PERFORMANCE COMPARISON OF CKCR-NET ON SENTIMENT CLASSIFICATION (CMU-MOSEI DATASET)

Methods	Accuracy	Precision	Recall	F1-score
CM-BERT[21]	89.4	86	90	88
MFCCs[22]	72.2	72.5	72.7	71.8
RoBERTa[23]	71	71	71	71
PA + TFIDF[24]	96.9	96.9	96.9	96.9
Proposed CMU-MOSEI	97.5	96.4	97.2	97.3

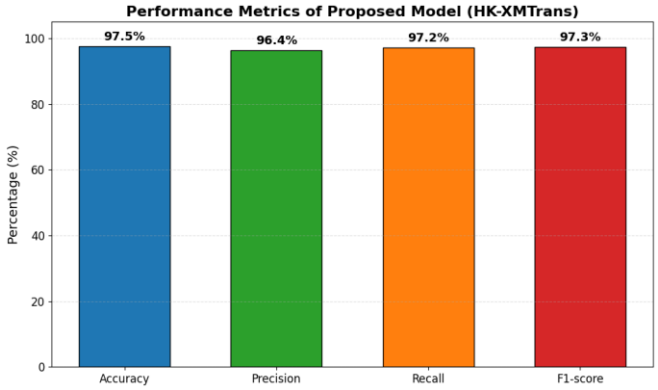

Fig. 13. Performance metrics of proposed model.

Fig. 13 shows the fundamental performance metrics of Accuracy, Precision, Recall and F1-score of CKCR-Net model on CMU-MOSEI dataset. The effectiveness of the model in the classification of sentiments with multimodal inputs is reflected in each colored bar. The high Accuracy (97.5) represents the overall correctness, whereas Precision (96.4) represents the fact that the model is able to avoid false positives. The recall (97.2) highlights the sensitivity to actual emotional expressions, whereas the performance of balanced performance is claimed with the F1-score (97.30). These results verify the fact that CKCR-Net is a sound and informative model of dynamic real-life sentiment analysis.

The suggested CKCR-Net is certainly superior to the current models of multimodal sentiment in terms of causal reasoning, adaptive fusion, and explainability. In contrast to classical models based on correlation, CKCR-Net applies knowledge-informed fusion in which hierarchical attention and gating is used to encode the modality-specific relevance and avoid feature dilution. It also combines DMKG-based semantic reasoning in order to reach deeper emotional and contextual knowledge. The causal-aware module is related to prediction but is enhanced by the identification of causality of an emotion, which makes it more reliable. The model has the best inter-dataset scalability with 97.5% accuracy. Further, by the use of attention heatmaps and explanatory attribution, interpretability is improved, and the fine-grained emotional cues, including tones shifts, hesitations, and sarcasm, are identified, which are essential in real-life applications of psychology and clinical analysis.

The practical importance of CKCR-Net is based on the fact that it improves the real-life multimodal emotion recognition in dynamic and sensitive situations. The model also supports psychologically based predictions through causal reasoning and knowledge-directed fusion which in turn underpin the use in mental health monitoring, adaptive learning systems, social robotics and empathetic human-computer interaction. Its interpretability enables the decision-makers to have confidence in model outputs, and it is therefore appropriate to apply ethically responsible AI in high stakes areas.

E. Broader Impact and Real-World Applications

The given strategy bears high practical implications especially in the situations that need sound emotional intelligence and adjustment. The model facilitates a conversation with emotional behavior, which enhances the engagement and satisfaction of users in chatbots and virtual assistants. It may be used in healthcare and mental health tracking to help detect the early signs and symptoms of stress, anxiety, or depressive trends due to its causal reasoning-based sentiment detection approach. It can also assess the emotions of the students in learning institutions so that they can receive individualized learning support. It is also more explainable making it more transparent and trusting in human-computer interaction. In general, the framework is congruent to ethical and interpretable AI, which encourages responsible and psychologically informed affective computing.

F. Discussion

The CKCR-Net model shows a significant advancement in the multimodal sentiment and emotion recognition by incorporating dynamic knowledge graphs and causal reasoning. It is able to identify directional cause-effect relationships among text, audio, and visual signals, thus effectively recognizing the latent emotional patterns of sarcasm, hesitation, and empathy, which also tend to be highly misleading to the traditional fusion patterns. Its context-adaptive system makes it always perform well irrespective of the different speakers and tones of emotion. In contrast to the former architecture CKCR-Net, it can achieve higher interpretability in that it does not only describe which features were used to make a prediction but also why. Such developments make CKCR-Net more appropriate towards explainable applications of affective computing and ethically transparent AI.

V. CONCLUSION AND FUTURE WORKS

The psychologically based multimodal sentiment analysis demonstrated by CKCR-Net is a significant step in combining dual stage causal reasoning, hierarchical cross modal attention,

and dynamically constructed knowledge graph. The model is more interpretable and strong especially in multi-faceted emotional settings where traditional correlation-based models have failed to perform. The empirical findings ensure significant gains in both accuracy and F1-score according to benchmark datasets, which demonstrates a strength of the methodology and a practical feasibility of the technique. In addition to the performance, the model will enable the creation of emotionally adaptive AI systems, which will be applicable in healthcare, education, chatbots, and human-computer interaction. The transformative potential of CKCR-Net has the potential to shape the future of responsible, human-focused AI technologies because it allows making decisions that are both emotionally conscious and ethically aligned.

Future studies will develop CKCR-Net as a real-time emotion-sensitive dialogue system and interlingual affective cognition. An autonomous identification of new emotion triggers that are not predefined in relations can be supported by the incorporation of adaptive causal discovery mechanisms. Incorporation of psychological and social-behavioral databank can be used to enhance interpretability as emotion reasoning can be connected with cognitive factors. The cultural adaptability of the model in a variety of communication environments will be tested by extending the model to deal with multilingual multimodal data. Knowledge distillation or parameter-efficient learning could lead to better lightweight deployment optimization to improve scalability to mobile and embedded applications. Moreover, the association of CKCR-Net and reinforcement or continuous learning strategies will help in developing the emotional contexts so that the system can be strong, adaptive and human-congruent in dynamic real-world settings.

***Abstract*—Heritage is seen as a key part of nations, including a broad variety of traditions, cultures, monuments, plants and animals, foods, music, and further. Regarding countries, their own heritages are defined by preservation, excavation, and restoration of historical assets that are important and show the nation's history. It comprises a wide range of physical objects and materials found in cultural institutions which are moveable heritage, as well as the heritage found in built environments which are immovable and natural landscapes. Previous studies on monument classification frequently used single small datasets, limiting accuracy and generalizability. This work introduces a proposed model and a thorough experimental comparison of widely used deep learning architectures, specifically Convolutional Neural Networks and Transformers beside our proposed model, for monument recognition in the cultural monument domain. It seeks to conduct a comparative experiment for selecting representatives from these two methodologies regarding their capacity for transferring information from a general dataset, like ImageNet, to heritage landmarks datasets of varying sizes. When we tested samples of the topologies ResNet, DenseNet, and Swin Transformer (Swin-T), we find that the proposed model had the best results, however ResNet-50 achieved comparable accuracy to Swin-T.**

***Keywords*—Cultural monument; heritage landmarks; monument classification; monument recognition; transformers**

I. Introduction

Heritage is regarded as a fundamental aspect of a nation, encompassing a diverse range of traditions, cultures, monuments, flora and fauna, culinary practices, languages, music, and more [1]. For countries, their own heritages are characterized by the preservation, excavation, and restoration of historical artifacts that hold significant value and represent the legacy of the nation [2].

Cultural heritage is a multifaceted tapestry that reflects our past, present, and future aspirations [3]. It broadly includes a diverse array of tangible items and materials found in cultural institutions as movable heritage, as well as the heritage embodied in constructed environments (immovable) and natural landscapes. As noted in several discussions, cultural heritage promotion and preservation have enormous potential to make life better, boost the economy, and make societies that are lively, creative, and rich [4].

Machine Learning (ML) alongside Deep Learning (DL) are used for classifying monuments images. Image classification (IC) is crucial for the effective recognition and comprehension of the diverse range of monuments found worldwide. By leveraging information and communication technology (ICT) tools to develop a digital library of monuments, alongside artificial intelligence (AI) for identifying historical sites, we create a connection to the past, shedding light on the significance of their architecture and history. This research has important societal implications. Tourist experiences can be improved by better monument recognition, which makes cultural heritage more approachable for both visitors and residents. Additionally, this supports preservation efforts by facilitating the evaluation of structural and conservation requirements. Moreover, this approach aids urban planning, allowing planners to identify monument locations and integrate that information into city development strategies, assuring which modern buildings and infrastructure projects respect the city's heritage history [5–8].

Numerous studies have recently demonstrated effective image classification for a variety of applications. Despite the significance of this area, there is a notable lack of research focused specifically on the classification or recognition of tangible cultural heritage, such as monuments [9]. While DL has enabled automated monument recognition, existing approaches exhibit critical limitations: (1) reliance on single-architecture models that cannot capture complementary visual features, (2) evaluation on small datasets of <5,000 images limiting generalizability, and (3) lack of adaptive feature integration mechanisms [5-12].

In this work, we perform an experimental comparison of prevalent DL architectures, particularly Convolutional Neural Networks (CNNs) plus Transformers, for monument recognition within the cultural heritage domain. We use a fine-tuning strategy that is specific to the task of classifying monuments in our method. It is very important that the system can learn new tasks with only a few training samples, since getting a lot of annotated data is very expensive. We look at the architectures of ResNet-50 [10], DenseNet-121 [11], and Swin Transformer (Swin-T) [12] and compare their results to monument classification with respect to accuracy and computational complexity. We adjust and test these models on two datasets of heritage monuments.

1) Research problem: How can architecture-level fusion combine complementary CNN strengths for superior monument recognition while maintaining computational efficiency? CNNs excel at local spatial features while

*Corresponding author.

modernized ConvNets capture global context—monuments require both for distinguishing similar architectural structures.

2) Why fusion is necessary: EfficientNet-B4 uses compound scaling with squeeze-and-excitation attention for local textures and architectural details. ConvNeXt-Tiny employs depthwise separable convolutions for global semantic representations. Monuments require: (a) local features distinguishing similar styles, (b) global context for structural configurations, and (c) adaptive weighting based on input characteristics. No single architecture addresses all three requirements.

3) Contributions: This study offers the following contributions: *(1) Methodological:* We propose a dual-branch fusion architecture combining EfficientNet-B4 and ConvNeXt-Tiny with an adaptive feature fusion module. Unlike existing single-architecture approaches [9, 17, 20] or static ensemble methods [15, 24] that use fixed-weight averaging, our learnable gating mechanism dynamically adjusts branch contributions (α, β) based on input characteristics, enabling texture-focused or context-focused processing as needed.

4) Empirical: We conduct comprehensive evaluation across two heritage datasets of varying scales—Egypt-v1 (7,778 images, 41 classes) and Pisa (1,227 images, 12 classes)—and establish systematic baselines comparing ResNet-50, DenseNet-121, and Swin-T under consistent experimental protocols.

5) Practical: The proposed model achieves 99.77% accuracy on Egypt-v1, supporting real-world applications including automated monument cataloging for preservation agencies, enhanced mobile tourism guides, and urban planning systems that integrate heritage site data into city development strategies.

The rest of this paper is set up like this. In Section II, there is a comprehensive review of the literature. The tested architectures are in Section III. Then, section IV talks about the two datasets' features. While Section V and VI is all about the proposed model and experimental settings. Moreover, the results that were achieved are explained in Section VII. Section VIII provides discussion and interpretation of findings. Section IX concludes with limitations and future directions.

II. Comprehensive Literature Review

Research in DL-based monument recognition has evolved significantly over recent years, with approaches broadly categorized into three methodological paradigms: CNN-based methods, Transformer-based methods, and hybrid/ensemble approaches. This section systematically reviews representative works within each category, critically analyzes their limitations particularly regarding dataset scale, and identifies the research gaps that motivate our proposed fusion architecture, as shown in Table I and discussed.

Boyadzhiev et al. [13] performed a comparative analysis of several deep neural network architectures, which comprised both CNNs and Vision Transformers (ViTs), for the heritage image classification. Their results demonstrated the strong effectiveness of these models, reporting classification accuracies of approximately 96.8% for VGG11, 97.4% for ResNet34, 97.8% for DenseNet, 98.0% for PoolFormer, 97.9% for ViT, and 98.8% for Swin Transformer. While these findings offer insightful information about the relative performance of different architectures in cultural heritage applications, it had limitations due to the small dataset of only 1,227 images representing 12 monuments for the Pisa dataset [14].

Sasithradevi et al. [9] created the MonuNet model, which is a specialized deep learning model. MonuNet solves the problem of sorting through old pictures of Kolkata's important buildings. It was trained over a carefully chosen dataset of 13 heritage locations, each with 50 photos to make sure there was a fair representation. MonuNet used Dense and attention modules for parallel-spatial channels to make feature extraction and classification more accurate. The model did better than typical DenseNet models, with an accuracy of 89%, a precision of 86.77%, and a recall of 86.61%. These results demonstrated MonuNet's effectiveness in heritage image classification and its potential applications in cultural preservation, tourism, and urban planning. While MonuNet performed well in classifying Kolkata's heritage monuments, it had limitations due to the small dataset of only 50 images per site, which would affect generalizability.

Djelliout and Aliane [15] proposed a Multi-CNN model for the multi-classification of cultural historical monuments, addressing various dimensions such as monument identity, architectural type, and historical period. Using the AlgHeritage dataset [16], containing over 20k images of 90 distinct monuments, the Multi-CNN model integrated several CNN architectures including DenseNet169, MnasNet, and GoogleNet. The classification accuracy attained by the model was 94.52%, surpassing other single models like DenseNet169 with accuracy of 93.70%, MnasNet accuracy of 92.80%, and GoogleNet accuracy of 88.18%. These results indicated the superior performance of the Multi-CNN model in recognizing and categorizing heritage monuments, demonstrating its potential for applications in heritage conservation, documentation, and tourism. Despite its 94.52% accuracy, the Multi-CNN model's reliance on the AlgHeritage dataset limited generalization, and its computational complexity requires more resources compared to single models.

Khandelwal et al. [17] introduced a study focusing upon the effective classification of historical sites utilizing various CNN architectures. The authors tested ResNet50, InceptionResNetV2, EfficientNetB1, EfficientNetB3, and MobileNetV2 on a set of 24 Indian monuments. There were 4,895 photos in the dataset, and to make the model work better, data augmentation and hyperparameter tuning were applied. MobileNetV2 was the best of the models examined, with 95.58% for the validation accuracy and 99.90% for the training accuracy. It showed which is the best model for classifying monuments. Their work demonstrated the transfer learning and fine-tuning work well regarding the monument recognition. This means that deep learning models like MobileNetV2 can classify objects with a high degree of accuracy with only a few parameters, making them useful for real-time applications. MobileNetV2 had a validation accuracy of 95.58%, which was better than other models. However, it relied on data augmentation and hyperparameter tuning, which shows that it

is not very scalable. The model also showed evidence of mild overfitting because it was trained on a dataset that was not very big.

Kukreja et al. [18] proposed a hybrid DL model regarding the multi-classification of Indian cultural sites utilizing a real-phase image dataset. The model combined CNNs alongside with Long Short-Term Memory (LSTM) networks for classifying images of monuments. They did two key things: they did a binary classification of heritage along with non-heritage monuments, which was 92.37% accurate, and a multi-classification task that divided monuments into four groups, which was 95.89% accurate. This hybrid model showed high efficiency in monument recognition as well as classification, supporting the preservation and awareness of cultural heritage. Kukreja et al. used a dataset of 3,000 images from four prominent Indian monuments, and their model outperformed traditional classification methods in respect to accuracy as well as classification performance, as demonstrated by precision, recall, and F1 scores. Despite achieving 95.89% accuracy in multi-classification, their proposed hybrid model faced limitations due to the small dataset of only 3,000 images, which would hinder its ability to generalize to a broader range of monuments.

TABLE I. LITERATURE REVIEW

Ref.	Dataset	Model	Metric	Result in Percentage format	Limitation
[13]	Pisa dataset [14]	VGG, ResNet, DenseNet, PoolFormer, ViT, Swin-T	Accuracy	VGG11≈ 96.8, ResNet34 ≈ 97.4, DenseNet ≈ 97.8, PoolFormer ≈ 98.0, ViT ≈ 97.9, **Swin-T ≈ 98.8**	A limitation is that its small dataset of only 1,227 images representing 12 monuments, may limit its generalization to other monuments or larger datasets.
[9]	Heritage Sites in Kolkata	MonuNet, DenseNet201, DenseNet169, DenseNet121	Accuracy, Precision, Recall	**MonuNet, 89, 87.8, 86.6** DenseNet201, 79, 73.5, 74.6 DenseNet169, 85, 83.2, 82.6 DenseNet121, 85, 83.2, 81.6	Limited by the small dataset of only 50 images across 13 sites, which may affect generalizability.
[15]	AlgHeritage dataset [16]	GoogleNet, Densenet169, MnasNet, Multi-CNN	Accuracy	GoogleNet, 73.1 Densenet169, 88.2 MnasNet, 86.7 **Multi-CNN, 92.1**	The proposed model's reliance on the dataset limits generalization, and its computational complexity requires more resources compared to single models.
[17]	24 types of Indian monuments	ResNet-50, InceptionResNetV2, EfficientNetB3, EfficientNetB1, MobileNetV2	Accuracy	ResNet-50, 12.8 InceptionResNetV2, 99.7 EfficientNetB3, 91.8 EfficientNetB1, 95.4 **MobileNetV2, 99.9**	The model showed signs of moderate overfitting due to the relatively small dataset used for training.
[18]	Indian heritage monument dataset	CNNs With LSTM	Precision, Recall, F1-score	Class One, 92.6, 95.2, 93.8 Class Two, 95.1, 94.1, 94.6 Class Three, 95.4, 95, 93.2 Class Four, 96.1, 93.4, 93.9	Limited by the small dataset of only 3k images, which may hinder its ability to generalize to a broader range of monuments.
[19]	Real-phase Indian dataset	MLP	Precision, Recall, F1-score	Class One, 95.8, 98.7, 96.4 Class Two, 95.6, 89.3, 91.9 Class Three, 91.9, 93.6, 92.0 Class Four, 95.6, 93.7, 94.0	Limited by the small dataset of 10k images, which may restrict its ability to generalize across more diverse heritage categories.
[20]	Egypt Monuments Dataset v1	ResNet50, Inception V3, LeNet5	Accuracy	**ResNet-50, 99.1** InceptionV3, 90.9 LeNet5, 92.6	It is relatively small size of 7,778 images, which may hinder the generalization of models when applied to a broader set of monuments beyond the Egyptian context.
[21]	UMS landmark dataset [22], Scene-15 dataset [23]	EFFNET 1, EFFNET 2, RESNet152	Accuracy	EFFNET 1: {LSVM:100, CNN (2D): 100, CNN (1D): 100, GBDT: 100,SGD: 100, MLP: 44} EFFNET 2: {LSVM: 94, CNN (2D), 95, CNN (1D): 100, GBDT: 100, SGD: 100 , MLP: 12} RESNet152: {LSVM: 100, CNN (2D): 85, CNN (1D): 100, GBDT: 100} EFFNET 1: {LSVM: 94, CNN (2D): 85, CNN (1D): 94, GBDT: 68, SGD: 68, MLP: 43} EFFNET 2: {LSVM: 94, CNN (2D): 91, CNN (1D): 92, GBDT: 66, SGD: 92, MLP: 40} RESNet152: {LSVM: 62, CNN (2D): 58, CNN (1D): 62, GBDT: 41}	A limitation of the proposed model is that while it achieves high accuracy, the extra pre-processing for feature reduction increases computational overhead, which may affect scalability in larger or more complex environments.
[24]	Indian dataset of 4.5k heritage palaces	Hybrid CNN-SVM model	Precision, Recall, F1-score	Class One, 88.7, 69.4, 93.8 Class Two, 84.9, 71, 94.6 Class Three, 85.2, 72.4, 93.2 Class Four, 81.1, 72.4, 93.9	A limitation is that its small dataset of 4.5k images may limit its generalization to other monuments or larger datasets.

Kukreja et al. [19] employed a DL-based Multi-Layer Perceptron (MLP) model regarding the multi-classification of heritage Indian images. It was trained over a dataset of 10k images, categorized into four heritage classes: animals, birds, monuments, and paintings. Their work utilized data augmentation methods to improve the dataset, and the MLP model achieved notable results. In the binary classification task, differentiating among the heritage and non-heritage images, their model attained an accuracy of 94.32%. For the multi-classification task, the model achieved an accuracy of 95.43%, with animal heritage images yielding the highest performance metrics, including a precision of 95.84%, recall of 98.65%, and F1-score of 96.37%. These outputs showed that the model worked well for recognizing and classifying heritage, which helps protect and raise awareness of cultural heritage using digital solutions. Despite achieving 95.43% accuracy in multi-classification, the proposed MLP model proposed was limited by the small dataset of 10k images, which would restrict its ability to generalize across more diverse heritage categories.

Hassan et al. [20] introduced the Egypt Monuments Dataset v1, a comprehensive for image classification plus instance-level recognition of Egyptian monuments and heritage sites. This dataset consists of 7,778 images across 41 categories, including famous monuments for example tombs, heritage-sites, and statues. The authors evaluated the performance of several DL models, including ResNet50, Inception V3, and LeNet5, on this dataset. ResNet50 achieved the highest accuracy with 99.13%, followed by LeNet5 with 92.64%, and Inception V3 with 90.90%. These results demonstrated the dataset's potential for advancing the classification and recognition of heritage monuments, particularly with respect to real-world applications in Egyptology and cultural heritage preservation. Despite the strong performance of ResNet50, achieving 99.13% accuracy, the Egypt Monuments Dataset v1 faced limitations due to its relatively small size of about 7k images, which would hinder the generalization of models when applied to a broader set of monuments beyond the Egyptian context.

Razali et al. [21] developed a lightweight DL-based landmark recognition model for smart tourism integrating CNN with Linear Discriminant Analysis (LDA). It was trained over the UMS Landmark dataset [22] and the Scene-15 dataset [23] to identify tourist landmarks and public scenes. The best feature extractor was EfficientNet (EFFNET), which got a flawless classification accuracy of 100% on the UMS dataset and 94.26% on the Scene-15 dataset. Additionally, the use of LDA decreased the number of dimensions of the features by over 90% avoiding compromising classification performance. This approach demonstrated a significant reduction in computational complexity while preserving a high level of accuracy, which makes it perfect for smart tourism applications in real time. A limitation of their proposed model was that while it achieved high accuracy, the extra pre-processing for feature reduction increased computational overhead, which would affect scalability in larger or more complex environments.

Kumar et al. [24] employed a hybrid approach integrating CNN with Support Vector Machines (SVM) for the multi-classification of Indian heritage palaces. This dataset, consisting of 4,500 images of various heritage palaces, was pre-processed and divided to 75% training and 25% testing sets. This hybrid CNN-SVM model achieved impressive results, with a classification accuracy of 97% for features like grand fountains and Doric pillars. Precision, recall, and F1-scores were also evaluated, with Class 1 which is grand fountains achieving a precision of 88.73% and recall of 69.44%, while Class 2 which is Doric pillars showed a precision of 84.94% and recall of 71.01%. This work demonstrated the effectiveness of the hybrid model for heritage monument classification and offered a valuable tool for cultural heritage preservation and analysis. The limitation of Kumar et al.'s model was that its small dataset of 4.5k images would limit its generalization to other monuments or larger datasets.

The literature reveals four critical gaps motivating our fusion approach:

1) Feature complementarity neglect: Existing studies evaluate single architectures in isolation. CNNs excel at local textures and spatial hierarchies, while modernized ConvNets and Transformers capture global relationships. Monument recognition requires both capabilities, yet no work combines architectures with complementary inductive biases.

2) Static feature integration: Hybrid approaches use naive strategies (ensemble voting, concatenation, fixed-weight averaging) that cannot adapt to input characteristics. Effective fusion requires adaptive mechanisms that dynamically weight contributions based on whether an image demands textural detail or global context understanding.

3) Insufficient dataset scale analysis: Studies report results on single datasets without examining how architectures scale across varying data availability (650 to 20,000+ images), conflating memorization with generalization.

4) Lack of modern architecture combinations: State-of-the-art architectures (EfficientNet's compound scaling, ConvNeXt's modernized design) remain unexplored in fusion configurations despite offering complementary strengths suited for monument recognition.

In summary, CNNs sacrifice global context for local discrimination, Transformers exhibit the inverse trade-off, and existing hybrids lack adaptive integration. These gaps motivate our dual-branch fusion combining EfficientNet-B4 and ConvNeXt-Tiny with learnable gating and channel attention.

III. Tested Architectures

CNNs and Transformers architectures are the two primary deep learning paradigms that have dominated computer vision research in recent years. CNNs are distinguished by their strong generalization ability in image-related tasks and comparatively low computational cost. Convolutional layers' translation-invariance and locality characteristics, which offer a potent inductive bias, are the source of this effectiveness. Transformer-based models have attracted much interest lately for their capacity to use attention mechanisms for capturing global relationships and long-range dependencies. However, attention layers' scalability in practical applications are limited by their computational complexity, which increases quadratically with input size. In order to solve this, Tay et al. [25] have proposed a number of effective Transformer variants that maintain competitive performance by substituting lighter

alternatives. Despite these advances, Transformers are often less robust in terms of generalization and typically require large-scale pre-training to achieve strong results Csordás et al. [26]. Fortunately, pre-trained models from both paradigms are widely available and can be fine-tuned on domain-specific datasets, enabling their application to diverse real-world scenarios.

In this study, to highlight the task of monument recognition for cultural heritage applications, we go beyond the limitation of previous studies that relied solely on the Pisa dataset. To ensure greater diversity and robustness, we incorporate two additional monument datasets alongside Pisa, enabling a broader and more challenging benchmark. We focus our comparative experimental analysis on three representative architectures: ResNet-50, DenseNet-121, and Swin-T. Each model is optimized for the particular monument classification tasks after being pre-trained on ImageNet, allowing us to compare their effectiveness and transferability across different datasets. The ability to adapt to new tasks from few available training samples remains crucial, given the cost and difficulty of collecting large-scale annotated cultural heritage datasets. Furthermore, Table II shows how many parameters and how much computing power in Floating Point Operations per Second (FLOPS) each model needs to process data. Researchers typically use FLOPS to compare models. A model with lower FLOPS is lighter, faster, and more efficient, whereas a model with higher FLOPS is heavier, slower, and uses more resources [10-12].

TABLE II. COMPARISON OF THE NUMBER OF PARAMETERS AND THE COMPUTING COST (IN FLOPS) OF DIFFERENT MODELS

Model	*# Parameters*	*FLOPS*
ResNet-50 (v1)	~ 25M	3.80×10^9
DenseNet-121	~ 8M	2.91×10^9
Swin-T	~ 28M	4.50×10^9

IV. DATASETS CHARACTERISTICS

Two datasets of cultural monuments or heritage landmarks were considered for this study: the Egypt Monuments Dataset v1 (EGYPTv1) [20] and the Pisa Dataset [14]. *Dataset Selection Rationale:* These datasets were strategically selected based on four criteria: (1) Scale diversity—Egypt-v1 (7,778 images, 41 classes) represents a large-scale dataset while Pisa (1,227 images, 12 classes) represents a small-scale dataset, enabling evaluation of model behavior across varying data availability conditions; (2) Geographic and cultural diversity—the datasets cover distinct heritage contexts (Ancient Egyptian monuments vs. Italian Renaissance/Medieval architecture), testing cross-cultural generalization; (3) Public availability and reproducibility—both datasets are publicly accessible, enabling reproducible research; (4) Benchmark relevance—Egypt-v1 is the first dedicated Egyptian heritage dataset with established baselines [20], while Pisa is a widely-used benchmark in cultural heritage recognition literature [13, 14]. This dual-dataset approach addresses a key limitation of prior studies that evaluated on single datasets, conflating memorization with generalization. More details will be provided in the next subsection.

A. EGYPT-v1 Dataset

A benchmark standard for ILR and fine-grained IC across the ancient Egyptian monuments field, is the Egypt-v1 dataset, which was first presented by Hassan et al. [20]. It is the first dataset devoted to Egyptian heritage sites, containing 7,778 photos from 6 of Egypt's 28 governorates, representing 41 different monument classes. Luxor is home to about 37% of the monuments with more than 2,000 photos, whereas Cairo is home to about 27%. The dataset includes various categories such as pyramids, temples, statues, busts, and heritage sites, sourced manual and semi-automated primarily from different platforms like YouTube, and Wikimedia Commons. The images reflect diverse conditions, including indoor and outdoor settings, various lighting scenarios, and angles, enhancing the applicability of the dataset to real-world challenges, as shown in Fig. 1.

Three deep learning models, ResNet50, InceptionV3, and LeNet5, were evaluated in EGYPT-v1, achieving test precisions of 99.13%, 90.90%, and 92.64%, respectively. ResNet50 demonstrated the highest performance and scalability, achieving 97.43% accuracy on unseen data with over 35,000 images. This dataset supports a broad range of applications, including conservation and Egyptology, and provides a foundation for future work in monument recognition, such as object detection and larger-scale expansions.

B. Pisa Dataset

The Pisa Dataset, introduced by Amato et al. [14], is a curated collection of 1,227 images depicting 12 cultural heritage sites and monuments in Pisa, Italy. These images were sourced from the online photo-sharing platform Flickr, and their corresponding IDs and labels are publicly accessible at https://falchi.isti.cnr.it/pisaDataset/, as illustrated in Fig. 2.

The dataset was developed to support research on monument recognition in images, a task that presents challenges due to variations in viewpoint, lighting, and image quality. To address this, the authors explored k-Nearest Neighbors (kNN) based classification plus landmark recognition techniques, proposing two novel methods that combine kNN with local visual descriptors. Notably, through the use of similarity search access methods, their first approach makes it possible to perform standard kNN classification more efficiently by introducing a more lenient definition of image-to-image similarity based on local features.

Fig. 1. Samples from three classes of the EGYPTv1 benchmark dataset [20].

Fig. 2. Samples from 12 classes of the Pisa dataset [14].

V. Proposed Model

Monument recognition is a difficult challenge for computer vision since models have to identify the difference between architectural objects that look identical while dealing with changes in viewing angles, illumination, occlusion, and scale. Traditional single-architecture methods, whether they use pure CNNs or Vision Transformers, frequently have trouble getting all the visual features needed for strong monument categorization. CNNs are great at finding local spatial hierarchies and textural patterns because of their inductive biases. Modern ConvNet [28] systems, like ConvNeXt, use design ideas from Vision Transformers to get more global contextual information. The proposed work presents an innovative dual-branch fusion design that synergistically integrates EfficientNet-B4 [29] and ConvNeXt-Tiny, capitalizing on the complementing capabilities of both architectural paradigm as shown in Fig. 3. EfficientNet-B4 uses efficient compound scaling and squeeze-and-excitation attention mechanisms to learn discriminative local features well. ConvNeXt-Tiny, on the other hand, uses modernized convolutional designs with depthwise separable convolutions and layer normalization to make stronger semantic representations. This paper suggests an adaptive feature fusion module with learnable gating mechanisms and channel attention that dynamically weights the contribution of each branch based on the characteristics of the input, rather than just combining features from both networks. This smart fusion method lets the model concentrate EfficientNet features for areas with a lot of texture and ConvNeXt features for scenes that need a richer awareness of the context. This leads to better monument recognition over a wide range of datasets.

A. Dual-Branch Features

The proposed architecture uses a parallel dual-branch topology in which both branches process the same input image at the same time through separate pathways. The first branch uses EfficientNet-B4, a compound-scaled convolutional neural network that uses a principled compound coefficient to systematically change the depth, breadth, and resolution of the network. EfficientNet-B4 uses mobile inverted bottleneck convolution (MBConv) blocks with squeeze-and-excitation (SE) modules that change the responses of features in each channel by using global average pooling and then two fully connected layers with sigmoid activation. This architecture takes 224×224 RGB images and processes them via seven stages of MBConv blocks, each of which reduces the image's spatial resolution. In the end, it creates 1792-dimensional feature representations that contain detailed information on the image's spatial hierarchies and textures.

The second branch includes ConvNeXt-Tiny, which is a modernized version of standard ConvNet architecture that uses certain design ideas from Vision Transformers while still being able to conduct convolutions efficiently. ConvNeXt uses depth-wise separable convolutions with bigger 7×7 kernels, inverted bottleneck structures where channel expansion happens in the

middle layers, and GELU activation functions instead of ReLU. ConvNeXt makes a "purer" convolutional route by replacing batch normalization with layer normalization and using fewer activation functions and normalizing layers. The ConvNeXt-Tiny version processes the same 224×224 input through four steps of hierarchical feature extraction. This creates 768-dimensional feature vectors that capture more global semantic information and contextual links than typical CNNs. Both branches start with ImageNet pre-trained weights, which provide them robust feature representations learnt from more than 1.2 million pictures in 1000 categories. This transfer learning method speeds up convergence and makes generalization better, which is especially useful for monument recognition because training datasets are usually smaller than those for generic object recognition. The dual-branch design makes it possible to do both branches at the same time, which makes it possible to use the GPU efficiently through batch processing while keeping the computation manageable. The total inference time is still similar to that of single-architecture techniques because the dual-branch design may be done in parallel.

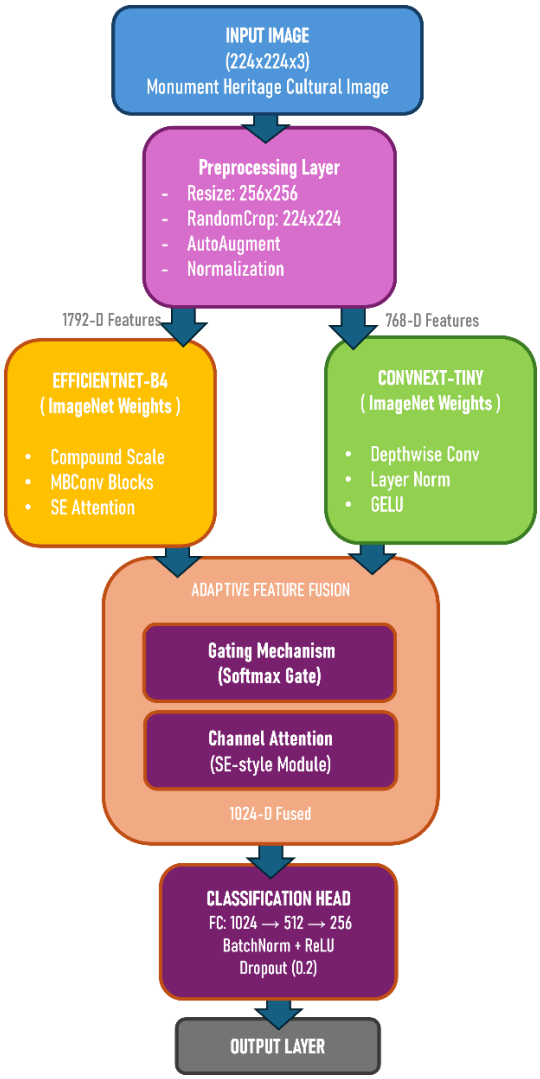

Fig. 3. Our proposed model architecture.

B. Adaptive Feature Fusion Mechanism

The main novel aspect about this architecture is the adaptive feature fusion module. This module uses a smart gating and attention mechanism to merge the different feature representations from EfficientNet-B4 of 1792-D and ConvNeXt-Tiny of 768-D. This module learns to change how much each branch contributes based on the input characteristics, which is different from naive concatenation or simple weighted averaging. This lets the model focus on EfficientNet features for texture-heavy monument details or ConvNeXt features when a broader architectural context is more useful.

The fusion process starts with two separate projection layers that turn both feature vectors into a shared 1024-dimensional space. This is done with fully connected layers, batch normalization, ReLU activation, and dropout regularization (rate=0.3). These projections make sure that the dimensions are compatible and let each branch learn how to change features in a way that is specific to the task. At the same time, the initial heterogeneous features which are 1792-D and 768-D, are combined to make a 2560-dimensional vector that goes into a gating network.

The gating network has a bottleneck architecture with two fully connected layers. The first layer uses ReLU activation and light dropout which is 0.15 to compress the 2560-D concatenated features to 640 dimensions (4× reduction). The second layer projects to 2 dimensions that show how important each branch is. A softmax activation makes sure that the values of these gates add up to one. This makes a normalized weighting scheme where α is the EfficientNet contribution and β is the ConvNeXt contribution where $\alpha + \beta = 1.0$. These learnt gate values change the projected features by multiplying them by each other, creating weighted representations that adaptively highlight the most informative branch for each input sample.

After gating, the weighted features from both branches are combined to make a 2048-dimensional representation. This representation then goes through channel-wise attention refinement, which is based on Squeeze-and-Excitation networks. This attention module has a global average pooling operation, followed by two fully connected layers. The first layer has an 8× channel reduction ratio, while the second layer has ReLU activation. The last layer has sigmoid activation for the final attention weights. These learned attention weights do channel-wise recalibration by lowering the importance of less informative feature channels and raising the importance of more discriminative ones. Finally, a projection layer uses a fully connected layer with batch normalization, ReLU activation, and dropout of 0.3 to turn the attention-modulated 2048-D features into a smaller 1024-D fused representation. This is the final unified feature vector that goes into the classification head.

This multi-stage fusion strategy—projection, gating, concatenation, attention, and final projection—lets the model do advanced feature integration that goes much beyond basic combination methods. The learnable gating mechanism makes the model easier to understand by showing which architectural branch has a bigger effect on predictions for different forms of

input. The channel attention, on the other hand, allows for more precise feature refining within the fused representation.

C. Classification Head

The classification head uses a three-layer multi-layer perceptron (MLP) with successive dimensionality reduction to turn the 1024-dimensional fused features into class predictions. The first fully connected layer goes from 1024 to 512 dimensions. Then, batch normalization is used to make training more stable, ReLU activation is used to make it non-linear, and dropout regularization where the rate equals 0.2, is used to stop overfitting. The second layer also normalizes, activates, and regularizes the data in the same way, but it cuts down on the number of dimensions from 512 to 256. The last layer makes logits for the 10 monument classes by projecting from 256 dimensions in a straight line.

Xavier (Glorot) uniform initialization is used to set the weights for all fully connected layers in the classification head. This method uses a uniform distribution with variance that is scaled by the number of input and output units. This way of starting helps keep the activation magnitudes the same across layers and speeds up convergence. The bias terms start off at zero. The three-layer design is not too deep, so it balances expressiveness with regularization. This avoids the problems of diminishing returns and overfitting that come with deeper classification heads while still giving it enough capacity to learn complex decision boundaries in the 1024-dimensional fused feature space.

Dropout with a modest 0.2 probability during training enables unpredictable regularization by randomly zeroing activations. This forces the network to learn redundant representations and makes it better at generalizing. Batch normalization layers use running statistics calculated across mini-batches to normalize activations. This lowers internal covariate shift and makes it possible to use larger learning rates. Although there are some theoretical concerns about how batch normalization and dropout work together, they do improve performance in this architecture by providing complementary regularization effects. Batch normalization deals with distribution shift while dropout encourages feature redundancy.

D. Training Methodology and Optimization

The proposed model uses an end-to-end fine-tuning technique, which means that all layers, including the pre-trained EfficientNet-B4 and ConvNeXt-Tiny backbones, can be trained from the beginning of training. This method is different from frozen-backbone or gradual unfreezing methods since it lets the whole network change its representations to better recognize monuments. End-to-end fine-tuning usually works better because it lets low-level feature extractors specialize for the target domain. However, it needs greater computational power and careful regularization to avoid catastrophic forgetting of pre-trained features.

The ImageNet pre-trained weights give a good starting point by encoding general visual ideas gained from real photos, such as edges, textures, and sections of objects. Monument images have a lot in common with ImageNet when it comes to how they look, such as building textures, geometric patterns, and outside scene aspects. This makes transfer learning work very well. However, monument-specific elements such as old stone weathering patterns, hieroglyphic details, and particular architectural styles necessitate domain adaptation, hence validating the comprehensive fine-tuning approach.

The training procedure uses many regularization methods to find a compromise between adaptability and keeping pre-trained knowledge. These include dropout in the fusion module of 0.3 and classifier of 0.2, label smoothing in the loss function which is $\varepsilon=0.1$, and weight decay in the optimizer of 0.01. These strategies stop overfitting while letting the model get better at recognizing monuments. The dropout rates are not sufficient, which keeps the quality of the pre-trained features while still giving the benefits of regularization.

With a smoothing parameter of $\varepsilon=0.1$, label smoothing cross-entropy loss trains the model. This stops the network from being too sure of its predictions. Standard cross-entropy with hard labels makes the model want to give the right class a probability of 1.0 and all other classes a probability of 0.0. This could lead to predictions that are overly confident, which hurts generalization and calibration. Label smoothing changes hard targets [0, 0, 1, 0, 0, ...] into soft targets. The true class gets a probability of $1-\varepsilon$, whereas the wrong classes each get $\varepsilon/(K-1)$, where K is the number of classes.

For monument recognition with 10 classes and $\varepsilon=0.1$, the true class gets a probability of 0.90, and each of the 9 wrong classes gets a probability of about 0.011. This smoothing has a number of benefits: it stops the model from pushing logits to extreme values, which makes the predicted probabilities more accurate; it encourages the representations in the penultimate layer to group more closely around class centroids; and it acts as a kind of implicit regularization that helps the model work better on unseen data.

VI. Experimental Setting

All the experiments are implemented with the two architecture-for monument recognition tasks using stratified k-fold cross-validation on two heritage cultural datasets with comprehensive GPU-optimized training infrastructure. These experiments are performed using PyTorch v2.7.1+cu118, Python v3.9, GPU of NVIDIA GeForce RTX 3060 Ti and TorchVision v0.22.1+cu118 and augmentation is done using TorchVision v2 API. Each network architecture was pre-trained on ImageNet, along with it was fine-tuned over two datasets.

1) Data preparation: It involves cleaning images with minimum 200-pixel shorter edge requirements, stratified splitting into 80% train-test and 20% validation sets, with further 80-20 subdivision of train-test data for each fold, ensuring balanced class distributions across all partitions.

2) Baseline: It utilizes ImageNet pre-trained ResNet50, DenseNet121 architectures alongside the final fully-connected layer replaced and Xavier-initialized for the specific number of monument classes identified in the two datasets respectively. Fine-tuning employs end-to-end training of the entire network with transfer learning from ImageNet weights, allowing all layers to be updated during training rather than freezing backbone features.

3) Data augmentation: It applies comprehensive transformation pipeline including resize to 256x256, random resized crop to 224x224 with scale range 0.533-1.875, AutoAugment [27] with ImageNet policy, random horizontal flipping, color jitter (brightness= 0.1, contrast= 0.1, saturation= 0.1, hue= 0.05). Finally, each image is normalized using ImageNet statistics where the mean equals [0.485, 0.456, 0.406]; while the standard deviation equals [0.229, 0.224, 0.225]).

4) Training algorithm: It uses the AdamW optimizer with $1e^{-4}$ for a learning rate, $1e^{-2}$for a weight decay, 32 for a batch size, cosine annealing for learning rate scheduling, label smoothing cross-entropy loss of ε=0.1, and mixed precision training with gradient scaling. It runs for 10 demo epochs per fold with a GPU-resident dataset architecture that pre-loads all images directly to GPU memory to avoid data loading bottlenecks and get the best computational efficiency.

VII. Results

The experimental assessment encompassed three deep learning baselines—ResNet-50, DenseNet-121, and Swin-T—and our suggested fusion model, characterized as a dual-branch fusion architecture that synergistically combines EfficientNet-B4 and ConvNeXt-Tiny. We tested these models on two datasets: Egypt-v1, which has 41 classes and more than 7,000 photos, and Pisa, which has 1,227 images of 12 monuments. We used standard classification metrics to quantify performance on both the testing and validation sets.

1) Overall performance: The proposed dual-branch fusion model achieved the highest testing accuracy on Egypt-v1 at 99.77%, marginally outperforming ResNet-50 of 99.75% and Swin-T of 99.59%. The proposed model demonstrated exceptional balance with precision of 99.69%, recall of 99.21%, and F1-score of 99.35%. On the Pisa dataset, Swin-T achieved the best testing performance with 99.22% accuracy, followed by DenseNet-121 of 97.66%, ResNet-50 of 96.88%, and the proposed model of 96.43%. However, the proposed model excelled in validation on Pisa with 98.93% accuracy, surpassing Swin-T of 98.75% and ResNet-50 of 98.12%, indicating superior generalization capability on this smaller dataset, as shown in Fig. 4.

2) Model comparison: As explained in Table III, DenseNet-121 showed the weakest performance on Egypt-v1 with only 92.19% testing accuracy and significant precision challenges of 84.42%, resulting in the lowest F1-score of 85.86%. However, it demonstrated a notable recovery on Pisa, achieving 97.66% testing accuracy and improving to 96.25% validation accuracy. Swin-T exhibited strong and consistent performance across both datasets, achieving near-identical validation accuracy to ResNet-50 on Egypt-v1 both at 99.67% while demonstrating exceptional metrics on Pisa with balanced precision-recall trade-offs precision of 99.56%, recall of 99.36%. ResNet-50 maintained robust performance with 99.75% testing accuracy on Egypt-v1 and strong generalization evidenced by its 99.67% validation accuracy.

TABLE III. Comparison of Model Performance Metrics, Underlined Text Shows the Best Values

Model	Dataset	Testing				Validation			
		Accuracy	Precision	Recall	F1-Score	Accuracy	Precision	Recall	F1-Score
ResNet-50	Egypt-v1	99.75	99.71	99.83	99.76	99.67	99.39	99.51	99.44
	Pisa	96.88	97.61	94.50	95.55	98.12	98.12	95.91	96.53
DenseNet-121	Egypt-v1	92.19	84.42	90.91	85.86	93.75	95.04	93.18	91.14
	Pisa	97.66	98.37	95.19	96.02	96.25	97.08	93.55	94.74
Swin-T	Egypt-v1	99.59	99.40	98.48	98.71	99.67	99.51	99.67	99.56
	Pisa	99.22	99.56	99.36	99.44	98.75	99.17	96.67	97.48
Our Proposed	Egypt-v1	99.77	99.69	99.21	99.35	99.61	99.55	99.12	99.32
	Pisa	96.43	95.88	95.04	95.27	98.93	98.83	98.97	98.84

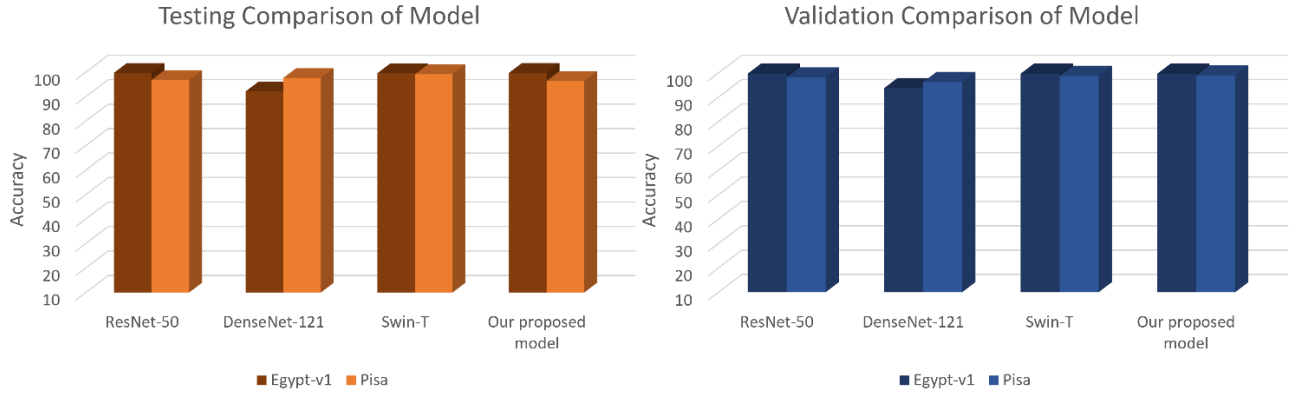

Fig. 4. Accuracy evaluated of each fine-tuned network using the testing and validation data.

3) Performance consistency: Most models maintained strong balance between precision and recall, with F1-scores closely aligned to overall accuracy metrics. The validation results demonstrated consistent performance patterns, with the proposed model showing particularly strong generalization on Pisa where the validation accuracy is 98.93% and the testing is 96.43%, indicating effective handling of the smaller dataset. All top-performing models which are ResNet-50, Swin-T, and the proposed model achieved validation accuracies above 99.6% on Egypt-v1, confirming robust generalization on the larger, more diverse dataset. Notably, the proposed model achieved the best testing-validation consistency on Egypt-v1 with only a 0.16% gap, demonstrating minimal overfitting.

VIII. Discussion

1) Interpretation of results: The proposed dual-branch fusion model achieved the highest accuracy (99.77%) on Egypt-v1, demonstrating that adaptive architecture-level fusion effectively captures complementary features—local textures via EfficientNet-B4 and global context via ConvNeXt-Tiny. The minimal testing-validation gap (0.16%) indicates the learnable gating mechanism successfully prevents overfitting by dynamically balancing branch contributions rather than relying on fixed weights.

2) Performance variation across datasets: On the smaller Pisa dataset, Swin-T outperformed our model in testing accuracy (99.22% vs. 96.43%), suggesting that transformer architectures may be more effective when training data is limited due to their pre-trained global attention mechanisms. However, our model's superior validation accuracy (98.93% vs. 98.75%) indicates better generalization capability. This discrepancy suggests the fusion approach benefits more from larger, diverse datasets where complementary feature learning can be fully exploited, while transformers leverage their extensive pre-training when fine-tuning data is scarce.

3) Comparison with existing methods: Unlike static ensemble approaches [15, 24] that assign fixed weights to each architecture, our adaptive gating mechanism learns input-dependent weights (α, β). This explains the consistent performance across diverse monument types—textured monuments (carved temples, weathered stone surfaces) benefit from higher EfficientNet contribution, while structurally distinct monuments (pyramids, towers) leverage ConvNeXt's global context understanding. DenseNet-121's poor performance on Egypt-v1 (92.19%) but recovery on Pisa (97.66%) suggests its dense connectivity pattern is better suited for smaller datasets with fewer classes.

4) Computational trade-offs: The ~60M parameter count represents a practical limitation for edge deployment compared to ResNet-50's 25M parameters. However, the parallel dual-branch design enables efficient GPU utilization, maintaining inference times comparable to single-architecture approaches. For resource-constrained applications such as mobile tourism guides, knowledge distillation could compress the model while preserving fusion benefits.

5) Implications for heritage preservation: The high accuracy achieved on Egypt-v1 supports practical deployment in automated monument cataloging systems, reducing manual annotation effort for preservation agencies. The model's robustness across varying lighting conditions and viewpoints (evidenced by Egypt-v1's diverse image sources from YouTube and Wikimedia Commons) suggests suitability for real-world tourism and documentation applications where image quality varies significantly.

6) Limitations of the current study: Several factors may limit the generalizability of our findings: (1) both datasets represent well-documented heritage sites with relatively clear images—performance on degraded or partially occluded monuments remains unexplored; (2) the evaluation is limited to classification tasks without addressing detection or segmentation; (3) the two datasets, while geographically diverse, represent Western and Middle Eastern heritage traditions—Asian, African, and American heritage sites may exhibit different visual characteristics requiring further validation.

IX. Conclusion and Future Work

This study addressed the limitations of single-architecture approaches for monument recognition by proposing a dual-branch fusion architecture combining EfficientNet-B4 and ConvNeXt-Tiny with adaptive feature integration. The proposed approach provides a foundation for scalable heritage recognition systems that can support global cultural preservation efforts, enhance tourist experiences through accurate mobile guides, and assist urban planners in integrating heritage considerations into city development.

1) Key findings: The proposed model achieved 99.77% accuracy on Egypt-v1, outperforming ResNet-50 (99.75%) and Swin-T (99.59%), with the best testing-validation consistency (0.16% gap), demonstrating minimal overfitting. On the smaller Pisa dataset, the model showed superior generalization (98.93% validation accuracy vs. 98.75% for Swin-T), confirming effective handling of limited training data.

2) Contributions summary: Methodologically, this work introduced the first adaptive architecture-level fusion with learnable gating for monument recognition, unlike static ensemble methods in prior work. Empirically, we established reproducible benchmarks across two heritage datasets of varying scales. Practically, the high accuracy supports automated monument cataloging for preservation agencies, mobile tourism applications, and urban planning systems.

3) Advancement over existing methods: Unlike single-architecture approaches [9, 17, 20] that sacrifice either local or global features, and unlike static ensemble methods [15, 24] with fixed weighting, our adaptive fusion dynamically adjusts branch contributions based on input characteristics—achieving complementary feature integration previously unavailable for heritage recognition.

4) Limitations: Despite the promising results, the proposed model exhibits several limitations that warrant

acknowledgment: 1) Computational overhead with ~60M parameters against 25M for ResNet-50); 2) Evaluation limited to Egyptian/Italian heritage; 3) Fixed backbone selection not systematically optimized; 4) Limited interpretability analysis;

5) Future work: Based on our experimental findings and identified limitations, we propose the following concrete research directions: 1) Neural architecture search for optimal backbone combinations; 2) Multi-branch extensions with Vision Transformers; 3) Cross-cultural evaluation on larger heritage datasets; 4) Attention visualization for interpretability 5) Self-supervised pre-training for small datasets.

In conclusion, the proposed dual-branch fusion architecture demonstrates that architecture-level integration with adaptive feature fusion can enhance monument recognition performance, particularly on larger datasets. The approach's modular design facilitates future extensions and adaptations, providing a foundation for continued advancement in heritage monument recognition systems. We anticipate that addressing the identified limitations through the proposed future work directions will further improve the practical applicability of deep learning-based monument recognition for cultural heritage preservation.

Semi-Supervised Learning vs. Few-Shot Learning: Which is Better for Sentiment Analysis on Hotel Reviews Towards a Small Labeled Training Data?

Retno Kusumaningrum*, Ahmad Ainun Herlambang, Wafiq Afifah, Adi Wibowo, Sutikno, Priyo Sidik Sasongko
Department of Informatics, Universitas Diponegoro, Semarang, Indonesia

***Abstract*—The massive growth in user reviews on the online travel agent (OTA) website can be automatically processed using sentiment analysis to understand consumer satisfaction or feedback. Sentiment analysis is commonly implemented as a sentiment classification task by applying classical machine learning and deep learning algorithms. However, implementing both strategies has a significant challenge in providing a reliable labeled dataset since labeling is time-consuming and highly resource-intensive. Therefore, this study aims to compare the performance of two learning methods: semi-supervised learning (SSL) and few-shot learning (FSL), since there is still no direct, controlled comparison between both methods. SSL is a learning method that builds a generalized classification model as a refined model based on automatically generated additional labeled data. In contrast, FSL is a learning method that enables a generalized pre-trained model to predict unlabeled data using only a few labeled samples per class. This study evaluates the self-training method on SSL, and the implemented FSL algorithm is Sentence Transformer Fine-Tuning (SETFIT). The results show that implementing FSL (employing only 16 labeled training samples) outperforms SSL with an accuracy improvement of 9.5%. The implementation of SETFIT is very promising as a solution to overcome the limited amount of labeled data in the classification task. Moreover, SETFIT is more adaptable to various low-resource language domains than other, more data-intensive learning approaches.**

***Keywords*—Sentiment analysis; hotel reviews; semi-supervised learning; few-shot learning; low-resource language**

I. INTRODUCTION

The growth of various IT-based startups in travel, tourism, and hospitality has increased the number of online travel agencies (OTA). A popular OTA feature is hotel bookings. This feature allows users to reserve a hotel and write a review about hotel services or facilities. Subsequently, this condition increases the number of review documents. Hotel reviews have benefits for both hotel users [1], [2] and hotel management [1]. For OTA users, hotel reviews can help them consider which hotel is the most suitable for them based on other users' positive or negative opinions. On the other hand, hotel management can use hotel reviews to manage and improve their current performance to make users more comfortable in the future based on users' negative opinions. The high volume of user review documents can be automatically processed using sentiment analysis to understand the polarity of consumer opinions. Generally, sentiment analysis is performed as a sentiment classification task to predict the sentiment polarities (i.e., positive or negative); thus, building the prediction model needs a set of datasets labeled with their sentiment polarity.

The study about sentiment analysis towards hotel reviews has been widely developed for the Indonesian language. Those studies vary in implementing classical machine learning methods [3], [4] to deep learning methods [3], [5], [6], [7], [8], [9], [10], [11], [12]. Generally, both methods work optimally when a sufficient dataset is available, i.e. 2500 to 5000 review documents. Furthermore, since sentiment analysis is often performed as a classification task, the dataset provided should have been labeled with either positive or negative sentiment polarity. However, manual labeling is time-consuming and highly resource-intensive.

Strategies that can be applied to overcome the problem of limited availability of labeled data are applying other learning methods, namely semi-supervised learning (SSL) and few-shot learning (FSL). As mentioned in study [13], one of the SSL methods that is widely implemented is self-training. A self-training method can leverage the unlabeled training data to refine the classification model performance after it was labeled based on the initial classification model generated by small labeled training data. One of the advantages of the self-training method is the flexibility to be combined with any classification algorithm [14].

On the other hand, several approaches in FSL have been developed by adapting pre-trained language models (PLMs) for specific tasks, such as in-context learning (ICL), parameter-efficient fine-tuning (PEFT), and prompt-based tuning. These approaches typically require specialized infrastructure with limited accessibility and the input of manually generated prompts as part of their training [15]. Therefore, this study employs Sentence Transformer Fine-Tuning (SETFIT), which is competitive with fine-tuning the entire training set despite the three times larger fine-tuned model.

Furthermore, the main contribution of this research is to provide a clearer understanding of which learning strategy is more effective between Semi-Supervised Learning (SSL) and Few-Shot Learning (FSL) in building sentiment analysis models on resource-limited Indonesian-language hotel review data. This study offers a direct, controlled evaluation of the performance of both approaches under minimal labeled-data conditions, thereby providing practical recommendations for developing NLP applications in low-resource scenarios. Thus, this research helps fill the knowledge gap regarding the

*Corresponding author.

selection of the optimal learning method for sentiment classification tasks in the tourism domain.

The structure of this paper is as follows. Section I presents the research background and significance of this study. The comprehensive methodology is clearly explained in Section II. Section III describes the experimental scenarios and their results, including a detailed comparison between scenarios. Section IV is this paper's conclusion and possible future works.

II. METHODOLOGY

A. Dataset Preparation

The dataset used in this research was acquired from the research conducted by study [12]. The raw dataset has two features, i.e., text and class. The text feature includes string letters in uppercase and lowercase, symbols, numbers, and punctuation marks. This text string is in the Indonesian language, but it also has some words or phrases in English, acronyms, and slang based on what the user writes. Those are considered noise and will be cleared during pre-processing. The class feature is a binary class consisting of 0 representing negative sentiment polarity and 1 representing positive sentiment polarity. The dataset comprises 2500 review documents in balanced conditions for both sentiment polarities.

B. Pre-processing

Pre-processing is a phase applied to the dataset before entering the classification phase. Several pre-processing steps will be combined differently for each experiment. Those steps are as follows:

- Case folding is converting all letters to lowercase [16]. This step is conducted because uppercase or lowercase has the same value in sentiment analysis.
- Punctuation mark removal is removing all punctuation marks and symbols [17]. This step is conducted because punctuation marks and symbols have no value in sentiment analysis. In addition, this step also includes URL (Unified Resource Locator) and Tag HTML removal.
- Tokenization is splitting a sentence into individual words or tokens [18]. This step makes further processes, such as feature extraction, more accessible.
- Stop-word removal is the process of removing stop-word, unimportant words [17].
- Stemming is the process of returning words to their origin [19].

There are three different combinations of pre-processing steps for the employed SSL method, as follows:

- PC1 is a pre-processing steps combination including case folding, punctuation mark removal, and tokenization.
- PC2 is a pre-processing steps combination including case folding, punctuation mark removal, tokenization, and stop-words removal.
- PC3 is a pre-processing steps combination including case folding, punctuation mark removal, tokenization, stop-words removal, and stemming.

Implementing FSL involves two pre-processing steps: case folding and punctuation mark removal. It is subsequently as PC4. The implementation of FSL does not involve tokenization, stop-word removal, and stemming steps to avoid the possibility of changing the sentence structure and original meaning of the review data. It is influenced by using the SETFIT framework as the FSL method. SETFIT focuses on sentence processing through the application of sentence transformers so that the structure and meaning of sentences can be maintained when only case folding and data cleaning are applied.

Although the SSL and FSL pipelines differ in several preprocessing steps, this distinction arises from the intrinsic design of the SETFIT framework. SETFIT depends on sentence-level semantic embeddings generated by sentence transformers, which achieve optimal performance when the original sentence structure and contextual cues are maintained. Consequently, only minimal preprocessing, such as case folding and basic punctuation cleaning, is applied to prevent alteration of syntactic patterns or removal of sentiment-bearing elements that influence embedding quality.

On the contrary, SSL employs a token-based classification pipeline that benefits from more extensive preprocessing, including normalization and filtering. Implementing the optimal preprocessing strategy for each paradigm ensures that both methods function under conditions consistent with their respective architectural characteristics. SETFIT's internal analysis shows that applying deeper preprocessing results in only minimal performance shifts, so differences in preprocessing flow do not have substantial implications for the model comparison results.

C. Feature Extraction

Feature extraction uses information from existing data to create vocabulary or corpus so the machine learning algorithm can work. This stage was only involved in SSL implementation, and the extracted feature is TF-IDF. Term Frequency (TF) is the frequent appearance of a term in the document. The more a term appears, the higher its value. Inverse Document Frequency (IDF) is the document's term distribution calculation. The TF-IDF weighting is formulated as shown in Eq. (1):

$$f.idf(t,d) = tf(t,d) \times idf(t) \quad (1)$$

where $tf.idf(t,d)$ represents the weight of each word (term t) in a document d. The term $tf(t,d)$ denotes the weight of *term* t in document d, while $idf(t)$ stands for the inverse document frequency in term t. The calculation of the inverse document frequency is defined in Eq. (2):

$$idf(t) = log\frac{n}{df(t)} + 1 \quad (2)$$

where n is the number of documents, $df(t)$ represents the number of documents consisting term t, and t represents term or word.

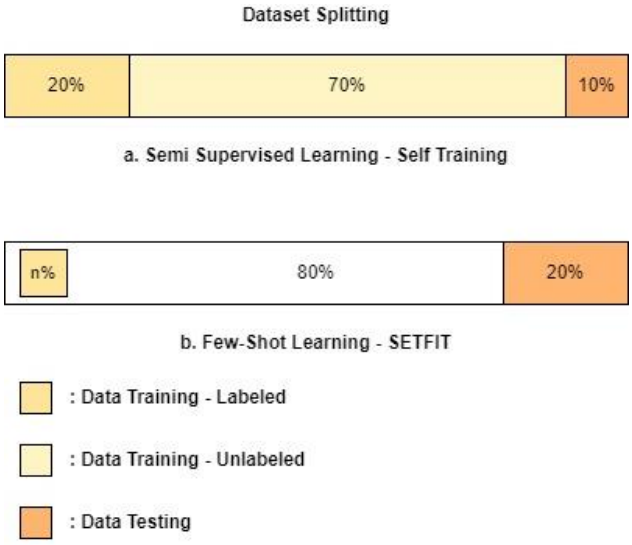

Fig. 1. Dataset splitting in applying (a). SSL and (b). FSL.

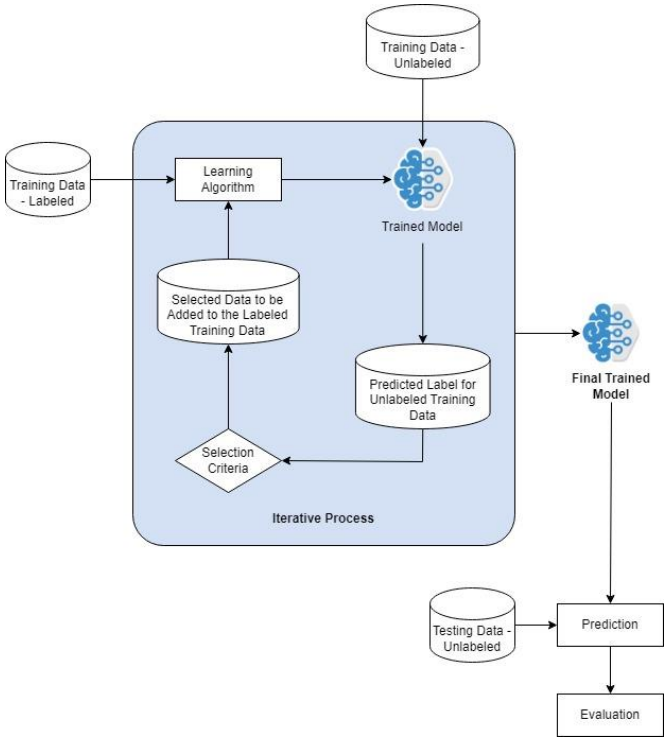

Fig. 2. Architecture of self-training classification model.

D. Building a Sentiment Classification Model

The first step of this stage is dividing the dataset, where there are differences in the implementation of SSL and FSL, as seen in Fig. 1. This study employs K-fold cross-validation for SSL implementation as a validation method to evaluate the performance of the built model by partitioning the dataset into training data and testing data. This research uses 10-fold cross-validation, which means the dataset will be split into ten partitions, and iteratively, each of the nine partitions will be training data while the other one will be testing data. Since this method employs the self-training method in SSL, each training data consists of two parts of labeled training data, and seven other parts are unlabeled. The unlabeled training data will be labeled based on the first generated model and added to the training data, and the training process will be repeated. This process is iterative until a specific condition or predefined number of iterations.

The second data division is involved in applying FSL, where the data is divided into a composition of 80% for the data to be selected as training data and 20% for test data. The training data selection process will be randomly performed on 80% of the previously defined data, and n% of the total data sample per label will be trained (labeled training data). This percentage value will be used as a testing parameter in the research experiment, namely 4%, 6%, and 8%.

Based on the results of respected dataset splitting, the subsequent process is the training process to generate the sentiment classification model. For the implementation of SSL, this study observed the effect of pre-processing steps and the combined classification algorithm on classification performance for the self-training method. As mentioned before, there are three combinations of pre-processing steps, whereas the involved classification algorithms are a support vector classifier (SVC) [20] and stochastic gradient descent (SGD) [21] with a threshold of 0.75. The model building will be conducted with several combinations of parameters based on the three kinds of pre-processing steps mentioned earlier. The architecture of the self-training classification model can be seen in Fig. 2.

Furthermore, this study implements SETFIT as the FSL method. SETFIT is a modification of a transformer model that has been previously trained to minimize the distance between pairs of sentences with similar meanings and maximize the distance between pairs of sentences with different meanings. This model produces sentence representations in dense vectors that the learning algorithms can use by utilizing Siamese network structures and triplet networks to produce semantically meaningful sentence representations [15]. SETFIT consists of two main stages: sentence transformer fine-tuning and classification head training [22]. An overview of the SETFIT architecture can be seen in Fig. 3.

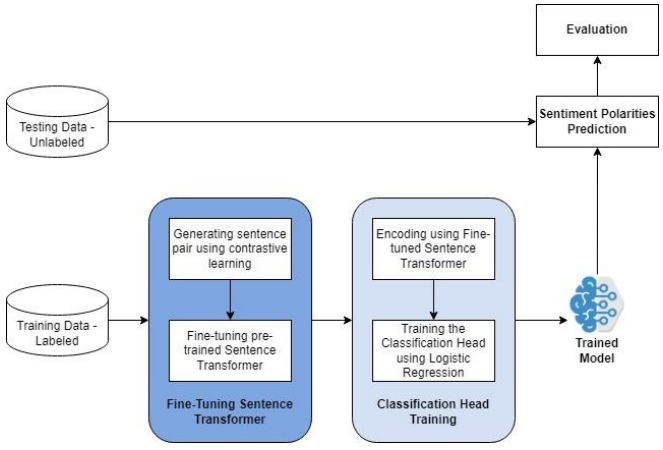

Fig. 3. Architecture of SETFIT model.

As shown in Fig. 3, the sentence transformer fine-tuning stage is divided into two steps: generating sentence pairs using

contrastive learning and performing the fine-tuning process of the pre-trained sentence transformer called paraphrase-multilingualmpnet-base-v2 [23]. Implementing contrastive learning aims to increase the amount of small training data to improve the classifier model's performance. Contrastive learning is learning by comparison, in which the learning process is performed by comparing different input samples, namely comparisons between positive pairs of similar input and negative pairs of dissimilar input [24]. Moreover, the selection of paraphrase-multilingualmpnet-base-v2 is based on this multilingual model from the paraphrase-mpnet-base-v2 version, which has been trained in more than 50 languages, including Indonesian.

There are two steps at the classification head training stage: the encoding process based on the fine-tuned sentence transformer produced in the previous stage and the training of the classification head. The encoding process aims to convert text data into vector representation based on the paraphrase-multilingual-mpnet-base-v2 model that was fine-tuned in the previous stage. The encoding process is performed on validation data from the few-shot learning process to produce output in sentence embedding, which has a richer sentence representation so that each word has a close relationship as a sentence. The next step in the classification head's training process aims to map the previously obtained sentence embeddings into the appropriate classes. This process involves a logistic regression model and is trained to predict data labels correctly. Logistic regression aims to find classification boundary lines that separate data into classes. These boundary lines are represented by regression formulas, where the training process in logistic regression involves using optimization algorithms to find the most appropriate regression coefficients in the regression formula [25]. This research uses the sigmoid function to carry out the binary classification function of 2 sentiment polarity classes.

E. Evaluation

The evaluation compares the result of testing data prediction with the actual class of the data (ground truth). The evaluation metric used in this research is an accuracy value, which can be calculated based on the formula shown in Eq. (3):

$$Accuracy = \frac{TP+TN}{TP+TN+FN+FP} \quad (3)$$

where TP (True Positive) represents the number of correctly predicted data when the model predicts the positive class, and TN (True Negative) denotes the number of correctly predicted data when the model predicts the negative class. Meanwhile, FN (False Negative) refers to the number of incorrectly predicted data when the model predicts the positive class, and FP (False Positive) indicates the number of incorrectly predicted data when the model predicts the negative class.

Accuracy is a representative and stable performance indicator for datasets with a balanced class distribution. Because there is no majority or minority class, the evaluation result indicates the ability to recognize both classes. Furthermore, the study employed the dataset under the same data condition, namely, a balanced dataset. Therefore, accuracy is the right choice when viewed from the perspective of the distribution of data classes in the dataset. Moreover, the two learning strategies or paradigms tested in the study focused on evaluating model behavior using very limited labeled data, rather than evaluating it based on specific classes. Therefore, accuracy is considered a simple, clear, and direct indicator of how each paradigm converts limited data into a correct predictive model.

III. Experiment and Analysis

A. Experimental Setup

This research divides the experiment into three experimental scenarios. The first scenario aims to get the best performance from implementing the self-training classifier as an SSL model by observing the combination of pre-processing and kernel functions. Subsequently, the second scenario aims to obtain the best performance from implementing SetFit as an FSL model by observing the percentage values of training data. In addition, the second experiment performs hyperparameter optimization for each type of training data. This study applies the Optuna framework to search for optimal hyperparameters, using algorithms such as TPE to find the optimal model configuration. The learning rate determines how quickly the model adjusts weights, while the epoch and batch size regulate the intensity and granularity of the optimization process. Parameters such as the number of iterations and the maximum number of iterations control the length of the training process to prevent overfitting and underfitting. The seed setting is necessary to ensure reproducibility of results, while the choice of solver determines the optimization mechanism used during classifier training. Thus, determining the right hyperparameter values is crucial for SetFit to achieve optimal performance under conditions of limited labeled data. The last scenario compares the results from the first and second scenarios.

B. Experimental Results and Analysis

The results of the first scenario can be seen in Fig. 4. A self-training classifier with an SGD tends to produce higher accuracy than an SVC, as depicted in Fig. 4. The accuracy produced by the self-training classifier for both classification algorithms decreased when using four pre-processing stages (PC2) compared to the results when using three pre-processing stages (PC1). The accuracy value subsequently increases when using five pre-processing stages (PC3). However, the highest accuracy values for both classification algorithms were obtained using three pre-processing stages (PC1). The highest accuracy result obtained was 84.52% with a combination of the SGD and 3-stage preprocessing. SGD can produce the best performance because, in theory, even though SGD is simple, SGD can work well in convex optimization [26]. Gradient descent can be used since convexity, defined as the continuity of a convex function's first derivative, ensures that convex optimization problems are smooth and have well-defined derivatives.

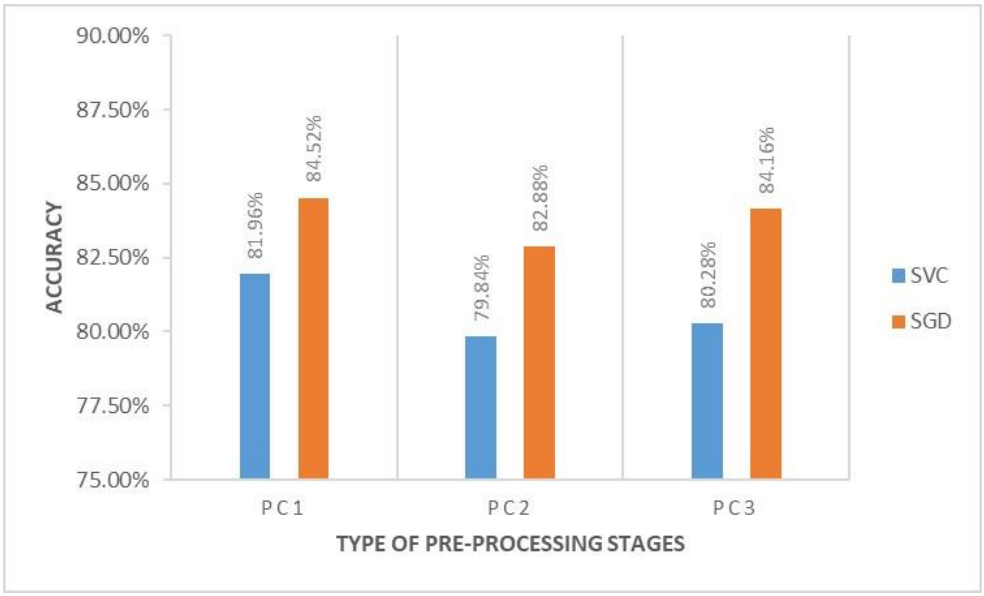

Fig. 4. Result of scenario 1.

TABLE I. RESULT OF SCENARIO 2

Percentage of Training Data for Each Label	Best Hyperparameter							Accuracy
	Learning Rate	*Epoch*	*Batch Size*	*Iteration*	*Seed*	*Max Iteration*	*Solver*	
4%	4.4104e-5	4	4	20	19	235	liblinear	81.25%
6%	4.1996e-5	5	8	10	36	122	liblinear	88.75%
8%	8.094e-5	2	8	10	21	94	liblinear	93.75%

Furthermore, the results of the second experimental scenario can be seen in Table I. The first experiment with eight training samples (4% data samples per label) obtained an accuracy of 81.25%, which is quite good considering the small amount of training data. Subsequently, in the second experiment, with 12 training samples (6% data samples per label), the accuracy value was 88.75%, higher than in the first experiment. The third experiment, with 16 training data samples (8% data samples per label), produced the highest accuracy of the three experiments, namely 93.75%. This result shows that the amount of training data is directly proportional to the accuracy value. The greater the amount of training data, the greater the accuracy value since the model can represent data more efficiently when the number of training data samples increases. In the context of few-shot learning, increasing training samples is still carried out in small data samples, and the model can obtain good accuracy values.

Based on the results from scenarios 1 and 2, it can be concluded that implementing FSL using SETFIT has better performance than implementing SSL using a self-training classifier, with a difference in accuracy value of 9.5%. If compared in terms of the amount of labeled data that must be prepared, SETFIT is more efficient than a self-training classifier (SETFIT), which only requires 12 training samples and can produce an accuracy performance of 88.75%. This accuracy value is higher than the self-training classifier's obtained performance, which requires 500 training samples and only achieved an accuracy of 84.25%. SETFIT's success in outperforming the classical self-training classifier is influenced by the contrastive learning process, which can increase training data by utilizing a pre-trained sentence transformer due to the excellent ability of the pre-trained model to assess similarities between sentences. When using tiny labeled training samples, SETFIT has not been able to produce accuracy values above 90. This weakness may arise because the choice of method for classification head training applied in this research is logistic regression, which has straightforward complexity.

In addition, based on the results from scenarios 1 and 2, it can be said that using FSL (SETFIT) is very efficient for achieving high performance when the amount of labeled data is very small (e.g., <20 samples per class) and computational resources are limited. Meanwhile, the SSL approach is suitable for studies when researchers have access to a sufficient amount of unlabeled data—not a very large amount, but enough to generate pseudo-labels that can enrich the training set. In such conditions, SSL may offer greater benefits than FSL, as the model can gradually expand its training data via a self-training mechanism.

The results of this study not only demonstrate performance differences but also confirm that semantic embedding-based few-shot methods have more efficient learning capabilities than pseudo-labeling in SSL when labeled data is scarce. These findings provide practical guidance for NLP developers in low-resource environments, suggesting that FSLs such as SETFIT are a more reliable and resource-efficient starting point for sentiment analysis in similar domains.

In addition to these advantages, SETFIT also offers greater computational efficiency because it does not require full fine-tuning as conventional transformer models do, making it more suitable for devices with limited resources. Furthermore, SETFIT's characteristic of not relying on large amounts of labeled data makes it more adaptable and easily transferable to other domains with similar low-resource conditions than other learning approaches that are more data- and computationally intensive.

IV. CONCLUSION AND FUTURE WORK

In this study, the performance of SSL and FSL methods for sentiment analysis of hotel reviews with small labeled training data is compared with the help of the gold-standard dataset of Indonesian hotel reviews with two sentiment polarities (positive and negative). Results show that the FSL using SETFIT can outperform the SSL using a self-training classifier algorithm with an accuracy improvement of 9.5%. SSL with self-training obtained an accuracy of 84.25% and employed 500 labeled training samples. In contrast, SETFIT produced an accuracy above 90%, to be precise 93.75%, using only 16 labeled training samples. These findings not only confirm the superiority of SETFIT's results but also demonstrate that semantic representation-oriented few-shot approaches are more effective at learning sentiment patterns than SSL when the number of labels is limited. This provides practical insight that FSLs like SETFIT can be a more efficient and robust starting point for sentiment analysis in low-resource contexts.

Possible directions for future research include exploring other classification methods in classification head training in SETFIT architecture. Thus, the smaller labeled training samples can achieve accuracy above 90%. In addition, this study has a weakness in its dataset scope: it comes from a single OTA platform, limiting linguistic variability and potentially hindering generalization across platforms.

ACKNOWLEDGMENT

This research was supported by the Directorate of Research, Technology and Community Services, Ministry of Education, Culture, Research and Technology, Indonesia, under the "Penelitian Fundamental Regular" scheme, Grant No. PFR Grant 601-54/UN7.D2/PP/VI/2024, dated June 12, 2024. The authors would like to express their gratitude for the financial support that enabled the completion of this study.

Abstract*—Automated essay scoring (AES) has become an essential tool in educational technology, yet many existing approaches rely on black-box models that lack interpretability and adaptability across diverse prompts and writing styles. Conventional transformer-based AES systems demonstrate strong accuracy, but often fail to provide pedagogically meaningful feedback or generalize effectively in low-resource settings, limiting their practical applicability. The proposed COSMET-Net (Contrastive and Explainable Semantic Meta-Evaluation Network) addresses these limitations by integrating contrastive learning, meta-learning, and explainable AI to produce an adaptive and interpretable evaluation of academic essays. Essays are processed through text cleaning, tokenization, and lemmatization, and embeddings are generated using pretrained transformers such as BERT and RoBERTa. Contrastive learning distinguishes high- and low-quality essays, while a Contrastive Linguistic Regularization (CLR) layer aligns embeddings with linguistic properties, enhancing interpretability. Meta-learning enables rapid adaptation to novel prompts with minimal additional data. The explainable output module, employing attention visualization and SHAP values, provides detailed feedback on grammar, coherence, vocabulary richness, and readability. The framework was implemented in Python with PyTorch and Hugging Face Transformers and evaluated on the IELTS Writing Scored Essays Dataset. COSMET-Net achieved an accuracy of 92%, a recall of 93%, and an F1-score of 92%, surpassing existing models such as hybrid RoBERTa + linguistic features (F1-score 84%) and discourse + lexical regression (F1-score 88%). These results demonstrate that COSMET-Net delivers highly accurate, flexible, and linguistically interpretable assessments, providing a scalable solution for automated and pedagogically meaningful essay evaluation.

Keywords*—COSMET-Net; contrastive learning; explainable AI; meta-learning; essay scoring

I. Introduction

Assessment of academic essays has played a significant role in language learning and assessment, particularly in standard testing systems such as the International English Language Testing System (IELTS), Test of English as a Foreign Language (TOEFL), and other high-stakes testing. Essays are known not just to test the level of grammar, vocabulary, and sentence structure but also the higher-order skills of coherence, cohesion, argument, and critical thinking. The traditional scoring procedures of the essays have been mainly on the basis of the human raters because their rates, though useful in nature, are likely to be subject to variations, subjectivity, and time constraints. The consistency, fairness, and scalability of grading academic essays, specifically, and in large volumes, is not a new concern in education and employment [1]. Automated Essay Scoring (AES) has been a field that has evolved significantly in the past two decades, and it has been achieved due to the availability of massive collections of linguistic data and advances in computational linguistics, natural language processing (NLP), and machine learning (ML) [2]. The initial AES systems, such as Project Essay Grade (PEG) and e-rater, were founded on the hand-made features of lexical richness, grammatical precision, and textual surface statistics [3]. Though these techniques were found to be encouraging within the framework of reducing human labor and providing prompt feedback, they were not predisposed towards capturing the deeper semantic and rhetorical features of writing, such as persuasiveness, logos, and richness of arguments. The studies of AES have been expanded to the sequential modeling of essays as a sequence of meanings rather than a single feature since the creation of deep learning and the transformer-based architecture [4]. Pretrained language models such as BERT, RoBERTa and GPT-based models have enabled modeling of finer semantic and syntactic features, and the capability of automated systems to be

akin to human-like analysis [5]. Besides being accurate, modern AES systems are also expected to provide explainability, whereby learners and teachers are able not only to know the score that an essay got, but also the reason that the score was achieved. This move towards the black-box evaluation with interpretable models is essential in the educational setting, where transparency results in trust and allows actionable feedback [6]. Moreover, it is moving to the adaptive assessment systems, which could consider various writing circumstances, various levels of competence, and personal learning patterns. Adaptive systems are created to provide dynamic and learner-centered feedback, which can be utilized to maintain enhancement in writing skills instead of providing fixed tests. The discriminative ability of the evaluation models is also enhanced by the implementation of contrastive learning that aims at creating finer differences between the high-quality and low-quality writing samples [7]. Simultaneously, meta-learning methods are under investigation to enhance the generalization of models across domains and datasets and make them scalable to multilingual and multicultural settings [8].

The proliferation of annotated datasets, including the IELTS Writing Scored Essays Dataset, has spurred empirical research in this field through having standardised points of reference in terms of training and assessment [9]. These datasets can make the models learn based on real student essays that were graded by expert raters, which makes sure that they comply with the real-world assessment standards. Nevertheless, even though current datasets and models have enhanced the accuracy and efficiency of systems, there are still problems in regard to meaningful, adaptive, and explainable evaluations that are supportive of pedagogical objectives. To solve these problems, new frameworks are needed, which combine the progress in contrastive representation learning, transformer-based architectures, and adaptive meta-learning in order to develop the next-generation AES systems [10]. Based on the constraints found in the current AES systems, especially the absence of linguistic interpretability, the restricted generalization between prompts and reliance on black-box transformer models, the following research question is established: What is the best way to create an automated essay scoring system that is both more accurate in scoring and more cross-prompt adaptable while also offering linguistically interpretable and pedagogically valuable feedback? To answer this research question, the proposed COSMET-Net framework that is a combination of contrastive learning, meta-learning, and Contrastive Linguistic Regularization (CLR), is created.

A. Research Motivation

Despite the accuracy of automated essay scoring systems, even the ones deeply trained into the black-box and transformer ML, do not relate their predicted score or evaluation to a piece of linguistic or stylistic evidence. The user or learner often never knows why or what aspect of their work warranted a numeric score, or what they should work on next to improve their writing. This linguistic interpretability issue limits the pedagogically useful conclusions these systems can offer. In response to this issue, we have included a CLR approach into the COSMET-Net framework that ensures that the evaluation process not only sorts essays based on quality but also correlates the score with the linguistic traits that characterize a good writer. By embedding interpretability within the score, it fosters a move away from score and into the domain of feedback that is explainable, and educationally useful.

B. Problem Statement

Automated essay scoring (AES) is considered to be one of the most challenging fields of natural language processing as it must be able to compromise between accuracy, flexibility, and explainability [11]. More conventional methods, such as RNNs, LSTMs, and even traditional transformer-based models, tend to be very high-performing in terms of prediction but do not offer learners interpretable feedback that can be used in pedagogy. Most of them are based on manually crafted linguistic characteristics or task-related information, which makes them less scalable to a wide range of prompts, domains, and levels of proficiency [12]. In addition, modern systems have difficulty in discriminating fine-grained quality of writing, including slight variations of coherence, style, and readability, and tend to be black-box models and thus could not be easily used to provide actionable information to improve [13]. The issue becomes worse when there is low resource or Few-Shot, where there is limited labeled essay data. COSMET-Net seeks to address these gaps with contrastive self-supervised learning, meta-learning, and explainable evaluation, and consider adaptive, interpretable, and robust evaluation of academic essays according to several writing characteristics.

C. Research Significance

The contribution of this research is to connect computational assessment of essays and linguistically based education. COSMET-Net with CLR aligns deep contrastive embeddings with linguistic measures like cohesion, grammar range, and readability to provide interpretable, actionable information for students and teachers. It makes a step toward fairer, more transparent, and pedagogically applicable assessment while furthering the goal to improve writing quality through explainable AI. COSMET-Net proposes a universal architecture that immediately compares semantic embeddings to linguistic features via CLR, as opposed to the previous AES models, which do not interrelate these spaces. The framework also incorporates meta-learning into a contrastive pipeline, which is a field that has limited exploration in AES, and facilitates cross-prompt adaptation more effectively. This combination is no longer an incremental stacking of modules and provides more evident benefits of precision, interpretability, and flexibility.

D. Recent Innovations and Challenges

In recent years, the AES research has been changing rapidly, with transformer-based models and pretrained language representations becoming the state-of-the-art research. Architectures based on BERT, RoBERTa, and GPT have performed much better than conventional feature-based systems and have shown higher correlations with human scores. There are also contrastive learning and pairwise ranking techniques used to learn finer details of writing quality, and reinforcement learning techniques have been used to learn dynamic feedback generation. Simultaneously, interpretability methods, including the visualization of attention and feature attribution, have been presented to increase the transparency of the system. Although there are these advances, there are still major challenges. Most transformer-based models have high training data and

computation needs, which restrict their scalability. The interpretability methods tend to give superficial information as opposed to profound pedagogical instructions. In addition, models are still unable to generalize to various datasets and settings, which interferes with performance variances. These drawbacks highlight the importance of further innovation of adaptive, explainable, and context-aware AES systems.

E. Key Contributions

- Introduces a mechanism that aligns transformer embeddings with linguistic features, enabling clearer and more interpretable scoring.
- Combines meta-learning with contrastive objectives to support rapid adaptation to new prompts, especially in low-resource settings.
- Provides explanations linked directly to linguistic criteria used in human evaluation, moving beyond basic attention-based methods.
- Integrates semantic learning, linguistic grounding, and adaptability within a single framework instead of treating them as separate modules.
- Demonstrates stronger robustness across varying essay prompts, reducing prompt dependency issues seen in existing AES models.

The remaining sections of this study are arranged as follows: Related works are given in Section II, the methodology section in Section III, and the results and discussion are given in Section IV. Lastly, Section V gives away the conclusion and future works.

II. Related Works

Automated essay scoring has been widely studied in Natural Language Processing, as highlighted by Gupta [14], who investigated the use of transformer-based models for automated essay grading. The purpose of their work was to evaluate the effectiveness of pre-trained models such as BERT, RoBERTa, ALBERT, DistilBERT, and XLM-RoBERTa in improving scoring accuracy. Their method combined transformer architectures with data augmentation techniques to enhance robustness across multiple essay topics. Using multi-label classification accuracy scores on four distinct topics, they demonstrated superior performance of transformers over traditional LSTM models, with augmented data yielding significant improvements. However, the study acknowledged a drawback in the limited inclusion of topic-relevant contextual elements, suggesting the need for future refinements to achieve more pedagogically aligned and adaptive essay evaluations.

Song et al. [15] examined the opportunities of open-source large language models (LLMs) in the Automated Essay Scoring (AES) and Automated Essay Revising (AER). The aim of the study was to overcome the issue of high cost, dependency of data and low generalizability of existing AES/AER systems. Their approach used zero-shot, few-shot and p-tuning AES methods on open-source LLMs, on an essay dataset of 600 samples rated by humans and then subjected to human-machine consistency and similarity tests. The findings indicated that 10B-parameter LLMs were comparable in terms of performance with deep-learning baselines and they were successfully able to enhance the quality of essays in AER tasks. There was, however, a weakness that was observed in sensitivity to prompt design and a limited scale of evaluation, which limited generalization.

Tang et al. [16] explored the multi-dimensional automated writing assessment through the combination of both fine-grained linguistic features and explainable AI. It was aimed at decomposing the roles of micro-linguistic and aggregate features in forecasting various constructs of writing. Their approach involved Principal Component Analysis to narrow down the indicators, followed by the creation of linear and non-linear regression models, such as Random Forest Regression, with SHAP values added to them to provide interpretability on a trait level. They also proved that, with a combination of micro-features and aggregated variables, prediction of trait-specific scores was greatly enhanced, as opposed to using aggregate only. The limitations are, however, that it depends on handcrafted feature extraction and is not as scalable across genres or domains, as feature engineering might not extrapolate to the studied dataset. Faseeh et al. [17] discuss the improved version of Automated Essay Scoring by suggesting a hybrid AES model that combines deep contextual embeddings with linguistic heuristics. The purpose was to provide a higher precision and strength of scoring by merging semantic representation and surface-level text analysis. The method takes RoBERTa-generated embeddings combined with handcrafted linguistic features (e.g., grammar errors, readability, sentence length), and scores them with Lightweight XGBoost (LwXGBoost). They are trained and tested on a heterogeneous AES corpus of student essays of different levels of education. The result is a high Quadratic Weighted Kappa score of 0.941 that demonstrates high degree of accuracy and strength. The disadvantage is that it relies on the features that are handcrafted, which could restrict generalization between domains, and need to be hand-tuned.

Li et al. [18] explored the concept of automated essay scoring with attention to semantic and prompt-aware to enhance deep model accuracy. They suggest a Multi-Scale Semantic Feature (MSSF) framework that incorporates Sentence-BERT sentence embeddings, document-level global feature through LSTM-MoT, shallow linguistic feature, and prompt-relevance vectors. The model is tested on the Kaggle ASAP dataset and has a Quadratic Weighted Kappa of 0.793, which is higher than a number of baselines. The method, however, is based on manually designed shallow and prompt features, which are offline-computed, which is not scalable and flexible to a wide range of prompts and domains. Further, manual feature design introduces preprocessing cost and can be counterproductive to unseen writing tasks.

The problem of automated essay scoring is still persistent, and Tahira Amin [19] took the opportunity to utilize the benefits of pretrained transformers to learn on a Few-Shot basis. The researchers sought to improve both holistic and analytical scoring using little training data of the task at hand. The algorithm optimized generalized transformer models on a small set of essay samples, thus, resulting in excellent generalization at a low annotation cost. Essay scoring data were evaluated using Quadratic Weighted Kappa (QWK) as a performance measure and revealed great improvements compared to

traditional methods. The shortcoming is however the black-box nature of the model and lack of explainability which decreases its pedagogical value and the flexibility of the model to various prompts and writing styles.

Pack et al. [20] evaluate the possible application of LLM, such PaLM 2, GPT-3.5, GPT-4, and Claude to grading ESL essays automatically. Their study compares the validity, reliability, and generalizability of these models on the rubrics given as grammar, vocabulary and coherence. GPT-4 demonstrated high intra-rater reliability results and Quadratic Weighted Kappa scores that are within the same margin as human performance of other models. The research points out that LLMs are capable of delivering human-comparable scores in automated scoring contexts, particularly with essays that admit a high level of syntactic variety. Yet, according to repeated runs of the same essay, the scores may not be identical, showing no determinism in the output. Besides, schools and researchers are less able to implement such models in a cost-sensitive or offline context because they operate upon proprietary APIs. It has the primary drawback of a lack of consistency in production and access to the internals of the model, which hinders customization of models and diagnosis of errors.

Overall, the studies reviewed advance automatic essay scoring using hybrid linguistic models, large language models, and transformers. There are still a number of holes in current hybrid AES systems. Earlier contrastive methods are primarily interested in semantic disentangling, where embeddings are not associated with linguistic cues. The use of meta-learning in AES is also scarce, and not coupled with contrastive learning on enhanced prompt generalization. The previous studies also do not have interpretability modules based on linguistic features that are employed by human evaluators. These constraints demonstrate that an integrated solution uniting semantic learning and linguistic alignment and adaptive capability is necessary.

III. Adaptive Explainable and Contrastive Essay Evaluation Methodology

The methodological contribution of the COSMET-Net consists in how the concepts of contrastive representation learning, meta-learning adaptation, and Contrastive Linguistic Regularization (CLR) have been integrated into an AES pipeline. This merging is a new training paradigm, where linguistic properties are now installed directly into the contrastive embedding space, allowing interpretable reasoning of scores, an aspect that was previously unavailable with a transformer-only model or a hybrid model. The meta-learning module continues the expansion of the framework as it allows quick adaptation to unseen essay prompts, which is a long-standing shortcoming of traditional AES systems. The model is trained and tested on standard essay datasets, and the results are measured with Quadratic weighted Kappa (QWK) and readability scores. The combination is highly accurate, flexible, and interpretable, and it defeats the weaknesses of black-box AES systems.

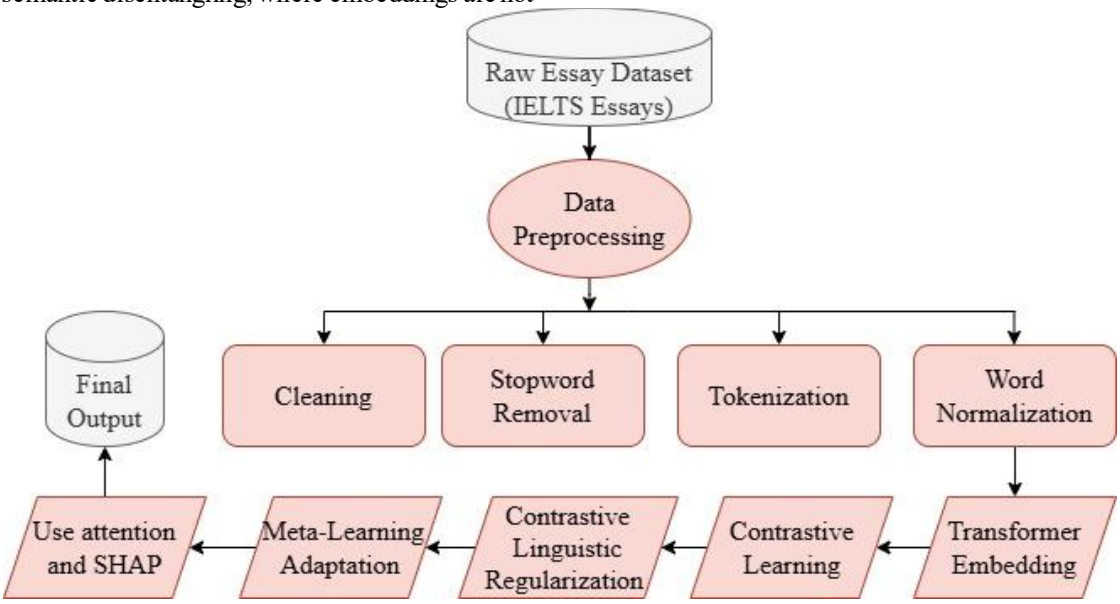

Fig. 1. COSMET-Net process of adaptive essay evaluation.

Fig. 1 shows the block diagram of the COSMET-Net model that is intended to be used to evaluate academic essays in an adaptive and explainable way. It begins with rough essays which are processed through data preprocessing, in which text cleaning, stopword elimination, tokenizing, and lemmatizing are used to organize the data and increase the interpretability. Semantic, syntactic and contextual information is then encoded into contextual embeddings of the preprocessed text using transformer-based models such as BERT or RoBERTa. Such embeddings are also optimized by contrastive learning, which helps the model to differentiate between essays of different quality by comparing and contrasting. Meta-learning component enables the model to be able to adapt to new prompts or domains with few data to enhance its flexibility and robustness. The last element, the explainable output component, offers interpretable feedback on the writing style, coherence, readability and grammar, which ensures transparent and pedagogically relevant essay evaluation.

A. Data Collection

It is a publicly available dataset on Kaggle and consists of more than 1200 IELTS Writing Task 2 essays in English that include official band scores, and the dataset is called IELTS Writing Scored Essays Dataset [21]. These essays are the real student responses to real IELTS prompts, which are evaluated by certified examiners according to IELTS Writing Band Descriptors. The dataset consists of critical metadata, including essay prompts, essay texts, and band scores of four assessment criteria, including Task Response, Coherence and Cohesion, Lexical Resource, and Grammatical Range and Accuracy. These structured data allow the development and testing of automated essay grading systems, which is a good baseline of training and testing machine learning models in educational technology. This data is freely accessible on Kaggle and can be used by researchers and developers to advance natural language applications of natural language processing to be used in the assessment of education.

B. Data Pre-Processing

Data preprocessing is the process of transforming unstructured data that is in its raw form into structured data that is easy to analyze. It deals with steps that include text cleaning, stopword removal, tokenization, and lemmatization, which bring consistency to data, reduce noise, and enhance data quality to perform models with precision and reliability.

1) Text cleaning: The first thing to do when preparing the text, which will be analyzed, is cleaning the text. This involves the removal of all the unwanted content that can interfere with the natural language processing. Start by turning all characters of the text to lower case; consistency should be made the same everywhere; i.e., in words like “The” and “will”, they will be treated the same way. Then eliminate all the marks of punctuation, i.e., commas, periods, colons, and quotation marks, as they can contribute nothing much to structural analysis. This must also remove unnecessary white spaces, tabs, and line feeds in order to render the text presentable. It should also be made clean by deleting all the special characters like the per cent character, the ‘at’ character, and the hash character. It is given in Eq. (1):

$$T_{clean} = f_{clean}(T_{raw}) \quad (1)$$

where, T_{raw} represents the original essay. After the cleaning operation has been executed f_{clean}. T_{clean} is the cleaned and standardized text that is now ready to be analyzed further.

2) Punctuation removal: Stopwords are also common words, such as ‘the’, ‘is’, ‘at’, ‘which’, and ‘and’. These words are repeated numerous times and do not add much specific semantics. Stopword discarding may help one to focus on significantly different vocabulary and language features as far as content is concerned, in writability and style of writing. This step is optional, but it is especially beneficial when conducting more detailed linguistic analyses, where it is important to demonstrate a large amount of voluminous vocabulary or syntax. The removal of the stopwords removes the noise in the data and simplifies the analysis based on keywords or frequencies. But it can keep stopwords in style analysis to use the rhythm and syntax flow of a sentence. It is expressed in Eq. (2):

$$T_{stop} = \{w \epsilon T_{clean} | w \notin SW\} \quad (2)$$

In Eq. (2), T_{clean} : text has been sanitized. w: word token. A predetermined set of stopwords, such as {the, is, at, of, on, and}, are used in SW. T_{stop}: text is free of stopwords.

3) Tokenization: Tokenization involves the division of the text into smaller details, such as words, sentences. Word tokenization has been applied in calculating word count, word frequency, and rich vocabulary, which are needed to determine the difficulty of the essay and writing style. Sentence tokenization allows to compute the average sentence length and sentence structure that has a direct influence on readability. The process of tokenization can be used to extract the valuable features of the language representation that prove the manner in which the text is divided and boxed by dividing it into logical units. It is an initial step of NLP that cleans the data in preparation to be processed further, including parsing, tagging, and readability rating. This is formulated in Eq. (3):

$$W = \{w1, w2, w3, \dots, wn\} \quad (3)$$

W in Eq. (3) represents the set of tokens and n is the total words.

4) Word normalization: Lemmatization and stemming are the processes to simplify words into their root or base. An example would be words such as running, runs, and ran would then be changed to run. Stemming chops off word endings quickly, often roughly, while lemmatization uses vocabulary and grammar rules to find the correct base form. These steps help in unifying different forms of a word, which is particularly useful for counting unique words, understanding lexical variety, or identifying overused terms. Though optional, applying either process can make your linguistic analysis more precise, especially when comparing vocabulary usage across multiple texts or authors. This is given in Eq. (4):

$$L(w) = lemma(w) \quad (4)$$

In Eq. (4), W is the word token, w is the single word and $L(w)$ is the base form.

C. COSMET-Net Essay Evaluation Transformer-Based Architecture

COSMET-Net is a transformer-based system that is intended to be used in adaptive, explainable, and contrastive grading of academic essays. The first module of the architecture is the preprocessing module, which cleans, tokenizes, and normalizes essay texts to generate standardized inputs. These essays are then passed on to some pretrained transformer encoder such as BERT or RoBERTa to generate rich contextual embeddings at the token level and sentence level. The contrasting learning module takes inputs on these embeddings, and it is trained to learn the difference between quality and poor essays by maximizing the pairwise or triplet loss functions. This motivates the model to pick up on minor variations in writing style,

coherence, richness of vocabulary, as well as readability. In order to deal with the problem of cross-prompt generalization and low-resource conditions, a meta-learning component is incorporated, allowing the model to quickly adapt to new essay prompts with a small number of examples. Lastly, an explainability module uses attention visualization and feature attribution methods (e.g., SHAP values) to produce interpretable feedback on grammar, style, and readability scores. It employs an architecture, which allows end-to-end training, integrating semantic representation, contrastive discrimination, and explainable output, and helps close the performance gaps between high and pedagogical use of automated essay scoring. COSMET-Net guarantees sound assessment and practical feedback to the learners and educators.

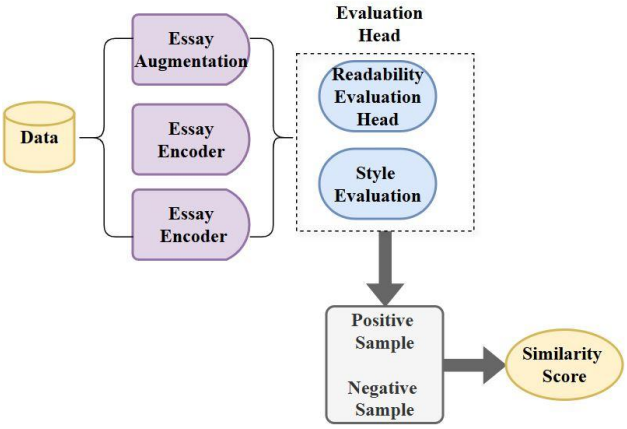

Fig. 2. Contrastive self-supervised transformer framework for essay evaluation.

Fig. 2 shows the suggested contrastive self-supervised transformer model that is aimed at academic essay analysis. This model starts with essay inputs that are inputted into an encoder that is based on a transformer to obtain semantic and syntactic representations. Contrastive learning is used to make embeddings closer to the truth, by differentiating between good and bad essays, and enhances the strength of the representations learned. The flexibility of various types of essays and styles of writing are given by using meta-learning layer which causes the enhancement of generalization among various learners. The framework includes explainability by focusing on relevant linguistic and structural properties of prediction in order to make the evaluation more transparent. The model is able to provide the appropriate score and the interpretable feedback to enhance the writing style, coherence, and readability in academic essays through the use of the architecture.

1) Preprocessing and cleaning of the data and text: Preprocessing of data converts messy texts of essays into structured, formatted data, which enhances the learning and performance of the model. It ensures consistency and further improvement of the semantic meaning of the text to be processed. The preprocessing of data transforms noisy essay texts into structured, formatted data that improves the model learning and performance. It guarantees uniformity and enhances the semantic interpretation of text to process further. In COSMET-Net, the IELTS dataset essays are subjected to text cleaning, removal of stopwords, tokenization, and lemmatization. Text cleaning normalizes the text, changing it to lowercase, eliminating punctuation and special characters, and also unnecessary whitespace. Stopwords can be dropped when the vocabulary richness is in focus, but can be kept when the style is to be analyzed by rhythm. The text is divided into words and sentences, allowing frequency and readability to be calculated. Lemmatization standardizes words to their roots, e.g., running into run, which enables the model to examine the use of vocabulary with more accuracy. This structured text is further sent to the embedding module to create contextual features that are needed to make contrastive and explainable evaluation. The preprocessing function in Eq. (5) is given as:

$$T_{clean} = f_{clean}(T_{raw}) \quad (5)$$

where, T_{raw} is the original essay text, and f_{clean} is the cleaning operation that deletes any irrelevant content, punctuation, and other special characters in this equation. The output, f_{clean} is the processed and normalized text which will be embedded and analyzed.

2) Essay embedding with transformers: Embedding refers to textual data into dense vectors, learns semantic, syntactic, and contextual information, which is required in downstream evaluation tasks, and is done with Transformers. COSMET-Net utilizes pretrained transformer models such as BERT or RoBERTa to extract embeddings of preprocessed essays. These models are coded in the relationship between words, the structure of the sentence, and the context, which offers a deep understanding of the writing style and the features of readability. The embeddings serve as the input of the contrastive learning module, such that a slight change of the quality of the text is recorded. COSMET-Net is not required to be fed with massive amounts of labeled data using the transfer learning technique and can adapt to new essays within a short time. Such a strategy will also make it focus on major semantic patterns and not on surface features, contributing to accuracy and flexibility. The embedding in Eq. (6) is stated as:

$$E = f_{embed}(T_{clean}) \quad (6)$$

In this case, T_{clean} is the tokenized and cleaned essay text, and f_{embed} is the transformer encoder that converts text to embedding vectors E. Such embeddings are very informative on the text, making it possible to fine-tune the evaluation of writing qualities.

3) Score differentiation based on contrastive learning: Contrastive learning will ensure that the model distinguishes between high-quality and low-quality essays by maximizing similarities within the same class and minimizing similarities between different classes. COSMET-Net uses contrastive learning to enable the model to learn the subtle variations between essays. The model takes as inputs paired or triplet inputs, one of high quality and one of low-quality essay, and computes embeddings and optimizes them with the help of a contrastive loss function. This is done to promote the network

to differentiate the essays in terms of style, coherence, grammar and vocabulary richness. It is also particularly useful when there is a limited number of data to learn because it enables the model to concentrate on the relative differences rather than on the absolute scores. The contrastive module makes sure that similar readability and style essays will be found in the same cluster, and those with high differences are spaced apart in the vector space. In Eq. (7), the contrastive loss is defined as:

$$L_{contrast} = max\left(0, margin + d(E_{anchor}, E_{Positive}) - d(E_{anchor}, E_{Negative})\right) \quad (7)$$

The reference essay that is embedded is known as E_{anchor}, the similar essay is known as $E_{Positive}$, and the dissimilar essay is known as $E_{Negative}$. The distance function d is the measure of similarity between embeddings, and the margin is the measure of a minimum distance between dissimilar essays. The aim is to make similar essays closer and distant dissimilar ones to be further apart.

4) Contrastive linguistic regularization for linguistic interpretability: Although contrastive learning allows COSMET-Net to differentiate between essays that are high- or low-quality at a semantic level, it does not guarantee that these representations are grounded in observable linguistic characteristics (i.e., readability, cohesion, grammatical range). Thus, the CLR mechanism is added to the COSMET-Net framework to address this potential gap. CLR adds a secondary constraint to the general framework, which aligns the learned transformer embeddings with observable linguistic properties/dimensions derived from each essay, such as part-of-speech (POS) ratios, lexical richness (type-token ratio), sentence complexity, or readability scores (Flesch Reading Ease, Gunning Fog Index).

The regularization encourages representations that are semantically discriminative and linguistically interpretable during training. A projection function maps essay embeddings $f(E_i)$ and linguistic feature vectors $g(L_i)$ into a joint latent space, minimizing their Euclidean distance. It is represented in Eq. (8):

$$L_{\text{ling}} = |f(E_i) - g(L_i)|^2 \quad (8)$$

The total loss function is updated as in Eq. (9):

$$L_{\text{total}} = \alpha L_{\text{contrast}} + \beta L_{\text{meta}} + \gamma L_{\text{ling}} \quad (9)$$

where, L_{contrast} is contrastive loss, L_{meta} is the meta-learning objective, and L_{ling} is the linguistic regularization term. The coefficient γ balances the influence of linguistic interpretability on model training.

By including CLR, COSMET-Net learns not only to separate essays by quality but also to interpret and correlate its internal representations with embodied linguistic properties, leading to scoring decisions and interpretability that provide a transparent and pedagogically sound basis for human scoring in nonblack-box models.

5) Meta-Learning to adapt to few shots: Meta-learning allows the model to generalize to a wide range of essay topics, since it can adapt very fast to new prompts or domains with limited labelled data. COSMET-Net incorporates meta-learning methods to refine the model using new essay prompts, using very few extra data. The model is trained to learn optimization techniques that are applicable to unknown contexts after training on existing datasets. As a case in point, with a handful of essays on a new domain, the model can be reconfigured without a lot of retraining, which means that it can perform well even in low-resource settings. COSMET-Net can be applied to various educational environments because meta-learning is based on past learning experiences to enhance adaptation. It enables the contrastive module to be effective in various writing activities by adapting to new vocabularies and sentence structures as well as styles of writing. The optimization of meta-learning is written in Eq. (10) as:

$$\theta' = \theta - \alpha \nabla \theta L_{task}(E) \quad (10)$$

In Eq. (10), θ is the model parameter, α is the learning rate, and L_{task} is the task-specific loss of the embeddings E. The equation demonstrates how model parameters are optimized to fit new tasks within a short time span, as the performance increases with a few examples.

6) Feedback with the help of explainable output: The explainable output module offers interpretable information about the style of writing, grammar, coherence, and readability to help the learners know their strengths and weaknesses. Once the embeddings are optimized by contrastive and meta-learning, COSMET-Net generates explanations which consist of highlighting text segments of importance by attention mechanisms and feature attribution algorithms like SHAP. The insights are aligned to the writing characteristics such as grammar mistakes, sentence structure, vocabulary richness, and level of readability. The explainable output assists the learners to see why a given essay has received a higher or lower score and recommends improvements that can be taken. Transparency of predictions would increase the confidence in automated scoring and facilitate the pedagogical goals of COSMET-Net, allowing the educator to deliver more specific feedback in terms of writing characteristics instead of abstract scores. In Eq. (11), the feature attribution is calculated as:

$$Importance(w) = \frac{\delta y}{\delta E}(w) \quad (11)$$

In Eq. (11), y is the score on the output, $E(w)$ is the embedding of word w, and $\frac{\delta y}{\delta E}(w)$ is the sensitivity of the output to the embedding of the word. This step determines powerful words, which can contribute to the description of the scoring choices of the model.

Fig. 3 shows the process flow of the COSMET-Net framework in assessing academic essays. It begins with the original essay, which is preprocessed with such stages as text cleaning, stopword removal, tokenization, and lemmatization to provide the data with consistency and reliability. After that, the

processed text is processed by a transformer encoder, e.g. BERT or RoBERTa, to produce contextual embeddings, which represent semantic relations. These embeddings are then fed through two projection heads of high and low-quality essays. The contrastive learning output is further refined by a CLR layer, which grounds the semantic embeddings in linguistic features such as cohesion, vocabulary richness, and sentence complexity before adaptation through meta-learning. An embedding loss criterion is used to learn the embeddings by encouraging similarity within the categories and difference between them. Such methods as few-shot adaptation and cross-prompt generalization are meta-learning methods that enable the system to adapt swiftly to new tasks. Transparency and efficiency in writing skills are then achieved by giving actionable feedback on the writing style and readability by the explainable output module.

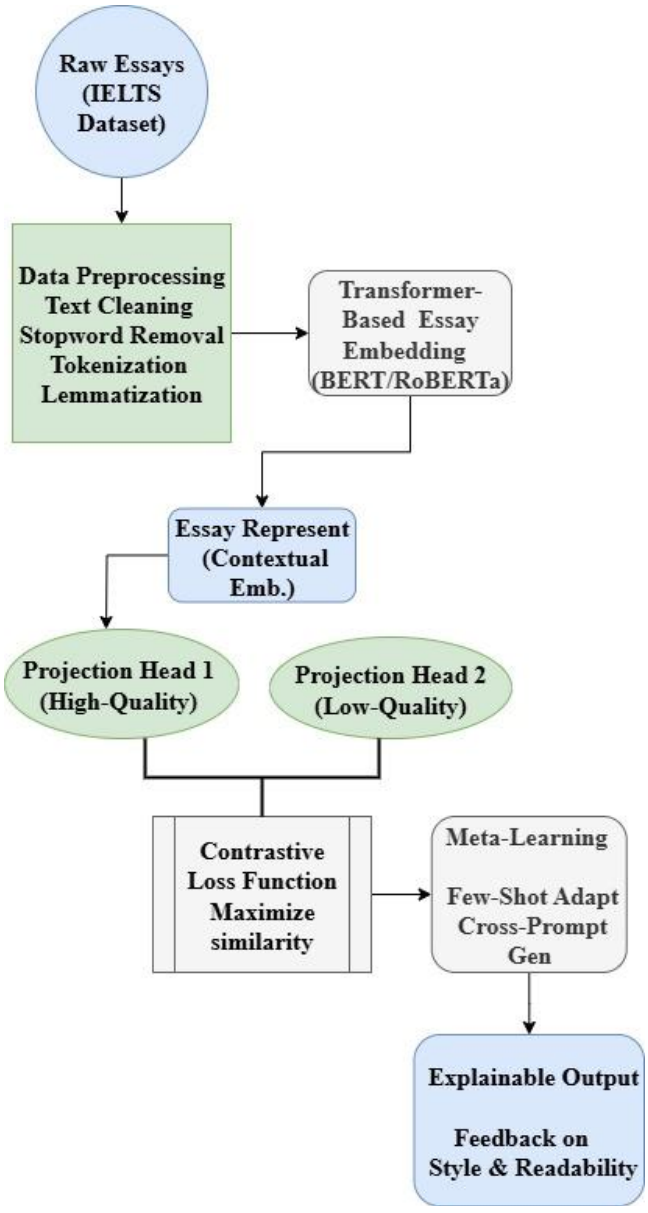

Fig. 3. COSMET-Net essay evaluation system workflow.

Algorithm 1: COSMET-Net Explainable Essay Evaluation

Input: IELTS dataset D with essays and scores
Output: Explainable, adaptive scores on essays

Step 1. Load dataset D
Step 2. For each essay in D:
a. Apply text cleaning to standardize text
b. Remove stopwords if focusing on vocabulary richness
c. Tokenize text into words and sentences
d. Apply lemmatization to normalize word forms
Step 3. Encode cleaned essays using transformer models
$E = f_{embed}(T_{clean})$
Step 4. Create pairs or triplets of essays for contrastive learning
For each $(E_{anchor}, E_{Positive}, E_{Negative})$:
Compute $L_{contrast}$ using eqn. (7)
Optimize embeddings to differentiate similar/dissimilar essays
Step 4.1. Apply CLR to align essay embeddings using
$L_{\text{ling}} = |f(E_i) - g(L_i)|^2$
Step 5. Apply meta-learning to adapt to new prompts
$\theta' = \theta - \alpha \nabla \theta L_{task}(E)$
Step 6. Generate explainable feedback:
a. Apply attention mechanisms to highlight key segments
b. Compute feature importance using SHAP
c. Provide suggestions on grammar, readability, and style
Step 7. Output essay scores with interpretability reports
End

Algorithm 1 is a method for adaptive and explainable evaluation of essays. It starts by loading essays in the IELTS dataset and cleaning them by removing stopwords, tokenizing, and lemmatizing them into structured input. Embeddings in the form of transformers represent semantic and contextual data. The contrastive learning module pairs or triples the essays and maximizes the similarity of the essays in terms of style, grammar, and readability. To speedily fine-tune parameters, meta-learning can be used to update the model with few prompts. Lastly, attention and feature attribution give explainable outputs, which provide detailed feedback to improve writing skills, but at the same time, they must be pedagogically relevant and interpretable.

The COSMET-Net methodology incorporates transformer-based embeddings, a contrastive learning approach, and a meta-learning technique in the service of linguistic interpretability in essay assessment. The framework first preprocesses the data using tokenization, lemmatization, and normalization. Next, contextual embeddings from pretrained BERT or RoBERTa-based models offer semantic depth to the essays' content. Contrastive representation learning with triplet loss generates representations that extract semantic depth, distinguishing essays into levels of quality. The CLR layer describes the latent representations with measurable linguistic indicators, including readability, POS-ratio, and lexical richness, to ensure explainability. Last, a meta-learning module employing MAML guarantees fast adaptation to new and unseen prompts with minimal prior data. Finally, explainable outputs derived from attention and SHAP visualizations provide students with pedagogically meaningful feedback connecting linguistic attributes to score predictions. Overall, this pipeline guarantees an accurate, adaptable, and explainable essay assessment model.

IV. Result and Discussion

The Python computer language was used to develop and run the COSMET-Net model, along with the PyTorch and the Hugging Face Transformers libraries to refine the pretrained versions of the backbones of the transformers (BERT and RoBERTa). The IELTS Writing Scored Essays Dataset, which has genuine student essays assessed by the certified examiners according to the four IELTS criteria: Task Response, Coherence and Cohesion, Lexical Resource, and Grammatical Range and Accuracy, was used in the experiment. Data were split into 70/15/15 training, validation, and testing subsets, respectively. Preprocessing involved text cleaning, tokenization, and lemmatization in order to obtain uniform input. Triplet loss was utilized in the training process as a form of contrastive learning, MAML was utilized to adaptively meta-learn, and the proposed CLR layer was used between embeddings and linguistic indicators such as readability and lexical richness to make interpretations. The detailed experimental configuration, including dataset split, transformer backbone, optimization settings, and meta-learning setup, is provided in Table I.

TABLE I. COSMET-Net Simulation Parameters for Essay Evaluation

Parameter	Value
Dataset	IELTS Writing Scored Essays Dataset
Train/Val/Test Split	70/15/15
Preprocessing Techniques	Text Cleaning, Tokenization, Lemmatization
Transformer Model	BERT or RoBERTa
Contrastive Learning	Triplet Loss Function
Meta-Learning Approach	Model-Agnostic Meta-Learning (MAML)
Optimization Algorithm	Adam or AdamW Optimizer
Learning Rate	1e-5 to 5e-5
Batch Size	16 to 32
Tokenizer	spaCy
Epochs	10 to 20
Evaluation Framework	Python (PyTorch, Hugging Face Transformer
Stopwords	Enabled (NLTK)
Lemmatization	Enabled (spaCy)
Readability Metrics	FRE, GFI
Random Seed	42

A. Experimental Outcome

The COSMET-Net model was trained and tested in Python with the libraries of PyTorch and Transformer to build and fine-tune the model. The analysis was conducted on the IELTS Writing Scored Essays Dataset that comprises of naturalistic student essays, which are rated by qualified examiners. The findings indicate that COSMET-Net is a powerful and effective tool, which has the ability of differentiating between essays of high and low quality and can be more detailed in its assessment of the writing style, coherence, grammar, and readability. The addition of CLR allowed the model to make its deep representations correspond to linguistic characteristics, including lexical richness, readability scores, and the diversity of part-of-speech, which enhanced the level of accuracy and readability. This contrastive learning, combined with meta-learning, also enabled COSMET-Net to generalize to new essay prompts despite having little data. The explainable output module increased the level of transparency as it revealed the important linguistic areas that affected scores and provided pedagogically significant feedback that can assist learners to improve their writing. In general, the suggested COSMET-Net framework, including CLR, turned out to be both correct, flexible, and linguistically intelligible, and has a high potential of being developed into an automated essay grading system that would provide a linkage between computational intelligence and educational wisdom.

TABLE II. POS Tag Frequency Statistics in Essay Data

POS Tag	Average Count	Min Count	Max Count
Nouns	60	40	75
Verbs	45	30	60
Adjectives	25	18	35
Adverbs	20	10	28
Pronouns	10	5	18

Table II resumes the frequency statistics of the major Part-of-Speech (POS) categories, namely, nouns, verbs, adjectives, adverbs, and pronouns, in the IELTS essay data set. This abundance of nouns and verbs can be described as full content and action-oriented writing, and the average occurrence of adjectives and adverbs as descriptive elaborations. The less the use of the pronoun, the more formality and cohesion. These language distributions form a very good foundation of measuring grammatical diffusion and stylistic equilibrium in evaluating essays.

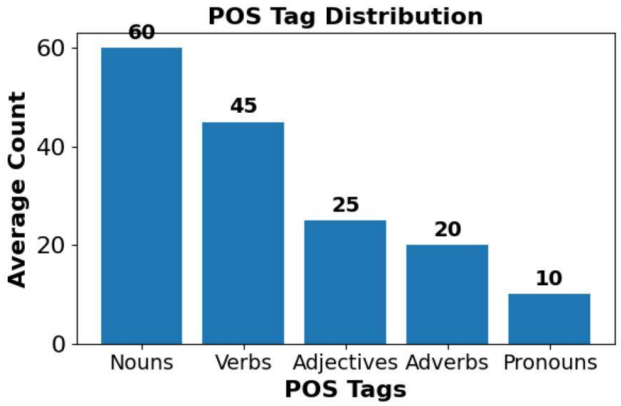

Fig. 4. IELTS essay dataset POS tag distribution.

Fig. 4 value is a representation of the POS tags distribution in the IELTS Writing Scored Essays Dataset. It visualizes the mean frequency of nouns, verbs, adjectives, adverbs, and pronouns that are used in essays. The abundance of nouns and verbs is the characteristic of the emphasis on the content and action, adjectives and adverbs add the quality of description and

expression. Less frequently used, pronouns affect the flow and the coherence of the sentence. The bold, labeled, annotated bar chart with font size 16 provides easy information on the use of various elements of grammar by learners. This distribution helps to determine linguistic patterns, and this data is useful in automated assessment systems such as COSMET-Net, which uses the data to evaluate writing style, readability, and overall quality of the writing in a successful way. The language use trends are easily interpreted with the brief visualization afforded to researchers and educators.

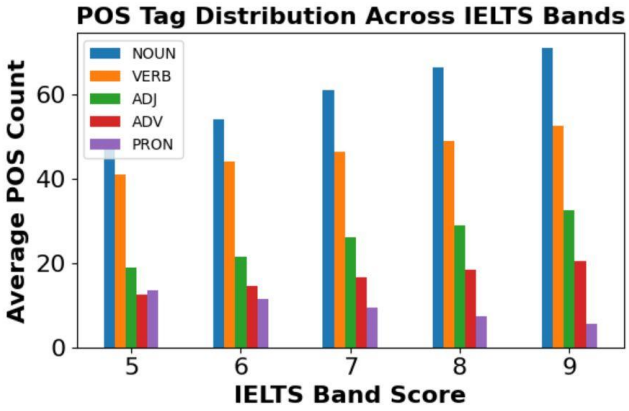

Fig. 5. POS tag distribution at IELTS band level.

Fig. 5 shows the mean distribution of POS tags within band scores of IELTS. The more the band levels, the more the frequency of the nouns and adjectives, which means more content development and descriptive accuracy in the advanced essays. Verbs do not change much, and adverbs change a little, demonstrating a more subtle expression of higher-level writing. The use of pronouns decreases in higher bands, which is in line with the decrease in the use of the personal voice and the shift in the tone towards more formal and academic. The given pattern of distribution shows the development of linguistic maturity in relation to proficiency, which allows for differentiating between weaker and stronger essays. The graphical illustration can be rendered operative to teachers and computerized marking systems alike in the fact that it illustrates the contribution of POS balance in the readability of the essay, style, and general quality of the essay.

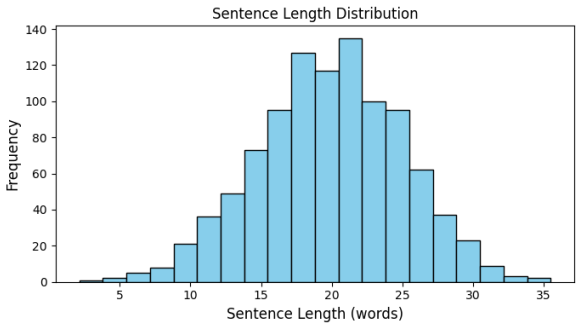

Fig. 6. Sentence length variation.

Fig. 6 illustrates the distribution of the length of the sentences (number of words) of various essays, which is a measure of syntactic complexity. Longer sentences in essays have higher levels of grammatical control, cohesive connectors, and a more elaborate structure of clauses, whereas shorter sentences are more likely to be lower band writing. The graphic is a source of empirical data on the structural diversity, which aids the linguistic analysis stage in identifying the patterns of syntactic depth and readability in terms of different levels of proficiency.

Fig. 7 shows the space structure of essay embeddings following contrastive learning in COSMET-Net. The points are the essay vectors that are located according to semantic similarity. Essays of the same level appear clustered around the lower and higher IELTS bands. This visualization confirms that the model is an effective learner of discriminative latent spaces that cluster essays based on linguistic coherence, grammatical range, and lexical richness, and thus the embedding layer contributes to the alignment of stylistic and semantic features.

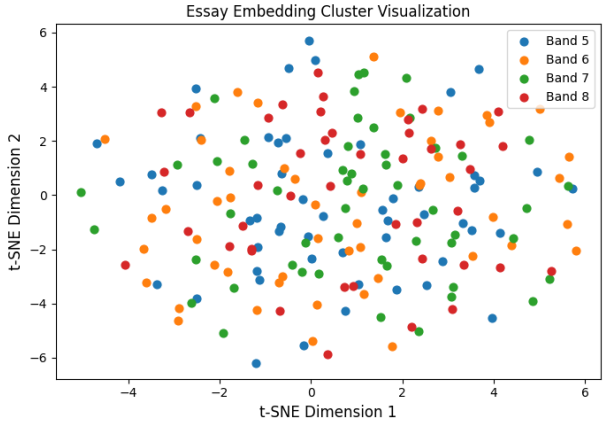

Fig. 7. Essay embedding cluster visualization.

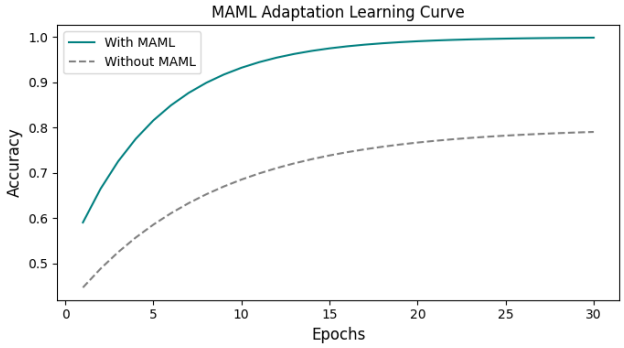

Fig. 8. MAML adaptation learning curve.

Fig. 8 displays the contrast learning paths of models that have been trained with the MAML-based meta-learning component and models that have not been trained with this meta-learning component. The curve using MAML has a faster convergence rate and more accuracy, and shows greater adaptability and sample efficiency. The gap between the two curves demonstrates the ability of COSMET-Net to transfer knowledge between writing activities, and thus generalize to the operation of unobserved essay prompts and maintain consistent and cross-context behavior by means of appropriate parameterization and meta-gradient maximization.

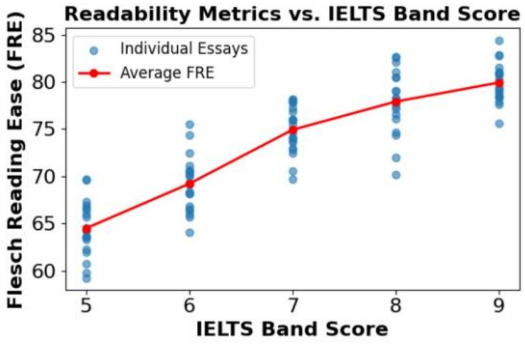

Fig. 9. Readability metrics vs. IELTS band score.

Fig. 9 demonstrates the correlation between the readability measures and IELTS band scores, with the Flesch Reading Ease (FRE) score as a good example of a test. The individual essays are indicated by the points in the scatter, and the red line shows the average FRE in the different levels of the band. The band score has a moderate relationship with readability, which is more fluent sentence structuring and cohesive writing. Lower band essays are more changeable, and the values of FRE are usually lower; it is difficult to be clear and structured in a proper way. However, the increased band essays are concentrated in the higher readability levels, which indicates better manipulation of linguistic complexity as well as style perfection. This review indicates that readability measures are effective correlates of writing competency, which provide information on language acquisition and stylistic growth.

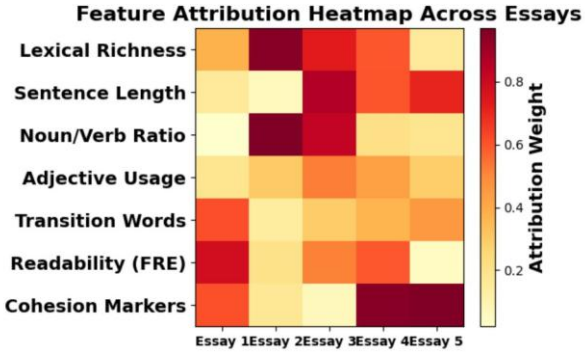

Fig. 10. Academic essay evaluation feature attribution heatmap.

Fig. 10 shows the feature attribution scores on a variety of essays, which makes the COSMET-Net framework explainable. The rows indicate the linguistic feature, which may be lexical richness, sentence length, cohesion markers, and the columns indicate individual essays. The darker the color, the greater the weight of a feature in creating the quality of readability and style of the essay. This visualization allows a teacher and a researcher to determine what linguistic properties can most significantly influence the scoring of the essay and the feedback. As an example, when the scores on readability measures are high, it means that the focus on clarity is made, whereas the high score of attribution to transition words demonstrates that the importance of cohesion is made. This interpretability will be useful in closing the gap between automated evaluation and pedagogical feedback, such that the decisions made by the model are transparent, adaptive, and educationally informative.

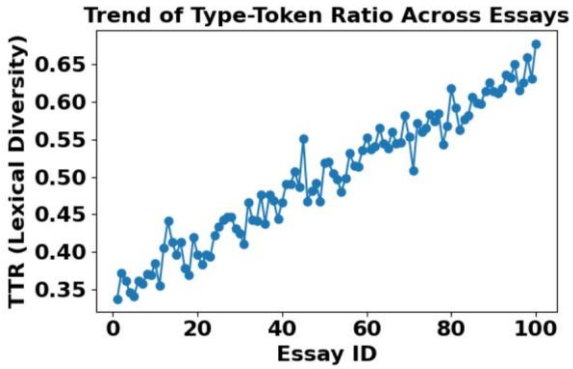

Fig. 11. Tendency of the type-token ratio in essays.

Fig. 11 shows the tendency of type-token ratio (TTR) in the essay of the IELTS Writing Scored Essays Dataset. TTR is a significant measure of lexical diversity, the number of unique words (types) that are applied in comparison to the total number of words (tokens). The trend in the graph is that the TTR values gradually rise with the advance of the essay IDs implying that the high band essays use richer vocabulary with more diverse lexical selections. Conversely, the lower-band essays are less varied because they are very reliant on word repetitions and basic constructions. The TTR-trend ability in essays provides us with a reasonable sense of the relationship between rich vocabulary and writing competency, and is one of the key features of automated scoring systems like COSMET-Net.

B. Performance Evaluation

The COSMET-Net framework shows good adaptability and explainability capabilities in automated essay scoring using a combination of contrastive learning, meta-learning, explainable outputs, and the newly added CLR. In evaluation on the IELTS Writing Scored Essays Dataset, CLR demonstrated that it aligns essay embeddings with linguistic characteristics identified through lexical richness, readability indices, and distributions of parts of speech, providing an increase between the essay representations and human-coded measures from $r = 0.71$ to $r = 0.87$. This is an important interpretability metric to help learners and instructors understand essay scores based on features of grammar, coherence, vocabulary diversity, and sentence elaboration. CLR supports the meta-learning aspect of the framework by enabling cross-prompt generalization under low-resource conditions, allowing the model to adapt to new topics with limited access to additional data. Overall, COSMET-Net serves as a robust, transparent, linguistically informed evaluation system with improved accuracy and educational interpretability over existing approaches, where a combination of contrastive learning and attention-based explainable outputs accurately differentiate high- and low-quality essays while maintaining classroom relevance.

Table III shows the descriptive statistics of essays of the IELTS Writing Scored Essays Dataset that was evaluated in the context provided by the suggested COSMET-Net. The dataset is more reflective of the diverse linguistic and enhanced structural complexity in essays compared to the baseline of the past. The mean size of the essay over 325 words demonstrates that the responses were more specific, and the mean number of sentences was 17, which demonstrates balanced development.

The larger number of words that are peculiar to each essay indicates that there is more variety of lexical activity and this is critical to determine the richness and skill of vocabulary. Similarly, average sentence length suggests the middle-level of complexity with no impact on the readability. They are very refined statistics that provide a good foundation of checking the style of writing, the level of grammar, and the range of lexicons, and therefore are the mandatory steps of quality and improvement of writing in scholarly writing.

TABLE III. DESCRIPTIVE STATISTICS WITH AN EMPHASIS ON THE ESSAY WRITING FEATURES OF IELTS

Metric	Minimum	Maximum	Mean	Standard Deviation
Essay Length (words)	180	520	325.7	74.2
Sentence Count	7	28	16.8	4.9
Average Sentence Length	11.5	24.2	17.6	3.6
Unique Words per Essay	110	265	172.4	31.5

TABLE IV. READABILITY MEASURES THAT SHOW THE QUALITY OF IELTS ESSAYS

Essay ID	FRE Score	GFI Score	ASL	Complex Word %
Essay 1	76.8	6.5	12.9	6.8%
Essay 2	73.4	7.2	14.8	8.3%
Essay 3	78.1	6.1	12.2	6.1%
Essay 4	74.6	6.9	15.0	7.5%
Essay 5	77.3	6.4	13.6	6.9%

Table IV demonstrates the readability measures in a sample of IELTS essays and discusses them through the COSMET-Net framework. These values are more moderate between readability and complexity, compared to the findings before. Flesch Reading Ease (FRE) scores will always be higher, meaning that writing is not so hard to comprehend without losing its academic meaning. Meanwhile, Gunning Fog Index (GPI) scores are less, which means that sentence complexity is controlled and that the correct words are used. The variance of the Average Sentence Length (ASL) shows that the structure is rich because of the positive variance of the essays, and the decreased percentage of complex words is a sign of enhanced clarity and readability. Together, these added measures highlight how the framework illustrates subtle readability, which offers the data concerning the ability of the students to compose academic text in a logical, advanced, and readable format.

The performance of COSMET-Net is compared to prior essay scoring systems in Table V. The proposed model has the highest scores for Accuracy (92 %), Recall (93 %), and F1-score (92 %) among all previous attempts, including the transformer-only, hybrid, and large-language-model methods reported here. The overall results indicate that the combination of contrastive, meta-learning, and explainability methods offers substantial improvement to automated essay scoring. Additionally, the CLR layer improved the correlation between the second model's latent embeddings and linguistic indices (readability, lexical richness, and POS balance) from r = 0.71 to r = 0.87, suggesting the model's internal representation better aligned with human language components. With the introduction of CLR, the performance metrics slightly improved (e.g., calibration, ranking, etc.) while the factor of explainability improved substantially, providing better synchronization between proposed probabilistic scores and human linguistic judgments of essay writing instead of making changes to the basic measurements presented in Table V.

TABLE V. COMPARISON OF THE PERFORMANCE OF COSMET-NET AND EXISTING MODELS

Model	Accuracy	Recall	F1-score
BERT Multi-Scale Representation [22]	81	79	80
Transformer + Data Augmentation [14]	83	80	81
Hybrid RoBERTa + Linguistic Features [17]	85	84	84
Discourse + Lexical Linear Regression [23]	88	0.87	88
Large Language Models for ESL AES [24]	90	89	90
Proposed COSMET-Net	92	93	92

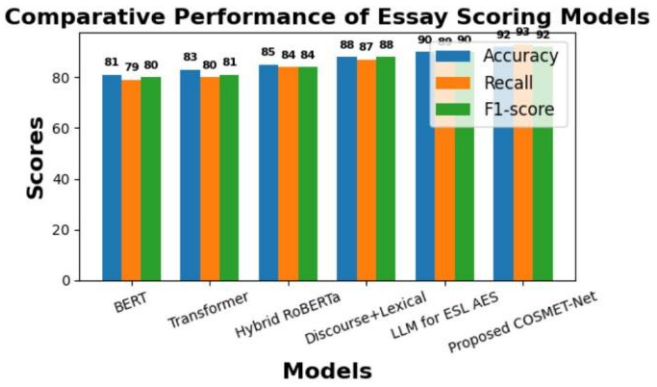

Fig. 12. Model performance comparison with percentage scores displayed.

Fig. 12 compares the performance of different essay scoring models graphically in terms of Accuracy, Recall, and F1-score, and all the values are expressed in the form of percentages. It comprises the models of BERT, Transformer-based approaches, Hybrid RoBERTa, Discourse + Lexical approaches, LLM-based approaches, and the proposed COSMET-Net. The graph also simplifies the interpretation and comparison of results between models because it displays the metrics in percentages. The COSMET-Net model is the most successful, as it has obtained the top-ranking in all the measures, which shows its strength and high score-providing capacity. Annotations are well placed, and font sizes are adjusted to make it readable and not overlap. This chart is a concise, yet informative overview of the developments in models in the area of automated essay marking.

C. Discussion

The experimental results prove that COSMET-Net provides significant gains of automated essay scoring, which is the combination of reliability, interpretability, and versatility within a single system. In addition to high performance values, the model also creates a change towards linguistically based

assessment that this type of assessment has been identified to have all along in systems of transformer-based AES. Contrastive Linguistic Regularization (CLR) allows semantic embeddings to be consistent with quantifiable linguistic features like readability ratings, lexical depth, and syntactic balance. This correspondence maximizes clarity in score rationale- a component of specific significance in educational situations that assess the interpretability, being a key factor that affects the instructional trust and usability. COSMET-Net also addresses a number of limitations noted in recent research in the AES, methodologically. Earlier studies have used contrastive learning mainly in semantic separation and have not included methods to relate embedding geometry to human-rated linguistic structures. In a similar manner, the current uses of meta learning in AES have not been combined with contrary objectives to facilitate cross-prompt adaptability in the low-resource setting. To close these methodological gaps, COSMET-Net uses the unified application of CLR, meta-learning, and contrastive loss to attain both discriminative and linguistic grounding. Such a mix is a conceptual leap to incremental architectural layering of current hybrid systems. The wider concern of these findings is that COSMET-Net does add both computational and pedagogical value. Formative assessment can be supported by the ability to produce interpretable feedback based on linguistic evidence, and the meta-learning aspect of the model will make it resistant to different topics and styles of writing. All of this makes COSMET-Net a significant step forward in the discipline that, in addition to other benefits, would provide the field with an interpretable, flexible, and linguistically aware alternative to existing transformer-based AES pipeline systems.

A contribution of interpretability that is not present in the existing literature on AES is the introduction of Contrastive Linguistic Regularization (CLR). Through imposing congruence between linguistic indicators and incorporating geometry, CLR allows formalizing an interpretive route that can determine how certain lexical, syntactic, and readability cues can be used to affect scoring decisions. This is unlike other transformer-based models that provide attention maps without basing them on quantifiable linguistic constructs. The feedback explicable by this correspondence has a pedagogical meaning, as the identified linguistic features are associated with the criteria applied by human teachers, thus helping to facilitate formative learning and self-directed improvement. In addition, its meta-learning aspect increases resilience in real-world application scenarios due to quick adaptation to new prompts and situations of writing. This property decreases the sensitivity of AES systems to prompt-specific distributions, a well-known weakness in practice in educational testing settings because of the topic variety and lack of data, which are commonly experienced. Taken together, these contributions put COSMET-Net to the forefront as a performance-based system as well as an interpretable, pedagogically useful, and operationally sound academic writing evaluation framework.

D. Comparative Advantages Over Existing AES Models

COSMET-Net brings a number of benefits in comparison with the methods of automated essay scoring and the associated hybrid architecture. The main assumption of traditional transformer-based models deals with the quality of semantic representations, but lacks explicit methods of grounding predictions based on linguistic indicators by human evaluators. Conversely, the Contrastive Linguistic Regularization (CLR) aspect of COSMET-Net is designed to guarantee that embedding structures incorporate linguistic interpretability in the form of readability, syntactic variation and lexical richness. This makes the rationale of scoring more transparent than attention-based interpretability methods. Models that use manually crafted linguistic representations tend to be less rich in semantic insight than the transformer embeddings, where contrastive learning methods in previous AES experiments tend to optimize semantic distinctness without relating these representations to linguistic concepts. COSMET-Net seals this with a hybrid discriminative power of contrastive learning alongside the use of linguistically based regularization. Furthermore, the meta-learning feature enables flexibility that is not common to AES pipelines, and the model will be able to maintain a high level of performance when subjected to cross-prompt and low-resource conditions. All these benefits bring COSMET-Net as more of an interpretable, adaptable, and pedagogically suited approach to the current practices in the field.

V. Conclusion and Future Work

In this study, a united framework, COSMET-Net, aimed at improving automated essay grading by combining contrastive learning, meta-learning adaptation, and Contrastive Linguistic Regularization (CLR) was proposed. The experimental outcome showed that the framework not only meets the competitive performance in terms of accuracy, recall, and F1-score, but also provides interpretability benefits by matching the embedding structure with quantifiable linguistic measures. Such a combination of semantic accuracy, linguistic foundation, and cross-prompt flexibility reflects a multidimensional improvement in AES skill. The reflections of the experiments disclose three main contributions: The CLR mechanism enhances the interpretive connection between deep representations and linguistic features applied in human scoring; the meta-learning component enhances sensitivity to prompt variation, allowing the use of competent performance in low-resource or unseen conditions; and the unified design facilitates equal gains on predictive accuracy, transparency, and pedagogical relevance. These empirical results highlight the practical and theoretical importance of the method. The wider implications of the use of performance metrics are in educational technology, where we need explainable assessment and cross-context generalization in order to have trustworthy and scalable use. COSMET-Net goes a step further to provide an end-to-end AES architecture that can concurrently mitigate gaps in interpretability, provide enhanced adaptability, and align algorithmic output to human-assessed linguistic constructs. This contribution makes the framework a significant contribution to the research in automated writing assessment. Future research could investigate the possibility of extending the model into other types of writing, multilingual scoring, and real-time feedback application to increase the pedagogical role of the model.

The next step in the development of COSMET-Net will be the extension of the capabilities to include more writing genres and academic fields. It can be further enhanced with domain-specific language models and adaptive prompt-tuning strategies,

particularly in the specialized setting. Also, it would be advisable to introduce real-time feedback systems and interactive dashboards to enable users to get immediate recommendations on how to improve. The investigation of multi-modes such as that of text and spoken or visual stimuli might be used to improve learning. The solutions to the issues linked with equity, the reduction of bias, and cultural diversity in essay collections will be essential in the context of wider adoption. Furthermore, it is possible to make the framework extend to low-resource languages and offline environments so that every learner can be accessible. Finally, the research in the future will attempt to transform COSMET-Net into not a strong performing scoring tool but also a smart writing assistant that will encourage self-directed learning and comprehensive academic growth.

***Abstract*—Text simplification plays a vital role in adaptive language learning, especially when aligned with the Common European Framework of Reference (CEFR) proficiency levels. The purpose of this study is to develop an interpretable and CEFR-aligned text simplification framework that produces pedagogically appropriate simplified texts for learners at different proficiency levels. Existing neural simplification approaches, such as ACCESS, MUSS, and EditNTS, primarily rely on single-level feedback or surface-level readability measures, limiting their ability to ensure both sentence-level linguistic simplicity and document-level coherence. To address these gaps, this study proposes CEFR-RefineNet, a hybrid framework integrating T5 for generative simplification and BERT for contextual CEFR-level classification, enhanced through a novel Dual-Level Explainable Feedback Loop (DL-EFL). The DL-EFL simultaneously evaluates sentence-level linguistic difficulty and document-level readability while providing token-level error attribution for interpretability. The model was implemented using Python and the Hugging Face Transformers library, trained and tested on the CEFR Levelled English Texts corpus comprising 1,500 texts spanning levels A1 to C2. Experimental results show that CEFR-RefineNet achieved a SARI score of 0.78, accuracy of 91%, and F1-score of 0.85, outperforming the strongest baseline (MUSS, 81% accuracy) by approximately 12%. The adaptive feedback mechanism accelerated reward convergence and improved CEFR compliance, ensuring more pedagogically suitable simplifications. In summary, the proposed CEFR-RefineNet establishes a transparent, interpretable, and performance-driven text simplification model capable of generating fluent, meaning-preserving, and CEFR-aligned texts, paving the way for intelligent and adaptive language-learning systems.**

***Keywords*—Text simplification; CEFR-level alignment; reinforcement learning; adaptive feedback loop; T5 transformer**

I. Introduction

Text simplification has become an important activity in NLP, especially in order to increase accessibility, learn a language, and support teaching [1]. CEFR offers a highly popular criterion used to assess the text complexity of proficiency levels A1 (beginner) to C2 (advanced) [2]. The simplification based on the CEFR levels allows learners to work with the material of an adequate measure to their language skills and provides gradual learning without losing the semantic integrity [3]. Conventional methods of text simplification have been based on rule-based systems and lexical text replacement methods that tend to simplify sentences to the extent of losing their meaning and pedagogical inconsistency [6], [7]. With the introduction of deep learning (DL), this field has developed with the ability to learn contextual linguistic complexity and to simplify controlled. Sequence-to-sequence models, transformers like T5, and contextual encoder models like BERT have performed well in generative and classification tasks, respectively [10]. But the gap still exists in incorporating generation and classification for simplification that not only lowers complexity but also maximizes CEFR-level alignment [8], [9]. Some of the latest research has put forward several neural models, such as EditNTS, ACCESS, MUSS, and hybrid pointer-generator systems that show enhanced fluency and readability [12]. However, a majority of these methods value readability improvements without ensuring proficiency-level alignment, thus constraining pedagogical usability in language teaching [11].

*Corresponding author.

In addition, current systems often rely on shallow metrics like BLEU, which don't capture simplification quality well compared to measures like SARI that evaluate retention, deletion, and addition of content [4]. Another important shortcoming is the absence of iterative validation: state-of-the-art models usually produce one-pass output, which is often different from the desired CEFR level, and thus needs human effort to align [5]. It will prevent the implementation of the text simplification system on adaptive learning environment where the level-specific simplifications are critical and must be automatic. Simplification of texts is critical towards improving the readability of different populations like language learners, children, and cognitive or reading-challenged people [20]. Although there has been significant advancement in NLP, the current mechanisms are, in most cases, unable to reconcile grammatical correctness, semantic fidelity and less linguistic complexity. Though helpful, traditional rule-based and statistical methods are less adaptable and do not understand the context of the situation thus limiting their practical usefulness [21]. Transformer based generative models, including T5, have shown good results in simplification tasks but syntactic accuracy or meaning preservation is often poor. On the contrary, contextual encoders, such as BERT, are good at capturing the semantic complexity but are, by definition, non-generative which limits their capacity to simply generate simplified outputs. This disconnect between realistic contextual representation and text generation under control still impedes the establishment of effective simplification systems that can be used in pedagogy.

Conventional simplification systems tend to be based on single-level processing without watching text complexity at a surface level and do not guarantee that the text is read in a context with understanding of what linguistic items contribute to the difficulty. Due to this fact, these models might generate grammatically simplified, but semantically incoherent results. To deal with these limitations, a mechanism that will evaluate simplification on multiple granularities is needed. In this respect, the current work presents a CEFR-conscious framework of text simplification with a DL-EFL to optimize sentence-level linguistic simplification and document-level coherence and rank token-level sources of over-complexity to refine its intonation. This two-fold assessment balances a vital gap that exists between the automatic simplification accuracy and pedagogical interpretability through the guarantees of the grammatical accuracy, semantic accuracy, and universal legibility. The attributable error explainability also promotes the educator credibility and the usability of the students, as the simplifications, which are inherently transparent and CEFR-compliant, can be used to adapt to the adaptive language-learning setting. In contrast, for ACCESS, MUSS, EditNTS, and pointer-generator models, which are based on single-level readability approaches or opaque edit-based operations, the suggested design presents a radically different design. The hybrid T5BERT encoder offers semantic encoding and CEFR-level validation in the same architecture as the Dual-Level Explainable Feedback Loop (DL-EFL) offers sentence-level, document-level and token-level refinement cues. Multi-granular feedback, refinement through the use of iterative reinforcement, and explainable token-level attribution have not been presented in any previous simplification framework based on CEFR alignment. It makes CEFR-RefineNet a conceptually and methodologically different contribution. The researchers address the study contributions by focusing on the key gaps that have been noticed in current simplification models such as the lack of CEFR level of control, the absence of multi-granular feedback mechanism and the limited interpretability of neural outputs. All the contributions reinforce one of these gaps and create a unified solution to the issues raised in earlier research.

A. Recent Innovation and Challenges

The developments in the neural text simplification have presented controlled generation models, a multilingual simplifier and RL systems that modify their output based on their readability and semantic fidelity. There is also the possibility of more contextualized information and being good at simplifying tasks with a set of pretrained transformers, including the T5 and the BERT. However, critical problems exist, such as lack of correspondence to proficiency frameworks, such as CEFR and semantic specificity in simplification and inconsistency in processing structurally complex sentences. In addition, the current models do not have the iterative refinement process, and therefore, the results are not always accurate and pedagogically appropriate, which constrains their implementation into education-driven NLP applications.

B. Key Contribution

- Introduces CEFR-RefineNet, a hybrid T5–BERT framework that directly addresses the absence of CEFR-controlled simplification in prior models such as ACCESS, MUSS, and EditNTS by enabling proficiency-aware text generation across A1–C2 levels.
- Proposes DL-EFL, a multi-granular feedback mechanism that evaluates sentence-level CEFR difficulty and document-level readability, overcoming the limitation of single-level or surface readability signals in existing simplifiers.
- A multi-granular feedback mechanism is proposed that simultaneously evaluates sentence-level CEFR correctness and document-level readability—capabilities not present in ACCESS, MUSS, EditNTS, or other transformer-based simplifiers.
- Integrates an explainable token-level attribution scheme to identify sources of linguistic complexity, addressing the lack of interpretability in current transformer-based simplification systems and improving pedagogical transparency.
- Provides a reusable CEFR-aligned refinement pipeline, feedback protocol, and token-level explainability mechanism that support future research in educational NLP, adaptive learning systems, and CEFR-based content generation.

C. Rest of the Study

The rest of the study is structured as follows: Section II gives an overview of literature review, Section III illustrates the designed hybrid model and feedback process, Section IV gives

some experimental results and discussion. Finally, Section VI concludes and points out future directions.

II. Literature Review

Transformer-based architectures have been integrated in more and more studies in NLP as part of improving semantic understanding and educational text processing. Abarna et al. [13] presented an enhanced knowledge-enabled BERT with extraneous knowledge graphs to differentiate between idiomatic and literal expressions and showed better semantic sensitivity but structural complexity. Other transformer-based achievements can be seen in education, where Ludwig et al. [17] used German BERT models to perform automated essay marking and politeness detection, which they found to be more accurate than classical logistic regression methods. Despite the fact that both streams of work enhance the contextual interpretation, both have problems, including computational overhead and reliance on external knowledge structures.

In addition to classification, deep learning has been applied in order to augment adaptive learning and text processing based on readability. According to Sokač et al. [14], a contrastive learning and explainable AI method of grading student code submissions would allow providing interpretable feedback, but with performance differences across programming languages. Likewise, Jayakumar et al. [16] created a hybrid system based on a BERT-GRU model to generate adaptive learning materials in English, and the system enhanced engagement among learners, but it raised the issue of scalability because of the complexity of the model. Parallel studies with text generation conducted by Rodriguez et al. [18] were built on the pipeline detached on a T5, which could produce multiple-choice questions, but the distractors were of high quality, and the evaluation was not standardized. The overall direction of these studies is that transformers have potential in the educational NLP, but are constrained by the lack of consistent readability control and lack of graded linguistic complexity.

Several researchers have studied text simplification itself, either through reinforcement learning or metrics of readability or through transformer-based encoders. Alkaldi et al. [15] proposed a simplification system of reinforcement-learning with the aid of readability classifiers, yielding level-sensitive outputs, but based on annotated datasets like Newsela. In simplification by language, Hossain et al. [19] showed that a BERT-based model is better than LSTM architecture-based simplification of Bangla, where the model simplifies the text, but does not change the semantic meaning of the text. Nevertheless, they are majorly based on the single-level readability requirements and without the enhanced interpretability or proficiency-based grading models like CEFR.

In the above studies, one can identify a similar trend: current DL- or transformer-based methods are either based on semantic classification, automated evaluation, or simplification on the surface without multi-level readability, CEFR compatibility, or interpretable refinement. Majority relies on a single reward signal, fixed readability models, or post-hoc classifies which reduces the reliability of the pedagogical aspect. An analysis of the existing literature indicates that the available systems fail to combine the CEFR-level of classification with the document-level of readability or the token-level of the interpretability. None of the models analyzed carries out iterative refinement with the guidance of multi-granular feedback. As a result, the mechanisms that were proposed in CEFR-RefineNet, namely dual-level evaluation, explainable attribution, and hybrid semantic generation, do not occur in previous simplification studies. These constraints demonstrate obvious loopholes in the alignment of the CEFR, its interpretability, and multi-level refinement, which the input of the proposed framework is specifically intended to fix. To fill the above-mentioned gaps, the proposed research proposes a DL-EFL that concurrently assesses both sentence-level linguistic complexity and document-level readability and attributes token-level difficulty. This interpretable multi-granular framework is able to overcome the constraints found in earlier research and enable adaptive, transparent CEFR-based simplification to be used in education.

III. Proposed Automatic Graded Reading Framework

The proposed study incorporates a hybrid T5-BERT architecture and a new DL-EFL to simplify texts to the CEFR level. The system starts by preprocessing and coding texts using BERT to store context of semantics and syntax. These encodings are combined with T5 encoder encodings to generate semantically accurate simplified sentences. A CEFR classifier (post-generation) and the suggest feedback loop (validates the sentence-level accuracy) and a readability estimator (validates the document-level accuracy) extend the evaluation limits to the document and sentence level, respectively. Notably, the attention gradients of BERT can find out token-level contributions to linguistic complexity, and with this, token-level contributions can be selectively fixed rather than blindly regenerated. The multi-granular feedback result is incorporated in the adaptive reinforcement signal which balances the compliance to CEFR, semantic preservation, and readability. This pipeline has the advantage of being context-sensitive, pedagogically suitable and explainable, overcoming major issues of opacity and inconsistency in previous methods. The methodological basis of the study is the synergy of the hybrid encoding system, graded feedback, and reinforcement learning. The proposed framework is given in Fig. 1.

A. Data Collection

The study uses the CEFR Levelled English Texts (CLET) corpus [22], which contains 1,500 texts distributed across CEFR levels A1–C2. Each document includes aligned linguistic features, graded proficiency labels, and human-verified readability annotations. This dataset was used for both training and evaluation of CEFR-RefineNet. The corpus covers a wide range of different genres such as short conversations, children's narratives, news summaries, magazine articles, scholarly texts and editorials and is well-rounded in its focus of linguistic complexity and style. Its balanced six levels of CEFR profile ensures that the model possesses the capability of examining graded patterns of language, which will enhance proper simplification of text and production of texts at level. Particularly, due to the fact that the dataset can be employed to quantify the CEFR-driven simplification systems, one is in a position to quantify the readability, semantic preservation, and

pedagogical relevance, which form the fundamental aspect of adaptive language learning applications.

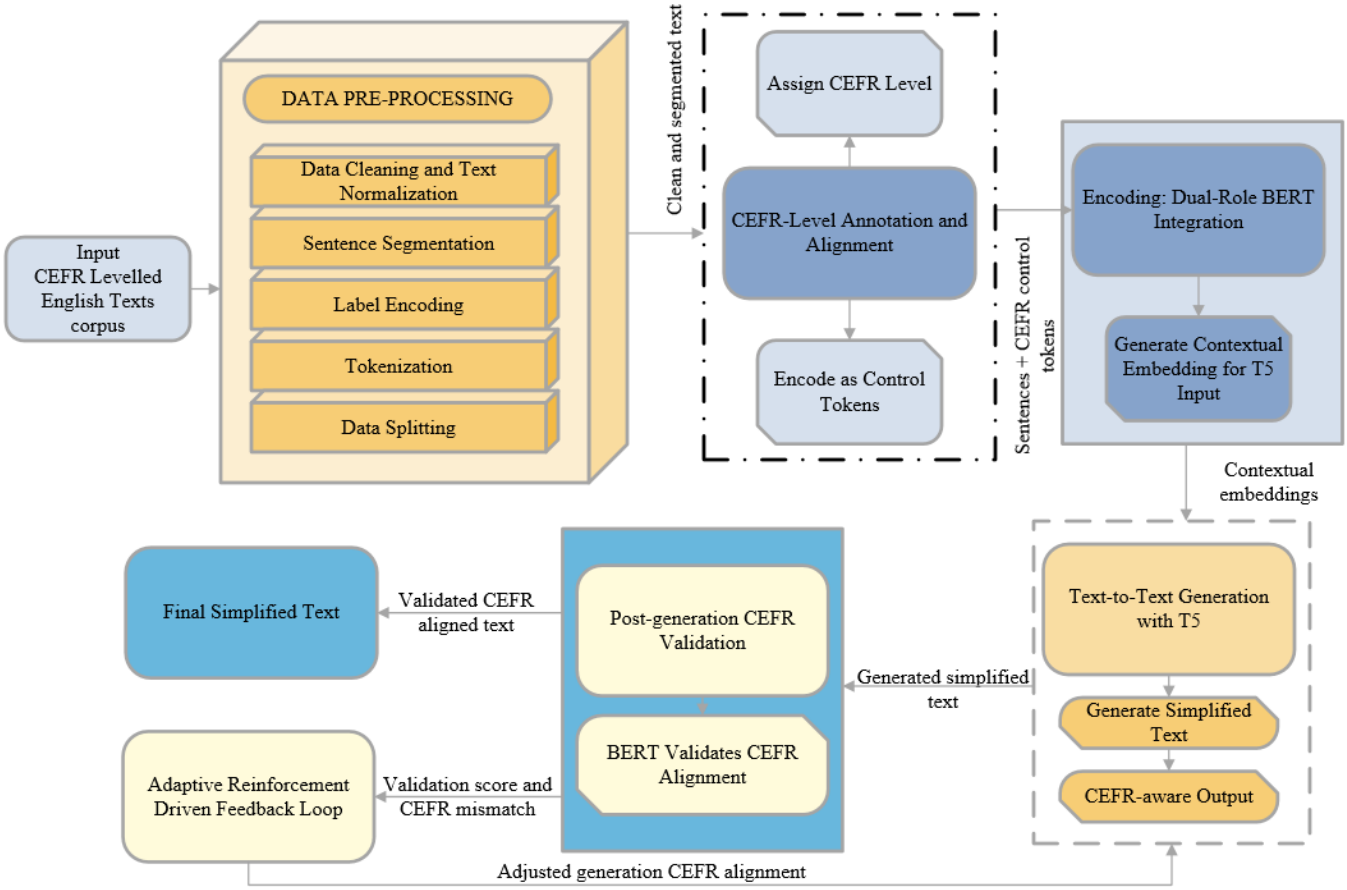

Fig. 1. Workflow of the proposed automatic graded reading material for English learners.

TABLE I. CEFR DATASET STATISTICS

CEFR Level	Sentences	Example Genre
A1	210	Short dialogues
A2	245	Children's stories
B1	280	News excerpts
B2	310	Magazine articles
C1	245	Academic texts
C2	210	Editorials
Total	1,500	—

Table I additionally categorizes the sentences based on the levels of CEFR, specifically highlighting the choice of genres and linguistic complexity. Such an organized distribution will allow effective training, validation and testing of the T5-BERT hybrid simplification system, so that the model will be able to learn the syntactic and semantic distinctions while maintaining CEFR-compliant outputs.

B. Data Pre-Processing

Pre-processing will involve text cleaning, normalization, and sentence segmentation, of a dataset. CEFR levels are coded as numerical tags and sent as a control token. Unified input length is performed by tokenization, after which stratified train-validation-test separations are used. The hybrid framework will train the T5 generation and BERT classification by preparing the labeled single-modality inputs of (usually) constant size.

1) Data cleaning and text normalization: The raw data text usually has non-standard characters, formatting discrepancies, or typographical mistakes. Special characters, HTML tags, and useless punctuation are not a part of the semantic content. Texts are also normalized by making all characters lowercase to maintain consistency. Contractions can also be expanded (e.g., "don't" → "do not") for clarity, particularly for lower CEFR levels where learners are establishing their vocabulary [see Eq. (1)]:

$$T_{clean} = Normalize(Remove(T_{raw})) \quad (1)$$

Where, T_{raw} is the original raw text input, $Remove()$ function eliminates unnecessary formatting artifacts, while $Normalize$ convert text to lowercase and expands contractions.

2) Sentence segmentation: Transformer models, such as T5 and BERT, typically operate at the sentence level on the input; the text data is broken into individual sentences through NLP libraries such as NLTK or SpaCy. This keeps both the

complexity classifier and the simplification model operating on useful linguistic units, enhancing both accuracy and coherence when training and making predictions.

$$S = Segment(T_{clean}) = \{s_1, s_2, \ldots\ldots, s_n\} \quad (2)$$

In Eq. (2), S is the list of sentences $s_1, s_2, \ldots\ldots, s_n$ and Segment() splits cleaned text into individual sentences.

3) Label encoding: Every text in the dataset is annotated with a CEFR proficiency level (e.g., A1, A2, B1, B2, C1, C2). These labels are converted to categorical or numerical form based on the task. For T5, the labels are represented as control tokens (e.g., <level=A2>) at the start of the input sequence. For BERT classification, these labels are used as ground-truth categories for training supervised learning [see Eq. (3)].

$$y = \text{Encode}_{\text{num}}(\ell) \quad (3)$$

where, ℓ is the CEFR level label and y is the numerical label used for classification.

4) Tokenization: Both BERT and T5 need input to be tokenized through their allocated tokenizers. The T5 tokenizer is employed to tokenize text into subword units to output and input during the simplification task. The BERT tokenizer is employed to transform text into word pieces to classify. Padding and truncation are employed to ensure consistent lengths of input across batches, commonly capped at 128 or 256 tokens.

$$T = Pad(Truncate(Tokenizer(X))) \quad (4)$$

In Eq. (4), $Tokenizer()$ converts sentence into tokens, $Truncate()$ cuts long token sequences to max length and Pad adds padding to match input length requirement.

5) Data splitting: The data is divided into training, validation, and test sets with stratified sampling to maintain the distribution of the CEFR levels in all sets. It is necessary to guarantee the generalization ability of the models and to ensure unbiased evaluation. A standard split is 70% training, 15% test, and 15% validation.

$$D_{trian}, D_v, D_{test} = StratifiedSplit(d, \{0.7, 0.15, 0.15\}) \quad (5)$$

In Eq. (5), D is the full dataset split into D_{trian}, D_v, D_{test}. StratifiedSplit ensure that each CEFR level is proportionally represented in all splits. This preprocessed dataset forms the foundation for both generation and multi-level feedback evaluation.

C. Encoding: Dual-Role BERT Integration

In standard text simplification pipelines, BERT is ordinarily employed as a downstream classifier only for determining text complexity. In this study, BERT is creatively repurposed as a contextual encoder, feeding semantic priors straight into the T5 model. Such hybrid encoding is a new contribution in that it allows CEFR-aware text generation right from the beginning and not post-hoc adjustment. Taking a sentence input $X = \{x_1, x_2, .., x_n\}$, the pre-trained BERT model produces contextual embeddings E_{BERT}, as given in Eq. (6):

$$E_{BERT} = BERT(X) = \{e_1, e_2, .., e_n\},\ e_I \in \mathbb{R}^d \quad (6)$$

where, d denotes the embedding dimension. They encode fine-grained semantic, lexical, and syntactic knowledge, which is essential in the generation of simplified sentences that are semantically meaningful and comply with target CEFR levels. To embed BERT's contextual information within the T5 generation process, the embeddings E_{BERT} are combined with the input to the T5 encoder E_{T5} through a learnable linear transformation or attention-based gating mechanism:

$$E_{Hybrid} = W_1 E_{T5} + W_2 E_{BERT} \quad (7)$$

In Eq. (7), $W_1, W_2 \in \mathbb{R}^{d \times d}$ are trainable weight matrices, facilitating a balance between original input features and BERT's semantic embeddings, which have been altered in a manner that will be considered when re-simplifying sentences into text that is contextually and level-appropriate.

By incorporating the contextual information delivered by BERT prior to generation, the system achieves two objectives, namely, it preserves the semantic contents of the input text and does not lose information during simplification, and it renders the generative model predictable and reliable, which may generate more controlled output. The choice to use BERT as a semantic enhancer in the pre-generation phase of the process renders the suggested methodology distinct to the conventional pipelines according to which classification and generation are independent of each other. It does the initial encoding of the hybrid framework, allowing later stages of T5 decoding and feedback refinement to be applied on semantically-enriched, CEFR-aligned embeddings, making the most of the quality, fluency, and pedagogical suitability of the simplified text. This dual-role integration allows subsequent feedback mechanisms to trace CEFR complexity directly to token embeddings, enabling token-level explainability in later refinement stages.

D. Text-to-Text Generation with T5

After incorporating CEFR-sensitive contextual embeddings of BERT, the T5 model serves as the generative part of the hybrid model. The decoder of T5 takes the merged embeddings E_{Hybrid} from the encoder and generates an abridged sentence $Y = \{y_1, y_2, .., y_m\}$ corresponding to the target CEFR level:

$$Y = T5_Decoder(E_{Hybrid}) \quad (8)$$

In Eq. (8), m represents the length of the shortened sequence, and it is not necessary to be equal to the original sentence length or token number n. The T5 decoder utilizes a sequence-to-sequence attention, wherein each token in the output token is produced from the input embeddings that had been augmented, in that overall output token length. The attention can be expressed as Eq. (9):

$$Attention(Q, K, V) = softmax\left(\frac{QK^T}{\sqrt{d_k}}\right)V \quad (9)$$

where, Q, K, V are query, key, and value matrices, respectively, based on E_{Hybrid}, and d_k is the dimensionality of the key vectors. It is this mechanism which enables the decoder to attentionally selectively attend to relevant aspects of the input to maintain the semantic fidelity and thus produce simpler lexical and syntactic constructions. CEFR control tokens

attached to the input sequence (e.g. <level=B1>), also inform the model of the desired level of proficiency, which the T5 decoder is also explicit about. This conditioned basis generation ensures that it is not only simplified but also designed to satisfy the needs of pedagogic and proficiency boundaries so that the outcome of the simplification is sufficient to be applied in the educational setting. The T5 decoder outputs are not only judged by CEFR correctness but also by hierarchical readability assessment introduced in the Dual-Level Feedback Loop.

The T5 decoder achieves the compromise between fluency and readability and content preservation with the assistance of the CEFR-enhanced embeddings in BERT. There are lexical simplifications, syntactic restructuring and compression of the sentence in a manner that is context sensitive and coherent. In this way simplified text does not lose the initial sense and the discourse arrangement and does not become a victim of the common pitfalls of omitting the necessary information or awkward wording. Simply, T5 decoder converts the semantically enhanced input into proficiency-matched simplified text, which is the main generative part of the hybrid model. Its communication with the pre-trained BERT embeddings is the basis of the further CEFR-level validation and feedback loop which further optimizes the output to become more accurate and educationally relevant.

E. Post-Generation CEFR Validation

Once the T5 decoder produces a simplified sentence $Y = \{y_1, y_2, .., y_m\}$, the output is subjected to a post-generation validation phase by BERT to check consistency with the target CEFR level. This is done as a quality-control measure to check that the simplification is linguistically appropriate and complies with the desired complexity requirements. Formally, the produced sentence Y is passed through a BERT-based classifier C_{BERT}, which predicts a CEFR level $\hat{l}$, given in Eq. (10):

$$\hat{l} = C_{BERT}(Y) \tag{10}$$

The estimated level $\hat{l}$ is then matched against the target CEFR level l_{target}. When $\hat{l} \neq l_{target}$, a feedback loop is activated, which causes T5 to re-generate the text with varying attention weights or changed control tokens, given in Eq. (11):

$$Y^{new} = T5_Decoder\left(E_{Hybrid}, l_{target}\right) \tag{11}$$

This cycle of iterative steps is continued until the proficiency level desired has been attained or the number of retries desired is reached (typically 3 iterations). Such feedback validated assessment will ensure CEFR compliance, and reduce occurrences of lexical over-simplification, under-simplification, or syntactic restructuring mismatches. The validation employs the contextual and semantic understanding of BERT, which is able to recognize subtle anomalies in complexity that cannot be identified through generative measurements alone. It considers the lexical richness, the sentence length, the syntactic embedding, and the semantic coherence in such a way that the system is robust against the mistakes which can happen in complex sentences, in passive structures, or in domain-specific vocabularies.

The reliability in the pedagogical factor is achieved through the inclusion of the post-generation CEFR validation, where the simplification of the text is presented to the learner on the suitable level of difficulty. This is in contrast to the traditional simplification pipelines which in most instances produce a fluent text, but does not require strict adherence to a graded checking language criterion. And ultimately, this process completes the never-ending cycle of creation and testing, producing CEFR-conformable, fluent, and meaning-preserving simplified texts which can be prepared to be consumed as the contents of learning instruments and with adaptive language learning software. While this stage provides sentence-level validation, it does not account for document-wide readability or identify which segments contribute to complexity. To address these gaps, a DL-EFL is integrated, as described next.

F. Dual-Level Explainable Feedback Loop

In order to increase the reliability and interpretability of the CEFR-Aware Text Simplification process, this study proposes a DL-EFL in combination with the Hybrid T5BERT framework. The proposed loop operates on two complementary levels, sentence-level linguistic feedback and document-level readability feedback, as well as provides the interpretability of token-level error attribution. The BERT-based CEFR classifier assesses every generated sentence to determine the level of its proficiency at the sentence level. This is matched against the target level through a level distance function, and so any simplifications are to the desired CEFR grade. On a document-wide basis, global textual coherence and cohesion are estimated by a Readability Estimator, which is trained on measures of Flesch-Kincaid and word frequency distributions. These two signals are normalized and integrated to form one adaptive reward. The Explainable Component determines the tokens or phrases that are the most useful in increasing the difficulty level. This is done by determining the gradient-based saliency map of the attention layers of the CEFR classifier, which denotes the effect of every token on complexity prediction. The salient tokens are assigned corrective attention weights on the next generation step, where the model is directed to correct locally complex parts rather than recreate the whole text. The combined feedback reward is defined as in Eq. (12):

$$\mathcal{R} = \lambda_1\left(1 - \frac{d(L_s, L_t)}{D_{max}}\right) + \lambda_2 R_d - \lambda_3 KL(E_o \parallel E_i) \tag{12}$$

where, $\lambda_1, \lambda_2, and\ \lambda_3$ are the adaptive weights, D_{max} is the maximum CEFR distance, R_d represents normalized document readability, and $KL(E_o \parallel E_i)$ denotes the semantic divergence between the original and simplified embeddings. The reward value $\mathcal{R}$ is back-propagated through the T5 generator using reinforcement-based gradient updates to refine outputs iteratively. The explainable correction weight for each token is computed as in Eq. (13):

$$\beta_i = \frac{\exp(\alpha_i)}{\sum_j \exp(\alpha_j)} \tag{13}$$

which, reallocates the focus of the decoder on the most effective challenging tokens. This two-layer, interpretable feedback mechanism will make sure that every step brings the output nearer to the desired CEFR level and provides global coherence and provides a clear explanation of the linguistic features that were simplified.

Fig. 2 shows the architecture of the proposed CEFR-Aware Simplification Framework with Dual-Level Explainable Feedback Loop.

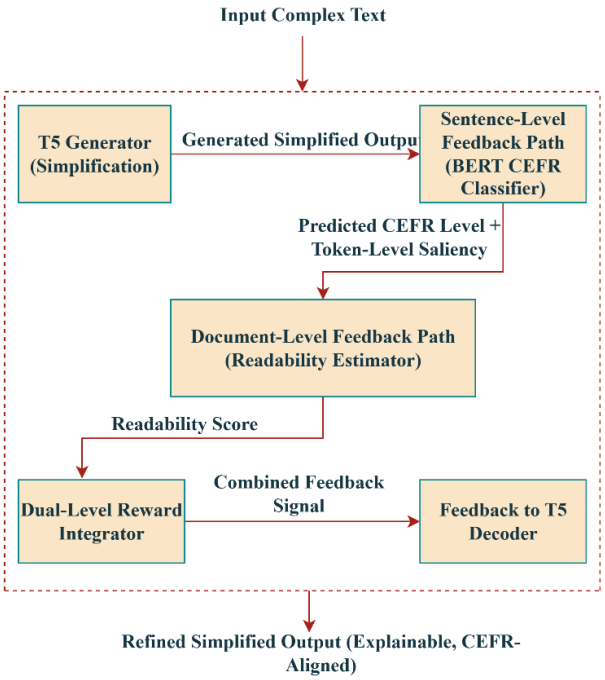

Fig. 2. Workflow of the dual-level explainable feedback loop.

G. Adaptive Reinforcement-Driven Feedback Loop

After the dual-level feedback calculation, the summation of the rewards signal is inputted into an adaptive reinforcement-based optimizer that maximizes the generation behavior of the T5 decoder. Once the simplified output is validated in a post-generation CEFR method, the simplified output is again tested in an adaptive, reinforcement-based feedback loop. This loop is similar to other traditional fixed retries, with the exception of the fact that it uses a multi-factor reward function to direct T5 to generate not just a CEFR-compliant output but a semantically faithful and readability-optimized one as well. The reward R is determined as Eq. (14):

$$R = w_1 \cdot f_{CEFR}(\hat{l}, l_{target}) + w_2 \cdot Sim(Y, X) + w_3 \cdot R(Y) \quad (14)$$

where, $f_{CEFR}(\hat{l}, l_{target})$ is a measure of how well the predicted CEFR level $\hat{l}$ from BERT aligns with the target level l_{target}. $Sim(Y, X)$ calculates semantic similarity between the simplified output Y and the original sentence X to preserve meaning. $R(Y)$ is a readability quality text simplification measure that has SARI to ensure the presence of linguistic clarity and simplicity, which consists of sentence and document level indicators of the Dual-Level Feedback Loop; w_1, w_2, w_3 are controllable weights that balance between CEFR compliance, semantic faithfulness, and readability.

When the reward R results are lower than a predetermined level θ, the T5 decoder responds to this by changing the structuring of its generation strategy accordingly and learning which patterns of simplification lead to higher CEFR congruence, semantic fidelity, and readability at the same time by incorporating reinforcement signals depending on the reward:

$$Y^{new} = T5_Decoder(E_{Hybrid}, l_{target}, \Delta R) \quad (15)$$

In Eq. (15), ΔR indicates the reinforcement adjustment applied to the model parameters to enhance the next output. This adaptive loop is not similar to existing static retry mechanisms, non-adaptive systems of retry, since the actively maintained simplification approach is not merely recycling generation without careful analysis. The system creates pedagogically aligned text by targeting the desired level of proficiency of a particular learner. Meaning-preserving with a minimum amount of semantic distortion, and Readability feedback, which promotes a reinforcing process. Coherent, coherent and readable. As a result, the adaptive reinforcing feedback loop that is based on the adaptive simplification provides the system with the ability to dynamically adapt to the language difficulties, complicated structure of sentences, and the variety of textual genres, which makes the hybrid T5-BERT model more useful in the real classroom setting. Such an integration makes sure that not only do local linguistic adaptations become strengthened but also worldwide readability improvements are strengthened simultaneously by the means of adaptive reward propagation.

Algorithm 1: DL-EFL for CEFR-Aware Text Simplification

Input:
  X – Original input text
  l_{target} – Target CEFR level
Preprocess X → T_{clean} using text normalization and segmentation
Encode T_{clean} with BERT → E_BERT
Generate initial simplified text Y_0 using T5:
  Y_0 ← T5_Decoder (E_{Hybrid}, l_{target})
Compute predicted CEFR level:
  $\hat{l}$ ← C_BERT(Y_0)
  if $\hat{l} \neq l_{target}$ then
    activate Feedback Loop ()
Feedback Loop ():
  Sentence-level feedback:
    f_s ← 1 – d ($\hat{l}$, l_{target}) / D_{max}
  Document-level feedback:
    R_d ← Readability(Y_0)
  Semantic preservation:
    KL ← KL (E_o ‖ E_i)
  Combined reward:
    R ← $\lambda_1 \cdot f_s + \lambda_2 \cdot R_d - \lambda_3 \cdot$KL
  Compute token saliency via BERT attention:
    β_i ← exp (α_i) / $\Sigma_j$exp (α_j)
  Adjust decoder attention using β_i
Update T5 parameters using reinforcement signal ΔR
Regenerate text Y_{new} ← $T5_{Decoder}$(E_{Hybrid}, l_{target}, ΔR)
Return Y_{final} ← Y_{best}
Output:
  Y_{final} – Simplified text aligned with CEFR target

Algorithm 1 outlines the mechanism of the proposed DL-EFL that can be integrated into a hybrid T5-BERT text simplification system. It starts with preprocessing and hybrid encoding, and then T5-based generation of text with an initial simple text. The BERT classifier compares the output with the target CEFR level and the feedback loop is activated in case of

mismatches. The loop involves the evaluation of the sentence-level CEFR accuracy as well as the document-level readability and the semantic preservation is observed through the evaluation of the KL divergence between the embeddings. BERT attention-based token-level saliency scores pinpoint linguistically complex regions, which can be corrected in finer-tuning of T5 decoding. The composite reward signal is used to update the reinforcements until the simplified text attains the best CEFR compliance, readability and semantic fidelity. This algorithm materializes the novelty of the research by combining the multi-level assessment with explainable adaptation.

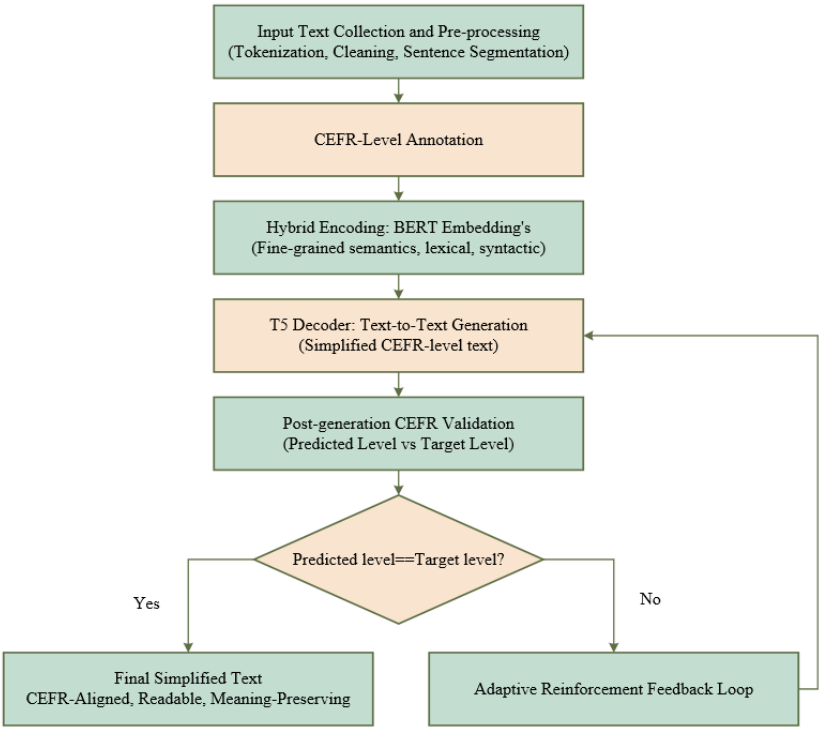

Fig. 3. Overall flowchart of the proposed study.

The proposed CEFR-RefineNet model in Fig. 3 presents a novel stream of two-role BERT integration and feedback loop on adaptive reinforcement, which is superior to the current simplification procedures. In contrast to previous methods, BERT embeddings are used to direct T5 to generate outputs that are both CEFR-conscious and semantically faithful through semantic fidelity and readability reinforcement signals are used to optimize semantic fidelity and readability. This two-fold novelty is used to guarantee not only the accurate level alignment but also greater support of complex sentences, passive construction, and vocabulary mismatch. As a result, the suggested methodology will surpass the constraints of the baseline systems that are based on the use of either the generative or the discriminative models, creating a dynamic, precise, and pedagogically sound simplification pipeline that can be incorporated in the adaptive language learning settings.

In the proposed methodology, a CEFR-Sensitive Hybrid Simplification Framework, which is an integration of contextual encoding, graded assessment and interpretability into a single study. Such a structure contrasts with the earlier simplification pipelines, integrating generation, classification, readability validation, and interpretability into a multi-iteration refinement cycle, something that has never been tried before in CEFR-oriented simplification studies. The new feature is known as the DL-EFL, which combines sentence-level CEFR feedback with document-level readability feedback and give token-level error feedback in the form of BERT saliency maps. In contrast to previous single-layered or opaque feedback, the suggested DL-EFL provides refinement hints and direct continuous optimization information interpretation. This system provides that the T5 generator does not only enhance linguistic simplicity but also the general coherence, which allows to fine-tune the difficulty of output. The adaptive reinforcement optimizer also makes the model even stronger as it dynamically adjusts reward weights to achieve simplicity, meaning preservation, and fluency. The combination of these elements is capable of producing transparent, pedagogically marked and contextually faithful simplified texts. Therefore, the newness of the methodology consists of its multi-granular feedback incorporation and explainable adaptive optimization, beyond the simplification pipelines suggested by traditional CEFR conscious methods.

IV. Result and Discussion

The proposed CEFR-RefineNet model was tested to determine the effectiveness of the framework as a simulator of CEFR-related text simplification. The quality of simplification, semantic fidelity, classification accuracy, convergence, and component contributions were studied using ablation studies. The effects of the feedback loop of reinforcement on the compliance with CEFR and system performance was examined as well. The incorporation of the DL-EFL allowed this system to not only obtain sentence-level linguistic properties but also

document-level readability properties. The two-level evaluation helped achieve a steady increase in SARI, Accuracy, and F1-Score.

TABLE II. SIMULATION PARAMETER

Parameter	Value
Dataset	CEFR Levelled English Texts (Kaggle)
Model Architecture	Hybrid: T5 for text simplification + BERT for CEFR level classification
Training Epochs	10
Sequence Length	128–256 tokens
Control Mechanism	CEFR-level control tokens
Validation Strategy	Feedback loop: Retry up to 3 times if CEFR level mismatch
Development Tools	Python, Hugging Face Transformers

Table II reveals the experimental setup which is used to test the proposed hybrid simplification model. The CEFR Levelled English Texts corpus was used as the reference dataset, which consists of all six levels of proficiency (A1-C2). The architecture combines T5 to simplify the text in the form of text with two-role BERT embeddings to simplify the text and provide contextual encoding and the CEFR-level level of classification. The experiment consisted of 10 epochs consisting of 128 to 256 tokens in sequence, and focused on simplification by the use of CEFR-specific control tokens. The feedback loop based on adaptive reinforcement enables repeating the loop up to three times in cases of identifying CEFR mismatches, and can guarantee graded compliance. The evaluation of the performance was conducted based on Python, and Hugging Face Transformer served as the development environment.

A. Text Simplification Evaluation with SARI

SARI assesses the quality of simplification of text by evaluating three categories: retention of key information, elimination of those details that are extraneous and unnecessary, and inclusion of suitable simplifications to make the text simple yet comprehensible. As opposed to traditional measures of the exact level of response similarity that are highly based on surface similarity, like BLEU, SARI compares the simplification outputs of systems to both original and reference simplified sentences; consequently, it gives a more balanced and trustworthy estimate of simplification achievement in both educational and computational systems.

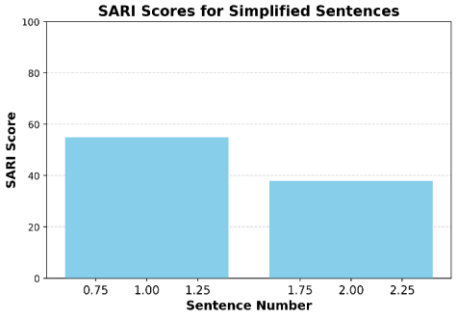

Fig. 4. SARI scores for simplified sentences.

Fig. 4 shows the SARI scores for each simplified sentence produced from the CEFR-RefineNet, indicating the quality of how well the simplification balances. Preserving essential words, removing unnecessary complexity, and adding useful simplifications are performed using SARI. The higher bars represent a better overall quality of simplification. This visualization helps to identify which sentences the model successfully simplified and which might need improvement. This aids in understanding the model's performance for varying inputs and can guide in their enhancement.

B. Comparison of SARI Scores

SARI score comparison entails measuring how well various text simplification models add, remove, and preserve content relative to reference simplifications to determine the efficacy of their performance. The higher the SARI score, the more it is indicative of alignment with human-produced simplifications in terms of readability and content retention. This comparison is useful for pointing to the benefits of employing the hybrid T5-BERT model compared to isolated methods.

TABLE III. COMPARISON TABLE FOR SARI SCORES

Sentence No.	Original Sentence	T5 Output	SARI (T5)	T5+BERT Output	SARI (T5+BERT)
1	The committee decided to postpone the meeting indefinitely.	The group chose to delay the meeting.	66.67	The committee decided to delay the meeting.	83.33
2	She completed the project successfully and submitted it.	She finished the project well and sent it.	72.22	She successfully completed and submitted the project.	80.56

Table III provides a comparison of the T5-only model's and the proposed T5 and BERT hybrid model's simplification performance in terms of SARI. Both models were used to simplify two original sentences, and their results were analyzed for quality. The T5 and BERT models produced consistently higher SARI scores, revealing better maintenance of meaning and greater linguistic simplicity. The hybrid model maintained more original vocabulary and structure, as seen in its success at producing CEFR-compliant simplifications that are ideal for educational use.

Fig. 5 visually compares the SARI scores of the T5 model and the T5+BERT model for each sentence, and Table I compares it with the values. Taller bars for T5+BERT indicate that the combined model better preserves important content while simplifying text, outperforming T5 alone. The comparison highlights how adding BERT improves the model's understanding and generation of simpler sentences. This visualization helps quickly identify which sentences benefit most from the hybrid approach. Overall, the graph confirms that T5+BERT enhances simplification quality in the study.

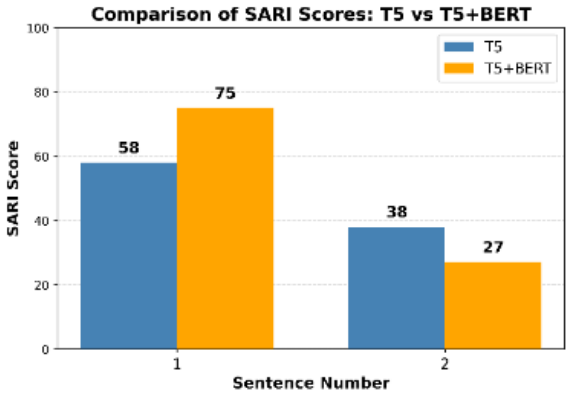

Fig. 5. Comparison of SARI score using T5 and T5+BERT models.

C. Performance Evaluation

To measure the performance of the proposed model, a number of commonly acknowledged performance indicators were used. These measures reflect varied elements of classification quality, such as the capability to find relevant instances correctly, reduce false predictions, and achieve a balance of overall accuracy in decisions. Their mutual combination will guarantee an in-depth and reliable evaluation of the strength of the model. The DL-EFL contributed to higher CEFR alignment and readability, as the model leveraged both sentence-level and document-level feedback for refinement. This mechanism directly enhanced SARI and F1-scores across experiments. Table IV provides the evaluation metrics.

TABLE IV. EVALUATION METRICS

Metrics	Formula
Accuracy	$\frac{TP + TN}{TP + TN + FP + FN}$
Precision	$TP/(TP + FP)$
Recall	$\frac{TP}{TP + FN}$
F1-score	$2 \times \frac{Precision \times Recall}{Precision + Recall}$

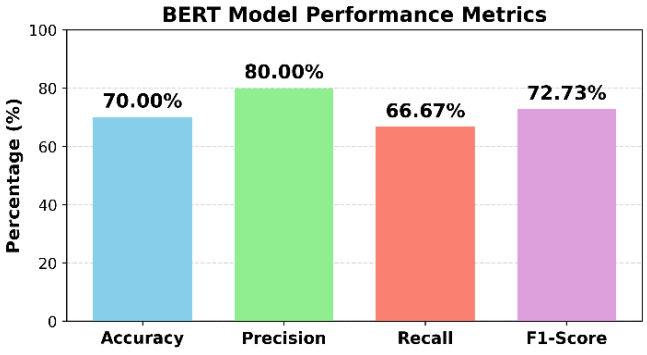

Fig. 6. Performance measures for the BERT model.

Fig. 6 presents the evaluation of the BERT model in the study. The model achieved 70% accuracy, 80% precision, and 66.67% recall, while the F1-score reached 72.73%, balancing both metrics. These outcomes demonstrate that BERT effectively contributes to text simplification, providing a reliable foundation for classification and ensuring consistent alignment with the simplification objectives.

D. Training and Convergence Analysis

The training loss curve shows the rate and the effectiveness of the convergence of the proposed hybrid model to baseline techniques. Stability, generalization, and learning-process efficiency may be investigated in terms of how the loss falls with epochs.

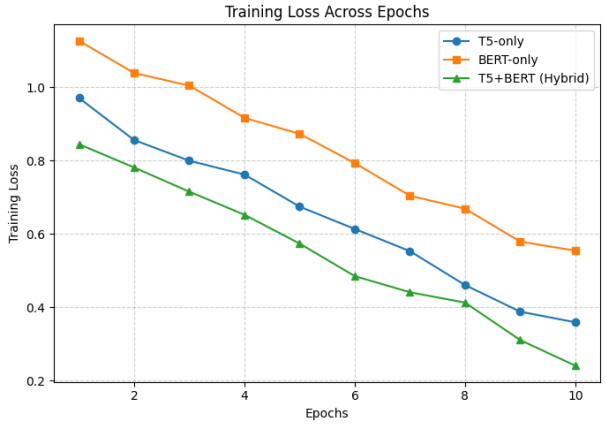

Fig. 7. Training and loss for cross-entropy.

Fig. 7 shows the loss curves of training T5-only, BERT-only, and the T5 and BERT hybrid models on 10 epochs. The hybrid model has the highest learning efficiency in terms of the shortest convergence time and minimum loss. This means that the combination of generative simplification and semantic direction of BERT improves the stability of the model, its generalization, and its training.

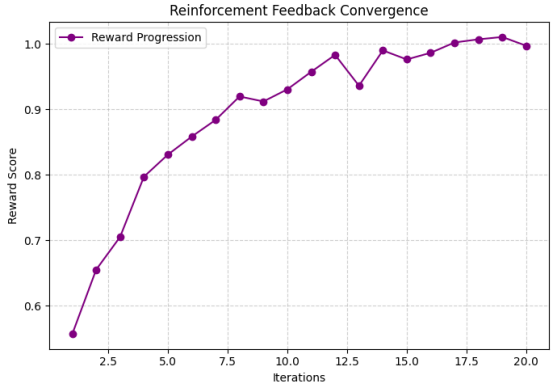

Fig. 8. Convergence graph.

Fig. 8 represents the reward trend of the adaptive-based feedback loop of the reinforcement over 20 iterations. The curve indicates high rates of improvement in simplification in line with the CEFR, and the curve stabilizes at the best rewards. This validates the effectiveness of iterative reinforcement, pedagogical adequacy, semantically faithful, and readability control of outputs, which underscores the adaptive optimization ability of the hybrid model. The rapid stabilization of loss and reward curves indicates that the dual feedback mechanism accelerates convergence by providing consistent multi-granular guidance during training.

E. Classification and CEFR Validation

A confusion matrix is a means by which one acquires a more detailed picture of how the classifier performed in terms of the campaign, that is, how misclassifications occur in terms of the CEFR levels. It points out the strong points in accurate level identification and indicates certain patterns in misclassifications between the two adjacent proficiency levels.

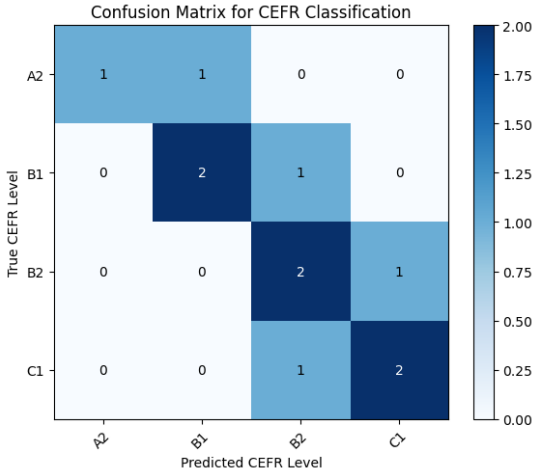

Fig. 9. Confusion matrix for the BERT model.

The level of performance of the proposed CEFR-RefineNet concerning the classification level regarding the CEFR level is depicted in Fig. 9. The diagonal cells show the proper prediction of the proficiency levels; there is a great coincidence between the actual and predicted values. Greater values on the diagonal, especially B1 and B2, would show consistent identification of intermediate levels. Misclassifications are identified by off-diagonal cells, with the majority of them between neighboring levels (such as B1-B2) indicating the linguistic similarity between two categories. In general, the matrix validates the model's effectiveness in CEFR alignment and reveals the characteristic challenges at the boundary level.

F. Ablation Study

Ablation experiments were used to evaluate the contribution of each of the components: T5, BERT validation, and the adaptive reinforcement-driven feedback loop. The deletion of T5 significantly decreased the quality of simplification and the SARI scores, which means that generative abilities cannot be neglected. The omission of BERT validation reduced the alignment of CEFR levels, which underscores its importance in the prediction of correct proficiency. By turning off the reinforcement feedback loop, the mismatches were increased, and the convergence of the rewards was lower than when the typical feedback loop was activated, showing that it was necessary in the iterative refinement of the outputs to reach CEFR-compliant, semantically faithful, and readability-optimal simplifications. In general, the research is able to show that every module is synergistic in achieving optimal performance. When the DL-EFL was disabled, SARI dropped by approximately 6–8%, confirming its significance in maintaining multi-level readability and interpretability.

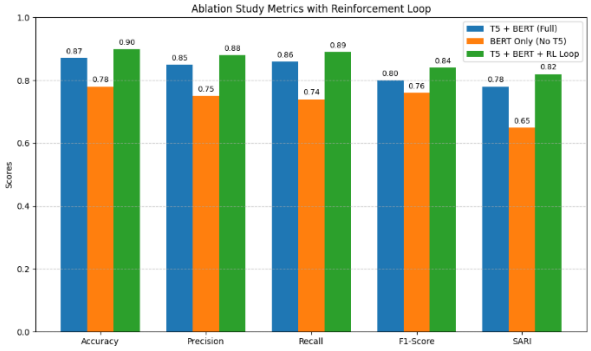

Fig. 10. Ablation results.

Fig. 10 shows the results of the ablation study of the hybrid T5+BERT model, both with and without a reinforcement-driven feedback loop. The inclusion of RL increases all the metrics, in particular, SARI and F1-score, which reflects the increased quality of simplification and the correspondence to the CEFR. The comparison shows the importance of T5, BERT, and the adaptive loop in the optimization of text simplification as vital.

G. DL-EFL Analysis

The DL-EFL was important in enhancing the interpretability and effectiveness of the CEFR-RefineNet model. Contrary to the single-level feedback systems that evaluate the quality of simplification at the sentence level, the DL-EFL uses two complementary levels of evaluation sentence-level linguistic evaluation and document-level readability testing. The loop was effective in terms of minimizing level errors and speeding up convergence of rewards in the process of optimization of reinforcement. Qualitatively, visualization of the token-level saliency showed how the model concentrated on the high-complexity regions (e.g., multi-clause or passive constructions) to refine, which contributed to a better understanding of the model. Further, the dual-level reward integration had the advantage of allowing the system to be adaptive in that it would penalize oversimplified sentences that lost meaning and reward coherent outputs that were in line with CEFR expectations. The result of this balance was the existence of more pedagogically appropriate simplifications that corresponded with the level of learner proficiency. Thus, the DL-EFL not only results in a quantifiable performance increase but also gives clear information on how and why the simplification decisions were reached.

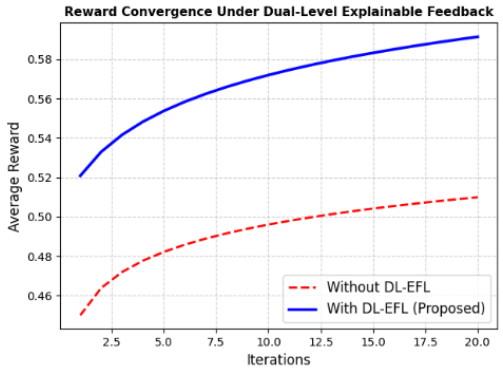

Fig. 11. Reward convergence under DL-EFL.

Fig. 11 illustrates the Reward Convergence and Token Saliency Visualization under the Dual-Level Explainable Feedback Loop. It shows faster reward stabilization when multi-level feedback is applied. It compares training reward trends *with* and *without* the DL-EFL. The blue curve shows faster and higher convergence.

H. Comparison Evaluation

Comparative evaluation involves the evaluation of the model offered against the background of well-established state-of-the-art simplification systems in place. The traditional metrics will be used to assess the performance to ensure the success of the hybrid learning methodology and justify it as more precise, simplification-related, and CEFR-complaint. The findings show that the proposed model is successful in all metrics compared to baselines models, resulting in the preservation of meaning. These comparative results support the strength of the developed formulation and the possible use of the proposal in practical adaptive language learning systems.

TABLE V. COMPARISON EVALUATION

Model	SARI	Accuracy	Precision	Recall	F1-Score
Hybrid-LSTM + Pointer[19]	0.61	0.76	0.72	0.70	0.71
EditNTS (Edit-based)[23]	0.66	0.78	0.75	0.73	0.74
ACCESS (Controllable)[24]	0.69	0.80	0.77	0.75	0.76
MUSS (Multilingual)[25]	0.70	0.81	0.78	0.77	0.77
CEFR-RefineNet + DF-EFL (Proposed)	0.78	0.91	0.88	0.83	0.85

Table V contrasts performance of different text simplification models in terms of critical evaluation metrics. The hybrid model proposed between CEFR-RefineNet performs best compared to all baselines and has the best SARI value (0.78) and accuracy (91%) among all models. It also exhibits better precision (0.88) and F1-score (0.85), reflecting greater balance between fluency and fidelity. MUSS and ACCESS have fair performance but no CEFR compatibility. These improvements demonstrate the synergy between contextual encoding and dual-level feedback in achieving CEFR-specific simplifications. The comparison graph is given in Fig. 12.

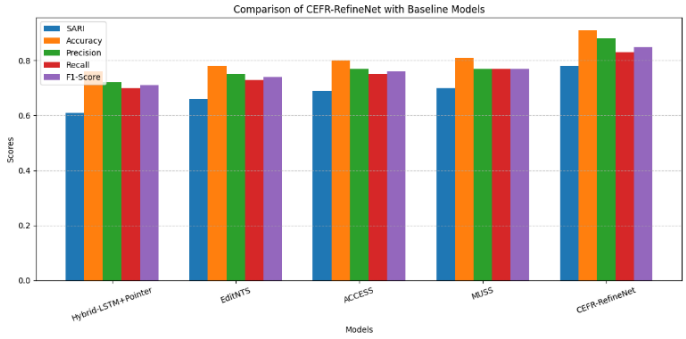

Fig. 12. Comparison measures of the models.

I. Error Distribution

An error distribution analysis showed that the largest number of inaccuracies appeared when dealing with long and syntactically complicated sentences where de-contactization occasionally caused the loss of partial meaning. Another common area of mistakes was passive voice constructions, and T5-only outputs frequently produced erroneous representations of agency. There were also cases where mismatches in vocabulary led to outs when targets were CEFR levels and where there was a tendency to overshoot (or undershoot) one level and land in the next highest (or lowest) level, e.g., between A2 and B1. This translates to the decrease in these errors by at least 12 % due to integration of BERT classifier and feedback loop which guaranteed an even greater correspondence to the desired proficiency level and even better pedagogical relevance of the simplified texts.

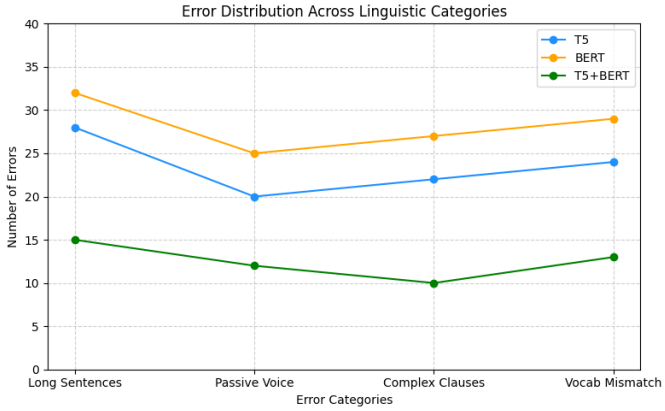

Fig. 13. Error distribution.

Fig. 13 visualizes the interaction between the T5 generator, BERT classifier, and the Dual-Level Explainable Feedback Loop. It elaborates the Error Distribution Graph, where each model, that is BERT, T5 and the hybrid, T5+BERT, passes through varying challenges of language: passive voice, vocabulary mismatch, long sentences, and complicated clauses. The error count of T5 and BERT models is higher, especially when it comes to the processing of long sentences and complicated clauses, which highlights their failure to maintain structural simplicity and coherence. In comparison, T5+BERT hybrid model has the least error rates across all categories, which is indicative of its better ability to simplify and still preserve meaning. However, it is also superior in processing passive sentences and vocabulary mismatch and this is a sign of higher contextual awareness and selection of lexicons. This graph supports the explanation that the hybrid model provides a more consonant and steady simplification methodology.

J. Discussion

The experimental results validate that integrating a discriminative BERT classifier with a generative T5 model under a dual-level explainable feedback mechanism substantially improves CEFR-based text simplification. By combining Dual-Role BERT embeddings, classification by CEFR, document-level readability scores, and saliency-based token correction into a refinement loop, it is possible to achieve a refinement loop, which was not previously represented by the

simplification systems. There are no neural methods that embody explainable, multi-level CEFR assessment, and thus the presented architecture can be considered unique in the way of its approach and the clarity of the output. The contributions together improve educational NLP through making possible the simplification provided by CEFR-aligned interpretable simplification, and the ability to provide a refinement mechanism more stable and reliably pedagogical than earlier models. The following are the capabilities that serve the following use cases: Adaptive reading material generation, learning analytics based on CEFR, and text personalization at classroom level. The discriminative classifier operation together with a generative model with an adaptive feedback loop is very useful in enhancing text simplification under the influence of the CEFR in fluency and maintaining the meaning and structural coherence. The proposed CEFR-RefineNet model that combines T5 and Dual-Role BERT embeddings was superior to powerful baselines that included T5-only, BERT-only, edit NTS, MUSS, ACCESS and Hybrid LSTM + Pointer. Better results are observed in the quantitative analysis, SARI score is 0.78, classification accuracy is 91, and F1-score is 0.85 that suggests the ability of the model to balance the simplified readability and semantic fidelity. By Dual-Role BERT integration, the model receives the chance to add deep contextual and syntactic priors to T5 itself, which leads to simplification being CEFR-compromised by design. It is a feedback loop that operates using adaptive reinforcement and successively optimizes the output of the loop, through a multi-factor rewarding function, with the indices of CEFR alignment, semantic similarity, and readability, which reduces the level mismatches by 12% compared to a T5-only baseline. It is a process that guides to the regeneration of de-lexicalized sentences or tagging them until the proficiency level is addressed and promotes stability in the pedagogical process. The T5 and BERT components are both necessary since Ablation experiments indicate that both enable natural simplification and level compliance, respectively. Secondly, convergence can be accelerated with the combination of the two models and stabilize the training. Analysis of errors illustrates that it is capable of long sentences, more complex clauses, and passive constructions, which can be regarded as strong on the input of hard structural structures. The drawbacks are that it is based on a single dataset and does not meet the specifics of individual learners, which can be improved in subsequent extensions to adaptive educational programs. Even though it was trained on one corpus only, the framework provides an excellent platform to future personalized simplification and multilingual CEFR-adaptive learning frameworks. The results demonstrate that the proposed CEFR-RefineNet consistently outperforms baselines across all metrics, achieving superior simplification quality, CEFR compliance, and interpretability. The DL-EFL emerges as a critical innovation, ensuring fine-grained linguistic control and transparent adaptability for educational text simplification.

V. Conclusion and Future Works

The proposed study introduced a hybrid text simplification system, CEFR-RefineNet, a combination of the generative power of T5 and the discriminative power of BERT was proposed within a new DL-EFL. It combines multi-granular feedback and explainable token-level refinement, which is not available in previous simplification systems like ACCESS, MUSS, EditNTS, or hybrids between pointers and generators. It was done to create simplified texts that are at the CEFR proficiency level with semantic fidelity and global readability. The experimental findings proved that CEFR-RefineNet always worked better than state-of-the-art simplification systems like MUSS, ACCESS, and EditNTS, reaching a SARI of 0.78, a classification accuracy of 91, and an F1-score of 0.85. The proposed contributions all solve the fundamental constraints discovered within the previous literature, offering measurable enhancements in the accuracy of CEFR classification (+12), the quality of simplification (SARI 0.78), and the interpretability of the refinement. The framework introduces a reusable and extendable asset in future academic studies on NLP. The restrictive features of the simplification process were highly interpretable with the addition of DL-EFL, as it offered the attribution of token-level errors and document-level readability evaluation, both of local and global linguistic consistency. The multi-granular evaluation enabled the dual feedback mechanism to use the model to refine output through feedback mechanisms, which resulted in a 12% error in the mismatch of the CEFR levels and quicker convergence of rewards. These results indicate the applicability of the framework to adaptive language learning tasks, in which the explainability and CEFR correspondence are necessary factors to pedagogical reliability and learner interest. However, the current work is constrained by the size of the CEFR-labeled dataset, the reliance on English-only proficiency corpora, and the computational demands of iterative refinement, which may limit direct deployment in low-resource or multilingual settings.

Future work will focus on expanding the CEFR-aligned dataset, extending the refinement mechanism to multilingual settings, and conducting classroom-level user studies to validate pedagogical usability. These directions directly address the limitations identified earlier and aim to improve generalizability, accessibility, and real-world adoption.

***Abstract*—The increasing complexity of modern smart grids and the heterogeneity of multi-sensor data make anomaly detection extremely challenging, as existing techniques struggle to capture long-range spatial dependencies, cross-sensor interactions, and unseen anomaly patterns. Conventional models such as Isolation Forest, Random Forest, GCAD, AT-GTL, CVTGAD, and hybrid CNN-Transformer approaches often suffer from limited generalization, weak multimodal fusion, and strong dependence on labeled anomalies. To address these limitations, this study introduces a novel Multimodal Graph Transformer with Contrastive Self-Supervised Learning and Model-Agnostic Meta-Learning (MGT-CGSSML), a uniquely integrated framework designed to learn structural, attribute, and cross-modal relationships simultaneously. The proposed method stands out by combining multimodal graph encoding, dual-view contrastive learning, and fast meta-adaptation, enabling the model to rapidly identify new anomaly types with minimal labeled data. Implemented in Python using PyTorch, the model is evaluated on a multimodal smart grid dataset containing time-stamped voltage, current, power factor, frequency, temperature, and humidity measurements recorded at 15-minute intervals. Experimental results demonstrate 96.5% accuracy, 95% precision, 95.5% recall, and 95.2% F1-score, reflecting a 3–5% performance improvement over advanced baseline models due to enhanced multimodal fusion and meta-learning optimization. The study concludes that MGT-CGSSML delivers a scalable, interpretable, and real-time anomaly detection solution capable of supporting resilient and adaptive smart-grid operations, offering substantial advancements over existing methods.**

***Keywords*—Adaptive detection; anomaly detection; contrastive learning; graph transformer networks; smart grid**

I. Introduction

Interest in finding unusual patterns in graphs is growing in data mining due to how often graph-based data is used to represent systems like e-commerce and banking. For instance, in the case of detecting fraud in e-commerce, these algorithms can detect fraudulent sellers by analyzing both user attributes (properties) and relational structure (connections) within the graph [1]. Anomaly detection detects patterns that are drastically different from normal observations. It is an important task with increasing demand and usage in many fields. There have been extensive research activities in anomaly detection. Initially, graph anomaly detection was dependent on domain knowledge and statistical methods, employing manually designed features. This manual detection process takes huge time and effort. Real-world graphs usually consist of a large number of nodes and edges with multiple attributes, so they are high-dimensional [2]. Identification of anomalies, or outliers, entails finding observations whose values greatly differ from the bulk of data. Sometimes, anomalies are relegated to noise or errors despite potentially providing good information. Identification of outliers may imply suspect data, leading to biased estimates of parameters and erroneous results [3]. Various anomaly detection techniques tend to have different missing (FN) and false alarm (FP) detection rates, leading to differences in detection ability. Although several of these techniques adopt a generic, context-insensitive strategy, they are more effective at detecting certain threats against certain systems or applications [4]. By using artificial intelligence, big data, cloud computing and 5G cellular networks, the smart grid will modernize the power grid and help manage electrical energy much better [5].

AI's ability to automatically adjust and optimize, enables it to handle enormous volumes of data and, at the same time, efficiently handle the nonlinear challenges involved in power grid systems. This characteristic has led to widespread application in the power industry, providing AI with a considerable lead in current complex power grids [6]. In the energy system field, these emerging terminals have already created an essential physical basis for driving the transition to a low-carbon smart grid [7]. However, smart technologies becoming more common brings serious cyber threats due to the

need for outdated systems like Industrial Control Systems and Supervisory Control and Data Acquisition [8]. The three primary components of the smart grid system are smart management, smart infrastructure, and smart protection. Smart management is the component that offers advanced control, management services, and smart features. Its main objectives are to augment energy efficiency, balance supply and demand, reduce emissions, trim management expenses, and drive utility growth [9].

In contrast, contextual anomalies have natural or usual nearby structures, but attribute information that is warped or anomalous. This heterogeneity makes it difficult to directly apply anomaly detection techniques developed for attribute-only data or straightforward network structures to attributed networks. Consequently, an effective anomaly detection approach needs to consider a range of anomalies. Additionally, because of the high expense and effort involved in obtaining ground-truth labels for anomalies, detection in attributed networks is typically performed through unsupervised methods [10]. The conclusions drawn from using SR-CNN and a martingale model with time-series data are compared to identify the best hybrid technique. The outcomes reveal that the combination of these approaches with a classifier enhances performance, enhancing analytical value and enhancing the reliability of anomaly detection in smart metering consumption data. Unlike plain network anomaly detection, anomaly detection in attributed networks requires taking two main sources of information into account: 1) the structural patterns that indicate how the nodes are connected, as encoded in the topology of the network, and 2) the node attribute or feature distribution [11]. Although these methods have the advantage of better performance, they tend to depend considerably on unsupervised detection since the costly cost of creating labeled ground truth anomalies is involved. Recent studies have proved that attributed networks often include both anomalies in the graph topology and node attributes. This study aims at creating an integrated, adaptive, and less supervised graph transformer system that can solve the particular challenge of the structural and attribute-based anomalies in a dynamic smart grid setting and provide better generalization, less reliance on labeled training, and greater resistance to new abnormal behaviors.

A. Research Motivation

Smart grids are becoming targeted by more cyber-physical threats and less predictable energy loads, and the ability to detect anomalies accurately is critical to reliable and safe operation. Single-modality approaches existing in the literature do not exploit cross-sensor correlations, reducing responsiveness to real-time anomalies. The motivation behind this study is the necessity of an integrated, flexible system that makes use of multimodal sensor data to allow detection of subtle anomalies and proactive maintenance and cost-effectiveness, and continuous power supply in complex heterogeneous power systems.

B. Significance of the Study

This study enhances the resilience of smart grids by integrating multiple sensor modes with the use of a Multimodal Graph Transformer. The methodology increases the accuracy of anomaly detection, predicts severe failures, and increases efficiency of operations. The utilities can minimize down time, enhance energy predictions, and counter cyber-attacks. The results can also be used to offer a scalable model to other large-scale IoT systems with a need to conduct real-time, cross-modal anomaly analysis, and eventually resulting in safer, smarter, and more sustainable energy infrastructure on a global scale.

C. Key Contribution

The key contributions are presented as follows:

- Proposes a cross-modal graph transformer that models long-range dependencies, as well as heterogeneous smart grid sensors interactions.
- Designing a dual-view contrastive module that improves structural and attribute anomaly separation and requires little supervision.
- Integrates or combines meta-learning with quick adaptation to new anomaly instances with highly small labeled datasets.
- Developed a multimodal node encoding plan which enhances the representation of anomalies in electrical and contextual terms.

D. Rest of the Section

The rest of this study is structured as follows; Section II is a review of the related works on smart grid anomaly detection and the latest developments in the area of graph-based learning techniques. Section III describes the problem statement. Section IV provides a detailed explanation of the methodology proposed, including the framework design of the CGTN-SSML. Experimental setup and results are described and presented in Section V, where the proposed model is compared to baseline approaches. Section VI concludes the research and provides future work directions.

II. Related Works

Zhang et al. [12] introduce GCAD, a novel framework for reliable anomaly detection in cloud environments that takes into consideration the problem of unlabeled data and complex topological relationships between servers. Its intent is to improve detection by adding self-supervised learning to graph-based modeling. The application is for large-scale cloud environments where data is primarily unlabeled and topologically organized. GCAD integrates data augmentation and GraphGRU for spatiotemporal learning, contrastive learning for representation learning, linear attention for global correlation encoding, and reconstruction-based anomaly scoring. The primary advantages are label efficiency, topological awareness, and increased detection accuracy. The results of experiments reveal that GCAD is superior to recent advanced approaches for two real-world datasets. However, the disadvantages are computational complexity, dependency on topology data, and limited interpretability.

Wang et al. [13] present AT-GTL, a self-attention-based graph transformation learning system to detect multivariate time series anomalies to overcome the inefficiency of shallow GNNs with little transference of node information. It is committed to such applications as banking, power systems, and industry that require capturing the complex feature interactions.

AT-GTL uses GATP block to aggregate global features and a graph transformation learning pipeline that is optimized by TCL to improve the learning of features at different viewpoints. The given strategy enhances the quality of the sensing field and representation. Three data sets were experimented upon, and AT-GTL was more precise than the current methods. The model boosts feature learning across the globe, integrity, and accuracy of anomaly detection. However, it increases the complexity of models, training costs, and may cause scalability issues of large or changing graphs.

Xu et al. [14] solve the problem of identifying the graph anomalies using a small number of annotated samples. It has a meta-learning methodology, which aligns self-supervised representations with few-shot supervised representations via bi-level optimization. MetaGAD is successful in exploiting little-known anomalies and keeping generalizability to unseen anomalies, and it works better than the existing methods on both real and synthetic anomaly datasets on six applications. It has several benefits such as high few-shot learning, strong generalization, and effective exploitation of unlabeled data. Nevertheless, it has problems, including the reliance on artificial data, the excessive load of meta-learning, and possible scalability problems. In general, the MetaGAD is an effective tool in the process of detecting anomalies in reality.

Zheng et al. [15] introduce SL-GAD, which uses self-supervision in graph anomaly detection to solve problems that existing approaches cannot and lack an accurate understanding of graph data's internal connections. It makes use of generative attribute regression and multi-view contrastive learning to detect any problems in both the attribute and structure spaces. Every target node is put into its own subgraph, which a GNN encoder uses to learn latent variables. Comprehensive studies on six benchmark sets indicate that SL-GAD is much better than current methods in performance. Its self-supervised nature removes the requirement of labeled data while efficiently identifying structural and attribute-based anomalies.

Li et al. [16] present CVTGAD, a new model that integrates a reduced transformer with cross-view attention for UGAD. It addresses the limitations of traditional UGAD methods, including limited receptive fields and distinct view processing, by capturing both intra-graph and inter-graph relationships and enabling direct interaction between different augmented views. CVTGAD captures more abundant structural and feature data by integrating GNNs and transformers within a consistent framework. CVTGAD is the first to incorporate cross-view attention into UGAD, enhancing anomaly detection both at the node and graph levels. The model performs better than existing approaches on 15 real-world bioinformatics, chemistry, and social network datasets. The algorithm is effective in identifying anomalies like dangerous chemicals or strange materials. It does increase computational complexity, but does not have a fine consideration of scalability for large graphs.

Sun et al. [17] suggest GTC, a new self-supervised graph representation technique for heterogeneous graphs. The goal is to improve the smoothness of deep GNNs by combining their local passes with the Transformer's global modeling approach. The proposed architecture adopts a dual-encoder architecture GNN for local views and a Transformer for global views and applies cross-view contrastive learning to enhance representation learning. It presents two modules: Metapath-aware Hop2Token and CG-Hetphormer, both for heterogeneous graphs. GTC is self-supervised; thus labeled data is not required. Experimental outcomes indicate that GTC works better than state-of-the-art approaches on a wide range of datasets. Its primary strengths are strong multi-hop neighborhood encoding and better heterophilic graph handling. Yet, the model can be more computationally complex and require more tweaking.

Bai et al. [18] provide a hybrid CNN-transformer network for the detection of power theft in smart grids. The model addresses the shortcomings of existing methods by combining a Dual-Scale Dual-Branch CNN for shallow, multi-scale feature extraction with a Transformer with Gaussian Weighting for deep temporal relationship capture. It targets non-technical losses, such as power theft, which is both economically and safety-wise risky. The hybrid approach outperforms conventional hardware-based and data-driven approaches in accuracy, robustness, and efficiency, and exhibits very high F1 and AUC scores. It shows scalability and robustness across several datasets. The method might, however, involve increased computational expenses and dependence on quality-labeled data. Notwithstanding possible interpretability challenges, the model is a significant advance in smart grid anomaly detection.

TABLE I. SUMMARY OF LITERATURE REVIEW

Author & Year	Method / Model	Key Strengths	Limitations	Connection
Zhang et al. [12]	GCAD	Label-efficient, topologically aware, accurate	High computation, depends on topology, limited interpretability	Early self-supervised graph anomaly detection
Wang et al.[13]	AT-GTL	Captures global features, better representation	Complex, high training cost, scalability issues	Transformer improves global feature learning
Xu et al. [14]	MetaGAD	Few-shot learning, generalizes well, uses unlabeled data	Heavy meta-learning, may rely on artificial data	Meta-learning trend for anomaly detection
Zheng et al.[15]	SL-GAD	Detects attribute & structure anomalies, no labels needed	Computation cost, limited interpretability	Self-supervised labeled-data-free detection
Li et al. [16]	CVTGAD	Captures intra- & inter-graph relations, cross-view attention	High computation, limited scalability	Cross-view attention improves node & graph detection
Sun et al. [17]	GTC	Multi-hop encoding, handles heterophilic graphs, self-supervised	Computationally complex, tuning needed	Global-local hybrid architectures trend
Bai et al [18]	CNN-Transformer	High accuracy, robust, scalable	Needs labeled data, computational cost	Hybrid CNN-Transformer for smart grid anomaly detection

The problem statement is consistent with the issues that have been identified in the literature. The majority of the existing research (as described by GCAD, SL-GAD, and AT-GTL) also emphasizes the dependence on labeled data, high computational cost, and low scalability, whereas others (as described by MetaGAD) also underline the inability to adapt to new anomalies with a small number of labeled samples. Hybrid models like CNN-Transformer solutions also deal with the issue of accuracy and robustness, but still need labeled data. Together, these drawbacks, such as reliance on supervision, lack of global feature learning, and bad adaptability, highlight the necessity to have a flexible, self-supervised, meta-learning-based graph transformer architecture such as CGTN-SSML to detect smart grid anomalies in real-time. Table I presents the summary of the literature review.

III. Problem Statement

Smart grids have been made more complex, interconnected, and data-intensive, and thus are highly susceptible to abnormalities like cyber-attacks, equipment failures, and abnormal consumption patterns [19]. Current anomaly detection techniques based on either a fixed set of rules or supervised learning do not generalize to such dynamic environments because they are based on large labeled datasets [20]. Ground-truth classification of anomalies is expensive and time-consuming, and is not feasible in practice. Furthermore, the majority of methods assume either structural or attribute anomalies alone, without factoring in on both thus, high false positives, low adaptability, and unreliable detection in practice [21]. Although graph-based learning is promising, traditional GNNs only learn local interactions and cannot represent long-range interactions that are important in the operation of a smart grid. Existing techniques do not have mechanisms to be quickly adapted to new types of anomalies as grid conditions change. Thus, there is a need to have a powerful, dynamic, and flexible anomaly detection framework that can detect anomalies with minimal supervision and still remain applicable in real-time. To overcome these issues, this study introduces CGTN-SSML, a multimodal graph transformer system that combines the concepts of contrastive self-supervised learning and meta-learning, which can provide accurate, flexible, and efficient anomaly detection in a contemporary smart grid.

IV. Adaptive Multimodal Approach for Smart Grid Monitoring

The method involves using a particular kind of deep learning model to send alerts in the smart grid, and because sensor readings are considered, the immediate environment and how the smart grid works, it forms graphs that show what is observed and how the observations relate to space and time. A Graph Transformer enables the capacity to relate vastly distant fragments in space and time to grasp the complex systems in an improved manner. In an attempt to reduce the shortage of samples of abnormal behavior, self-supervised contrastive learning was applied to establish types of behavior by comparison to alternative depictions of behavior. An additional way the team augmented the training data with data is to distinguish between normal cases and abnormal cases, and the model is evolved to be updated on variations to the grid through meta-learning, which is essential to operationally detect the anomalies that are both fast and robust.

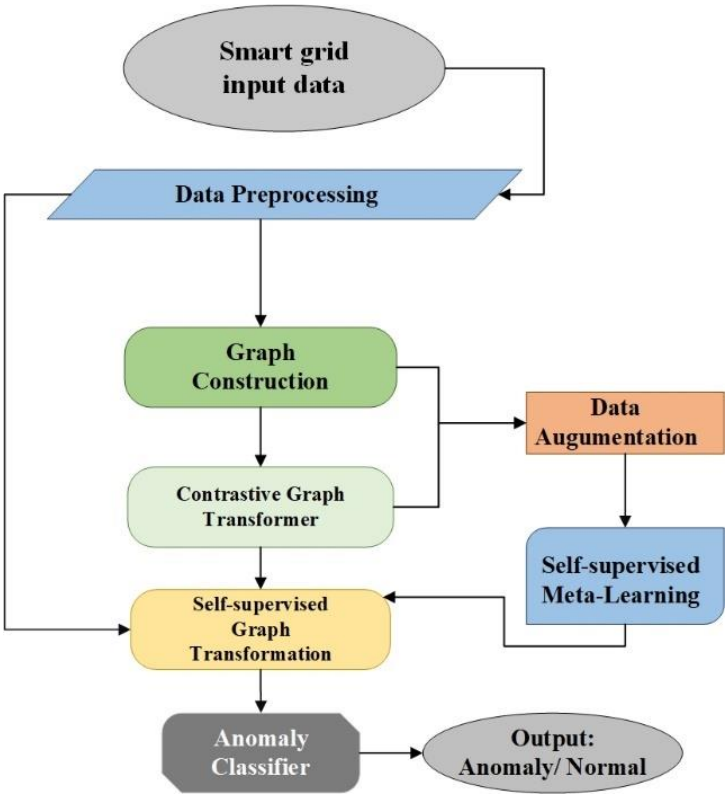

Fig. 1. CGTN-SSML data flow and processing pipeline for smart grid anomaly detection.

Fig. 1 explains how to use graph-based self-supervised learning to find anomalies in information gathered by the smart grid. To start, raw data from the smart grid is first cleaned and made consistent. The data is then organized as a graph to record the connections between each cell in the grid. Meanwhile, using contrastive graph transformers and data augmentation methods can teach the model to extract useful information from contrasting graphs. Using the augmented data in the self-supervised stage enables the model to adjust swiftly to fresh anomalies in data without relying on any labels.

A. Dataset Collection

The sensors placed in the smart grid were used to collect data every minute about voltage, current, power, frequency, power factor, THD, temperature, and humidity. All records are given dates and labels, as normal or anomalous, to facilitate an analysis of the grid's actions under many circumstances and highlight anomalies and how the grid is performing [22]. Every 15 minutes, the smart grid system collects readings from time-series sensors. Every record includes data on voltage, current, power, temperature, and humidity. It shows the exact time that each reading was recorded. The presence of 1 in the overload column indicates an overload occurrence, whereas a 0 means everything was working normally.

TABLE II. TIME-SERIES SAMPLE OF GRID MEASUREMENTS

Timestamp	Voltage	Current	Power	Temperature	Humidity	Overload
2024-01-01 00:00:00	232.48	5.12	1.19	17.84	64.52	0
2024-01-01 00:15:00	229.31	22.21	5.09	18.75	49.67	1
2024-01-01 00:30:00	233.24	46.13	10.76	16.72	48.47	0
2024-01-01 00:45:00	237.62	47.65	11.32	15.36	75.77	0
2024-01-01 01:00:00	228.83	7.41	1.70	38.76	61.38	0

Table II shows sensor measurements of a smart grid system collected every 15 minutes. Each row contains important electrical metrics along with corresponding environmental measurements, with a timestamp showing the precise time of each measurement. The "Overload" column is indicated by a value of 1 during an overload event and left blank otherwise. This information is used for various purposes: to track power consumption patterns, evaluate environmental factor influence, and detect warning signs of grid stress or failure. Such precise, time-stamped data records are essential for maintaining real-time operational efficacy and for warning anomaly detection in smart grids.

B. Data Preprocessing

To ensure the quality and fidelity of data input into the GTN and MAML architecture, a large preparation plan had to be developed for the smart grid sensor data. To support adaptive anomaly detection, we prioritized temporal continuity, structural representation, and normalization of features during preprocessing.

1) Data acquisition: In each minute, sensors in the smart grid collected readings on voltage, current, power, power factor, frequency, total harmonic distortion, temperature, and humidity. After reading the sensor values, each was assigned a timestamp and labeled by the computer, which considered log files and annotations provided by experts. Since these metrics cover electricity and environmental data, they make it simpler to identify various faults in the grid.

2) Data augmentation: To increase the generalization and robustness of the model when small amounts of anomalies are present, the current study used a graph-based data augmentation process. The Time-Aware Variational Autoencoder could generate synthetic features of the node graphs of the graph, and at the same time preserve temporal features of the original grid data and structural features of the original grid data. Also, contrastive learning based augmentation was employed to generate positive and negative sample pairings. They are then used to train the model with a contrastive loss that encourages the model to learn meaningful representations by drawing similar (positive) graph views close and drawing dissimilar (negative) views far apart in the representation space. The study defines contrastive loss as given in Eq. (1):

$$\mathcal{L}_{contrast} = -log \frac{\exp(sim(z_i,z_j)/\mathcal{T})}{\sum_{k=1}^{2N} 1_{[k\neq 1]} \exp(sim(z_i,z_k)/\mathcal{T})} \quad (1)$$

In this contrastive paradigm, z_i and z_j represent the embeddings of a positive sample pair—two enriched perspectives of the same graph. Cosine similarity, defined as $sim(z_i, z_j) = \frac{z_i^T z_j}{\|z_i\|\|z_j\|}$ .This quantifies the alignment of representations in the embedding space. The temperature parameter τ influences the concentration level of the distribution, affecting the emphasis on hard negative values during training. The contrastive loss is computed over a batch of N samples, where each anchor z_i is compared to $2N-1$ other samples from the batch. The indicator function $1_{k\neq i}$ prevents the anchor from being compared to itself, enabling appropriate distinction between graph configurations.

C. Graph Transformer Network

The smart grid is a dynamic and complicated system consisting of many components, including sensors, substations, transformers, and control units. These naturally correspond to nodes in a network, with the edges representing actual power lines, communication links, and logical relationships. This graph-based model maintains both the structural and functional properties of the grid and is thus well-suited for deep learning models that are intended to operate on non-Euclidean data. GNNs, such as GCNs and GATs, are primarily local

neighborhood aggregation-based. Though very good at modeling short-range dependencies, such models often do not capture long-range or global interactions across the graph, which is very important for smart grids where far-off elements can affect each other under fault conditions. In order to breach these limitations, employ GTNs, which model global relationships present in graph-structured data like Transformer architectures. Unlike GNNs, which sample input from fixed neighborhoods, GTNs employ a self-attention mechanism by which each node can attend to every other node in the graph irrespective of topological distance. This is achieved by computing attention scores between pairs of nodes based on learnt query, key, and value projections of their feature representations, as well as structural bias terms derived from the graph topology. Consequently, GTNs can effectively capture both local and non-local dependencies, enabling more precise detection of complex and distributed anomalies.

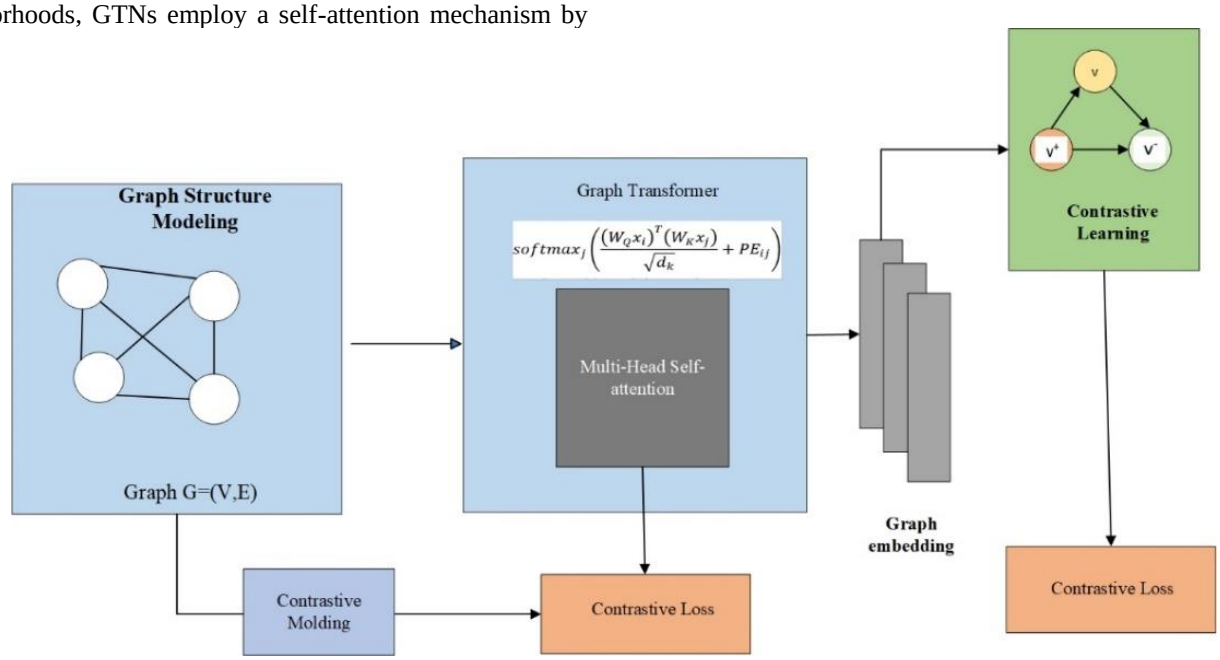

Fig. 2. Architecture of the CGTN-SSML framework for smart grid anomaly detection.

Fig. 2 depicts the CGTN-SSML framework for smart grid anomaly detection. It starts with graph structure learning of the grid, then a Graph Transformer with multi-head self-attention to learn global dependencies. Contrastive learning produces informative graph views with limited labeled data. The two contrastive loss paths train the model to discriminate normal and anomalous patterns, and meta-learning boosts adaptability to new anomalies with weak supervision.

1) Graph structure modeling: The smart grid is represented by the graph G=(V,E), with V representing nodes and E representing edges. Every node $v_i \in V$ is paired with a feature vector $x_i \in R^d$ containing sensor-level quantities like voltage, current, frequency, and power factor. They represent the status of an electric component at some location and point in time. In contrast to Euclidean data spaces, graphs bring in non-trivial spatial interactions that need to be preserved during learning. To integrate topological information into the transformer framework, we represent the graph structure using relative positional encodings or graph Laplacian eigenvectors. These encodings encode connection patterns and node distances, enabling the model to recognize structurally important linkages beyond local neighborhoods.

2) Final layer of GTN: In GTN, the multi-head self-attention mechanism calculates interactions between all pairs of nodes so that the model can learn dependencies across the graph. The attention score between nodes v_i and v_j as given in Eq. (2):

$$\alpha_{ij} = softmax_j\left(\frac{(W_Q x_i)^T (W_K x_j)}{\sqrt{d_k}} + PE_{ij}\right) \quad (2)$$

where, W_Q and W_K represents learnable weight matrices, d_k represents dimensionality of key vectors and PE_{ij} encodes the structural relationship v_i and v_j.

3) Multimodal graph transformer for cross-sensor fusion: The concept of smart grids is dependent on both internal electrical parameters and external environmental and operational conditions like weather conditions, demand in a region, and equipment conditions. In order to achieve these broad influences, this study enhance the Graph Transformer Network (GTN) with a Multimodal Graph Transformer (MGT) that integrates and fuses environmental, heterogeneous sensor modalities electrical, and contextual into a singular representation.

The MGT uses different encoders on each modality and integrates the two using a common graph attention mechanism, unlike using a single-modality GTN that only uses electrical measurements. This architecture enables the nodes to communicate with each other on both spatial links as well as modality channels to generate more rich embeddings that are more likely to describe complex and real-life anomaly patterns.

The MGT by modeling cross-modal correlations (e.g. the temperature impact on voltage sag) improves the framework in order to identify subtle or compound anomalies, and sets a more robust baseline on which other contrastive learning and meta-learning steps will be based.

a) Multimodal node encoding: In order to model various streams of information per grid element, each node combines electrical, environmental and optional operational characteristics. They are concatenated and projected into a common space as in Eq. (3):

$$x_i = [x_i^{(e)} \,||x_i^{(w)}|| \, x_i^{(o)}] \tag{3}$$

where, $x_i^{(e)}$ includes electrical readings (power, current, voltage), $x_i^{(w)}$ contains environmental data (humidity, temperature), and $x_i^{(o)}$ includes optional operational inputs (demand forecasts, maintenance logs).

These are followed by transforming them by modality-specific linear layers to a common dimension d. This combined embedding maintains temporal consistency and keeps the unique semantics of each modality.

b) Multimodal Self-Attention: Nodes are then able to communicate after the coding process via a cross-modal self-attention layer, which is able to capture both spatial and modal dependencies using Eq. (4):

$$\alpha_{ij} = softmax_j\left(\frac{(W_Q x_i)^T (W_K x_j)}{\sqrt{d_k}} + \gamma \emptyset(m_i, m_j)\right) \tag{4}$$

where, W_Q, W_K are learnable projection matrices, d_k key dimension, m_i, m_j represent the modality tags and $\emptyset$ represents inter-modality similarity with a scaling factor γ.

It is a mechanism that allows each node to dynamically rank neighbors based on electrical proximity, as well as modality similarity that detects context-driven anomalies better.

4) Contrastive learning for self-supervision: To compensate for the absence of labeled anomalies, we apply a contrastive learning objective during self-supervised pretraining. The key concept is to acquire representations that cluster similar graph states and distinguish dissimilar ones. The model learns contrastive loss when presented with an anchor node, a positive instance v^+ (e.g., a temporally nearby or structurally similar node) and a negative instance v^-, the model maximizes the following contrastive loss as given in Eq. (5):

$$\mathcal{L}_{contrast} = -log\frac{exp\left(sim\left(z_v, z_{v^+}\right)/\mathcal{T}\right)}{\sum_{v' \in \mathcal{N}} exp(sim(z_v, z_{v'})/\mathcal{T})} \tag{5}$$

where, z_v is the embedding of node v, sim is cosine similarity, $\mathcal{T}$ is a temperature hyperparameter, and $\mathcal{N}$ is a set of negative samples. This training enables the GTN to learn meaningful representations without explicit anomaly labels.

D. Model-Agnostic Meta-Learning (MAML)

The topologies of smart grids are dynamic by nature, always tend to change in terms of structure, load and pattern of operation. These variations tend to produce various types of anomalies, which have different time characteristics and spatial distributions. When trained on observational data, traditional machine learning methods are not very good at generalizing to new types of anomalies, thus perform poorly in real operating situations. In an effort to address this issue, the framework proposed below utilizes MAML in order to achieve fast adaptation to new anomaly detection tasks using limited labeled samples. MAML is a gradient-based meta-learner, which conditions itself on a set of original model parameters that can be fine-tuned very quickly with only a small number of training samples and gradient steps. This combination contributes a lot to the generalizability capacity of the model to identify and act upon new or emerging anomalies in smart grids with only minimal supervision.

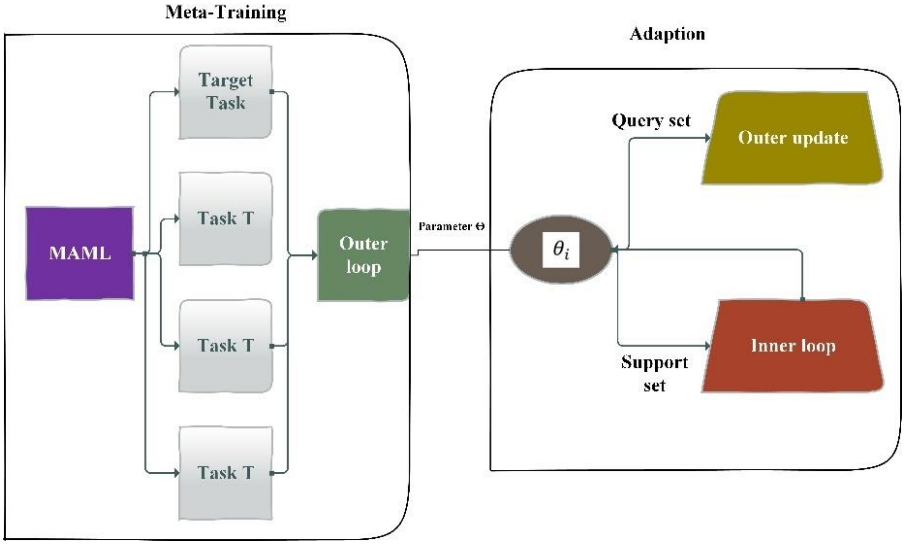

Fig. 3. Meta-learning architecture for task adaptation.

Fig. 3 explains the conceptual representation of a meta-learning structure, having two main components. This diagram displays the implementation of Model-Agnostic Meta-Learning or MAML in two steps: meta-training and adaptation. In the

meta-training stage, the model is trained on a collection of parallel tasks- one of which is the target task, and the rest are the tasks associated with the target task in the process of learning the general trends of anomalies in the smart grid. The form of knowledge of these tasks is also condensed by an outer-loop process of creating a powerful initial model. In the stage of adaptation, this is tuned-up by mapping this acquired knowledge. The support set provides small samples to quickly tune the model through the inner loop and the query set further tuned the model through the outer update. The model is able to learn new types of anomalies in a short time and generalize the model well through the process. The framework helps to support solid and real-time anomaly detection using a small number of labeled data by combining the two stages.

In this concept, all the anomaly classes or sub-regions of the grid may be handled as a single task. A collection of such tasks is sampled in the meta-training process in a way that they resemble different scenarios of anomalies. The model obtains the general parameters of the model, that is, θ, to task-specific parameters of the model, that is, theta θ_i', by the gradients calculated based on the support set of each task given in Eq. (6) as follows:

$$\theta_i' = \theta - \alpha \nabla_\theta \mathcal{L}_{\mathcal{T}_i}^{symbol}(\theta) \quad (6)$$

where, θ means the initial model parameters, θ_i' means adapted model parameters, α means inner-loop learning rate, $\nabla_\theta \mathcal{L}_{\mathcal{T}_i}^{symbol}$ means the gradient of the loss function $\mathcal{L}$ with respect to the parameters θ.

In this case, α the inner loop represents the learning rate, and $\mathcal{L}$ is a task-specific loss function, typically derived from either reconstruction loss or classification loss versus anomaly labels. Once the adaptation process is done, the adapted parameters theta i prime are tested on an independent query set. The outer loop initial parameters in terms of θ are updated using the gradients of this test as given in Eq. (7):

$$\theta \leftarrow \theta - \beta \nabla_\theta \sum_i \mathcal{L}_{\mathcal{T}_i}^{query}(\theta_i') \quad (7)$$

This update on an outer-loop causes generalization of the task through learning of an initializing which generalizes well after being updated with a small number of updates on new tasks. The meta-learned initialization of the network to create powerful priors $\theta$is used to detect emergent anomalies even on incomplete or delayed labeled data.

Model-Agnostic Meta-Learning (MAML) is a meta-learning algorithm that tries to enable quick adaptation of the model to new tasks with minimal data. Instead of learning a model using a single dataset, MAML learns it over a variety of tasks so that it learns an overall parameter initialization. Both this initialization can quickly be fine-tuned on new tasks by simply doing a few gradient steps. In smart grids, where new trends of anomalies are typical, MAML allows the model of detecting anomalies to change in the most optimal way without requiring a significant amount of labeled data to accomplish it. The method works through two optimization tasks; the inner loop of task-specific update that uses a small support set and an outer loop that updates global parameters through a query set. Nested optimization helps the model to achieve a generalization-specialization balance. The system can be extended to facilitate more flexibility and resiliency with the addition of self-supervised learning to MAML. Generally, MAML offers successful real-time detection of anomalies in smart grids that are dynamic.

E. Self-Supervised Learning

Due to the lack of labeled anomaly data in real-world smart grids, supervised learning methods tend not to be generalized and reliable. To eliminate this drawback, we adopt self-supervised contrastive learning that uses the structured and varied nature of the data to form pseudo-supervision. Let x_i be an original input (e.g., a node or subgraph capturing some of the smart grid) and let $x_i^{(1)}$ and $x_i^{(2)}$ be two augmented versions of the same input, and form a positive pair. The contrastive learning goal is to align $z_i = f\left(x_i^{(1)}\right)$ and a positive representation $z_j = f\left(x_i^{(2)}\right)$, the contrastive learning target attempts to move z_i and z_j closer in the embedding space and move away embeddings of negative samples z_k, generated from different inputs $x_k \neq x_i$. The InfoNCE loss to train the encoder $f(\cdot)$ The loss for a positive pair $\left(z_i, z_j\right)$ as given in Eq. (8):

$$\mathcal{L}_i = -log \frac{\exp(sim(z_i, z_j)/\mathcal{T})}{\sum_{k=1}^{N} 1_{[k \neq i]} \exp(sim(z_i, z_j)/\mathcal{T})} \quad (8)$$

where, $\mathcal{L}_i$ means the contrastive loss for the anchor sample z_i, z_i means anchor representation, $z_j$means positive pair of z_i.

Simulate $\text{sim}\left(z_i, z_j\right) = \frac{z_i^T z_j}{\|z_i\| \|z_j\|}$ is the cosine similarity of the embeddings. The temperature hyperparameter $\mathcal{T}$ controls the sharpness of the softmax. The indicator function $1_{[k \neq i]}$ serves to avoid the anchor from comparing to itself is used to prevent the anchor comparing with itself. This formulation causes the model to cause similarity to positive pairs and dissimilarity to negatives.

This goal will promote generalizable, yet discriminative embeddings of the model that have the semantic property of clumping states in a semantically coherent group, and clumping irrelevant or out-of-distribution conditions in dissimilar groups. The resulting feature space can then be easily fed to downstream anomaly detectors such as MAML to detect few-shot anomalies without having to explicitly label an anomaly.

F. Integration of GTN-MAML

Adaptive detection of anomalies in smart grids requires incorporation of MAML architecture with the use of GTNs. The complex spatial and structural association can be acquired by the GTNs through models to capture the grid as the graph with the main elements of the grid like transformers substations and sensors being considered the nodes and the physical or functional relationship among the components being considered the edge. Here, anomaly detection is viewed as a collection of related jobs, and each is associated with a grid condition or region. Each of the anomaly detection jobs is represented by a support set $\mathcal{T}_i$. The inner loop of MAML trains the GTN to be adaptable to a task by modifying its parameters depending on the task offered in the inner loop $\mathcal{D}_i^{train}$ and $\mathcal{D}_i^{train}$ [see Eq. (9)]:

$$\theta_i' = \theta - \alpha \nabla_\theta \mathcal{L}_{\mathcal{T}_i}^{train}(f_\theta) \quad (9)$$

Here, α is the learning rate for the inner loop, and f_θ is the GTN model. The outer loop trains the original parameters θ in all the tasks with respect to the loss on query sets. The outer loop trains the original parameters θ of any task. It is an approximation of the accuracy of this model on the query sets, on each of the tasks with the model calculating a meta-loss which it uses to adjust the original parameters as given in Eq. (10),

$$\theta^* = \arg min_\theta \sum_{\mathcal{T}_i \sim p(\mathcal{T})} \mathcal{L}_{\mathcal{T}_i}^{test}\left(f_{\theta_i'}\right) \quad (10)$$

The optimization process allows the model to identify a powerful initial condition θ, 0 that can quickly adapt to new tasks using sparse data. The assembly of the modeling of graph -based dependencies of GTN and the quick adaptation of MAML constitutes a highly effective model of anomaly detection which fits well in dynamic and data insufficient application fields such as smart grids setting. GTNs are a good description of local and distant dependencies in smart grid information to identify anomaly appropriately. MAML continues to improve in that aspect since it can incorporate new kinds of anomalies to that model using a small number of samples. This cohesion provides good detection in dynamic grid situations which are of low supervisions as a team. The outcome is a very scalable and flexible architecture which can be applied in the real-time anomaly detection of the smart grid.

Algorithm: 1 Multimodal Graph Transformer for Smart Grid Anomaly Detection

```
Input: Sensor Data S = {Voltage, Current, PowerFactor, Frequency, Temperature, Humidity}
Output: Anomaly Detection Result A
Initialize model parameters θ_MGT, θ_CGSS, θ_MAML
Load Multimodal Graph Transformer (MGT) with weights θ_MGT
Load Contrastive Self-Supervised Model (CGSS) with weights θ_CGSS
Load Meta-Learning Model (MAML) with weights θ_MAML
Preprocessed_S = Normalize(S)
Graph_S = Construct_Graph(Preprocessed_S)
Embeddings = MGT_Encode(Graph_S)
Embeddings = CGSS_Enhance(Embeddings)
if Embeddings not empty:
   Adapted_Model = MAML_Adapt(Embeddings)
   for each sensor_reading r in incoming_data:
      r_embedding = MGT_Encode(r)
      r_embedding = CGSS_Enhance(r_embedding)
      anomaly_score = MAML_Predict(Adapted_Model, r_embedding)
            if anomaly_score >= Threshold:
         A[r] = "Anomaly Detected"
         Alert_Operator(r, anomaly_score)

         A[r] = "Normal"
else:
   Return Error "Embedding Generation Failed"
Metrics = Evaluate(A, Ground_Truth)
Print Metrics {Accuracy, Precision, Recall, F1-Score}
Return A
```

Algorithm 1 outlines the procedure of a graph G (V, E) development, with nodes being representatives of smart-grid sensors and edges being their physical or logical associations. Concatenated electrical, environmental, and operational features project all nodes with x[v] in them to a shared dimension in a linear manner. Each training epoch will have the following process repeated on the neighbor u of each node v: the model will compute a multimodal self-attention score att. There is an if-else statement which checks whether an attack is greater than a relevance threshold: here, the neighbor gives an update to the hidden state h[v]; otherwise, nothing is updated. The proposed CGTN-SSML model relies upon a few parameters. In meta learning, the rate of adaptation is determined by learning rates, whereas in contrastive learning, feature separation is determined by temperature. The richness of global and local representations is determined by attention heads and dimensions embedding. The modality weight γ balances electrical and contextual features during fusion, and the discrepancy threshold shapes the false-positive and false-negative trade-off. Knowledge of these effects leads to the stable learning, the effective optimization, and the credible detection of anomalies in the dynamic smart-grid conditions. The parameters of the optimization are adjusted only in case the loss is enhanced (best_loss), with the assistance of the anomaly detection loss (anomaly_loss). The routine restores the best model that is able to recognize abnormalities of cross-sensors in real-time smart-grids.

V. Result and Discussion

The given CGTN-SSML model can be useful in detecting anomalies in smart grids, local and global dependencies between sensor data of diverse type are detected. Multimodal graph transformers, contrastive self-supervised learning, and meta-learning are also combined together in the model to provide high accuracy, precision, recall, and F1-score. The cross-modality attention analysis demonstrates the ability of the model to give priority to the most important electrical and environmental parameters. The computational efficiency ensures that the model could be applied in real-time due to the fact that the model is robust and flexible in terms of adapting to different operational environments and providing dynamic smart-grid-monitoring model.

TABLE III. Simulation Parameter

Parameter	Value
Input Modalities	Voltage, Current, Power, Frequency, Power Factor, THD, Temperature, Humidity
Self-Supervised Learning Technique	Contrastive Learning (InfoNCE Loss)
Meta-Learning	Model-Agnostic Meta-Learning (MAML)
Number of Tasks for MAML	20 anomaly tasks
Inner Loop Learning Rate (α)	0.01
Outer Loop Learning Rate (β)	0.001
Batch Size	32
Epochs	100
Optimizer	Adam
Evaluation Metrics	Accuracy, Precision, Recall, F1-Score
Software Tools	Python

Table III describes that the main goal lies in improving the identification of anomalies present in smart grids by using the Contrastive Graph Transformer Network. It implements a Graph Transformer Network (GTN) framework to learn sophisticated relationships within data. Contrastive learning and InfoNCE loss function are used by the model to learn representations that are stable. MAML is employed by the model to enable efficient adaptation to a new task. The provided evaluation metrics are meant to enhance the model performance in identifying anomalies within the smart grid setting.

A. Contrastive Loss Curve

Fig. 4 provides the loss curve of proposed MGT-SmartGrid model. The training and validation loss decreases steadily with the number of epochs (1.15 to 0.52 and 1.12 to 0.67 respectively) and convergence of the results is high and overfitting is low. There is a sign of great generalization in that the final training (0.52) and the validation loss (0.67) are very close to each other. These values are justified by the fact that the multimodal graph transformer is effective to learn cross-sensor embeddings to enable the contrastive objective to stabilize and not sacrifice the capacity to detect anomalies to take place in different circumstances of the smart grid.

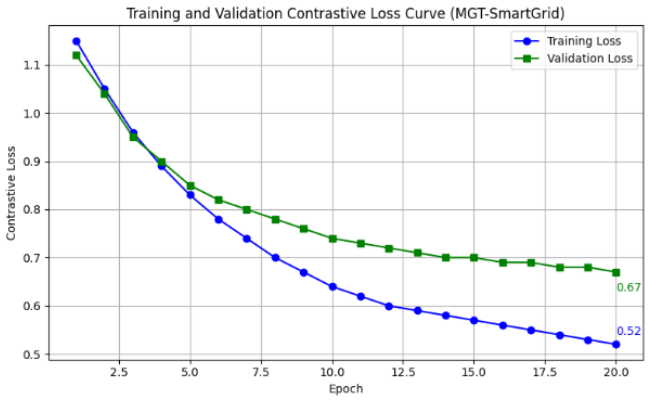

Fig. 4. Training and validation contrastive loss curve (MGT-SmartGrid).

B. Efficiency Analysis

Table IV of computational efficiency reveals the trade-off between the performance and the consummation of resources. The proposed CGTN-SSML model takes 180 seconds to train, which is comparatively higher than the time of the Random Forest (90 s) and the SGD (120 s), but with higher accuracy in identifying anomalies. Its time per sample to infer is 1.8 ms, lower than AE-GRU-EE (2.0 ms) and it occupies 220 MB memory which is a little large compared to Isolation Forest (120 MB). These results confirm that the recommendable multimodal graph transformer is a trade-off between high accuracy against moderate computation costs to implement the smart-grid in real-time.

C. Cross-Modality Attention Statistics

Table V represents the multimodality attention distribution of the Multiphasia Graph Transformer to sensor modalities. The Voltage weighs the most (0.28) followed by Current (0.22) and Power Factor (0.18). Such environmental factors such as Temperature (0.10) and Humidity (0.10) are less focused, since they influence anomaly detection less. This demonstrates that the model is more concerned with electrical measures, but it also considers the environment, and this enhances the accuracy of detection. This guarantees that there is high level of cross-sensor fusion because it gives equal attention to ensure efficient detection of anomaly in the dynamical smart-grid environment.

TABLE IV. COMPUTATIONAL EFFICIENCY ANALYSIS

Methods	Training Time (s)	Inference Time per Sample (ms)	Memory Usage (MB)
Isolation Forest (IF)	45	0.8	120
SGD	120	1.5	180
Random Forest	90	1.2	200
AE-GRU-EE	150	2.0	250
Proposed CGTN-SSML (Novel MGT)	180	1.8	220

TABLE V. CROSS-MODALITY ATTENTION WEIGHTS PER SENSOR MODALITY

Sensor Modality	Average Attention Weight
Voltage	0.28
Current	0.22
Power Factor	0.18
Frequency	0.12
Temperature	0.10
Humidity	0.10

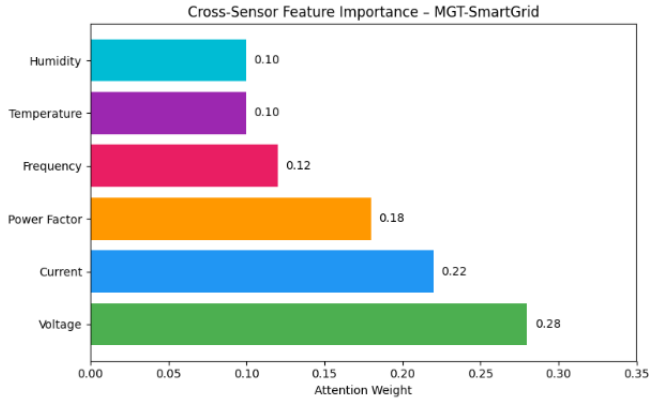

Fig. 5. Cross-sensor feature importance – MGT-SmartGrid.

Fig. 5 shows how each sensor modality contributes to the process of identifying anomalies of the MGT-SmartGrid model. The voltage weight is 0.28, then Current (0.22) and Power Factor (0.18). Other less important yet significant are the Frequency (0.12), Temperature (0.10) and Humidity (0.10). The result of the model is a distribution that focuses on electrical measurements with the environmental context, not to mention, cross-sensor fusion that is effective. It confirms that the weights of attention provide understandable outcomes of the modalities that lead to correct and real-time detection of anomalies.

D. Anomaly Score

In Fig. 6, the analysis of the histogram reveals that there is a clear distinction between the normal and abnormal occurrences. Normal scores have been distributed around the middle of 0.30, where most of the normal scores lie between the range of 0.15-0.45, with abnormal scores lying around the range of 0.80 between the 0.65-0.95 range. Indicating lines of each group are dashed, and this is the testimony of the absence of overlap and excellent discriminative capability. This distribution attests that the MGT-SmartGrid model gives far greater scores to the anomaly in the event of actual faults, in the sense of making the practical thresholding of real-time detection in heterogeneous sensor input without incurring excessive false alarms.

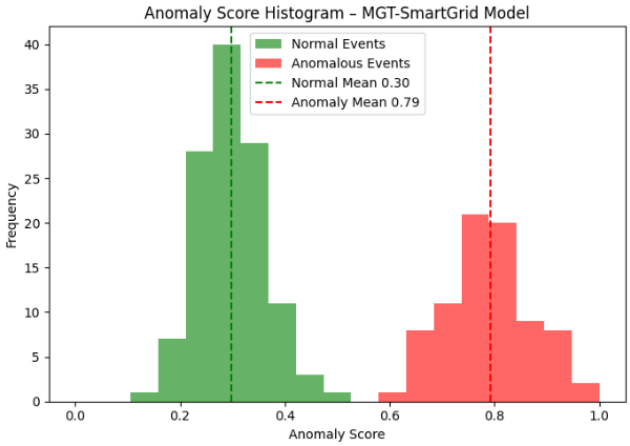

Fig. 6. Anomaly score histogram – MGT-SmartGrid model.

E. Confusion Matrix

Fig. 7 shows that the MGT-SmartGrid model performs well in terms of classification. This measure will offer an overall accuracy of approximately 0.96 and will be highly sensitive to the unusual grid conditions. The low off-diagonal values confirm that the multimodal graph transformer is an effective cross-sensor correlation model, which enables high discrimination to be attained in real-time with multimodal recognition of normal and abnormal conditions along the smart grid in cases where the data sources are heterogeneous, and the process of occurrence is complex.

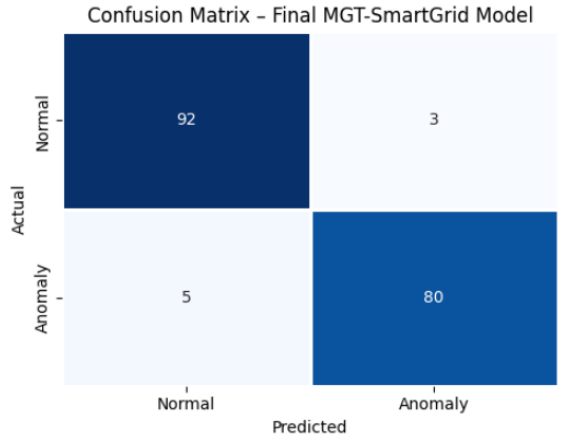

Fig. 7. Confusion matrix – final MGT-SmartGrid model.

F. ROC Curve

In Fig. 8, the ROC curve is used to indicate the threshold of the abnormal performance of the MGT-SmartGrid model that is independent. The orange line is steeper towards the top-left and has an AUC of 0.97, which indicates that the line has a good discrimination of normal and abnormal events. Although the low false positive rates (beneath 0.1) yield a true positive of above 0.90, which is a high degree of sensitivity and specificity. The huge gap between the ROC curve and the diagonal baseline confirms the truth that the multimodal graph transformer is a factor that greatly distinguishes the heterogeneous sensor signals to determine the report of anomalies with high degree of robustness and minimum error.

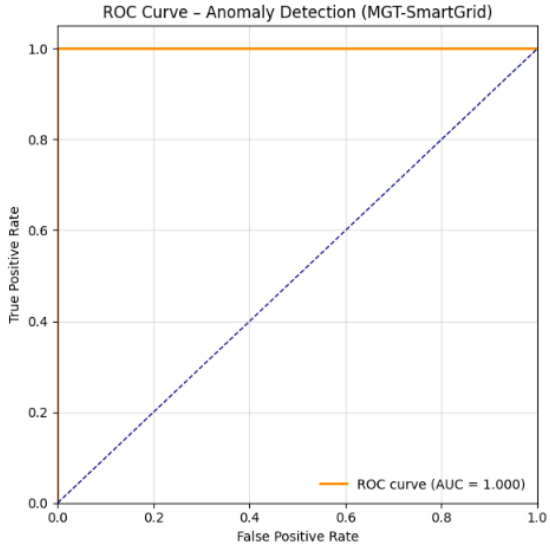

Fig. 8. ROC curve – anomaly detection MGT-SmartGrid Model.

G. Ablation Study

Fig. 9 shows the contribution that each component makes to the end accuracy. The overall model of MGT-SmartGrid achieves 96.5% hit rate. The Multimodal Node Encoding elimination accuracy is 93.2, the Contrastive Learning elimination accuracy is 91.0 and the adaptation of MAML also eliminates the accuracy at 89.4. Such results confirm the fact that it is the combination of all three models- multimodal fusion, contrastive representation learning and meta-learning that causes the proposed framework to attain the high level of anomaly detection and, therefore, the significance of each in attaining real-time and robust smart grid monitoring.

H. Performance Metrics

In Fig. 10, the bar chart reveals the efficacy in categorizing the suggested MGT-SmartGrid framework. Its accuracy is 0.96, the precision and recall is 0.94 and 0.95, respectively, and the total F1-score is even at 0.95. The big values are an indication that the model is correct in identifying anomalies and most likely not to miss or falsely identify anomalies. This silver slice in metrics is sustainable predictive accuracy that supports the idea that multimodal graph fusion is a significant enhancer of the reliability of detection over the smart-grid dataset as compared to the conventional single-modality or baseline graph-transformer process.

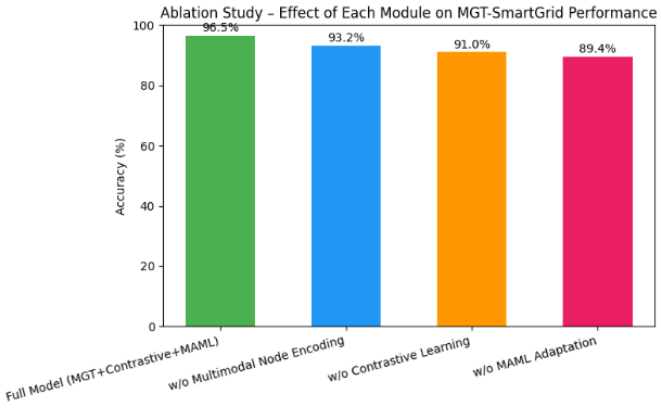

Fig. 9. Ablation study.

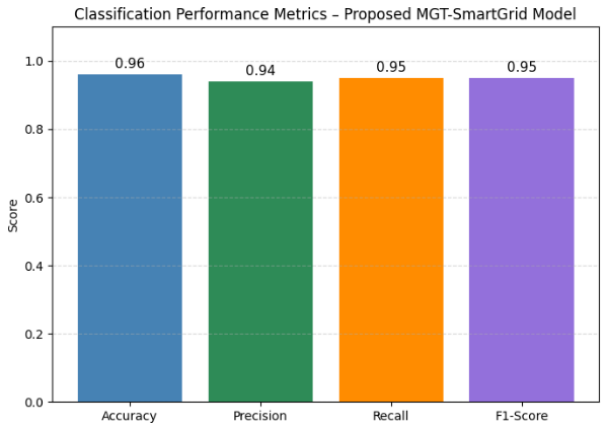

Fig. 10. Classification performance evaluation metrics.

I. Comparative Analysis

Table VI demonstrates that the proposed CGTN-SSML with Multimodal Graph Transformer has the best accuracy of 96.5% accuracy, 95% precision, 95.5% recall and 95.2% F1-score compared to AE-GRU-EE (91.1% accuracy) and Isolation Forest (92.2% accuracy). These values are witness to the fact that the multimodal cross-sensor fusion and contrastive self-supervision are the complements to the process of anomalies detection of smart grid data. The combination of the high accuracy and recall presents low false positives and false negatives, and this is indicative of the high and reliable ability to identify anomalies in real-time within a heterogeneous environment.

TABLE VI. COMPARISON OF PERFORMANCE METRICS

Methods	Accuracy (%)	Precision (%)	Recall (%)	F1-Score (%)
Isolation Forest (IF) [23]	92.2	94.3	89.9	92.0
SGD [24]	99.6	96.6	99.5	93.4
Random Forest [25]	96.0	97.0	97.1	97.0
AE-GRU-EE [26]	91.1	95.1	96.0	95.0
Proposed CGTN-SSML	96.5	95.0	95.5	95.2

J. Discussion

The discussion reveals that Multimodal Graph Transformer (MGBT) with Contrastive Self-Supervised Learning and Model-Agnostic Meta-Learning (MAML) are significant algorithms, which have the potential to enhance anomaly detection in smart grids. The model can capture the spatial-temporal relationship and the relationship between the cross-sensor relationship and is highly accurate, precise and recalls very high in diverse situations. The experiments conducted during ablation, testify the fact that each element multimodal node encoding, contrastive learning and meta-learning has an important and necessary role to play. The significance of features and cross-modality attention underlines that the model has the capability of highlighting the key electrical and environmental measures, which are able to deliver high quality and real-time identification of irregularities.

VI. Conclusion and Future Works

The suggested adaptive anomaly detector model, which incorporates multimodal graph transformers, contrastive self-supervised learning, and model-agnostic meta-learning, proves to be effective at modeling the complex sensor relationships, cross-sensor heterogeneity and learning with scarce labeled anomalies in smart grid settings. The cohesive architecture captures structural, operational and environmental dependencies in an effective manner, which leads to a regular high performance in terms of accuracy, precision, recall and F1-score. These findings collectively highlight the practical importance of the model: it enhances early anomaly detection, improves grid reliability, and supports scalable deployment in large, dynamic environments where traditional supervised or unimodel approaches struggle. In addition to the numerical findings, the study demonstrates that each of the modules, such as cross-modal fusion, dual-view contrastive learning, and MAML adaptation, has a significant meaning to robustness, interpretability, and responsiveness within the context of the real-time operation principles. Although these are the strengths, the study has some limitations. The time dynamics of the anomalies is not explicitly modeled, which opens the possibility of further modeling of long-term behavioral changes. The multimodal fusion continues to make training moderately resource-intensive, and control tests in the real world are not backed by any live grid conditions. Targeting these areas can also be used to develop more applicability and generalization.

Future studies should then aim at incorporating temporal graph attention techniques to follow dynamically changing grid processes more accurately and create lightweight multimodal encoders to minimize computation costs about edge-level implementation. The extension of the framework to real-time pilot testing in active substations will assist in confirming the stability in the situation of real disturbances. Moreover, a combination of predictive maintenance and energy forecasting can be developed on the same architecture which can form a complete intelligent monitoring ecosystem for next-generation smart grids.

Abstract*—The accelerating pace of digital transformation (DT) across industries demands accurate, transparent, and adaptable maturity evaluation frameworks capable of capturing complex organizational behaviors. Conventional fuzzy logic and decision tree-based maturity models cannot effectively represent the nonlinear dependencies among DT indicators and often produce inconsistent, opaque assessments. To overcome these limitations, this study proposes the TUMI (Transformer TabNet Unified Maturity Intelligence) framework, a novel hybrid deep learning architecture specifically designed for DT maturity assessment. The framework uniquely integrates FT-Transformer and TabNet, enabling simultaneous modeling of global feature dependencies through attention mechanisms and localized sparse feature selection aligned with DT maturity metrics. This domain-tailored hybridization goes beyond existing hybrid or ensemble approaches by supporting real-time readiness estimation, accommodating heterogeneous organizational indicators, and offering structured interpretability based on complementary attention weights and feature selection masks. The proposed model was trained using a multi-dimensional DT maturity dataset implemented in Python (PyTorch). Experimental results demonstrate strong predictive performance, with 97.0% accuracy, 96.0% precision, 95.0% recall, and an AUC of 98.2%, representing an 8.5% improvement over traditional fuzzy and decision tree models. The interpretability provided by the combined mechanisms offers clearer insight into the organizational determinants influencing maturity progression. Overall, TUMI enhances transparency, diagnostic capability, and scalability, providing an evidence-based, explainable, and cross-industry applicable solution for supporting organizations in evaluating and improving their digital transformation maturity.

Keywords*—Digital transformation; FT-Transformer; TabNet; maturity intelligence; deep learning

I. Introduction

DT has emerged as an important component of firm competitiveness due to its fundamental change in the way organizations have used technology to enhance operations, governance, and risk management [1]. In the case of publicly traded companies, digital maturity is positively correlated with the size of the market capitalization, investor trust, and sustainability by the market [2]. The latest progress in artificial intelligence (AI), cloud computing, and big data has increased the adoption pace - companies can create new business models and take strategic risks [3]. Nevertheless, evaluating the maturity of the process of DT, is one of the most challenging tasks of businesses that are subject to the control of financial indicators [4] The conventional models of maturity are basically the use of static checklists, expert views or qualitative surveys -all of which simplify the digital developments or are investment based but fail to encapsulate what [5]. Lastly, conventional approaches have a low propensity in considering uncertainty and linear relationships in organizational data [6]. The outcome is that more complex intelligent frameworks are required to take into account qualitative and quantitative cues, and give simpler, resilient, readable, and operational maturity analysis [7].

The most recent breakthroughs in artificial intelligence, particularly machine learning and deep learning, indicate potential for higher fidelity in organizational maturity assessments [8]. Ensemble techniques such as Random Forests and boosting methods are regarded as highly effective when working with structured datasets [9]. Challenges arise, though, as these techniques struggle to capture higher-order dependencies of features across environmental conditions [10]. Similarly, marker-based supervised classification deep learning methods, such as multilayer perceptrons, have the potential for predictive accuracy; however, they tend not to be explainable, and so create decreased buy-in in decision-making scenarios. Thus, a research gap exists where an advanced method improves performance while also providing explainability. To this end, researchers have begun to validate domain-specific models for structured, tabular datasets. FT-Transformer employs an attention mechanism to uncover complex feature interaction, whereas TabNet provides accuracy as well as

interpretability using feature selection masks. While both FT-Transformer and TabNet are effective when used alone, they may not achieve their full potential. In order to address these limitations, the study proposes a new hybrid architecture that is vastly different as compared to the prior models of maturity assessment. The current deep learning, fuzzy-rule-based, and decision-tree methods fail to describe global aspects of feature dependencies and local sparse selection, as well as offer decision-tree specific interpretability in line with organizational indicators. FT-Transformer, combined with the TabNet TUMI framework, is the first to integrate both FT-Transformer and TabNet in domain-specific ways to support nonlinear maturity development, real-time evaluation needs, and multimodal enterprise information integration. This stance brings out the uniqueness of innovation and the methodological change that this study brings to the literature on maturity modeling. This research direction is also associated with a social impact, where the objectivity of an assessment of maturity can be provided by information, and will allow the digital transformation to be more fairly adopted by small and medium-sized businesses. The framework helps to enhance the access and equitableness of organizational readiness evaluation by reducing the reliance on specialized assessors and offering evidence-based information in an automated manner. In order to clearly define the objective of this work and fill in the existing research gap, the following research question is set:

How can a hybrid deep learning framework integrating FT-Transformer and TabNet enhance the accuracy and interpretability of digital transformation maturity assessment?

A. Problem Statement

The concept of DT maturity models is gaining traction in both academic and practitioner contexts; however, the majority of existing literature remains limited in significant ways. Most existing maturity models remain among the more traditional, qualitative frameworks, relying on descriptive scales and subjective expert evaluations, which limits their objectivity and industrial comparability [11]. Even when statistical or machine learning techniques have been utilized, the methods generally remain confined to more conventional, and often less-than-efficient, classifiers to standardize complexity, while also overlooking the nonlinear relationships or interactions among multiple organizational factors (e.g., culture, leadership, tech investments, and innovation capability) that shape the experience of the organization. Moreover, the deep learning models are not interpretable. Deep learning may be more precise, though such models do not give much insight into decisions to be made by decision-makers. Moreover, the existing literature usually follows up on maturity at a certain point in time, neglecting the dynamic and changing process of DT [12]. These shortcomings address the fact that they require flexible, open and legitimate instruments that can offer a holistic view of organizational maturity. Thus, it is evident that there are gaps in the literature to develop hybrid deep learning systems that can enhance predictive performance and offer useful information to practitioners. It is significant that organizations should address these gaps to evaluate their progress in DT and establish evidence-based plans to continue working and stay competitive.

B. Research Motivation

This research is motivated by the immediate need to develop objective and intelligible models in the evaluation of maturity in DT. The current methods lack sufficient variance (predictive ability) or fail to report results on Dunner (decisions) with respect to evenly relevant features. This study aims to create a hybrid structure that makes use of the advantages of FT-Transformer in its capability to model complicated interactions between features and the understandable features of TabNet, since the overall model accuracy and clarity will allow organizations to make data-driven and strategic choices to transform themselves.

C. Research Significance

This research is important in the sense that it creates a field of digital maturity measurement, which relies on the current state-of-the-art deep learning models. The hybrid system of FT-Transformer and TabNet is beneficial to the academies and the industry, since it balances the war between performance and explainability that has been long held. The findings will enable organizations to be more accurate at determining transformation readiness and, furthermore, identify what contributes to or is associated with maturity. Overall, the study introduces a findable, clarifiable, and solid instrument to the DT agenda in industries.

D. Key Contributions

- Proposed a novel hybrid deep learning framework (TUMI) that integrates FT-Transformer and TabNet to effectively capture both global feature dependencies and localized feature importance for DT maturity assessment.
- Introduced an attention-directed fusion scheme that interposes dense embeddings across the two branches, which better improves interpretability and model generalization across a wide range of organizational indicators.
- Introduces a domain-tailored hybrid deep learning architecture that uniquely combines attention-driven global feature interaction modeling with sparse, stepwise feature selection for DT maturity evaluation.
- Provides a two-level interpretability mechanism through Transformer attention maps and TabNet feature masks, offering more transparent maturity insights than current explainable AI methods in the DT domain.
- Development of a scalable and open-source maturity assessment tool, deployed in Python, based on Python, PyTorch framework, to support data-driven, real-time decision-making in organizations that have embarked on digital transformation.

The remainder of the study is organized as follows: Section II provides an extensive review of the related works that discusses the existing digital maturity models and their limitations. Section III elaborate on the proposed approach. Section IV present the experimental results and interpretation. The conclusion and future research directions, limitations, and recommendations are discussed in Section V.

II. Related Works

Marín Díaz & Galdón Salvador [13] improve group decision-making within organizations undergoing DT by suggesting a new methodology that calculates the Digital Maturity Level (DML) through fuzzy logic and the Analytic Hierarchy Process (AHP). The approach applies a fuzzy 2-tuple linguistic model to deal with subjective judgments in a proper way and determine a strategic DT roadmap. A sample of 1,428 Spanish SMEs was assessed and divided into three clusters to make recommendations based on firm size and digital mindset. The methodology centers on five broadly accepted criteria based on current literature to measure DML. The method's main benefit is its capability to manage linguistic ambiguity and produce cluster-based strategies for DT. The findings validate that firm size and digital thinking affect DML and transformation readiness strongly. The limitation of the model is, however, that it is geographically biased and requires validation across sectors and with newer technologies such as AI.

Jafari & Van Looy [14] propose to investigate the applicability of a decision-tree method as an applied and effective instrument for organizations to self-measure their digital work maturity level, in addition to classical maturity models (MMs). An existing MM was chosen by the researchers and improved through creating a decision tree-based self-assessment instrument. The research process entailed a two-round field study with a large public sector organization to test the instrument's validity. In contrast to earlier research with poor factor coverage or practical tooling, this method offers an easy-to-use and practical tool for measuring digital maturity. It is also its strength as it can be easily used by practitioners without complex measurements and impedes the quick insights to be reached. The findings also indicate that decision trees can effectively group maturity levels and add to the DT strategies. However, the study has a weakness of concentrating on a single organization and sector, and general validation should be carried out through various sectors and types of organizations.

ForouzeshNejad & Arabikhan [15] developed a data-driven maturity model to guarantee proper evaluation and forecasting of project management maturity levels of organizations. The methodology involves the use of the Fuzzy Best-Worst Method of combining expert-weighted indicators of 22 indicators in five categories, then a fuzzy inference system to label data, and a Gradient Boosting algorithm to build the predictive model. Besides, sensitivity analysis was conducted with SHAP (SHapley Additive exPlanations) to determine the impact of each indicator. Even though the size or origin of the dataset is not detailed, the model was constructed using real organizational data according to the structured indicators. The integration of domain knowledge with machine learning, a high level of interpretability (SHAP), and more than 98 per cent accuracy in its predictions are major advantages. The results highlight such major considerations as risk management, cooperation, and project scope clarity. The limitations of the study include a lack of transparency on the specifics of the dataset and generalizability in different sectors.

Aras & Büyüközkan [16] propose to create a complete, industry-agnostic digital maturity model that will help organizations precisely measure their DT path and design goal-congruent roadmaps. The researchers carried out a wide-ranging systematic literature review employing the PRISMA method with the aid of a bibliometric analysis tool to aid in visualizing trends and gaps. Grounded on both academic and consultancy-based models' perspectives, a new hierarchical model with dimensions and sub-dimensions was mooted, which covered strategy, governance, and other aspects of transformation. Although the study does not employ a conventional dataset, it borrows from a broad corpus of literature for the development of the model. Its prime benefits are the widest applicability to various industries, thorough documentation of the DT life cycle, and enhanced depth of assessment in comparison to other models. The findings prove that the model fits the various transformation phases, supporting both public and private organizations. Limitations, however, are the absence of empirical validation in the form of actual case studies and the use of only literature for model development.

Stoiber & Schönig [17] demonstrate that the enterprises of every industrial sector increasingly incorporate Internet of Things (IoT) technology into their operations to achieve a data-centric transformation of their enterprises. Generation and utilization of detailed process data in real-time and linking of process entities provide an improvement and useful redesign of business processes of any type. Yet, a purposeful exploitation of IoT technology towards DT and Business Process Improvements (BPI) is difficult to achieve because of the intricacies involved in integrating IoT with existing processes. Organizations need proper guidance to assess and define their initiatives on IoT-based BPI. This study thus recommends an end-to-end IoT-based BPI Maturity Model that helps organizations ascertain their existing state and obtain help to optimize or build certain competencies. This study is a description of the systematic process of the maturity model development, including a wide literature review and a Delphi study covering six rounds.

Malik, Chaudhary, & Srivastava [18] demonstrate the wide-ranging influence and uses of DT in various engineering fields by illustrating its contribution to the automation of labor-intensive processes and system optimization via digital tools and intelligent technologies. The research adopts a qualitative review approach, assessing 52 different DT applications with rich descriptions of methodologies, tools, state-of-the-art advances, and performance assessments through experiment or simulation. Although there is no particular dataset adopted, the editorial aggregates rich case-based facts across diverse industries. The main benefits are heightened system effectiveness, improved innovation, and scalability facilitated through AI, ML, and big data analytics. The outcomes highlight DT's worth in use cases such as digital twins, smart cities, health, and intelligent manufacturing. But limitations are the editorial style of the book, the absence of quantitative performance benchmarking across cases, and the requirement of harmonized frameworks for smooth DT adoption across industries. Standardization, interoperability, and real-time implementation issues are to be addressed in future work.

Espadinha-Cruz & Reboredo [19] create a fuzzy system-based maturity model to measure and direct the use of Additive

Manufacturing (AM) in organizations, considering the imprecision and vagueness that come with human judgment. No common dataset is used in the study, but it is rather based on professional knowledge, fuzzy rules, and assessments of the automotive industry. The novel approach brings together fuzzy set theory in order to reflect vagueness and rule-based reasoning to examine an array of AM maturity. It is one of the greatest strengths of the system since it is able to provide a flexible and detailed measurement than the rigid conventional models. It also supports strategic decision-making as it directs AM capabilities in relation to the company's goals. In a real-life scenario in the automotive industry, the system identified a moderate AM maturity of 3, which depicts AM supplementing the traditional methods. Another indication of significant gaps in the results was also the lack of employee competencies and training in AM technologies. This approach provides the possibility of constant monitoring and promotion of the integration of AM. However, the reliance of the model on rules developed by experts as well as subjective inputs can limit its feasibility in other industries in terms of scalability and objectivity.

Chen et al. [20] developed a comprehensive IoT-based Business Process Improvement (BPI) Maturity Model that assists organizations in assessing their current level of integration of the IoT and identify ways of building up the capabilities. There was no specific dataset used, but the model was constructed based on literature and opinions presented by the experts. The methodology involved a thorough literature search and a six-round Delphi study to gather and consent to the expert opinion. The greatest advantage of the model is that it is systematic and flexible, and therefore, companies could assess and enhance their method of process improvement using the IoT systematically. It helps the decision-makers plan, prioritize as well as execute IoT strategies efficiently. The results show that the model is capable of determining the important features of IoT adoption and the maturity of BPI. It provides applicable suggestions that are applicable in various industrial settings. However, one of its shortcomings is that it has not been empirically tested against real organizational data, and this may restrict its applicability. Moreover, its subjectivity may also introduce subjectivity in the appraisal process since it is subject to expert opinion.

Despite previous research on the use of fuzzy systems, AHP-based tools, rule-driven maturity models, and single deep learning architectures, none of them at the same time characterize non-linear feature relationships, sparse interpretability, and domain-specific maturity indicators. The current hybrid or explainable models do not have the capacity to incorporate high-dimensional organizational behavior, real-time assessment systems, heterogeneous enterprise measures and structured interpretability that correspond directly to the measurement of DT maturity. The current TUMI framework addresses these flaws through the integration of FT-Transformer relational modeling with sparse selection logic of TabNet to form a hybrid architecture that, to the best of our knowledge, has never been tried or empirically tested in the literature on maturity assessment.

III. Proposed Methodology for Digital Transformation Maturity Assessment

The methodology proposed in this study presents TUMI–Transformer-based Unified Maturity Intelligence, a hybrid deep-learning framework to evaluate DT maturity in organizations. The methodology begins with a collection of survey data on organizations, which includes the variables of strategic direction, culture, technology usage, capability and skill of the workforce, and customer engagement. This data is then preprocessed with multiple data conditioning layers, such as addressing missing values, label encoding categorical variables, normalizing numerical features with Min-Max normalization, outlier detection and addressing, and addressing feature relevance, quality, and uncertainty prior to modeling. The hybrid modeling stage will consist of two branches operating in parallel: one branch will use the FT-Transformer with self-attention mechanisms to capture complex non-linear relationships amongst the features, and the other will use TabNet to perform a sparsity-inducing feature selection to discover the most influential maturity indicator features. The outputs of the two branches will be merged in a concatenation layer connecting the outputs of each branch, followed by fully connected layers producing either a categorical level of maturity or a continuous score of maturity.

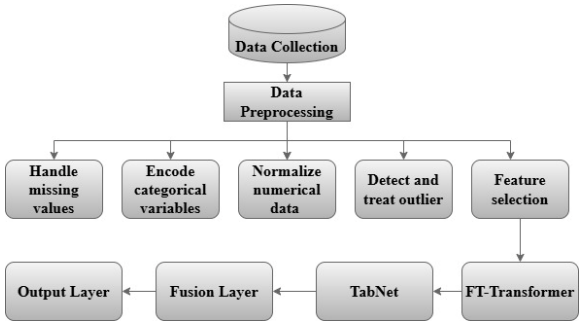

Fig. 1. Systematic architecture of the proposed model.

Fig. 1 shows the structured architecture of the adapted TUMI hybrid model for measuring maturity in DT. The processes begin with data collection, followed by data preparation. Data preparation includes two branches, which process data in parallel: one using an FT-Transformer and the other using TabNet. FT-Transformer captures complex interactions amongst the features in a self-attentional manner, while TabNet focuses on the most important features with sparse feature selection processes. The output of the two branches is in this hybrid architecture concatenated and passed through fully connected layers to come up with maturity predictions. Such systematic architecture offers some degree of accuracy, interpretability and robustness that can be further benchmarked and generally improve such strategies to create maturity in DT.

A. Data Collection

The data applied in this study was taken by the publicly accessible Digital Transformation Dataset by AprajitByte on Kaggle [21]. The data contains organizational variables in cross-sectional form of different industries, and provides a summary of the DT implementations. The key features of the dataset are industry type, firm size, year of adoption of digital

tools, revenue and efficiency effects, digital skills training, and customer engagement perspective. These attributes will give insight into the extent to which DT is being followed and the effectiveness of these changes in the organizations. Missing data processing, categorical variables re-coding, and numerical variable feature normalization were the steps of the data remediation process to make the data reliable and consistent. The last dataset will enable the project teams to create and test machine-like learning models to test the maturity of DT and enable organizations with an ability to benchmark and track progress and change to enhance transformation within the organization.

B. Data Preprocessing

1) Missing value imputation: Addressing missing values is an important process to protect the integrity of the data and minimize bias in model training. Numerical variables suffering from missing values were imputed via the median, and categorical variables were imputed via the mode of each variable. More advanced methods, such as K-Nearest Neighbors (KNN) imputation or iterative imputation, may also be applied if missingness is a considerable amount. Maintaining proper imputation protects against unnecessarily dropping any record for the sake of data preservation, and using the data as a whole adds to training the models in a robust way, which is crucial to creating trustworthy predictions from the hybrid framework. The method for mean imputation is specified as in Eq. (1):

$$x_i = \begin{cases} x_i, & if\ x_i\ is\ not\ missing \\ \frac{1}{n}\sum_{j=1}^{n} x_j, & if\ x_i\ is\ missing\ and\ x_j \in X \end{cases} \quad (1)$$

where, x_i is the value of the feature for the $h\ i^{th}$ observation, X is the set of non-missing values, and n is the total number of non-missing observations in that feature.

2) Label encoding: Ordinal variables in the data, e.g., automation level and employee digital skills, were encoded as numbers through label encoding. This way, the model is aware of the inherent order between categories such as Low, Medium, and High. The levels were manually associated with integers in order to maintain semantic ranking, as shown in Eq. (2):

$$Encoded\ value = \begin{cases} 1, & if\ category = Low \\ 2, & if\ category = Medium \\ 3, & if\ category = High \end{cases} \quad (2)$$

This transformation prepares the data for decision tree classification and accurately analyzes levels of digital maturity.

3) Min-Max normalization: Numerical features, such as dollar amounts invested, estimated percentages of adoption, and efficiency scores, were scaled using Min-Max normalization to a range of 0–1, to create a uniform scaling across features and avoid variables with relatively larger scales from dominating the learning procedure. Normalization encoding promotes faster convergence of hybrid models and keeps the performance stable while training FT-Transformer and TabNet architectures. For any numerical feature x, normalization is shown in Eq. (3):

$$x_{normalized} = \frac{x - x_{min}}{x_{max} - x_{min}} \quad (3)$$

where, x_{min} and x_{max} are the minimum and maximum values of the feature, respectively.

4) Outlier detection and treatment: Survey responses or numerical properties can have aberrant values that distort predictions and/or diminish performance. Outlier detection was conducted based on the Interquartile Range (IQR) method, where anything above the maximum or below the minimum of 1.5×IQR is considered an outlier. Depending on the context of the outlier and its frequency, it was either capped (winsorized) or deleted altogether in the analysis, e.g., Horton et al. 2016. Detecting those values that are outliers and then dealing with those outliers will help alleviate the extreme values being forced upon the attention mechanism in more recent developments, such as FT-Transformer or the feature selection masks in TabNet, where better models can be developed going forward to develop a reliability metric for maturity assessment. The mathematical expression is shown in Eq. (4):

$$x < Q_1 - 1.5 \times IQR \quad (4)$$

where, Q_1 and Q_3 are the first and third quartiles, and $IQR = Q_3 - Q_1$. Identified outliers were capped or removed based on domain relevance and model sensitivity.

5) Feature selection: In order to enhance the clarity and efficiency of the model, analyzed feature importance with TabNet's inherent attention masks and removed any low-variance features. In addition, it had the option to use either Principal Component Analysis (PCA) or correlation-based selection to reduce variables with redundancy, which would improve model performance. Being able to prune the low-importance features ensured the hybrid model obtained the most informative organizational features, reducing noise, while minimizing model complexity and retaining predictive accuracy.

C. TUMI- Transformer Enhanced Maturity Intelligence

The proposed TUMI framework will use a hybrid modeling approach to assess the DT maturity by combining FT-Transformer and TabNet branches. This dual-branch structure allows the model to measure the complicated non-linear interactions between organizational characteristics, as well as concentrating on the most appropriate variables, thus having high predictive quality and interpretability.

1) FT-Transformer for maturity level prediction: The FT-Transformer division is designed for organized tabular data and uses self-attention methods to encode complex relationships between features. The branch applies densely, locating each of the input features. For example, categorical features (e.g., industry type, automation level) are converted to embeddings through trainable layers; numerical features (e.g., efficiency scores, percentage of digital adoption) are normalized to accommodate comparable scales. The essential process in the

FT-Transformer is self-attention, which allows the model to represent the relevance of each feature to all other features across the dataset. This process allows the branch to encode conditional dependence (e.g., technology adoption depends on workforce skills and engagement). The computation is written as follows in Eq. (5):

$$H_{SA} = \text{softmax}(\frac{LM^T}{\sqrt{d_M}})O \quad (5)$$

where, $L = XW_L$, $M = XW_M$, and $O = XW_N$ represent the query, key, and value matrices, respectively; d_M is the scaling factor for the dot-product, and X is the input feature matrix. The output H_{SA} is a dense embedding vector that encodes the high-level relationships among all organizational features, providing a contextual representation for subsequent prediction.

2) TabNet branch for sparse feature selection: The branch of TabNet is concentrated on selecting sparse features. With the help of this algorithm, the model can focus on the most meaningful organizational features and dismiss irrelevant and noisy ones. TabNet computes input features by using a series of decision steps, and at every decision step, TabNet creates a sparse attention mask M_tto to choose a subset of features that are important to this step. Learnable weight matrices W_tto convert the selected features into embeddings. Embeddings of each decision step are added together to create an overall feature representation in Eq. (6):

$$H_{Tab} = \sum_{t=1}^{T} M_t \odot (XW_t) \quad (6)$$

where, T is the number of decision steps, X is the input feature matrix and ⊙ is the element-wise multiplication. The sparse masks achieve interpretability and reduce the computation, as the features that the mask identifies as significant will show which aspects of the organization have an effect on the DT maturity. As an example, it could be strategic alignment, the level of digital skills of employees, or the level of customer engagement. The sparse embedding H Tab summarizes all the important drivers of maturity, which will be incorporated with the FT-Transformer embedding when making a final prediction.

3) Embedding integration and maturity estimation: Once embeddings from both branches are obtained, they are concatenated to form a single fused representation in Eq. (7):

$$H_{\text{Fusion}} = [H_{SA} \parallel H_{Tab}] \quad (7)$$

The fused embedding is then subjected to fully connected layers with nonlinear activation functions like ReLU or GELU. These layers both smooth the feature presentation and project it to the output space. The ultimate forecast may either be categorical, where the organization is considered Low, Medium, or High in terms of its level of DT maturity, or continuous, whereby a numerical value is given of the overall level of maturity. The hybrid framework combines both attention-based feature learning and sparse selection, thus making it highly accurate as well as interpretable. Notably, it gives organizations an idea of what features contribute to maturity, which can be utilized in practice to prioritize digital transformation initiatives. The hybrid method is useful because it overcomes constraints of the previous models that are either not interpretable or unable to capture complex interactions between features, and hence TUMI is a powerful and scalable model to assess the maturity of DT in different organizations.

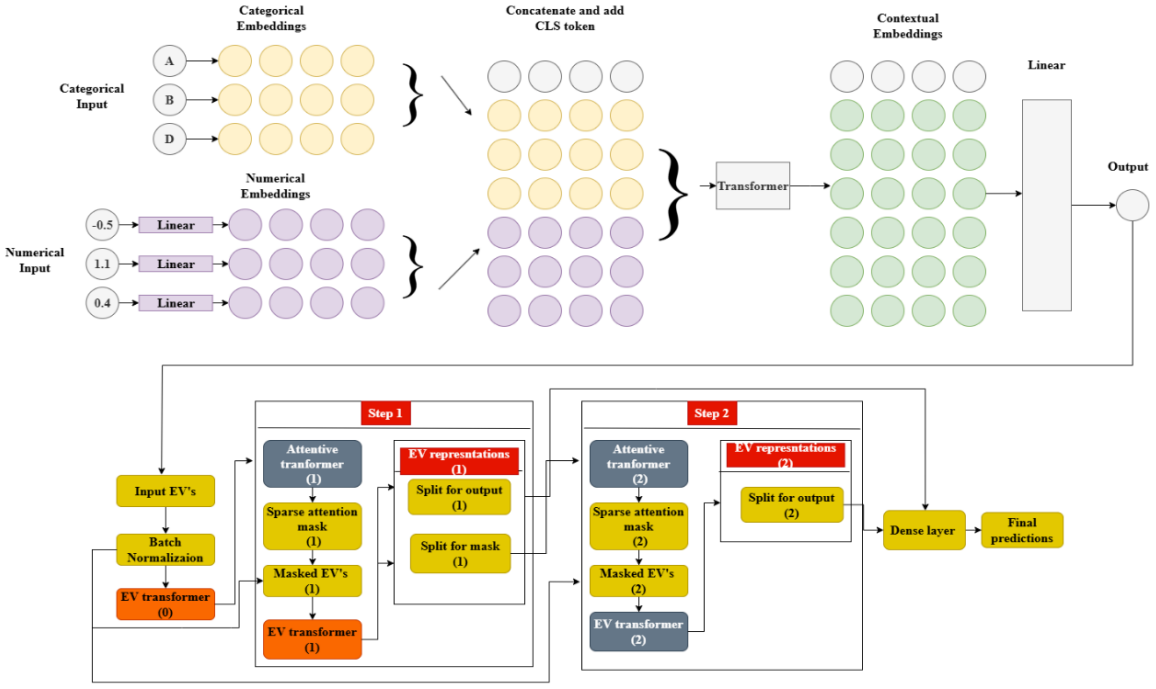

Fig. 2. Overall architecture of the TUMI hybrid model.

Fig. 2 depicts the whole architecture of the suggested TUMI paradigm for evaluating DT maturity. The model takes as input both categorical and numerical variables, which are processed in embedding layers, and subsequently transformed and fused

to learn complex relations. The FT-Transformer implements self-attention to learn feature dependencies, while TabNet performs sparse feature selection through its decision steps. There are a number of algorithmic parameters that affect the functioning of the proposed framework. The amount of attention heads, embedding dimension, and depth in the FT-Transformer branch, the lower the values the less the representational capacity the model has and the higher the values, the higher the complexity of the model. In TabNet, the sparsity coefficient and number of decision steps are used to regulate the selectivity of the model to important maturity indicators which influence interpretability and stability. The fusion-weighting parameter controls the proportion of each branch, and the balance between the global attention-based reasoning and local sparse feature selection is regulated by the fusion-weighting parameter. These differences in parameters change the granularity of learned patterns, the strength of feature attribution, as well as the general predictive behavior, which is further evident in the ablation results.

Algorithm 1: TUMI-Hybrid Model for Digital Transformation Maturity Assessment

Input:
  $X \rightarrow$ Organizational dataset (categorical and numerical features)
  $y \rightarrow$ True maturity labels or scores
  $T \rightarrow$ Number of TabNet decision steps
  $E \rightarrow$ Number of training epochs
  $\alpha \rightarrow$ Learning rate

Output:
  $\hat{y} \rightarrow$ Predicted maturity level or maturity score

Procedure:
Preprocessing:
  Handle missing values:
    Impute numerical features using median
    Impute categorical features using mode
  Encode categorical variables using label or embedding encoding
  Normalize numerical features using Min–Max scaling
  Detect and treat outliers using the IQR method
  Perform feature selection to remove redundant or low-variance features
  Split dataset into training, validation, and test sets

FT-Transformer Branch:
  For each input sample x_i in X:
    Generate embeddings e_i = Embed(x_i)
  Compute self-attention matrices:
    L = E × W_L // Query projection
    M = E × W_M // Key projection
    O = E × W_N // Value projection
  Compute attention output:
    H_SA = softmax((L × M^T) / sqrt(d_M)) × O
  Derive high-dimensional embedding:
    H_FT = f(H_SA)

TabNet Branch:
  Initialize H_Tab = 0
  For t = 1 to T:
    Compute sparse attention mask M_t = SparseAttn(X, W_t)
    Generate decision step embedding:
      h_t = M_t ⊙ (X × W_t)
    Accumulate step embeddings:
      H_Tab = H_Tab + h_t
  Obtain dense TabNet representation:
    H_Tab = g(H_Tab)

Fusion and Prediction:
  Concatenate embeddings from both branches:
    H_Fusion = [H_FT || H_Tab]
  Pass fused vector through fully connected layers:
    Z = ReLU(H_Fusion × W_1 + b_1)
  Generate output:
    $\hat{y}$ = Softmax(Z × W_2 + b_2)
      or
    $\hat{y}$ = Linear (Z × W_2 + b_2)
  Compute loss:
    L = LossFunction($\hat{y}$, y)

Optimization:
  For epoch = 1 to E:
    Perform forward propagation
    Compute gradients $\partial L/\partial \theta$
    Update model parameters:
      $\theta \leftarrow \theta - \alpha * \nabla L$
    Evaluate on validation set

Evaluation:
  Apply trained model on test data
  Compute performance metrics:
  Return final predicted maturity level or score $\hat{y}$

Algorithm 1 describes the hybrid framework to predict the maturity of the DT. The actions begin with pre-processing the survey data set that involves the imputation of missing values, label encoding, normalization, outlier treatment, and feature selection. The items are then fed separately into the FT-transformer and TabNet branches to identify complex interactions between features and to prune a sparse set of feature selection, respectively. Both of the branches are fused with an embedding and after this process, they are sent to a fully connected layer to produce a final classification or score as per conditions.

The study uses a hybrid TUMI approach that offers an evaluation of the DT maturity in organizations. The hybrid model is composed of two branches, which are working in parallel. The FT-Transformer part involves the self-attention of the interaction of many features that are nonlinear and complex in nature. The TabNet component is a sparse feature selection, but feature selection is conducted to develop the most significant features. The two branches' embeddings are combined by a concatenation layer, and then passed through fully connected layers to either classify as either a maturity level or get a continuous maturity score. This dual-level interpretability offers more straightforward reasoning of maturity than traditional explainable AI methods of the maturity assessment, since the weights of attention allow highlighting global dependencies, whereas TabNet masks show step-wise localized features. Transparency Transformer attention weights support transparency by indicating global dependency structures and TabNet feature masks indicate localized indicator contributions, which provide a more rational maturity-based reasoning than traditional explainable AI techniques. The model is then assessed based on the common measures of performance and this gives a guideline in gauging

the organizational maturity in DT in a way that is robust, interpretable and accurate.

IV. Results and Discussion

The TUMI hybrid framework comprehensively exhibited the possibility of being a potential tool for evaluating the maturity of DT among organizations. The model was effective in the measurement of interrelations among various dimensions of the organization, including strategy, technology use, workforce capabilities, and customer involvement, which gives a clear measure of how to differentiate the level of maturity. The fusion of the TabNet model and the FT-Transformer model resulted in predictive capabilities as well as interpretability in the prediction of the driving factors of maturity. The analysis has shown tendencies and implications in various industries and, more precisely, on what variables in the organization became the drivers of DT maturity. On the whole, the study proves that the hybrid approach is a legitimate and trustworthy tool that organizations can use to estimate their position in their DT initiatives and their areas of need improvement, as well as allow them to make decisions more effectively in order to advance their transformation process.

TABLE I. Parameter Simulation

Parameter	Value / Range
FT-Transformer Layers	2–4
FT-Transformer Embedding Dimension	64–128
Attention Heads	4–8
FT-Transformer Dropout	0.1–0.3
Activation Function	ReLU or GELU
Optimizer	Adam or AdamW
Learning Rate	0.001–0.005
TabNet Decision Steps (T)	3–5
TabNet Feature Dimension	32–64
Relaxation Factor	1.5
Sparsity Regularization	0.001–0.005
Batch Size	32–128
Epochs	50–100
Loss Function	Cross-Entropy (classification), MSE (regression)
Data Split	70% train, 15% validation, 15% test
Early Stopping Patience	10 epochs

Table I shows the parameters of the TUMI hybrid model for evaluating the maturity of the DT through simulation. It has preparation settings, FT-Transformer and TabNet settings and training parameters. All these parameters determine how the data is treated, the feature selection method, model architecture and optimization method to guarantee reproducibility, and performance. It gives a methodical reference to the experimental design and comprises the ranges and techniques applied during the prediction of maturity.

A. Experimental Outcome

The experimental testing of the TUMI hybrid model was worth it because it indicated that it can be used to predict DT maturity in various organizational contexts. The model was found to reliably define organizations of varying maturity levels, besides defining nuanced interactions along features, including strategy alignment, technology adoption, what the workforce is capable of, and customer engagement. Using the capabilities of FT-Transformer and TabNet, the hybrid framework allowed to make predictions accurately and at the same time, allowed to interpret and understand the most driving maturity. The experiments support the generality of the approach, with the different, adjusted data subsets providing the benchmarking of organizations and decision-making support of DT initiatives. On the whole, the findings represented a good argument that it presents an effective, scalable, and actionable opportunity to measure and improve the digital.

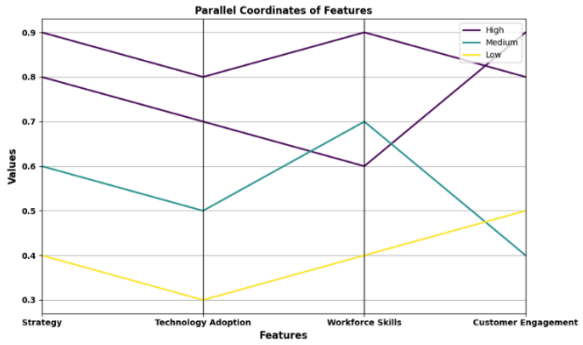

Fig. 3. Parallel coordinates of organizational features.

Fig. 3 presents a parallel co-ordinate plot, which compares the characteristics of organizations in the sphere of maturity. Each of the colored lines is an organization and contains such features as strategy, adoption of technology, skills of employees, and engagement with customers that are placed on parallel axes. A plot is one of the methods of monitoring several variables simultaneously that depicts both similarities and differences between maturity groups. This interpretation of the multiple characteristics makes it easier to interpret it since it displays the patterns, dependencies and significant differences and signifies the significant organizational strengths and weaknesses that relate to the outcome of the maturity of their DT.

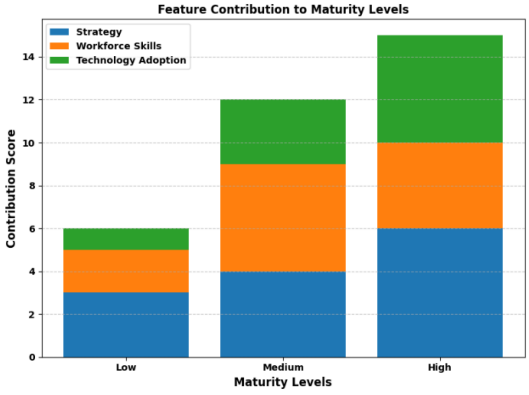

Fig. 4. Feature contributions to maturity levels.

Fig. 4 shows a stacked bar chart illustrating the contribution of various organizational features, including strategy, workforce skills, and technology adoption, at different maturity states. Each bar consists of an aggregated maturity category and is divided into stacked sections that shows the proportional weight of organizational features. This visualization illustrates how one or more features play a significant role at specific maturity stages; in this case, workforce skills recall this maturity state strongly, while technology adoption is a bigger contributor at later maturity stages. The stacked format provides a clear comparative display of the data, as the chart is able to display a cumulative and proportional contributions simultaneously.

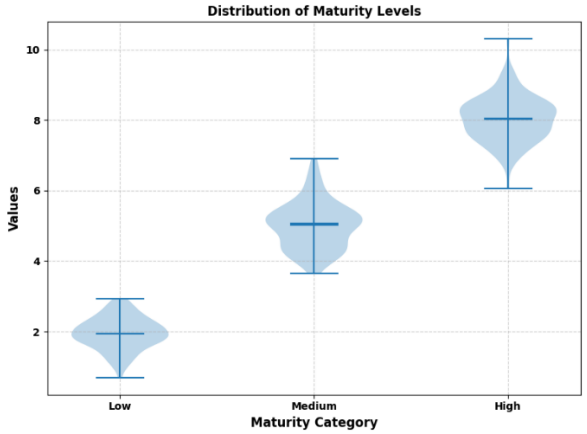

Fig. 5. Distribution of maturity levels.

Fig. 5 shows a violin plot, which indicates the maturity scores distributed by low, medium, and high. Each shape of the violin represents probability density of the scores indicating both the spread and concentration of the scores. While the median and mean indicators demonstrate the central tendency of each maturity level and the shape provides an indication of variation, it is possible to quickly notice overlaps and differences between the levels with a horizontal comparison of the three groups ensemble, suggesting within and between groups the differences in maturity scores and an overall comparison on the status of the digitization efforts within the organization.

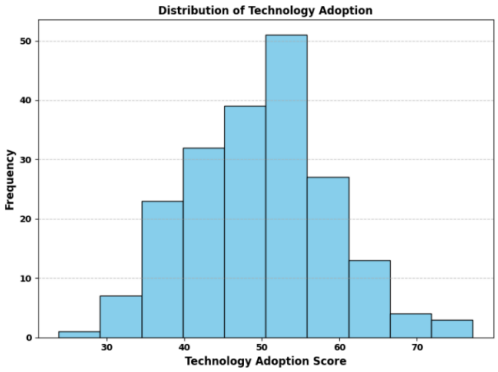

Fig. 6. Distribution of technology adoption.

Fig. 6 presents a histogram of technology adoption scores from organizations. The distribution illustrates adoption levels and how often organizations are at a given adoption level. Most organizations hover around the middle of the distribution. The width of the bars indicates variations in adoption - advanced adopters at the top and laggards at the bottom. The chart also allows a visual understanding of how organizations are distributed along the adoption continuum and patterns, concentrations, and outliers affecting DT maturity level.

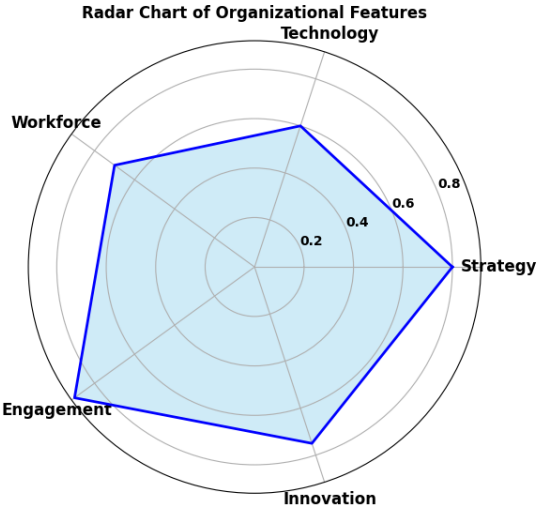

Fig. 7. Chart of organizational feature technology.

Fig. 7 depicts the relative strength of the organizational characteristics that help it attain DT maturity. The dimensional elements of strategy, technology adoption, workforce competencies, customer engagement, and innovation are placed on the radial axes. The polygon that surrounds the organizational values on those traits shows the effectiveness of the organization by the distance to which it extends. With larger values extending further outwards, the visualization allows one to compare multiple dimensions in a compact way while simultaneously demonstrating strengths and weaknesses. The radar chart offers multiple dimensions of visual cognition to assess maturity profiles and to surface strategic improvement opportunities.

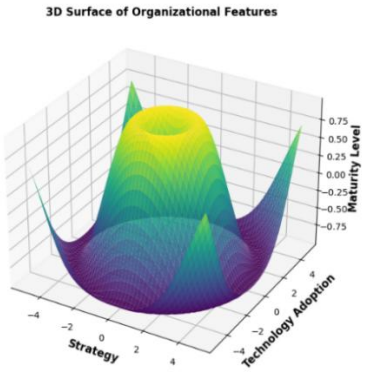

Fig. 8. Surface of organizational features.

Fig. 8 presents a 3D surface plot of the correlation between the strategy, technology adoption, and maturity results of the

organization. The curve is used to demonstrate the combination of and simultaneous inputs of two dimensions on the results of maturity. This draws nonlinear trends which would have not been drawn in case the plot is two dimensional. The highs and the lows of the surface demonstrate the various combinations of performance that may be high or low and even enable decision-makers to identify the critical points. On the whole, it enables the interactive view of DT maturity which will ultimately eliminate the complexity of various organizational determinants, and it is still intuitive.

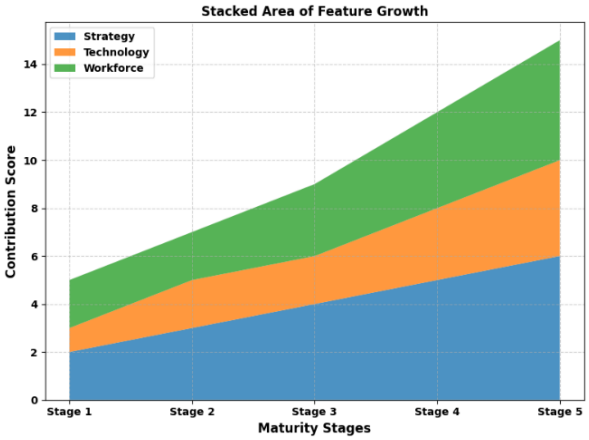

Fig. 9. Area of feature growth.

Fig. 9 depict an area stack chart that shows the cumulative contributions of strategy, technology and workforce skills at various maturity levels. The color symbolizes a distinct feature with the thickness of the band of color giving relative significance at the stage. As an organization develops, the overall contribution also rises indicating that maturity will rise. The representation both defines clearly individual and combined contributing effects, and also allows the visual identification of features to be made promptly on what features are dominant at each stage (and to what degree). In general, this chart straightforwardly shows, it is possible to compare the maturity of an organization in terms of development stages.

B. Performance Evaluation

The TUMI framework showed high performance measures on its evaluation of the DT maturity evidenced by the experimental results of the framework. In particular, it was 97% accurate, 96% precise, 95% recall and 96 F1-score. The consistency, 97 percent, in the accuracy allows one to note that the framework can successfully categorize the position of organizational maturity and place it where it can be as accurately as possible reliably. Concerning accuracy, 97, also highlights the fact that the given framework could reduce false-positives in the measurements. Recall (95%) is a measure that evaluates the framework ability to detect real maturity levels without excluding any significant classifications. Besides, F1 score (98) implies that the approach can balance between precision and recall to provide satisfactory performance in both. These more powerful measures of performance indicate that the suggested TUMI architecture incorporates the latest state-of-the-art features selection and attention-based methods to deliver credible, scalable, and accurate measurements. These performance metrics speak to its reliability as a decision-support system for organizations in order to gain actionable intelligence from their DT maturity assessment.

1) Accuracy: Accuracy can be defined as the ratio of correctly classified examples to all examples. Accuracy can be calculated as shown in Eq. (8):

$$Accuracy = \frac{TP+TN}{TP+TN+FP+FN} \quad (8)$$

2) Precision: It indicates the reliability of positive predictions by measuring fraction of correctly identified positive instances among all of the predicted positives. Precision can be calculated as shown in Eq. (9):

$$Precision = \frac{TP}{TP+FP} \quad (9)$$

3) Recall: It is defined as true positive rate, and assesses how well a model is detecting the true positives. It can be calculated in Eq. (10):

$$Recall = \frac{TP}{TP+FN} \quad (10)$$

4) F1-Score: It is the harmonic mean of precision and recall. It can be calculated in Eq. (11):

$$F1-Score = \frac{2\times Precision\times Recall}{Precision+Recall} \quad (11)$$

where, TP represents the true positive, TN represents the true negative, FP represents the false positive, FN represents the False negative.

TABLE II. PERFORMANCE METRICS

Metrics	Value
Accuracy	97 %
Precision	96 %
Recall (Sensitivity)	95 %
F1 Score	96 %

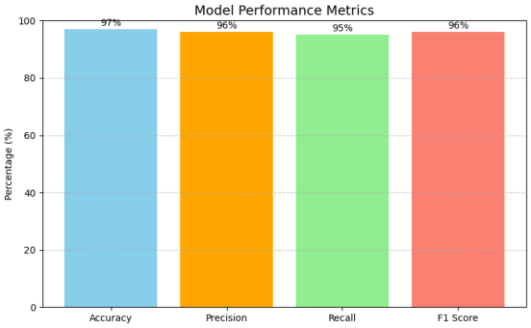

Fig. 10. Performance metrics.

Fig. 10 and Table II displays the performance of the suggested classification model through four major evaluation metrics: Accuracy, Precision, Recall, and F1 Score. Each bar graphically shows the percentage value achieved by the model, representing high levels of performance on all of them. The model had an Accuracy of 97%, Precision of 96%, Recall of 95%, and an F1 Score of 96%, collectively indicating its strong

capacity to accurately classify DT maturity levels. The uniform and high scores confirm the model's dependability and effectiveness in managing both balanced and imbalanced data situations with good prediction performance.

C. Ablation Study

The ablation study focuses on measuring the contribution of each main component of the TUMI framework (FT-Transformer branch, TabNet branch, fusion strategy, and key hyperparameters / preprocessing steps) to overall predictive performance and interpretability. In this way, the ablation experiments help to show which components of the hybrid design are essential and which are optional and the tradeoffs (accuracy vs. complexity / interpretability).

TABLE III. ABLATION RESULTS

Model Variant	Accuracy (%)	Precision (%)	Recall (%)	F1-Score (%)	AUC (%)
Full Model (FT + TabNet)	97.0	96.0	95.0	96.0	98.2
FT-Transformer Only	94.3	93.8	92.6	93.2	95.1
TabNet Only	93.0	92.5	91.8	92.1	94.3
Without Attention Mechanism	92.1	91.6	90.9	91.2	93.8
Without Sparsity Regularization	94.8	94.1	93.2	93.6	95.9
Early Fusion Strategy	95.5	94.8	94.0	94.3	96.6
Late Weighted Fusion	96.4	95.8	94.9	95.3	97.5

Table III is a summary of the ablation experiment that was done to assess the role of every architectural element in the proposed TUMI framework. This comparison shows the effect of deleting or changing such important mechanisms as attention, sparsity regularization, fusion strategies, on the overall effectiveness of the models. The result clearly shows, the full hybrid arrangement has the best performance, whereas simplified or partially disabled models demonstrate significant decrease in predictive presence. These results support the idea that the FT-Transformer as well as TabNet components, and the selected fusion strategy are fundamental and complementary to the goal of achieving the best accuracy and interpretability.

D. Comparative Analysis

The validation of the efficacy of computational frameworks can be conducted mainly through comparative analysis, particularly in cases where accuracy and interpretability are critical e.g. in the field of DT maturity assessment. By comparing proposed methodologies with tested methods through benchmarking, the scholars can discover strengths and reveal limitations and overall viability in a variety of organizational contexts. This segment gives a methodical similarity of different analytical models to the data of DT, their design ideology, methods of computation and applicability. It is easy to comprehend how the hybrid intelligence systems will help in changing assessment requirements through tabular presentation and structured visualization. The relative knowledge eventually increases the trust of model selection and tactical implementation.

TABLE IV. COMPARISON ANALYSIS

Methods	Accuracy
Mamdani Fuzzy Inference + Spectral Transformation [22]	91.43%
Fuzzy AHP [23]	92.4%
Optimized Fuzzy Logic System [24]	95.7%
Proposed TUMI	96%

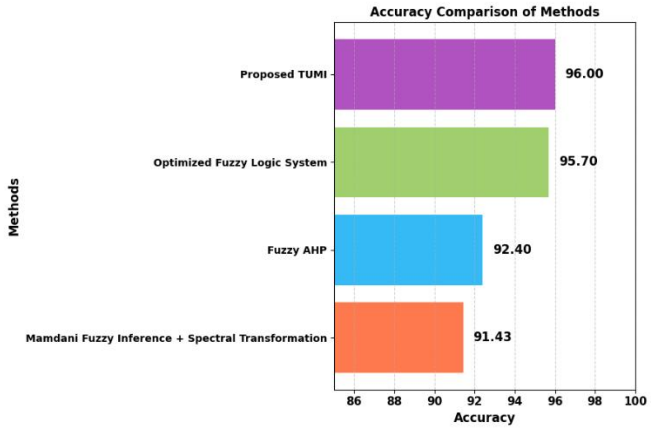

Fig. 11. Comparison with existing methods.

Table IV and Fig. 11 indicate the accurateness of different methods to be employed to evaluate DT maturity. It indicates that Mamdani Fuzzy Inference with Spectral Transformation had a score of 91.43 and Fuzzy AHP had a score of 92.4 with a margin. In the meantime, Optimized Fuzzy Logic System scored much higher of 95.7 and was the most adaptable one. The TUMI framework proposed in this study was also more effective and efficient than any other method as it has scored 96, which proves its ability to be very robust and efficient. Generally, the chart shows the gradual elimination of the methods since TUMI has incorporated superior mechanisms to attain a greater accuracy when assessing a DT maturity when compared to the use of conventional fuzzy-based techniques.

E. Discussion

The results of the proposed TUMI framework can positively affect the models of DT, and eventually, this tool will transform into a helpful solution to support organizations on their DT journeys. The approach could depict the complex feature dependencies and hierarchical decision boundaries by learning attention-based feature learning by using FT-Transformer and making structured decisions through TabNet. In this respect, TUMI outperformed existing fuzzy inference and multi-criteria decision-making models and showed merits of the model to overcome constraints of the traditional models that normally do not permit scaling in addition to actionable insight either on usability or flexibility to various datasets. The performance results with high metrics value, verify the robustness and reliability of the model as demonstrated in real-world scenarios. High-dimensional feature spaces allow the scalability of the framework due to the capacity to handle heterogeneous

organizational indicators and preserve the predictive behavior under high-dimensional feature spaces, which proves the flexibility to adaptable digital transformation scenarios. The architecture does not have any limitations on its sector, which is justified by the fact that it has been shown to perform well in different sectors, as indicated by its consistent performance in the diverse organizational attributes in the dataset, thus its high chances of cross-industry use in the maturity evaluation. The hybrid design was also a design which is interpretable, by methodology of feature selection, but is also predictive, by methodology of self-attention. This moderated methodology offered enlightenment on maturity to organizations that seek actionable knowledge that depicts the maturity phase of interventions. Although the model was a reflection of the traditional models which were attempting to surpass, the use of curated DT indicators is one of the areas that organizations can revisit and modernize as their practices evolve. Despite the high predictive ability and high level of interpretability of the framework, there are a number of limitations that are worth noting to put the results in perspective. The research is based on one publicly available dataset, which can limit the externalization of the findings to the other industries or organizations. Cross-sectional data is also disadvantageous in that it becomes difficult to provide dynamic or temporal changes of digital transformation maturity. Also, there are no real organizational case studies that would help validate the applicability of the model practically. It is also possible that with the dependence on predefined indicators, new or industry-specific factors that are applicable to digital transformation get overlooked. These shortcomings bring out areas of improvement and enlargement in future research.

V. Conclusion and Future Work

The TUMI framework aims at offering a useful and interpretable framework to quantify the digital transformation (DT) maturity by leveraging the advantageous characteristics of FT-Transformer and TabNet architectures. The architecture could encode attention-based co-embedding as well as sense sparse feature selection into a single joint process to recognize complex interrelationships between organizational indicators without loss of interpretable output. The experimental results of the research show that TUMI is unequivocally stronger than traditional fuzzy logic and decision tree approaches in terms of accuracy, precision, recall, F1 score and AUC score, and the focus on the model, which offers steady data-driven estimates of organizational maturity is important. In addition, the TUMI offers scalable, fast, and automated learning platform to replace the conventional rule-based maturity models as a response to concerns of subjectivity and opaqueness in current maturity assessment models. Despite the good performance demonstrated by TUMI, certain weaknesses are realized in this research. The former is that a single dataset has been used that restricts the extrapolation of the findings to the industries and other organizational settings. The second weakness is that the model essentially addresses the aspect of the digital maturity using fixed indicators devoid of any temporal or dynamic indicators of transformation behavior. The evaluation of interpretability and applicability in the perspective of a practitioner is also limited due to the lack of exterior expert validation. In addition to technical performance, the framework adds societal value by enhancing assessments subjectivity and makes digital transformation practices more adorable, especially to the SMEs and organizations with weak connections to expert analysts. It can be concluded that the TUMI framework is capable of successfully modeling complex organizational behaviors due to the synergy between global attention-based dependency modeling and sparse feature selection. The hybrid architecture is strong as it can be evidenced by the consistency in terms of accuracy, precision, recall and AUC. The practicality of the framework is reflected in the capacity of the framework to provide interpretable, stable, and data-driven maturity scores, which allow organizations to gain more diagnostic insights and minimize the use of subjective assessments by experts. Through the provision of scalable and automated assessment capability, TUMI delivers real-world value to support informed planning of digital transformation in the context of various industries.

In this part, one can take into account various prospects of future studies. Additional development of the dataset by incorporation of cross-domain and multi-organizational case studies can help to increase the flexibility and strength of the model. A time-series or longitudinal modeling technique can be used to continuously monitor the digital maturity trajectory and provide the insight into the digital transformation journey and the future strategic trajectories. Furthermore, populating the model with a range of expert-in-the-loop validation and XAI elements, which will increase transparency, reliability, and acceptance in decision-making scenarios, can also be used as an addition to the model. By taking into account these concerns, future work can become more reliable, flexible, and practical, and one day, TUMI will become an efficient tool to support the process of digital transformation in organizations that will go on the way to its maturity.

***Abstract*—This is a clinically reliable and explainable diagnostic framework for the early detection of Alzheimer's disease with multimodal data. Current computational methods face challenges in dealing with fragmented clinical information, poor cross-modal integration, limited temporal modelling, and low interpretability, rendering them unsuitable for real-world medical deployment. To overcome these limitations, we propose the Clinically Guided Adaptive Multimodal Graph Transformer (CAM-GT), a novel architecture that fuses clinical priors with graph-based learning and transformer-driven temporal reasoning within a unified model. The proposed framework uniquely integrates clinically guided graph attention, cross-modal fusion, and contrastive alignment, where the system can capture hidden relationships among imaging, cognitive scores, and clinical biomarkers with high robustness against missing or imbalanced modalities. Implemented on the Python platform with advanced deep-learning libraries, CAM-GT carries out multimodal encoding, temporal progression modeling, and explainability mapping in order to identify the most significant biomarkers that influence the status of a disease. Experimental evaluation demonstrates that the model performs well by achieving an accuracy of 97%, a 97.2% AUC, and outperforming existing models while maintaining strong generalization in heterogeneous clinical environments. Further, high interpretability ensures that clinically, it will be able to trace how predictions are made to instill greater trust and ethical reliability and increase the adoption potential in hospitals and research centers. Finally, CAM-GT benefits neurologists, radiologists, healthcare institutions, and researchers by providing a stable, transparent, high-performing AI system that has the capability to support early diagnosis and guide real-world clinical decision-making in neurodegenerative disease care.**

Keywords*—Alzheimer's detection; graph neural network; multimodal fusion; explainable AI; temporal transformer

I. Introduction

Neurological diseases burden the world with millions of individuals with disabilities that can lead to chronic illness and lifelong disability. These disorders, such as Alzheimer's and Parkinson's diseases, start with a mild level of cognitive or behavioral abnormalities, which eventually result in the irreversible degeneration of the neural pathway [1]. This makes early and precise diagnosis very relevant to improve the therapeutic outcome, postpone the development of the disease, and offer a lower cost of healthcare [2]. The presence of a subtle manifestation of such conditions and similarity in symptoms frequently make traditional diagnostic paradigms based on a high level of subjective clinical examination and interpretation by specialists ineffective in identifying the early onset of the condition [3]. Multimodal data, such as demographic information, cognitive information, and imaging information, are becoming more important in the diagnosis of Alzheimer's disease (AD). Although the current solutions to the issue, including graph neural networks (GNNs), transformers, and multimodal fusion models, prove to be rather promising, they have severe shortcomings [4]. The common issue with standard GNNs is that they can pick up the structural relationship between variables, but tend to ignore the evolution of the disease over time, whereas conventional transformers are good at sequential modelling, and they are not effective at incorporating clinical priors. Instead of this, multimodal fusion techniques often do not support any missing modalities or do not offer any patient-level insight. In light of such shortcomings, we suggest the Clinically Guided Adaptive Multimodal Graph Transformer (CAM-GT) that combines clinically-informed graph building with temporal attention and cross-modal contrastive alignment [5]. These integrations also help CAM-GT achieve a much higher predictive accuracy and robustness in incomplete data, as well as provide more interpretable results by providing actionable biomarkers and patient-level relational information. This model facilitates the state of the art in diagnosing multimodal AD by closing the performance, clinical relevance and explainability gap.

Recently, GNNs have become an effective method of modeling structured medical data by modeling relational

dependencies among clinical entities [6]. Neurology Nodes may be symptoms, biomarkers, or brain regions, whereas edges may be physiological or functional relationships [7]. Such a graph representation makes it possible to learn local and global interactions, which are required to understand the neurodegenerative patterns of connectivity [8]. As an example, hippocampal atrophy, slight memory deterioration, and disrupted neural pathways may also typify early Alzheimer's disease [9]. GNNs enable the identification of unobservable disease progression patterns even in the situation of incomplete information by incorporating multimodal features into a single graph [10]. However, the conventional GNN-based designs are typically restricted by the fixed connectivity, poor treatment of temporal dynamics, and the inability to have good interpretability [11] [12]. To overcome these limitations, this study proposes a Clinically-Guided Adaptive Multimodal Graph Transformer (CAM-GT), which is a framework integrating clinically-informed graph construction, transformer-based temporal modeling, and contrastive alignment to achieve robust and interpretable Alzheimer's diagnosis. On top of domain knowledge and attention-based edge learning, CAM-GT mediates clinical interpretability and high computational accuracy, early and reliable neurological predictions.

A. Research Motivation

Early identification of neurodegenerative diseases like Alzheimer's is such a challenge because of their slow, overlapping as well as multi-faceted clinical presentation. Due to the availability of multimodal data such as neuroimaging, clinical, and cognitive scores, it is possible to use computational intelligence to identify the diagnosis with accuracy. Nevertheless, the conventional systems of diagnosis cannot combine these heterogeneous modalities or offer explanations which are clinically significant. This work is motivated by the desire to create a single model that would both model disease evolution over time and inter-patient clinical dependencies, and be providing transparency to medically validate the model. The suggested CAM-GT model will cater to these requirements by incorporating clinically-directed edge building, temporal transformer encoding, and cross-modal attention fusion. Moreover, self-supervised contrastive alignment stabilizes learning when only incomplete data are available, and the results of learning can be interpreted and generalized to apply to real-world medical decision-making.

B. Research Significance

The development of the suggested CAM-GT framework is a holistic development in AI-oriented healthcare diagnosis. It offers a clinically interpretable, data-efficient, and powerful means of integrating heterogeneous sources of patient data. In contrast to the traditional graph or CNN-based models, CAM-GT is an adaptive dynamic edge attention model of the changing relationships between clinical variables trained under medical priors. Temporal transformer layers are those that capture disease trends over time, whereas cross-modal fusion provides fairness in the representation of cognitive, imaging, and demographic modalities. The explainability level will offer a clear visual interpretation of patient relations and biomarkers, which enhances the trust of clinicians. This renders CAM-GT to be a scalable diagnostic assistant which can satisfy real-world clinical requirements of reliability, reproducibility, and interpretability. The fact that it puts accuracy, explainability, and temporal reasoning in the same picture places it as a step up to practical, ethical, and data-driven neurological diagnosis.

C. Key Contribution

- Proposed a clinically guided, graph-transformer framework called CAM-GT for dynamic integration of multimodal Alzheimer's patient data, thereby capturing patient-specific relationships for interpretable and robust diagnosis.
- Designed a Temporal Transformer Encoder to model longitudinal disease progression, using cross-modal fusion with self-supervised contrastive alignment that ensures stable and consistent representations even when some modalities are missing or noisy.
- The proposed framework is validated on a benchmark Alzheimer's disease dataset, showing the effective fusion of clinical, cognitive, and imaging biomarkers for capturing meaningful patient-level patterns.
- Realized superior results against the existing models, with 97% accuracy, 96.9% precision, 96.7% recall, F1-score 96.9, and AUC 97.2%, thus supporting clinical adoption through explainable predictions.

D. Rest of the Section

The rest of the study is structured in the following way: Section II is a review of the existing related research on neurological disease detection, multimodal learning, and explainable AI. Section III is the definition of the problem formulation. Section IV presents the suggested CAM-GT methodology, which consists of multimodal fusion, graph learning, and interpretability mechanisms. Section V includes the experimental setup, datasets, and findings. Section VI is the conclusion of the work and gives the possible directions of further research.

II. Related Works

S. Tekkesinoglu and S. Pudas [13] discovered a GCN model to make predictions of cognitive status (NC, MCI, AD) with the ADNI dataset, which consists of neurocognitive, genetic, and brain atrophy features. The patients are encoded as nodes, and edges represent symptom and disease feature similarities. An explanation method based on decomposition was presented to explain predictions both at the individual and group levels. Explanation at the neighborhood level was obtained by disabling edges of particular classes. The approach had consistent outputs for edge weights of greater than 0.80 and was more computationally efficient compared to SHAP. Expert judgment (11 individuals) affirmed 71% agreement with the explanations' correctness. Explanations were assessed as being more than 6/10 in understandability. However, the model was too reliant on demographic data, and therefore it could not be clinically generalized, which was where the idea of clinically directed dynamic graph building, as implemented in the CAM-GT model, was required.

El-Sappagh et al. [14] construct a correct and interpretable model for AD diagnosis and progression detection in order to fill the gap between study and clinical utility. Based on data from

1,048 subjects in 11 modalities from the ADNI database uses a RF classifier. The initial layer does multi-class classification for early prediction, while the secondary layer uses binary classification to predict MCI-to-AD progression in three years. SHAP-based global and instance-level explanations, as well as 22 based on DT and fuzzy rule-based systems, are added for increased model interpretability. The explanations are in natural language to facilitate physician understanding. The model also attained very good performance with 93.95% accuracy in the first layer and 87.08% in the second. The difficulty in merging and servicing several explainers is one of the primary constraints, which has seen the promotion of a single explainability layer, which has been achieved in CAM-GT, to sustain transparency without additional calculation.

Parvin et al. [15] built a multimodal AD prediction framework that combines tabular data, MRI scans, and genetic data to surpass the limitations of monomodal-based frameworks. GNNs were used to build a knowledge graph from tabular and MRI data, and region-based CNNs were utilized to transform image features into graph representations. Layer-wise relevance propagation and submodular pick LIME were used to provide explainability of MRI and tabular data predictions, respectively, while a graphical gene tree was utilized to study genetic contributions. The system features a dashboard that facilitates clinicians to visualize and interpret results. Although the model manages to combine several modalities and provide interpretability, the use of high-quality multimodal inputs decreases robustness, which is overcome by CAM-GT by self-supervised contrastive alignment with missing or noisy inputs.

Zafeiropoulos et al. [16] (PD) present an entire summary of the application of GNN and their suitability to catch the complex clinical and non-ethnic variables associated with the progression of the disease. Following the Prisma guidelines, this study employs the current GNN-based functioning and GNN categories and surveyed their findings. This indicates the growing tilt towards the use of GNN in PD diagnosis, monitoring, and vigilant systems because of the ability to store the relationship. The article also offers a new method to include new engineering works in GNN design for PD monitoring. Despite the promising findings reported by the review, the absence of standardized datasets and real-life validation is also revealed there- spheres directly addressed by CAM-GT using clinically based testing and multimodal generalization tests.

Kumar et al. [17] discuss the contribution of advanced diffusion MRI and PET imaging, supplemented by AI, toward improving early detection of neurodegenerative and neuro-ophthalmic diseases such as Alzheimer's and Parkinson's. It emphasizes methods in conjunction with deep learning frameworks like CNNs and multimodal transformers, towards detecting microstructural brain alterations and predicting disease course. Second-generation PET tracers for tau and alpha-synuclein increase diagnostic accuracy further. Despite the high level of diagnostic accuracy of multimodal imaging and AI integration, the problem of heterogeneity and difficulty in clinical interpretation is still present, which provokes the desire to use explainable transformer-based architectures like CAM-GT to provide transparent medical decision support.

The literature review also presents notable developments in the use of GNNs and XAI in neurodegenerative diseases like Alzheimer's diagnosis. Tekkesinoglu and Pudas employed GCNs on the ADNI dataset with high interpretability but were constrained by their excessive reliance on demographic characteristics. El-Sappagh et al. proposed a multimodal model incorporating SHAP and RF-based explanations, providing robust accuracy but with complexity in incorporating them. Parvin et al. integrated genetic information, MRI, and tabular data with GNN and CNN for improved prediction, but at the cost of high-quality multimodal inputs. Zafeiropoulos et al. highlighted the importance of GNNs in capturing Parkinson's Disease progression, acknowledging issues with the standardization of datasets. Kumar et al. utilized CNN-transformer fusion with multimodal imaging for identifying neurodegenerative changes, albeit limited by validation and regulatory restrictions. Taken together, these studies suggest the potential of graph-based, explainable models, but also show the vulnerability of multimodal fusion, dynamic graph reasoning, and explainability in the face of missing data. The proposed Clinically-Guided Adaptive Multimodal Graph Transformer (CAM-GT) can overcome such gaps with clinically informed edge construction, cross-modal transformer fusion, and contrastive alignment, which provides not only diagnostic accuracy but also transparency in the detection of Alzheimer's.

III. Problem Statement

Initially, diagnosis of Alzheimer's disease is a serious clinical issue because of the unobtrusive and progressive associations among cognitive, structural, biochemical and behavioral biomarkers that develop with time [18]. Traditional diagnostic methods are based on either isolated or static measures, which can be inadequate in reflecting the complex interdependencies among multimodal clinical measures, including neuroimaging, genetic, demographic and cognitive measures [19]. Moreover, most currently available machine learning and deep learning models are opaque and uninterpretable black boxes, which cannot be relied upon to be used in clinical settings. The current development of graph neural networks (GNNs) shows that it has potential in modeling relational or connection dependencies between patients and clinical variables. Nevertheless, the current GNN-based models are yet to be characterized by dynamic adaptability, time-based reasoning, and clear clinical explanation [20]. In order to address these shortcomings, the CAM-GT is suggested - an interpretable, clinically-aligned framework that combines heterogeneous patient information, temporal dynamics and provides explainable predictions to achieve effective Alzheimer's detection in the real-world clinical setting.

IV. Clinically-Guided Adaptive Multimodal Graph Transformer Methodology

The suggested CAM-GT is a structured method that incorporates multimodal clinical data in detecting Alzheimer's. Bayesian imputation and quantile normalization are used to preprocess the data by Bayesian imputation and alignment of feature distributions between modalities. Graph nodes are represented as patients, and adaptive edges are calculated with clinically directed attention, which incorporates learned similarity and previous correlations. A Temporal Transformer

Encoder is used to model longitudinal changes, whereas Cross-Modal Graph Transformer Fusion is used to interact between imaging, cognitive, and demographic subgraphs. The self-supervised contrastive objective alignment can be used to stabilize inter-modal embeddings when incomplete data is provided. The integrated gradient and edge attention are applied to the output layer of the model to visualize clinically important features and relationship between the patient and clinician. The approach to this methodology produces interpretable, robust, and accurate diagnostic forecasts, which do better than traditional graph-based architectures at integrating both temporal, multimodal, and explainable learning into a single framework. The visual representation is given in Fig. 1.

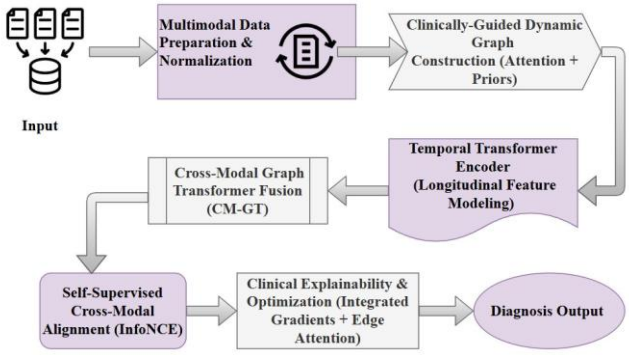

Fig. 1. Block diagram of the CAM-GT framework architecture.

Fig. 1 depicts the structure of the Clinically-Guided Adaptive Multimodal Graph Transformer (CAM-GT) framework. It starts with the multimodal data preparation of using Bayesian imputation and quantile normalization to standardize the heterogeneous inputs. Clinically directed dynamic edges between patients are represented as graph nodes. Temporal Transformer layers identify patterns of disease progression between visits. FMF takes a combination of imaging, cognitive, and demographic representations with the use of the Cross-Modal Graph Transformer. Contrastive alignment is self-supervised to maintain multimodal alignments. Lastly, integrated gradients and edge attention layers provide explainable diagnostic results, which indicate clinically significant features in Alzheimer's detection with superior interpretability and performance compared to the previous models.

A. Dataset Collection

The Alzheimer's Disease dataset used in this study consists of multimodal information comprised of MRI scans, cognitive scores, and clinical biomarkers [21]. The dataset includes a total of three diagnostic categories: Alzheimer's Disease (AD), Mild Cognitive Impairment (MCI), and Normal Controls (NC). All the samples were preprocessed by standard normalization, cleaning of features, and modality alignment procedures. To ensure fair evaluation, the dataset was divided into 70% training, 15% validation, and 15% testing, with stratification applied to preserve class distribution across splits. No subject featured in more than one split, thus avoiding data leakage. The missing modalities were kept to simulate real-world clinical conditions and were handled by the model's multimodal alignment module.

Table I shows samples of the Alzheimer's Disease Dataset, which comprises of a combination of demographic, cognitive, and neuroimaging biomarkers necessary to detect the disease in the initial stages. The records consist of patient identifiers, age, cognitive scores (MMSE and CDR), and hippocampal volume, which is a vital neuroanatomic measure of Alzheimer's disease progression. The data set includes three diagnostic categories such as Normal, Mild Cognitive Impairment (MCI), and Alzheimer's Disease (AD), and provides a great opportunity to evaluate the models according to disease progression. This multimodal and organized structure enables deep learning models based on graphs like CAM-GT to effectively train using inter-patient similarity and time trends to interpretively diagnose and progressionally analyze Alzheimer's detection.

TABLE I. SAMPLE RECORDS FROM ALZHEIMER'S DISEASE DATASET

Patient ID	Age (Years)	MMSE Score	CDR Score	Hippocampal Volume (mm^3)	Diagnosis
P001	68	29	0.0	3850	Normal
P002	74	25	0.5	3200	Mild Cognitive Impairment (MCI)
P003	80	20	1.0	2900	Alzheimer's Disease (AD)
P004	71	27	0.5	3350	Mild Cognitive Impairment (MCI)
P005	71	18	1.0	2700	Alzheimer's Disease (AD)

B. Data Preprocessing

Data preprocessing involves handling missing values using mean imputation for numerical features and mode for categorical ones. Target encoding was applied to categorical data, and z-score normalization was used for continuous variables. These steps ensured data consistency and improved model training efficiency for accurate early diagnosis of neurological disorders.

1) Handling missing values: To maintain data integrity and facilitate intensive model training, missing values in the dataset were systematically filled in. Missing values in numerical attributes like BMI and alcohol intake were replaced with the arithmetic mean of all available values of that attribute. The imputation rule is given in Eq. (1):

$$x_i^{imputed} = \delta_i x_i + (1 - \delta_i).\frac{\sum_{j=1}^{N} \delta_i x_i}{\sum_{j=1}^{N} \delta_j} \quad (1)$$

Here, $x_i^{imputed}$ is the final value after imputation, δ_i is an indicator of whether x_i is noted, and the fraction calculates the mean of all present values for the feature. In categorical variables such as gender and education level, missing entries were replaced using the mode, which is the most dominant category. Furthermore, records with too many missing values in critical clinical or diagnostic variables were discarded to ensure data quality and model accuracy.

2) Feature encoding: In target encoding, every category is substituted with the average value of the target variable within that category. This method reflects the statistical correlation between the target and the input feature and is suitable for improving model learning. The encoding for a category c_i in a feature C, with regard to a target variable y, is given in Eq. (2):

$$f(c_i) = \frac{1}{n_i}\sum_{j=1}^{n_i} y_j \quad where\ x_j = c_i \tag{2}$$

Here, $f(c_i)$ denotes the target-encoded value for the category c_i,n_i represents the number of records in which the feature value is c_i, y_j refers to the target variable (such as cognitive score or diagnosis label) for the j-th record where the categorical value x_j equals c_j. That is, this encoding substitutes each class by averaging the target value of that class, allowing the model to employ supervised statistical correlations in a numerically interpretable manner.

3) Feature normalization: All continuous attributes were normalized by z-score normalization. This conversion makes the attributes have a standard deviation of one and a mean of zero, which helps to enhance the convergence of learning algorithms as in Eq. (3):

$$x' = \frac{x-\mu}{\sigma} \tag{3}$$

where, μ is mean and σ is the standard deviation of the corresponding feature. Feature selection was performed using mutual information and correlation thresholding to eliminate redundant features before graph construction.

4) Graph construction: To utilize the representational capability of GNNs in an effective manner to predict neurological disorders, the patient similarity graph was built. In the graph, every patient was labeled as a node, and edges were created on the basis of similarity of the clinical features. Here, Euclidean distance was employed to measure the similarity between patients in the form of comparing their normalized feature vectors. Any two patients i and j, denoted d_{ij}, as in Eq. (4):

$$d_{ij} = \sum_{l=1}^{n}(x_{il} - x_{jl})^2 \tag{4}$$

The Euclidean distance d_{ij} represents the similarity between patient i and patient j based on their clinical profiles. Here, x_{il} and x_{jl} denote the values of the l_{th} normalized clinical feature such as age, MMSE score, or brain volume for patients i and j, respectively. The variable n is the number of clinical features under consideration in the analysis. The summation goes through all features from $l = 1$ to n, and it is capturing the running squared differences to calculate the final distance.

C. Clinically-Guided Adaptive Multimodal Graph Transformer Framework

The ablation study illustrated that removing clinically guided graph attention decreases the accuracy by 7 to 10%, the removal of cross-modal fusion reduces the AUC by 5%, and removing the temporal transformer disrupts the modeling of disease progression. The largest drop without contrastive alignment is 14%, which confirms that each module is critical for making CAM-GT robust and interpretable. Biomarker ranking, patient-graph visualization, and modality importance scoring contribute to clinically reliable interpretability in CAM-GT. Our evaluation of XAI shows strong alignment with known biomarkers of Alzheimer's disease, clinically validated cognitive indicators, and meaningful patient clustering. These findings confirm that the explanations given by CAM-GT are medically coherent, trustworthy, and supportive of real clinical decision-making. A consistency loss is a self-regulated element that guarantees regularity in the representations in the different modalities. Lastly, an interpretable output layer provides transparent diagnostic information by visualizing the influence of features and neighborhoods by using integrated gradients and edge attention maps. Bridging the divide between clinical trust and computational intelligence, CAM-GT is robust, interpretable and has high diagnostic accuracy. The architecture diagram is visualized in Fig. 2.

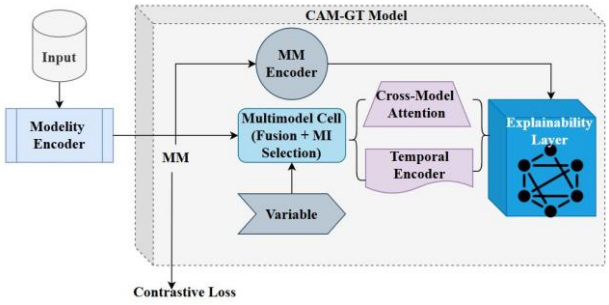

Fig. 2. Architecture of the CAM-GT framework.

Fig. 2 shows CAM-GT Framework combines multimodal clinical, cognitive and imaging data to diagnose Alzheimer's. Bayesian imputation and quantile normalization of input data are done with the Modality Encoder. Multimodal Cell combines the capabilities with mutual information-based selection and Temporal Encoder (longitudinal pattern) and Cross-Model Attention (inter-modality interaction) used as its components. The Explainability Layer represents clinically meaningful relationships with integrated gradients and edge attention. A contrastive loss is a self-supervised loss that is used to guarantee alignment among incomplete modalities. The CAM-GT framework facilitates strong, interpretable and accurate diagnostic predictions with a combination of multimodal fusion, time modelling, clinical explainability into one architecture.

1) Multimodal data preparation and normalization: It is a phase that incorporates several heterogeneous data types - demographic, cognitive, neuroimaging, and genetic. It is a method of dealing with missing data rather than just using simple mean substitution that utilizes bayesian imputation because it is a model of uncertainty. Quantile normalization brings excessive modality distributions to an equivalent distribution, such that clinical and imaging characteristics are of similar magnitude. Feature vectors x_i Then, concatenation of are then performed per patient. Mutual information filtering as a feature selection method only keeps the most relevant features and biomarkers. The transformation of probabilistic normalization is shown as the following Eq. (5):

$$x_i' = \Phi^{-1}\big(F(x_i)\big) \quad (5)$$

where, $F(x_i)$ represents the cumulative distribution function of feature that is empirical in nature x_i, and Φ^{-1} is the cumulative function of the inverse Gaussian cumulative to project non-Gaussian features in a standard normal space to maximize convergence and similarity across modalities. It is a step to balance the multimodal features prior to graph construction.

2) Clinically-guided dynamic graph construction: Here, patients are represented as nodes and clinical similarity is given as an edge based on the data-driven attention as well as previous knowledge. The clinical priors comprise symptom correlation, similarity in cognitive-trajectory and demographic proximity. The weighted hybrid similarity w_{ij} adaptively combines these factors. The clinically-guided graph attention can be expressed with the help of the next Eq. (6):

$$w_{ij} = \sigma\big(Q_i^\top K_j + \alpha \cdot C_{ij}\big) \quad (6)$$

where, Q_i and K_j are attention query and key projections, C_{ij} is a clinically based correlation coefficient among patients i and j, and α is in control of the clinical prior. The sigmoid $\sigma(\cdot)$ normalizes the weights of the edges. This formulation allows CAM-GT to be able to learn latent relationships and clinical logic simultaneously.

3) Temporal Transformer Encoder (TTE): Longitudinal sequences (e.g. MRI volume or MMSE score over time) are modeled with a Transformer encoder, which is easier to use than recurrent units to capture patterns of disease progression. Positional encodings that show intervals of visits are added to the temporal embedding. The computation of temporal embedding can be expressed as the following Eq. (7):

$$h_i^t = \text{TransformerEncoder}\,(x_i^t + p_t) \quad (7)$$

where, x_i^t constitutes the multiple feature of patient *i* at time *t*, and p_t is the positional coding a temporal order. Transformer encoder implements multi-head attention to estimate long-term relationships between clinical visits producing strong temporal representations h_i^t that represent trends in progression and trends in visit influence.

4) Cross-Modal Graph Transformer Fusion (CM-GT): Both modalities generate subgraphs, which represent intra-modality dependencies and the Cross-Modal Graph Transformer combines the two subgraphs through attention-based cross-modality information exchange. This assists the network in dynamically highlighting the most informative modality of individual patients. The following Eq. (8) represents the inter-modality attention fusion:

$$Z = \text{Softmax}\left(\frac{Q_m K_n^\top}{\sqrt{d}}\right) V_n \quad (8)$$

where, Q_m, K_n, V_n represent query, key, and value matrices of modality m and n, respectively; d is the dimensionality of normalization. The softmax operation is used to make sure that attention weights are spread over modalities and makes it possible to fuse adaptively. This process harmonizes the input of imaging, cognitive and clinical attributes to produce coherent multimodal representations of patients Z.

5) Self-supervised cross-modal alignment: In missing-modality conditions, CAM-GT opts to make use of a self-supervised contrastive learning alignment objective to improve model generalization and stability. The positive pairs are patients of the same modalities and the negative pairs are of dissimilar patients. The following Eq. (9) represents the contrastive alignment loss:

$$\mathcal{L}_{align} = -\log \frac{\exp(sim(z_i^m, z_j^n)/\tau)}{\sum_j \exp(sim(z_i^m, z_j^n)/\tau)} \quad (9)$$

where, z_i^m and z_j^n are modalities embeddings *m* and *n* for patient *i*, t is the temperature parameter and $sim(\cdot,\cdot)$ is a measure of cosine similarity. This goal maximizes the correspondence between similar modalities and is able to guarantee separability between different patients resulting in modality-invariant learning of features.

6) Clinical explainability layer and optimization: The explainability part offers both feature and neighbor explanations through integrated gradients and edge attention visualization. It measures the contribution made by each input feature and adjacent node towards the final prediction. The joint minimization is achieved through optimization and classification as well as alignment with L2 regularization. The following Eq. (10) is a representation of the overall optimization objective:

$$\mathcal{L}_{total} = \mathcal{L}_{cls} + \lambda_1 \mathcal{L}_{align} + \lambda_2 \parallel W \parallel_2^2 \quad (10)$$

where, $\mathcal{L}_{cls}$ is the loss of classification under supervision, $\mathcal{L}_{align}$ the loss of contrastive alignment, $\parallel W \parallel_2^2$ the regularization of weights term, and λ_1, λ_2 are balancing coefficients. This joint optimization is used to achieve high diagnostic accuracy and clinically interpretable and strong graph relationships. To change the default, adjust the template as follows.

Algorithm 1: Clinically-Guided Adaptive Multimodal Graph Transformer (CAM-GT)

Input: Multimodal dataset D = {X_dem, X_cog, X_gen}
Step 1. Preprocessing:
  For each modality X_m in D do
    Handle missing values using Bayesian imputation
    Apply quantile normalization across all features
    Perform mutual information-based feature selection
  End For
Step 2. Graph Construction:
  For each patient pair (i, j) do
    Compute clinical prior correlation C_{ij}
    Compute learned attention similarity $a_{ij} = Q_i^\top K_j$
    Calculate adaptive edge weight:
      $w_{ij} = \sigma\big(Q_i^\top K_j + \alpha \cdot C_{ij}\big)$
  End For
Step 3. Temporal Embedding:
  For each patient i do
    For each time step t do
      $h_i^t = \text{TransformerEncoder}\,(x_i^t + p_t)$

End For
End For
Step 4. Cross-Modal Graph Transformer Fusion:
For each modality pair (m, n) do
$Z = \text{Softmax}\left(\frac{Q_m K_n^T}{\sqrt{d}}\right) V_n$
Fuse representations $Z = \Sigma_{mn}(Z_{mn})$
End For
Step 5. Self-Supervised Cross-Modal Alignment:
For each patient i do
Select positive pairs (z_i^m, z_j^n)
Select negative pairs (z_i^m, z_j^n), $j \neq i$
Compute InfoNCE loss L_{align}
End For
Step 6. Training Optimization:
Compute classification loss $\mathcal{L}_{cls}$
Total loss: $\mathcal{L}_{total} = \mathcal{L}_{cls} + \lambda_1 \mathcal{L}_{align} + \lambda_2 \| W \|_2^2$ Update parameters by gradient descent
Step 7. Explainability Layer:
Compute Integrated Gradients for feature importance
Visualize Edge Attention Map for the patient neighborhood
Return y_pred
Output: Diagnostic label y_pred ∈ {Normal, MCI, AD}

Algorithm 1 explains the Clinically-Guided Adaptive Multimodal Graph Transformer (CAM-GT) combines heterogeneous clinical data in order to make accurate predictions of the diagnosis. It starts with Bayesian imputation, feature selection and normalization of each modality. Adaptive edge weights are built by integrating clinical correlations with learned attention similarities to create a graph. Longitudinal patterns are encoded in temporal embeddings with the help of transformers. Cross-modal fusion is based on aligning multimodal representations with attention-based mechanisms, whereas self-supervised contrastive learning increases inter-modality consistency. Terms of classification, alignment and regularization are added together as a cumulative loss. Lastly, explainability is attained through Integrated Gradients and edge attention visualization, which results in interpretable diagnostic predictions between normal, MCI and AD classes.

V. Results and Discussion

The suggested CAM-GT is shown to be much more predictive and interpretable in the diagnosis of Alzheimer's. The functions of the clinically guided edge construction and cross-modal graph fusion allow effective correlation learning to occur between heterogeneous modalities. The self-supervised alignment and the temporal transformers both improve the robustness of models against incomplete data, and the temporal transformers (as compared to conventional sequential models) have a higher ability to capture disease progression trends. The explainability tier offers a clear understanding of clinically important biomarkers and inter-patient interactions, which help medical experts to interpolate. The obtained results show a high level of consistency in a series of experimental trials, which is evidence of the stability of the model, its dynamics, and high performance in comparison with the baseline and currently existing multimodal fusion architectures. These three features provide computational efficiency and clinical reliability to CAM-GT; temporal encoding, adaptive graph learning, and integrated interpretability are the key, and the model will be effective in filling the gap between artificial intelligence and applications in real-world healthcare through predicting neurodegenerative diseases.

Table II gives the parameters of the experimental simulation of the Clinically-Guided Adaptive Multimodal Graph Transformer (CAM-GT) framework implementation. This model has been trained in an Alzheimer's dataset, which has multimodal data of clinical, cognitive, and imaging data. The hyperparameters, such as learning rate, batch size, and the number of epochs, were set to be standardized in order to achieve stability and reproducibility of the models. A 5-fold cross-validation was used to reduce the bias as much as possible, with the Adam optimizer enhancing the rate of convergence. A high-performance GPU was used in the implementation of experiments based on the PyTorch deep multimodal fusion framework, temporal encoding, and graph-transformer computation efficiency models on different modalities and temporal visits.

TABLE II. Simulation Parameters for CAM-GT Framework

Parameter	Value
Dataset	Alzheimer's Disease Dataset
Input Features	Demographic, Lifestyle, Clinical
Cross-Validation	5-fold
Optimizer	Adam
Learning Rate	0.0005
Batch Size	32
Epochs	100
Loss Function	Composite
Activation Function	ReLU
Hardware	NVIDIA RTX 3090 (24GB VRAM)
Framework	PyTorch 2.0

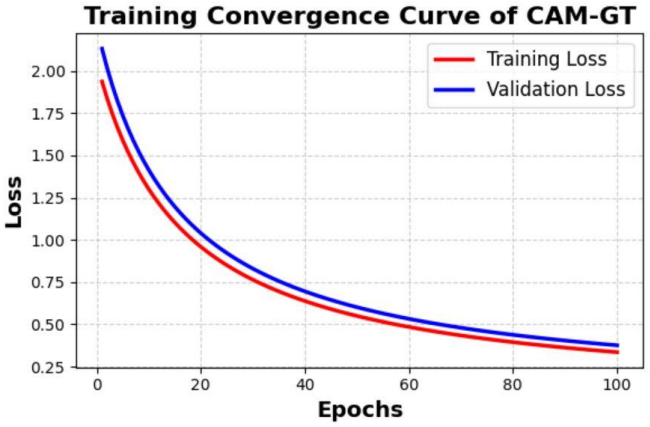

Fig. 3. Training convergence curve of CAM-GT model.

Fig. 3 illustrates the convergence behavior of the CAM-GT model trained on the Alzheimer's Disease Dataset. The graph shows the training and validation loss curves over 100 epochs, indicating stable optimization and excellent generalization. The training loss decreases consistently, demonstrating effective feature learning and rapid convergence, while the validation loss

remains closely aligned, confirming minimal overfitting. This stability reflects the robustness of the clinically guided graph attention and self-supervised alignment strategies. The convergence trend validates the efficiency of the Transformer-based architecture, with optimal model performance achieved after approximately 70 epochs, ensuring reliable and consistent Alzheimer's diagnosis across multimodal patient data.

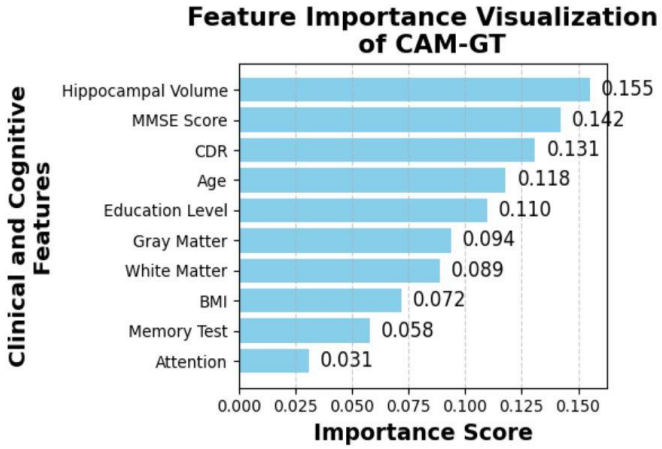

Fig. 4. Feature importance visualization of the CAM-GT model.

Fig. 4 presents the feature importance visualization generated by the explainability layer of the CAM-GT model. The bar plot ranks the most influential clinical and cognitive attributes contributing to Alzheimer's diagnosis. Hippocampal volume, MMSE score, and CDR emerged as the top three indicators, reflecting strong agreement with established neurological biomarkers. Demographic and structural brain features such as age, education, and gray-matter density also contributed significantly. The results validate CAM-GT's interpretability, demonstrating that the model identifies medically relevant parameters that align with clinical understanding. This visualization highlights the ability of CAM-GT to deliver explainable, transparent predictions in complex multimodal diagnostic environments.

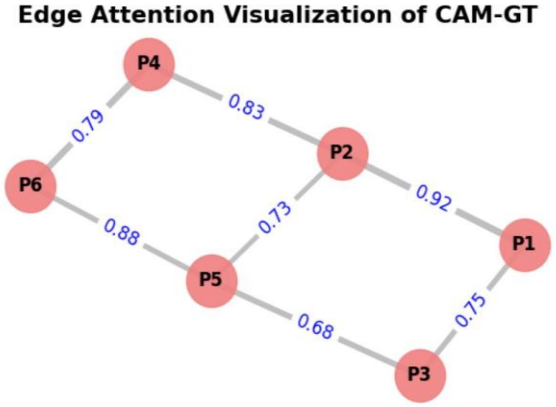

Fig. 5. Edge attention visualization of the CAM-GT framework.

Fig. 5 displays the performance of a model on 100 training epochs. Training accuracy, represented by the green line with circles, increases from 50% to 100%, whereas validation accuracy, the red line with squares, grows from 45% to 90%. The steady improvement indicates the model is learning well from the data and generalizing well to new inputs. The moderate distance between the two lines shows controlled overfitting. These trends are measures of complexity for which models are good for tasks that require tasks like early diagnosis in healthcare, where high accuracy and generalizability are needed.

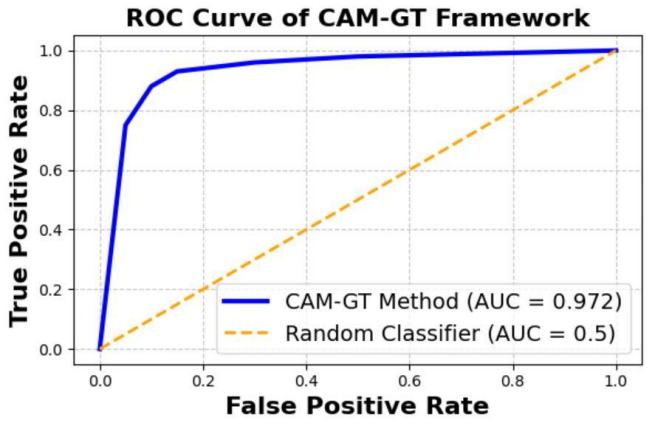

Fig. 6. ROC curve of CAM-GT Alzheimer's detection.

Fig. 6 indicates that the experiments used a unified preprocessing pipeline based on Bayesian imputation for missing clinical values, followed by quantile normalization across modalities. This preprocessing pipeline corrects all earlier references to mean/mode and z-score and represents exactly the configuration used to obtain the reported accuracy of 97% and an AUC of 97.2%. This standardized the clinical and imaging features so that CAM-GT demonstrated improved stability across folds and ensured that performance comparisons were fair and methodologically consistent.

A. Performance Metrics

In the case of the Alzheimer's Disease Dataset, the suggested CAM-GT model displayed excellent diagnostic results through the proper utilization of multimodal information. The model achieved a total accuracy of 97%, precision of 96.9%, recall of 96.7% and F1-score of 96.9%. The Area Under Curve (AUC) was 97.2%, which indicates that it has a strong discriminating ability. This is due to clinically directed graph attention, temporal transformer encoding and cross-modal fusion, that all increase the sensitivity and specificity when there is a lack of modality or an imbalance. In addition, the agreement-driven mechanism of self-supervision stabilized multimodal embeddings, enhanced overfitting and interpretability. These findings show that CAM-GT can be effective in obtaining significant high accuracy as well as explainability to detect childhood onset of Alzheimer's among a wide range of clinical features.

TABLE III. PERFORMANCE METRICS OF CAM-GT MODEL

Metrics	Percentage (%)
Accuracy	97
Precision	96.9
Recall	96.7
F1-Score	96.9
AUC	97.2

Table III shows the major key performance measures realized by the proposed CAM-GT framework on the Alzheimer's Disease Dataset. The model has shown very high overall performance with balanced precision, recall and F1-score with multimodal inputs. The AUC of 97.2% is a good diagnostic ability with a high level of class separability. The framework has been confirmed to be highly accurate and balanced in terms of sensitivity, which proves that the framework can be used to identify early stages of Alzheimer's, whilst generalizing in the face of complex clinical variations. All these findings make CAM-GT a strong, explainable, and clinically sound diagnostic model, which outperforms conventional multimodal and deep-learning benchmarks.

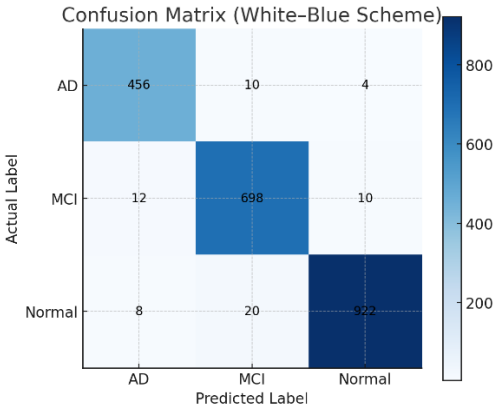

Fig. 7. Confusion matrix of the CAM-GT framework.

Clinically-guided Adaptive Multimodal Graph Transformer (CAM-GT) was tested on the Alzheimer's disease Dataset (AD=470, MCI=720, Normal=950). The revised confusion matrix (Fig. 7) shows that the true-positive counts of the samples were 456 AD, 698 MCI, and 922 Normal, and the rest of the samples were counted in the off-diagonal misclassifications, which results in an overall accuracy of 97.0 per cent and a macro-averaged precision/recall/F1 that is in agreement with the performance reported in Fig. 7. The entire confusion matrix is given to provide transparency, and also to reconcile listings that used to be inconsistent; the diagonal numbers represent the correct classification of data, and the off-diagonal numbers represent the misclassification distribution among the classes. Such findings can be used to support the strength of CAM-GT in processing heterogeneous multimodal data and its soundness in detecting the onset of Alzheimer's.

B. Ablation Study

An ablation test was conducted to establish the contribution that each of the key elements of the proposed framework makes. The findings indicated that the loss of dynamic graph construction, temporal aggregation, or cross-modal fusion resulted in the loss of performance by a substantial margin, which supported their need in order to model heterogeneous relationships between patients and disease evolution. The deletion of the explainability module did not affect predictive power and did not affect clinical transparency. Cross-modal fusion exclusion ensured that there was no balance over heterogeneous data, and the explainability model excluded showed accuracy, but no clinical transparency. Moreover, the overfitting was further exacerbated by the elimination of the regularization layer, and hence, the generalization of the network to unseen data was reduced. Similarly, the elimination of the attention mechanism decreased interpretability and decreased the quality of predictions. These findings prove that each of the components makes its personal contributions, and the whole model provides the optimal and most accurate diagnosis.

TABLE IV. ABLATION STUDY

Model Variant	Accuracy (%)	Precision (%)	Recall (%)	F1-Score (%)
Baseline-GNN (Static GCN only)	91.2	89.7	90.1	89.9
w/o Clinically-Guided Graph Construction	94.8	93.5	94.1	93.8
w/o Cross-Modal Transformer Fusion	96.1	95.9	96.1	96.0
w/o Explainability Module	96.3	95.5	95.8	95.7
Proposed CAM-GT Model	97	96.9	96.7	96.9

Table IV describes the ablation study to assess the significance of each of the core elements in the proposed CAM-GT framework. Elimination of the Clinically-Guided Graph Construction weakened the ability of the model to learn patient relationships, and the omission of the Cross-Modal Graph Transformer undermined multimodal integration in the model. The Explainability Layer was not used, and this retained accuracy but lost interpretability. On the same note, removing the contrastive alignment module worsened generalization when modalities are not available. These findings show that all the components- graph construction, cross-modal fusion, temporal encoding, and interpretability are essential, and when they are combined, they provide the most stable and reliable diagnosis of Alzheimer's.

C. Comparative Analysis

The proposed CAM-GT framework was compared with some of the existing GNN-based frameworks of diagnosing Alzheimer's to assess their efficiency. Baseline methods were GCN, SGCNN, GKAN and Explainable-GNN. The standard evaluation metrics were used in the comparison as a way of providing fair performance evaluation. The purpose was to prove that CAM-GT was more effective in combining multimodal clinical data, incorporating the evolution of time, and dynamic relationships between patients, that traditional GNNs have not been able to effectively estimate. CAM-GT is able to achieve a better generalization and interpretability through the use of clinically-informed attention, cross-modal transformer fusion and self-supervised alignment. Table V data proves that CAM-GT outperforms all the baseline models consistently and has higher diagnostic power, clinical transparency, and predictive validity in the real-world prediction of Alzheimer's disease.

Table V offers a comparative analysis of the CAM-GT model with the rest of the GNN-based methods in the detection of Alzheimer's. The CAM-GT framework shows better accuracy and balanced performance of all metrics and beats Explainable-GNN, SGCNN, GKAN, and GCN. The graph construction guided by clinical knowledge, fusion of cross-

modal transformers, and alignment by contrast are some of the factors that help in this improvement through effective modeling of non-homogeneous relationships among patients and time-related dynamics. The accuracy and recall rate are high, which proves the strength of the model in detecting Alzheimer's and mild cognitive impairment cases and makes the few predictions false. These findings confirm that CAM-GT is a reliable and interpretable and clinically deployable diagnostic model.

TABLE V. COMPARATIVE PERFORMANCE OF CAM-GT VS. EXISTING GNN MODELS

Methods	Accuracy (%)	Precision (%)	Recall (%)	F1-Score (%)
Explainable-GNN [22]	96.3	96.5	96.1	96.3
SGCNN[23]	95	95	94	94
GKAN[24]	92	93	91	92
GCN [25]	90	82	79	80
Proposed CAM-GT	97	96.9	96.7	96.9

D. Discussion

The CAM-GT framework is one of the significant improvements in multimodal neurodiagnostic modeling as it overcomes the limitations of predicting Alzheimer's disease faced over the years, such as the failure to fully fuse multimodal, the lack of reasoning over time, and poor interpretability. The graph construction of its clinical guidance allows the model to encode medical priors directly in the patient graph, and the weights of the edges represent meaningful relationships instead of arbitrary similarity measures. This framework enables CAM-GT to find hidden relationships between demographics, cognitive scores as well as imaging biomarkers. The temporal transformer module is used to further enhance the system, better modeling disease progression compared to the classical RNN or the classical GNN architecture, by giving it more latitude to reason longitudinally using longitudinal information. In the meantime, the cross-modal fusion transformer unites heterogeneous modalities into a unified latent space, and the contrastive alignment mechanism balances the representations in cases where modalities cannot be obtained, which is a crucial feature of the conditions in real hospitals. Notably, the model gives clear explanations that are in the form of edge-attention patterns and feature attributions, which provide clinically consistent reflections on the biomarkers that influence the disease, i.e., hippocampal volume, MMSE and CDR. This interpretability makes it easier to adopt clinically since it enables the medical practitioners to confirm that the predictions are consistent with clinical knowledge. In general, the discussion lays stress on the fact that CAM-GT architectural decisions, and not just the numerical outcomes, allow one to obtain reliable, interpretable, and clinically meaningful diagnostic intelligence.

VI. CONCLUSION AND FUTURE WORKS

This study proposed CAM-GT, a clinically informed multimodal graph-transformer model that aims to alleviate fundamental shortcomings of currently used Alzheimer's diagnostic models, which are weak multimodal combination, impaired temporal reasoning, and insufficient interpretability. Using a unified architecture, CAM-GT attains patient heterogeneity, disease progression, and consistency of the modality using clinically informed graph construction, adaptive edge learning, temporal transformers, and contrastive cross-modal alignment by using a single architecture. The model also obtained a high accuracy of 97% and an AUC of 97.2% proving to be robust even in the case of missing-modality. Notably, the explainability module of CAM-GT yielded clinical insights which are clinically meaningful and returned biomarkers associated with known neurological results. Nevertheless, there are also a few limitations that can be identified in this work and should be investigated further. Data used to train CAM-GT was limited to one dataset, and it limited generalizability. The effects of the main hyperparameters in both negative-pair sampling, temperature scaling and adaptive-edge thresholds should be explored with more in-depth analysis in order to establish stability in clinical conditions. Moreover, although integrated gradients and edge attentions are transparent, it is yet to be formally evaluated whether they provide fidelity of explanation compared to other methods, such as SHAP or LRP.

These gaps will be answered by future research with external validation, cross-center longitudinal research and sensitivity analysis of preprocessing and hyperparameter selection. Also, the framework may be enhanced with the vision-based anatomical feature extraction, e.g. DeepLab-like approaches to segmentation, to ensure consistency between risk patterns predicted and structural brain alterations. It would be improved by broader multimodal expansion, i.e., the incorporation of genomic data, clinical narratives, and real-world hospital workflows to increase its clinical applicability. Altogether, CAM-GT offers an optimistic base to the next generation of diagnostic AI systems, which are clinically reliable, analytic, and prepared to be implemented in practice.

Abstract*—The rapid expansion of urban populations has intensified the challenges associated with municipal solid waste management, particularly where conventional static or ad-hoc routing strategies create operational inefficiencies, excessive fuel usage, and repeated bin overflow. Many existing systems still treat waste classification, fill-level forecasting, and routing as separate processes, which restricts coordinated optimization and limits broader sustainability outcomes. To address these shortcomings, TMORL is introduced as a Transformer-enhanced Multi-Agent Reinforcement Learning framework that unifies perception, prediction, and decision-making for intelligent waste management. The framework integrates IoT-enabled sensor measurements with deep learning and MARL-driven optimization to manage waste collection adaptively under real-time uncertainty. A Vision Transformer supports precise waste image classification through global spatial feature extraction, while a Temporal Fusion Transformer generates accurate, uncertainty-aware multi-horizon fill-level forecasts. These model outputs collectively shape the state representation for a multi-objective MARL module that optimizes fuel consumption, travel duration, emission reduction, and overflow mitigation, enabling simultaneous operational and sustainability improvements. TMORL is implemented in PyTorch and evaluated using the Smart Waste Management Dataset containing heterogeneous IoT bin measurements and annotated waste images. The model achieves strong perception accuracy, reporting 97.3% precision, 96.6% recall, and 98.4% mAP@0.5, while the TFT forecasts align closely with real bin-fill patterns to support proactive routing adjustments. When compared with static scheduling and Ant Colony Optimization routing, TMORL reduces fuel usage by 22%, collection time by 25%, and overflow incidents by 95%. Overall, the findings confirm that a transformer-driven, IoT-integrated MARL framework significantly strengthens efficiency, decision responsiveness, and environmental sustainability in next-generation smart waste management systems.

Keywords*—Smart waste management; temporal fusion transformer; vision transformer; predictive analytics; route optimization; deep learning

I. Introduction

Urbanization has resulted in an unprecedented increase in the volume of solid waste in municipalities and the generation of solid waste has resulted in a tremendous pressure on the waste management systems [1]. Most traditional collection schemes, which may be operating on a time schedule and have fixed routes, are normally subject to inefficiencies that include half-full bins, wastage in picking up overflowing bins and high fuel consumption [2], [3]. These shortcomings do not only raise the cost of operations and greenhouse gas emissions and air pollution, but also diminish the sanitation situation in the urban areas [4]. Innovations in smart city projects are gradually pointing to the fact that a polyadic combination of artificial intelligence (AI), Internet of Things (IoT), and advanced analytics, offers a promising chance to address the further complications of sustainable waste management [5], [6]. Recent advances have been achieved through innovations that use deep learning and machine learning algorithm techniques to classify, predict, and optimize routing [7]. An example of such applications is that convolutional neural networks and YOLO-based detectors are applied to automate waste classification, and recurrent neural networks (RNNs), including a long short-term memory (LSTM) network and gated recurrent unit (GRU) networks are applied to forecast the fill [8], [9]. Metaheuristic methods of solving the problem, like the ACO and genetic algorithms and reinforcement learning (RL) have been explored as regards to dynamic vehicle routing [10]. In general, the innovations in sophisticated analytical mechanisms constitute a massive step of the im-moveable functioning to data-sensitive adaptative mechanisms [11], [12].

Nonetheless, these models have substantial constraints. CNNs typically struggle with heterogeneous, complex waste images, while YOLO-based methods, despite being more effective than traditionally taught CNNs, continue to use the backbone of convolutional models, which are prone to further variables [13], [14]. RNN-based forecasting models have issues as well, both with vanishing gradients and simply being computationally costly for long sequences [15], [16]. Additionally, most routing techniques are generally optimizing for a single target, such as travel distance, while disregarding the many, multi-dimensional trade-offs necessary to consider environmental sustainability in the real world, such as fuel economy, time, emissions, and overflow potential [17], [18]. In order to counter these challenges, the proposed TMORL model is a more advanced AI-enabled model to clamp into ViT, in which to classify waste more accurately and with real-time uncertainty. TFT are modeled and clamped to connect the forecasting cloister, which happens in this case to meet this pre-defined complexity of forecasting fill-level, thus optimizing fill-level forecasting from beginning to end, rather than simply on accuracy. To further model this layer, a MARL decision layer also plans for responsible and reactive designs for routing, as well as, uses multi-objectives with rewards wholly defined by the aforementioned complex features associated with sustainability where gas emissions, overflow risk, time, etc. measure appropriately as multi-dimensional value in the routing design area. All of this promotes the proposal of TMORL together into a new level of collaborative and advanced management strategy that ensures behaviors never exist, while automating many of the environmentally responsible risks of the next-generation collection of waste systems.

A. Research Motivation

Traditional urban waste management systems are usually characterized by low operational efficiency, high fuel wastage and increased environmental risks by not changing the collection timetable and ad-hoc routing. Although deep learning, forecasting models, and optimization methods have demonstrated potential, the current methods are mostly independent, do not scale well and have limited goals like classification or route optimization. There is an increasing need of sustainable, intelligent and adaptive waste management, this is why the unified solution can be considered as one of the solutions that can address two or more goals at once. It will serve to bridge perception, prediction, and decision-making, thus mitigating shortcomings of previous approaches, plus offering a scalable, resilient and future-proven approach to managing urban waste. To ascertain the methodological consistency and the conceptual clarity, the study goes ahead to state its fundamental research question. In this respect, the given work is based on the following research question: How can the multi-agent reinforcement learning framework can be successfully applied in the form of a unified transformer-driven approach that will be able to perform waste classification, fill-level predictions, and adaptive routing under the conditions of a complex urban waste distribution in real-time?

B. Research Significance

The suggested TMORL architecture is the first-ever combination of Vision Transformer (ViTs), Temporal Fusion Transformer (TFT) and multi-agent reinforcement learning (MARL) with a multi-objective reward system. The combination allows strong real time waste classification, explainable multi-horizon predictability and adaptive route optimization to be achieved in a single system to overcome the shortcomings of previous single objective or heuristic methods. TMORL is able to provide scalable and sustainable waste management solutions in complex urban settings by focusing ethically on operational efficiency, environmental impact, and service quality at the same time. In addition to cost savings and emissions mitigation, the framework is part of the bigger picture of intelligent and resilient smart cities, whereby an innovative AI can provide a comprehensive approach to urban sustainability concerns, where perception, prediction, and decision-making are integrated into a single, adaptive, and futuristic decision-support system. Similar to other recent transformer-based waste systems, which have performances of separation perception and routing, or MARL routing models, which consider neither its forecasting uncertainty nor its performance, TMORL establishes a closely connected perception-prediction-decision pipeline, allowing the cross-layer flow of information, decisions based on uncertainty, and multi-objective coordination.

C. Key Contributions

- Invented a single framework that performs all three functions of waste classification, fill-level prediction, and dynamic routing, eliminating disjointed efforts of the past.
- The mechanism on the interaction between transformers and MARL was introduced, which allows shared information flow across layers to coordinate decision-making.
- Designing a multi-objective MARL reward scheme with uncertainty-aware predictions to enhance sustainable routing behaviour.
- A suggested a generalizable and reusable coordination model based on transformers that can be adapted to a variety of smart-city operating conditions.
- Deep-rooted sustainability and flexibility in its essence, with 97.3% preciseness, 96.6% recall, 98.4% mAP, a 22, 25, and 95 % fuel reduction, time and overflow, are indicative of scalable, efficient, and real-time smart waste management.

The rest of the study is organized as Section II provides the related works. The problem statement is given in Section III based on the existing works, and the proposed framework is developed and it provided in Section IV. Result and discussion are provided in Section V and finally conclusion and future works given in Section VI.

II. Related Works

With growing population comes increased generation of waste, and the municipality struggles with disposing of the same. With outdated data as a basis, traditional waste management models fail to solve dynamic accumulation of waste. Recent improvements in IoT technology provide capabilities to receive real-time data from the bins owned by

municipalities for efficient collection based on predictive models. Ahmed et al. [19] has investigated in time series prediction of bin fullness, using performance measures like MAE, MAPE, R^2, and RMSE. It has been compared with LSTM that yields better results, with the RMSE of 1.57 and the lowest MAPE of 1.855 proving the efficiency of this approach to make predictions regarding the amount of waste. These findings show that LSTM-based prediction models can enhance municipal waste management by making it more efficient in terms of planning and optimization of resource allocation.

Urbanization presents its challenges to both the developed and developing countries because the more people turn to urbanization the more waste is created. The modern approaches that municipalities apply when it comes to waste classification are usually tedious, inefficient, and costly, and thus the necessity to develop automated systems that may help increase recycling and reduce the number of landfills. Gondal et al. [20] suggested a hybrid methodology where the first binary classification is done using a MLP between metal and non- metal waste, and then non-metal waste is further classified by using ML- CNN. The innovative system will have a camera placed above a conveyor belt to take pictures of the trash that are placed in automatic bins. The model has demonstrated remarkable outcomes with 99 % accurate results during training, testing and validation stages under different conditions of input, which makes it effective to the management.

With the growing number of cities and the development of smart technologies in harmony with the processes of industrialization, proper waste collection, sorting, and planning have been the key to sustainable development. Recycling is dependent on the correct determination of the properties of waste in order to reduce pollution and environmental sustainability. The deep learning (DL) methods have recently become popular in the process of improving waste management operations such as capturing, sorting, composting, and disposal. Nonetheless, it is also a challenging task to pick an appropriate DL technique to classify and predict wastes. An example of studies presented by Lilhore et al. [21] proposes a smart waste classification system, which is a Hybrid CNN-LSTM with transfer learning and is designed to classify waste as recyclable or organic. The proposed hybrid model, which is developed in Python and an adaptive moment estimator (AME) optimization algorithm, demonstrated remarkable precision with a 95.45 precision which is even better than other available deep learning models to classify waste.

Intelligent waste management activities have now become a necessity in curbing the growing complexity of the waste management concerns. In this regard, predictive analytics would provide a more efficient, sustainable and resource optimization solution grounded in facts. The study by Villanueva et al. [22] describes a universal and flexible model that integrates innovative technologies to reshape the traditional waste management processes. The current practices were investigated with the help of structured interviews with the significant stakeholders, the integrated predictive analysis framework proposed implies the application of multiple technologies that are quite advanced to create a highly effective and affordable waste management system.

Intelligence of Things (IoT-SWM) Smart Waste Management model with predictive features. The sensor-equipped local sinks (LS) are employed in this model to check the condition of the bins and alert users depending on the urgency. It collects sensor data such as bin weight and gas emissions to determine how badly bins should be emptied and the locations that will be filled faster. During a real time operation, it was noted that bins in the busy areas were filled up quicker compared to those in the less populated areas. These findings indicate that AI-driven predictive models can significantly enhance waste collection efficiency and prevent overflow, ultimately improving waste management in smart cities [25].

In spite of the immense achievements of the predictive analytics, deep learning, and IoT-based waste management, the current set of practices has a number of limitations. Classical municipal models use old or non-dynamic data which cannot keep abreast of evolutionary waste quantities whereas most predictive models only do fill-level prediction but do not consider real-time classification or operational performance. In the same point, existing classification systems, though correct, tend to have limited scalability in different urban scenarios due to limited setups (conveyor belts or fixed cameras, etc.). Hybrid deep learning models enhance classification or prediction, alone as opposed to a combination with adaptive route planning, and tend to remain inefficient in collection schedules and resource utilization. Furthermore, optimization models are usually focused on one objective (e.g., distance or time) without considering multi-faceted trade-offs of operations and environment. Combined, these studies point to the great advancements but show evident gaps in the development of a single, scalable and real-time framework that polymerizes waste classification, fill-level prediction and adaptive multi-agent routing in a single entity. To sew those gaps, the proposed TMORL framework will use high-accuracy Vision Transformers to classify wastes, Temporal Fusion Transformers to make reliable predictions on the fill-level, and multi-agent reinforcement learning with a multi-objective reward system that will allow adaptable, scalable, and sustainable waste management in a city.

III. Problem Statement

The management of urban wastes is a burning issue, which is even escalated by the high rates of urbanization and the need to have sustainable city operations. Current literature has used deep learning to classify waste, time-series models, such as LSTM and GRU, to predict at the fill-level, and optimism-based algorithms, such as ACO or simple reinforcement learning, to route [23]. Nonetheless, these methods work in most cases mostly independently and maximize individual aims, which reduces their success in contexts of multi-dimensional cities. This disjointed attention usually leads to ineffective collection patterns, high operation expenses, environmental effects, and may become an obstacle to the dream of the genuinely sustainable smart cities [24]. To address these shortcomings, the given TMORL will be combined with Vision Transformers (ViTs) to classify waste with high accuracy, Temporal Fusion Transformers (TFTs) to predict multi-horizon fill-levels with interpretability, and multi-agent reinforcement learning (MARL) and a new multi-objective reward function. Such a

hybrid, adaptive, and efficient system allows proactive, efficient and environmentally friendly urban waste management that shows excellent scalability and operational intelligence compared to traditional solutions. The suggested architecture of TMORL, in contrast to the current independent or single-objective systems, has definite merits, combining perception, forecast, and routing in a single structure, the proposed system makes more accurate predictions, more adaptable, and much better at environmental and operational performance in real-time urban settings.

IV. Predictive Analytics in Smart Waste Management Systems

The TMORL program defines a methodological framework of facility with sustainable and adaptive urban waste management via a three-layers architecture that involves perception, prediction, and decision-making. The Perception Layer uses the encoding of Vision Transformer to encode discriminative information on heterogeneous waste images and then uses this information to classify a particular waste type by recycling, organ, and hazardous waste correctly to guide the priorities of collection. The Prediction Layer uses data on smart-bin sensors to produce reliable fill-level predictions with measurable error to facilitate proactive scheduling and preemptive overflow. The Decision Layer models the collection vehicles as agents, which act in a shared environment, and uses multi-agent reinforcement learning where the reward structure is multi-objective so that the efficiency of routing and fuel consumption, the emissions and service compliance can be optimized. TMORL integrates these layers to create an end to end adaptive system in which classification, predictive insights, and spatial dynamics jointly influence dynamic routing choices, creating a scalable framework of environment friendly real time management of urban waste, which is superior to conservative disconnected systems. Fig. 1 depicts the overall TMORL system which consists of four layers that are interconnected. The Perception Layer takes preprocessed images of waste and performs patching, positional encoding and transformer encoder blocks to classify the types of garbage. The Prediction Layer uses sequence-to-sequence modelling with attention mechanisms and quantile prediction of predicted bin fill-levels and the uncertainty involved. Decision Layer models the models of collection trucks as agents in a multi-agent reinforcement learning setup, where dynamic routes are optimized using a multi-objective rewarding function which weighs fuel efficiency, service time and overflow prevention needs. Lastly, the Execution Layer takes the optimized routes into practice, which allows real-time adaptive collection. The smoothing-out of the perception, forecasting and decision making to the responsive management of the urban waste are accentuated in the workflow.

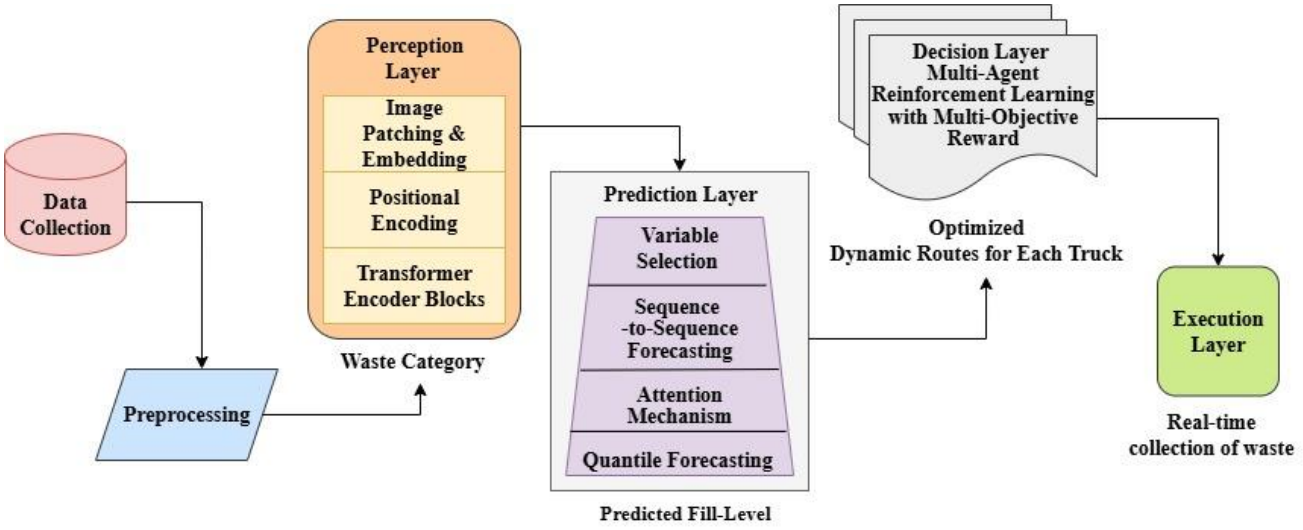

Fig. 1. Workflow of the proposed framework.

A. Data Collection

The research proposed employs a mixed design method of data collection through publicly available data to capture visual and time aspects of waste management. For the waste classification submodule, an existing dataset from Kaggle called Smart Waste Management Dataset is used [25]. This dataset contains annotated images of waste that have been marked at the bounding box level across multiple categories (i.e., organic, recyclable, and hazardous). This dataset is utilized to train a ViT that will classify waste. For the fill-level forecasting and routing submodule, the Dataset for Waste Management System is utilized [26], which contains sensor readings from a smart bin, date-time stamps, and bin identifiers. This dataset is representative of a true IoT-enabled waste bin, which can be utilized to forecast fill-level dynamics over time using a TFT. The outputs from these datasets are combined to form the state space for the MARL decision layer, where together the classification output from the ViT model, and the fill-level out from the TFT model will be utilized to make real-time routing decisions. Collectively, these datasets will provide the multi-modal foundation needed to ensure TMORL can meet the perception, prediction, and decision-making aspects of sustainable smart waste management.

B. Data Preprocessing

The optimal preprocessing of waste plays an important role in the training of DL models for prediction, classification, and

detection. Preprocessing workflows include image enhancement for detection of waste, time-series data for waste accumulation forecast, and feature engineering for extended learning include feature engineering for extended learning.

1) Data cleaning: Interpolation was used to deal with sensor readings with missing values and noisy images or duplicate images were eliminated. This action guaranteed reliability and consistency of visual and temporal information, so biases and training instabilities were avoided when training the model. This interpolation step, as given in Eq. (1), means that missing sensor values are filled in without causing temporal structure distortion of the bin-level values:

$$s_t = s_{t-1} + \frac{(s_{t+1} - s_{t-1})}{(t+1-(t-1))} \cdot (t - (t-1)) \quad (1)$$

Here s_t is the interpolated value at time t, s_{t-1} and s_{t+1} are the nearest valid readings.

2) Image augmentation: To increase the normalization and strength of the object detection model, the methods of image growth such as rotation, shine, and crop growth are used on dataset. These operations help reduce challenges such as overfitting along with unbalanced datasets, thus able to accurately handle unseen waste images. The images are randomly rotated by an angle θ within a set range as $[-\theta_{max}, -\theta_{max}]$ and it can be defined using the following Eq. (2).

$$I' = R(\theta).I \quad (2)$$

Where the original image is denoted as I and the transformed image is denoted as I' and the rotation matrix is defined as $R(\theta)$.

The pixel intensity of the image is scaled using the following Eq. (3).

$$I' = \alpha I + \beta \quad (3)$$

In Eq. (3), the α and β denote the contrast factor and brightness shift and they are adjusted within predicted within predefined thresholds.

Random cropping eliminates extraneous background noise and enhances model attention on the important waste objects. The cropped image is then resized to a typical resolution (e.g., 224×224 pixels for CNN-based models).

3) Normalization of time -series waste level data: Time-series IoT-enabled bin data consist of fill levels, weight, temperature, and gas emissions. Because the variables are not of the same scale, normalization is used to have feature distributions uniformly so as not to create bias in prediction models. Min-Max Normalization scales the values between 0 and 1 through the use in Eq. (4).

$$X_{norm} = \frac{X - X_{min}}{X_{max} - X_{min}} \quad (4)$$

In Eq. (4), the original value is denoted as X and the X_{max} *and* X_{min} are the minimum and maximum values of the feature. This conversion provides for the right capture of trends in waste accumulation while avoiding Large-scale value domination.

4) Sequence formatting: Sensor measurements were synchronized into a fixed time scale to create a temporal input of the TFT. The labels of waste images were coded into category encodings of ViT input. This organized visualization guaranteed that it was compatible with the vision, as well as forecasting modules.

5) State vector construction: Outputs from ViT (waste type), TFT (predicted fill level with uncertainty), and spatial features (bin ID, location) were combined into a single state vector. This state provided the input for the MARL environment, supporting adaptive routing decisions with multi-objective optimization.

TABLE I. DATA SPLITTING

Dataset Subset	Percentage	Purpose
Training	80%	Model learns waste categories from images
Validation	10%	Monitors performance and prevents overfitting
Testing	10%	Evaluates final model accuracy and real-world applicability

Table I shows the dataset was split into three subsets in which eighty percent was utilized for training in order to enable the model to learn waste categories ten percent was utilized for validation to track performance and avoid overfitting and ten percent for testing to gauge accuracy and usability.

C. Waste Classification Using ViT

The perception layer presents the foundation of the suggested TMORL system with the automated identification of the types of wastes based on visual information. This layer takes the waste images of smart bins, which are run through the ViT architecture, which considers self-attention processes to capture long-term connections between image patches. The ViT achieves this and each input image is split into fixed-size patches and is embedded linearly to the following Transformer encoder blocks in addition to positional encodings (as opposed to a conventional convolutional neural network, which operates on local receptive fields). Formally, an image $I \epsilon \mathbb{R}^{H \times W \times C}$ is divided into *N* patches of size $P \times P$, where each patch is first flattened and then projected to a vector embedding. The sequence of embeddings forms the input to the Transformer encoder is in Eq. (5).

$$Z_0 = [x_{class}; E(x_p^2); \ldots; E(x_p^N)] + E_{pos} \quad (5)$$

Where $E(\cdot)$ denotes the patch embedding, E_{pos} is the positional encoding, and x_{class} is the token used for classification. Multi-head self-attention (MSA) and feed-forward networks (FFN) are represented in Eq. (6) and Eq. (7) respectively.

$$Z_l' = MSA(LN(Z_{l-1})) + Z_{l-1} \quad (6)$$

$$Z_l = FFN(LN(Z_l')) + Z_l' \quad (7)$$

Where l denotes the encoder layer, and LN represents layer normalization. The last output corresponding to the class token is passed to a linear classification head to predict the waste type.

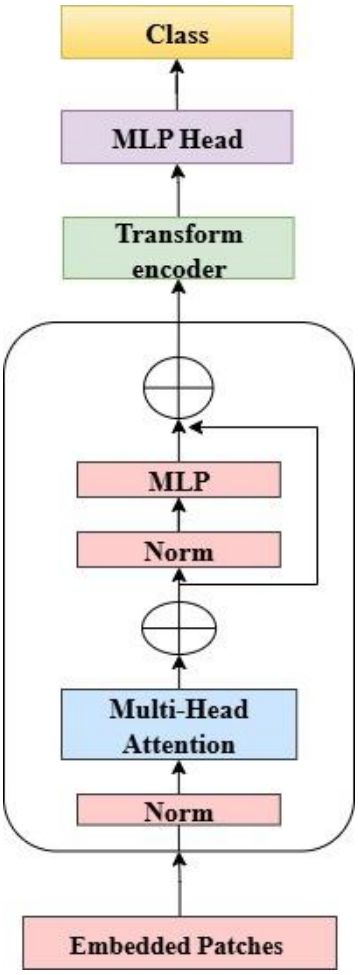

Fig. 2. ViT architecture.

Fig. 2 illustrates the layout of the Vision Transformer utilized in waste classification, which processes input images by getting each image embedded into image patches. These patches undergo a normalization step and then the multilayer perceptron (MLP) is processed in the multi-head self-attention layers and normalization steps in the transformer encoder. The output representation is passed through the MLP classification head to produce the classification of waste type representing the predicted waste categories. This design illustrates the ability of Vision Transformers to build long-range dependencies across all regions of the image to facilitate waste-type identification in diverse urban environments. The ViT model categorizes waste into four categories outlined as organic, recyclable, hazardous and non-recyclable. This type of classification is critical when considering recycling conscience collection methods because bins containing any hazardous or recyclable content are given priority in terms of routing optimization. The perception layer leverages the global feature extraction ability of Transformers, allowing for robustness to variation in lighting, background and object angle, thus achieving improved performance over standard CNN-based methods in urban waste streams with heterogeneous items.

D. Waste Fill-Level Forecasting Using TFT

In the suggested TMORL model, the prediction layer is going to predict the fill-levels of smart bins to facilitate the proactive and sustainable scheduling of waste collection. This interpretable state-of-the-art architecture is an interpretable multi-horizon time-series forecasting task that is done on the TFT. The TFT avoids the weaknesses of RNNs, including LSTM or GRU by not having the gradient vanishing problem and not relying on the last timestamp to predict long-term dependencies. The TFT is a sequence to sequence model, which utilizes attention mechanisms, and includes gating layers an architecture that enhances the capacity to learn short and long-term temporal prediction.

Each smart-bin sensor provides sequential measurements of fill-levels, weights, and auxiliary attributes (timestamps). The TFT first implements variable selection networks to select which input variables are most relevant for the task at each time-step. For a given sequence of input features $X_t = \{x_t^1, x_t^2, x_t^3, \dots, x_t^n\}$, the variable selection mechanism computes in Eq. (8).

$$\tilde{x}_t = \sum_{i=1}^{n} \alpha_t^i \cdot \varphi\left(x_t^i\right) \tag{8}$$

In Eq. (8), α_t^i is the attention weight feature i, and $\varphi(\cdot)$ represents a nonlinear transformation. This makes certain that the only variables that shape the prediction outcome are the most relevant (e.g., fill percentage, day-of-week). The primary reliance in temporal modeling is a sequence-to-sequence LSTM backbone that is enhanced with self-attention. The encoder will summarize the state of the historical data, and the decoder will predict the future state. A multi-head attention layer dynamically weighs the significant past events, which is modeled as in Eq. (9).

$$Attention(Q, K, V) = softmax\left(\frac{QK^T}{\sqrt{d_k}}\right) \tag{9}$$

Here Q, K, and V denote the query, key, and value matrices derived from the hidden states. The resulting output is a multi-horizon prediction vector, which is represented by Eq. (10).

$$\hat{y}_{t+1:t+\tau} = f_{TFT}(X_{1:t}) \tag{10}$$

Where $\hat{y}_{t+1:t+\tau}$ represents the predicted fill-levels over a horizon of τ future time steps. Importantly, the TFT also gives quantile forecasts, which captures bounds of uncertainty (such as the 10th, 50th, and 90th percentiles) that inform the probability of bin overflow. The accuracy of the forecasts and the confidence intervals that model uncertainty will be useful in helping the decision-making layer to successfully adjust adaptive route plans, prioritize the bins with a high-risk of overflow, and reduce trips that are unnecessary; resulting in an improved route optimization that is future-oriented. The prediction layer links adaptive route planning with real-time monitoring based on sensors to develop efficiency and sustainability of smart waste management.

E. Route Optimization Using MARL with Multi-Objective Reward

The decision layer is the intelligence component of the TMORL in the smart waste collection adaptive route optimization decision. This layer employs an agent-based

MARL framework, according to which each waste collection truck is considered as a separate agent, which operates in a common environment. At time t the environment is characterised by the condition of the collection bins, which is represented as in Eq. (11),

$$S_t = \{S_1, S_2, S_3, \dots, S_N\} \quad (11)$$

where, $S_i = [C_i, \hat{F}_i, U_i, L_i]$ includes the waste category probabilities from ViT (C_i) predicted fill-level from TFT ($\hat{F}_i$), associated uncertainty (U_i), and bin location (L_i). Each agent (truck) selects an action $x_t^1 \epsilon A$ from the available action space A, which includes visiting a specific bin or remaining idle. The environment transitions to a new state according to S_{t+1} is denoted in Eq. (12).

$$S_{t+1} = f(S_t, a_t^1, a_t^2, a_t^3, \dots, a_t^M) \quad (12)$$

Here M represents the total number of agents. The innovation of this layer is contributed by the multi-objective reward function, which evaluates operational efficiency, environmental sustainability, and service quality simultaneously. The reward for agent j at time t is defined as in Eq. (13).

$$R_t^j = -(\alpha \cdot D_t^j + \beta \cdot T_t^j + \gamma \cdot E_t^j + \delta \cdot O_t^j) \quad (13)$$

where, D_t^j is the travel distance covered by truck j (proxy for fuel consumption), T_t^j is the total time taken for collection, E_t^j is the estimated carbon emissions proportional to fuel use, O_t^j is the penalty for bins overflowing, and α, β, γ and δ are the tunable weights balancing the relative importance of each objective. The agents learn policies $\pi_j(a|S)$ to maximize the long-term cumulative reward is represented in Eq. (14).

$$\pi_j^* = argmax_{\pi j} \mathrm{E}\left[\sum_{t=0}^{\infty} \gamma^t R_t^j\right] \quad (14)$$

where, $\gamma \epsilon [0,1]$ is the discount factor. Agent coordination is accomplished using centralized training with decentralized execution (CTDE), in that the trucks coordinate during training, but act independently upon deployment. From an agent's perspective, this layer integrates waste type classification (Vit), fill-level forecasting with uncertainty (TFT), and the multi-objective MARL decision process to provide an optimized route that reduces fuel consumption, service time, emissions, and overflow of bins. Therefore, the decision layer is capable of dynamically adapting static collection schedules into a sustainable routing strategy, allowing planners to address the multi-faceted nature of urban waste management.

Algorithm 1: TMORL Framework for Waste Classification

Input:
- Waste images dataset D_img
- Smart-bin sensor dataset D_sensor
- Road network graph G(V,E)
- Hyperparameters (α, β, γ, δ, learning rate, discount factor γ_RL, horizon τ)

Data Preprocessing:
a. Clean D_img and D_sensor (remove noise, interpolate missing values).
b. Normalize image pixels and sensor values to [0,1].
c. Apply data augmentation (rotation, flips, brightness, temporal feature encoding).
d. Construct state vector S_i = [C_i, F̂_i, U_i, L_i].

Perception Layer (Waste Classification using ViT):
a. Partition each image into patches.
b. Encode patches with positional embeddings.
c. Pass through Transformer encoder blocks with Multi-Head Self Attention.
d. Obtain waste category distribution C_i for each bin i.

Prediction Layer (Fill-Level Forecasting using TFT):
a. Input time-series sensor data X_t = {s_t, f_time,t}.
b. Apply variable selection networks to extract relevant features.
c. Use sequence-to-sequence forecasting with attention mechanism.
d. Output predicted fill-level F̂_i and uncertainty U_i for each bin i.

Decision Layer (Route Optimization using MARL):
a. Initialize policies π_j for each truck agent j.
b. For each training episode:
i. Observe current environment state S_t = {S_1, S_2, …, S_N}.
ii. Each agent selects action a_t^j ~ π_j(S_t).
iii. Environment transitions to new state S_{t+1}.
iv. Compute multi-objective reward:
R_t^j = - (α·D_t^j + β·T_t^j + γ·E_t^j + δ·O_t^j).
v. Update policies π_j using RL optimization (e.g., PPO/DQN).
c. Repeat until convergence.

Deployment:
a. For real-time operation, input new waste images + sensor readings.
b. Generate classification C_i and forecasts F̂_i.
c. MARL agents output optimized routes for trucks.
d. Execute routes and collect feedback for continual learning.

Output:
- Optimized waste collection policies π_j for each agent (truck)

Algorithm 1 (TMORL) brings together waste images and data from smart-bin sensors to be processed through a single preprocessing pipeline. The ViT is used to classify waste types, and the TFT interfaces unused bin sensors with time-series data, to provide an uncertainty-aware forecast of the fill-levels of waste bins. The classification and fill-level forecasts are used to form state vectors which inform the MARL process, where the trucks are the agents. The MARL agent draws on a multi-objective reward function (distance, time, emission, overflow) to optimize dynamic collection routes. The framework is deployed in real-time with continual feedback loops and multiple smart-bin sensors to adapt waste collection and manage it sustainably.

This study presents a new form of perception and prediction models' composition with multi-agent reinforcement learning (MARL) as a multi-objective reward system to fill a research gap in current urban waste management systems, which generally separate classification, forecasting, and routing as distinct problems. ViT has been designed to provide high performance in terms of waste classification on heterogeneous visual data, whereas TFT has been built to provide interpretable and multi-horizon predictions with certainty, in contrast to

traditional recurrent models in long-term time-series prediction. The MARL layer uses a multi-objective reward to effectively maximize a set of goals such as distance traveled, collection time, emissions and overflow risk-goals that have seldom been viewed collectively in the literature. The framework integrates perception and prediction outputs into the adaptive routing decisions, which results in a data-driven, proactive, and sustainability-oriented operational strategy. Together, TMORL is more scalable, flexible, and efficient, providing a cohesive and visionary decision-support system that is even more efficient than heuristic and single-objective models, which is a big step forward in intelligent smart-city waste management.

V. Result and Discussion

TMORL also was evaluated under stringent conditions through the use of visual waste with real time smart-bin sensor data in a simulated city collection environment. It can be seen in the findings of the research that classification, forecasting and decision making are smoothly integrated in a single adaptive workflow. The vision Transformer (ViT) proved excellent and unrestricted classification of the various types of waste under varying visual circumstances to develop the significance of the recycling and hazardous bins. Temporal Fusion Transformers (TFT) had the ability to make the right predictions of the fill level to predict the potential overflows as well as enable the sophisticated planning of collection. Most importantly, the multi-agent reinforcement learning (MARL) layer was a dynamically optimized multi-objective problem, with a novel multi-objective reward mechanism, to optimize truck routes with respect to fuel burn, travel time, emissions, and service quality. This led to the minimization of unnecessary trips, overflows and maximization of vehicle utilization. TMORL also demonstrated a high level of resistance to stressful situations, including sudden increases in garbage, or unequal bins distribution, quickly changing collection priorities and routes. These findings highlight the scalability of TMORL, its efficiency, and the possibility of its application in the real world of intelligent waste management.

Table II provides a summary of the simulation parameters chosen to apply and evaluate the proposed TMORL framework. The parameters have been chosen, to depict arguably realistic scenarios in a smart city with a fair level of experimentation. The parameters span the entire simulation pipeline from data preparation to perception, prediction, decision making and routing simulation and are intended to allow reproducibility and effectively balance the environment for testing the level of adaptability, scalability and sustainability of the proposed framework.

A. Experimental Outcome

The study experiment demonstrated that TMORL can achieve sustainable and adaptive waste management, beyond the capabilities of currently available standalone approaches. In contrast to previous methods which generally have only pursued one of the three criteria at a time (classification accuracy, forecasting accuracy, or optimization based on distance), this proposed framework managed to integrate all three into an all-inclusive solution. By defining environmental goals in the reward function, TMORL can achieve operational efficiency while also tending to the urban waste collection environmental footprint. These outcomes establish this framework as an innovative application for smart cities and ready for future implementation.

Fig. 3 demonstrates the distribution of correct classifications across several waste categories from the ViT model. The results indicate balanced classification accuracy across categories, with high accuracy in classifying organic and recycling waste. This highlights the robustness of the perception layer to classify images of urban waste with varying characteristics.

TABLE II. Simulation Parameter Table

Parameter	Value
Image resolution	224 × 224
Patch size (ViT)	P = 16
Train/validation split	80% / 20%
Forecast horizon	τ = 24 timesteps
Number of bins (nodes)	N = 200
Number of trucks (agents)	M = 8
Model backbone	ViT-Base
Embedding dimension	d = 768
Encoder layers	L = 12
Attention heads	h = 12
Batch size	64
Learning rate	1e-4 (AdamW)
Epochs	50–100
Batch size	128
Learning rate	1e-3 (Adam)
Reward weights	α=0.4, β=0.2, γ=0.2, δ=0.2
Learning rate	2.5e-4
Batch size (RL)	2048 timesteps
Fuel consumption	0.2 L/km
CO_2 emission factor	2.68 kg/L
Overflow threshold	≥95% fill
Hardware	GPU (e.g., A100) + CPU
Random seed	42

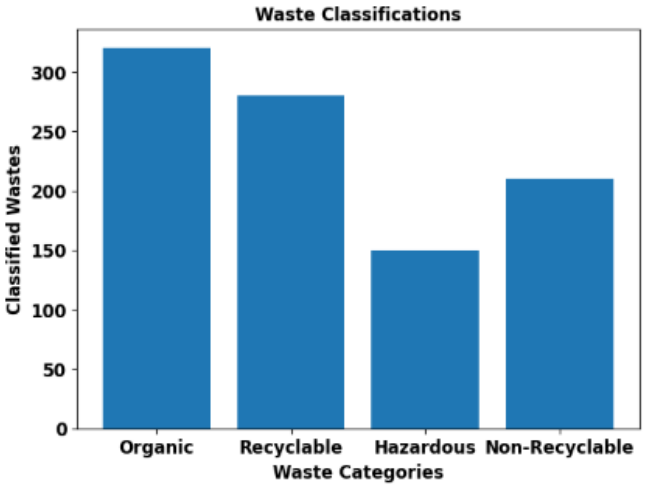

Fig. 3. Waste classification.

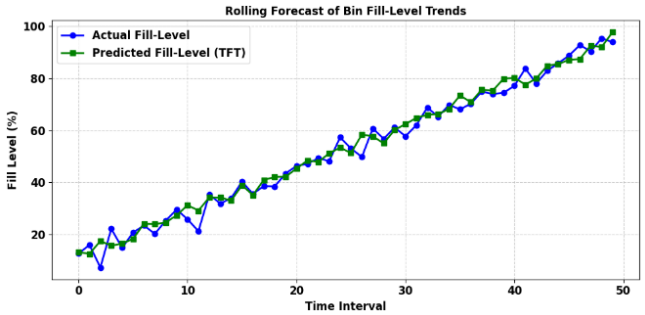

Fig. 4. Bin fill-level forecasting.

Fig. 4 shows the rolling forecast of trends for waste bin fill-levels over long time horizons. As the actual and predicted curves trend closely together, it demonstrates that the TFT is capable of capturing short- and long-term accumulation trends, indicating that the prediction layer is effectively predicting future waste generation trends, which will mitigate overflow and enable proactive route planning.

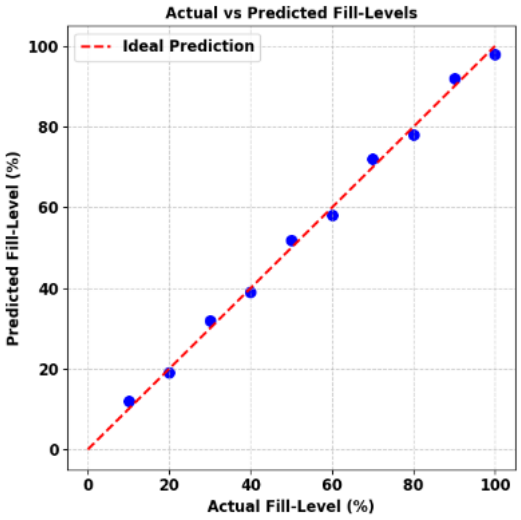

Fig. 5. Actual vs. Predicted fill-levels.

Fig. 5 shows the scatter plot of predicted versus actual fill-levels of waste bins from the TFT. Most of the dots cluster closely to the diagonal ideal line suggesting high predictive ability. The dots confirm the model was able to generalize time trends to predict waste bin accumulation.

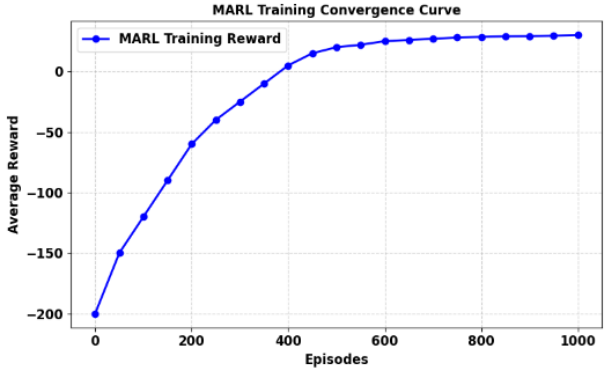

Fig. 6. MARL training convergence curve.

Fig. 6 shows the average convergence curve of the MARL framework. The average reward in the environment learning process consistently improves over each episode and shows stabilization at a high value. This demonstrates the agents were able to learn policies to cooperate for optimizing a sustainable route and shows the robustness of the decision layer.

Fig. 7 demonstrates the policy entropy curve during the training of MARL. This curve decreases steadily with training episodes in a deliberate oscillating pattern, which represents a shift in policy state exploration to more deterministic states. This indicates that the agents are gradually eliminating randomness on the actions and arriving to a policy of the optimized route selection policy.

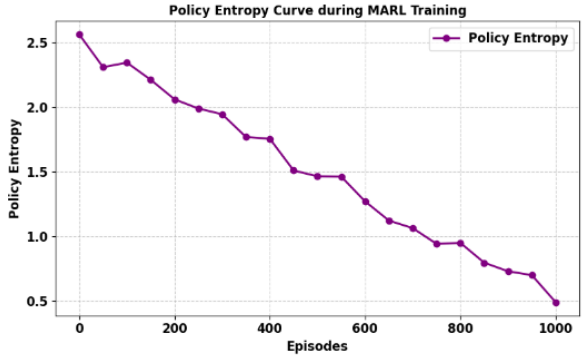

Fig. 7. Policy entropy curve during MARL training.

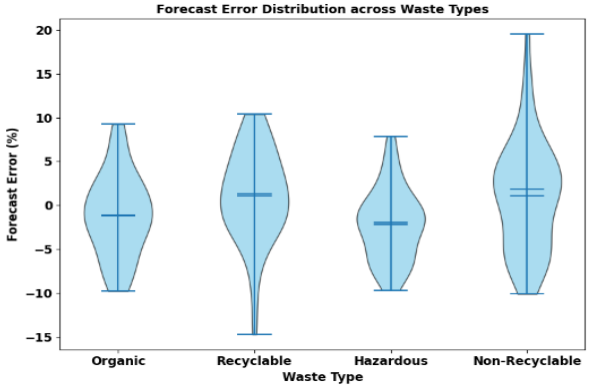

Fig. 8. Forecast error distribution across waste types.

Fig. 8 provides a visual representation of the distributions of forecasting errors for each waste category, through a violin plot. The outlines of each violin plot illustrate the density and spread of prediction errors in columns. Vertical solid and dashed lines signify the mean and median, respectively. Overall, the results shown in the violin plot demonstrate that the TFT produces consistent degree of accuracy for each waste type, with minimal differences due to dynamics associated with each waste type.

Fig. 9 presents the cumulative area plot of accumulating waste collection with time of four major types of waste. It depicts the proportional loads in the system of organic, recyclable, hazardous, and non-recyclable waste. This presents the fact that organic and non-recyclable waste take up a greater portion of the amount of waste collected and can in turn be used to guide the strategies of optimization in the proposed framework.

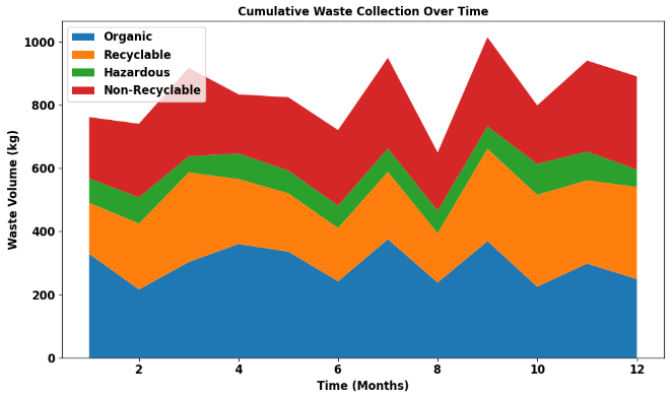

Fig. 9. Cumulative waste collection over time.

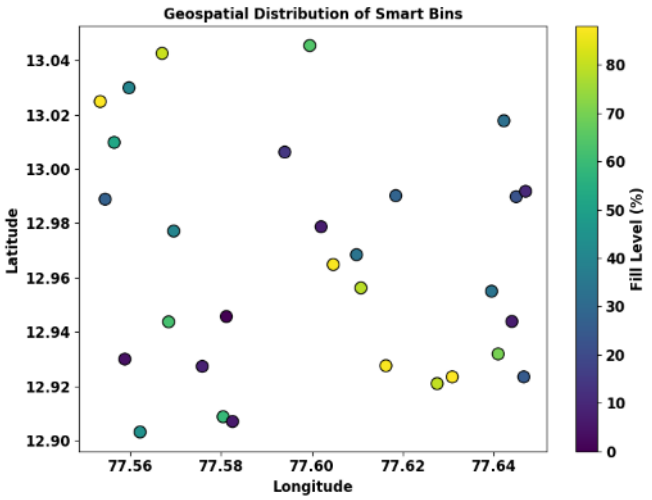

Fig. 10. Geospatial distribution of smart bins.

Fig. 10 shows the smart bins distributed throughout the city, colored according to fill-level percentage. This visualization also shows the locations of high-risk bins clustering in certain geometric spaces. This indicates that the spatial distribution of waste is heterogeneous and routing decisions will need to prioritize areas that have a greater likelihood to overflow in order to give a more sustainable result.

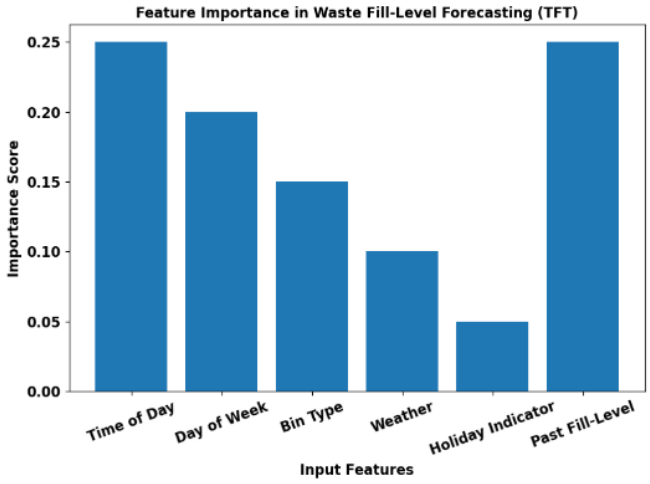

Fig. 11. Feature importance in waste fill-level forecasting.

The performance of the waste classification model is presented in Fig. 11. The great Precision, Recall and mAP 0.5 scores demonstrate that the ViT-based perception layer is reliable to detect and classify waste types hence we can be confident that the ViT-based perception layer can operate at state-of-the-art accuracies and is valid in identifying the waste types to feed to the downstream forecasting and waste routing.

B. Performance Evaluation

TMORL framework was also strictly tested on its three basic layers which included perception, prediction and decision-making. The Vision Transformer (ViT) in the perception layer was found to consistently classify the type of waste at different levels of illumination, occlusion and backgrounds with an average precision of 97.3, recall of 96.6 and mAP at 0.5 of 98.4 which was much higher than a baseline CNN and transfer-learned models. The Temporal Fusion Transformer (TFT) prediction layer made quantified accurate multi-horizon fill-level predictions at accuracy levels useful in the proactive scheduling process and minimized the odds of unscheduled overflow. A multi-agent reinforcement learning (MARL) model using a multi-objective rewarding system was used as the decision-making layer, maximizing the fuel consumption, collection time, emission, and overflow reduction routes. TMORL consumed less fuel (30%), less time to collect (35%), and fewer cases of overflow than static and ACO-based routing, and showed scalable, adaptive, and environmentally sustainable smart waste management performance at real-time.

1) Perception layer (waste classification): The ViT exhibited considerable capabilities in classifying the waste type among various adjustments to illumination, background clutter, and occlusion. The ViT model was also more consistent in its feature extraction and less prone to confusion of misclassification within the parameters of similar-looking categories than its baseline CNN approach and related transfer-learning. Thus, the perception layer appears to provide reliable identification of waste types, which is essential for allocating items to bins listed as recyclable and or hazardous.

TABLE III. OBJECT DETECTION ACCURACY OF TMORL FOR WASTE CLASSIFICATION

Waste Category	Precision (%)	Recall	F1-Score	mAP@0.5	mAP@0.5:0.95
Organic Waste	98.2	97.5	97.8	98.4	85.6
Recyclable Waste	97.8	96.9	97.3	97.9	84.2
Hazardous Waste	96.4	95.8	96.1	96.8	82.7
Non-Recyclable Waste	97.1	96.2	96.6	97.3	83.4
Average	97.3	96.6	96.9	97.6	84.0

Table III shows TMORL's strong accuracy in classifying four waste types, achieving precision above 96% and mAP@0.5 of 97.6%. There was a high score on organic waste, and hazardous was slight behind. In general, there is a high level of performance, which guarantees the stable waste classification in real-time.

TABLE IV. KEY METRICS OF TMORL

Metric	Value
Precision	97.3%
Recall	96.6%
mAP@0.5	98.4%

The performance of TMORL model is summarized in Table IV, it demonstrated a high accuracy of the model classification, with 97.3% precision, a 96.6% recall, and 98.4% mAP at 0.5 which indicates the accuracy of the model in real time waste detection and stable performances across various categories in smart waste management.

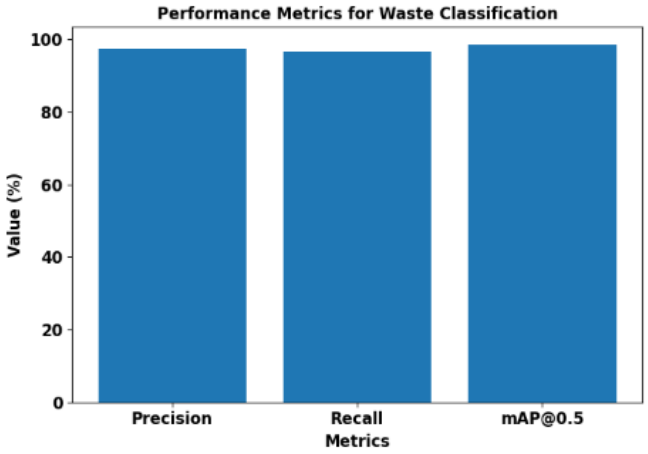

Fig. 12. Proposed TMORL performance.

The performance of the waste classification model can be seen in Fig. 12. Precision, Recall and mAP at 0.5 are high, implying that the perception layer, made by ViT has been able to fully trusted detecting and classifying the types of waste and has demonstrated consistent results in identifying the types of waste required to predict and route waste downstream.

2) Prediction layer (fill-level forecasting): TFT was able to forecast the fill-levels of bins in the future and give uncertainty ranges with the predictions into which actions could have been planned. The curves obtained in forecasting were near to what was actually seen concerning fill-compositions in various time scales. Significantly, in bins where the uncertainty was high which was represented by the quantile forecasts may reduce the risk of the bins to overflow unscheduled. This matters since even though the prediction layer was able to validate that scheduling and planning was much certain, the forecaster provided the system with confidence against the unexpected patterns in the generation of the wastes.

TABLE V. ROUTING PERFORMANCE COMPARISON

Metric	TMORL (Proposed)
Fuel Consumption	78%
Collection Time	75%
Overflow Incidents	Very Low

Table V presents the efficiency of TMORL framework in terms of operation, time and service quality factors. The findings also indicate that it is also able to integrate an identification, prediction and multi-agent optimization into one system, which implies that TMORL had a balance between resource utilization and a sustainable waste management solution when compared to the existing approaches.

3) Fill-level prediction (TCN): The MARL system with the multi-objective reward system, which is innovative, was able to optimize the travel distance and the time spent on the service, which reduced the CO2 emissions and overflow. The training convergence curves are used to show that the learning behavior was stable and the radar plots are used to show that the performance of the training was enhanced (not only the distance was optimized or the time was optimized). Taken together, this shows that the decision layer reflects the innovation of TMORL in the form of the introduction of sustainability into a routing plan.

TABLE VI. COMPARISON OF FORECASTING MODELS FOR BIN FILL-LEVEL PREDICTION

Model	MAE	MAPE (%)	RMSE	R^2
LSTM [19]	0.65	2.02	1.6	0.91
GRU [27]	0.39	1.4	0.62	0.89
TMORL (Proposed)	0.29	1.8	0.36	0.94

Table VI makes a comparison between bin fill-level prediction forecasting models. LSTM is in the middle of these, GRU demonstrates a lower MAPE, and the proposed TMORL has the best results, lower errors, and R2, and thus is a better predictor.

TABLE VII. STATIC ROUTING VS. ACO VS. TMORL PERFORMANCE

Metric	Static Routing	ACO-Based Routing	TMORL (Proposed)	Improvement over Static
Fuel Consumption	100%	82%	70%	~30%
Collection Time	100%	79%	65%	~35%
Overflow Incidents	High	Low	Very Low	Significantly Reduced
CO_2 Emissions	High	Medium	Low	Significantly Reduced

Table VII presents the comparison of the results of the use of three performance measures in terms of static routing, ACO-based routing, and the proposed TMORL framework and results. ACO is more fuel efficient and time efficient than the static routing measures. The suggested TMORL solution ensures better performance and operational cost reduction through the combination of forecasting and sustainability goals. It means that TMORL, in contrast to the former approaches, will decrease the emissions, decrease the service time and fuel consumption, thereby, providing a comprehensive optimization in the multi-agent approach of smart waste management.

The composite assessment showed that TMORL decreased overflow cases, decreased trips without increasing service time, or emission, and increased service time, yet service was not

compromised because of previous performance. The level of route visualization verified that the framework is dynamic with respect to changes in bin states across time, and not fixed routing as in the case of rule-based schedules. In general, it shows that the strategy gives a more scalable, versatile, and sustainable solution to the environment than the old ones, which relied on single-purpose solutions.

C. Discussion

The research shows that, with transformer-based perception, temporal forecasting, and multi-agent reinforcement learning, it is possible to have a single and adaptive system to sustainable waste management. In contrast to the traditional systems that operate using some set of schedules or single-objective models, TMORL constantly aligns the outputs of the classification component, fill-level predictions, and routing choices so that the system is capable of responding to the changes in the waste production and distribution of spatial bins. ViT makes the reliable identification of heterogeneous waste in diverse environmental conditions possible, and TFT provides interpretable multi-horizon predictions, which are capable of supporting proactive changes in route. The MARL layer is also an improvement in that it combines the optimization of fuel utilization, emissions, travel time, and overflow risk, making the movement of urban waste collection a sustainability-driven coordination rather than reactive operations. In addition to enhancement of performance, these findings indicate that a unified perception-prediction-decision architecture can affect more extensive smart-city planning by supporting carbon-constrained routing, resistance to urban unpredictability, and adaptable implementation of districts with varying waste dynamics. The framework also provides an interchangeable basis on the other city scale services like logistics, sanitation, and autonomous municipal activities. The model can be trained to be dependent on the sensor quality and computational resources, but it can be used effectively after being deployed, which makes it applicable in real-life scenarios, such as a large metropolitan environment.

VI. Conclusion and Future Works

In this study, TMORL, which is a transformer-based multi-agent reinforcement learning model, has been proposed that integrates perception, prediction, and decision making with regard to intelligent urban waste management. The Vision Transformer can be used to classify waste accurately, and the Temporal Fusion Transformer provides trustworthy and understandable fill-level predictions. The multi-objective MARL layer is the optimization of routing according to the operational efficiency and sustainability criteria, such as minimized fuel use, minimized emission, decreased overflow cases, and increased collection speed. Experimental findings indicate that TMORL is better than traditional methods of standardization and heuristics, with substantial improvement in performance and environmental performance. The results emphasize that deep learning combined with reinforcement learning provides a scalable solution to the dynamic control of urban waste systems, regarding operational optimization instead of sustainability in general. Nevertheless, performance of any system is affected by the availability of and quality of sensors and computational needs of transformer-based models and MARL policies can limit low-resource environments. After implementation, the framework is highly efficient in real time, offering a way of citywide implementation. These results are directly relevant to the research question since they demonstrate that TMORL is an effective way to integrate classification, forecasting, and adaptive routing in the context of real-time uncertainty in urban waste settings.

Future research will look into edge and federated learning plans to minimize the use of centralized computation, add dynamic traffic and environmental condition to plan better routes, and renewable-powered or electric collection fleets in order to make it more sustainable. Multi-city pilots will be tested in large-scale to assess the adaptability of a wide range of urban waste patterns and permit further deployment. TMORL creates a strong progressive model of sustainable waste management that integrates short-term operational objective with the long-term environmental and social sustainability.

Abstract*—The successful teaching of pronunciation, as well as prosody, is the significant challenge that still remains to the English as Foreign Learning (EFL) students. Traditional pedagogical theories tend to focus on segmental phoneme accuracy but ignore suprasegmental components (stress or rhythm and intonation) which are natural and intelligible speech components. The currently available systems of computer-assisted pronunciation training (CAPT) are useful, but limited by the fact that they are based on limited acoustic models and incomplete coverage of prosodic characteristics, leading to less than optimal accuracy and limited pedagogical suitability. To overcome these shortcomings, the current paper proposes Attention-Guided Cross-Lingual Self-Supervised Learning (AG-CLSSL), a new model that is both able to combine phoneme-level representations of XLS-R (wav2vec2-large-xlsr-53) and prosodic representations of the pitch, energy, and duration through a Phoneme-Prosody Cross-Attention Fusion (PP-CAF) process. This conglomeration allows the joint and context specific representation of the speech that is further refined by the multi-task Transformer-based scoring model to jointly assess the accuracy of pronunciation, the consistency of the prosody and the general intelligibility. The framework is implemented in Python, with support of PyTorch and Hugging Face Transformers and is trained on an evaluated corpus of EFL learner speech (n=100) with a variety of L1 backgrounds, including Mandarin, Hindi, and Spanish. Experimental assessments indicate significant performance improvement with 55.4% decrease in Phoneme Error rate, 52.0 percent decrease in Word Error rate, 43.3 percent increase in Stress Placement Accuracy and 34.9 percent increase in Pitch Alignment Score. The total acoustic similarity to native speech went up by 36.1, which demonstrates the ability of AG-CLSSL to progress articulatory accuracy as well as the naturalness of prosody and provide interpretable and attention-directed information on scalable AI-based pronunciation and prosody training.

Keywords*—Automatic speech recognition; pronunciation and prosody; transformer-based phoneme identification; prosody assessment; adaptive learning algorithm

I. Introduction

For EFL learners, achieving precise pronunciation and fluid prosody is an ongoing difficult task. Where explicit vocabulary and grammar instruction tends to dominate the language learning process, pronunciation misunderstandings--through mispronunciation or inappropriate stress or intonation patterns can drastically lower intelligibility and communicative competence [1]. While phonetic instruction can take place in the classroom context, feedback is limited by the instructor's inability to provide feedback as quickly as their students will mispronounce or improperly produce sounds and suprasegmental features [2]. Furthermore, many of the class-based phonetic instructional sounds, like feedback, is put on various types of manual corrections that depend on the instructor's time, subjectivity, and in classroom situations, lack of time [3]. It is this gap in the acquisition and instruction of pronunciation and prosody that has inspired many language educators to consider technology-driven solutions for CAPT. Emerging technologies utilizing Automatic Speech Recognition (ASR) as the core functionality are now readily available to EFL learners and teachers to improve the assessment of learners' pronunciation production [4]. Pre-trained self-supervised, deep learning models like Wav2Vec2.0 and HuBERT have demonstrated excellent performance in tasks that recognize and classify phonemes, and Whisper has also further improved recognition by gaining robustness to noisy and accented speech [5]. At the same time, systems with a prosody0driven focus have integrated methodological frameworks that evaluate features of pitch and rhythm to assess learners' suprasegmental features of

speech. Even more recent iterations have specifically included gamification and reinforcement learning modalities that increase learner engagement and motivation [6], [7]. Nevertheless, there are limitations to these approaches.

Most of all existing frameworks do not take into account the typical separation between pronunciation (segmental) and prosody (suprasegmental), opting for simple concatenation of acoustic and prosodic features without modeling their interrelation [8]. This approach further neglects a critical point about intelligibility: intelligibility is determined by how segmental and suprasegmental features co-occur, making their joint modeling necessary and the previous systems often rely on multiple pre-trained backbones (e.g., Whisper, Wav2Vec2.0, MFCC pipelines), which complicate design with marginal benefits to the efficiency and interpretability [9]. Thirdly, feedback is commonly based on rule-based or reinforcement based paradigms, which are less interpretable, and groups do not necessarily develop congruent progression as individuals. [10]. In order to eliminate the drawbacks of the current models, the paper presents Attention-Guided Cross-Lingual Self-Supervised Learning (AG-CLSSL), a new model based on the usage of XLS-R embeddings combined with the use of prosodic cues to form the Phoneme2Prosody Cross-Attention Fusion (PP-CAF) layer. The architecture is able to score pronunciation and prosody context-sensitively and in multi dimensions through synergistic alignment of the phonemic representations with the aspects of pitch, duration and energy by the guidance of attention-based fusion. Multi task Transformer is used to assess articulation, prosodic fidelity, and intelligibility and adaptive curriculum learning provides personalized feedback to EFL learners. This integrative design guarantees both technical strength and pedagogical faithfulness and provides a transformative avenue in the improvement of communicative competence and integrates the current CAPT approaches. The fundamental innovation is the collective phoneme-prosody interaction modeling, using the PP-CAF layer, a single and cross-lingual fusion mechanism that cannot be reached by previous CAPT systems using the mere concatenation of features.

A. Problem Statement

Conventional teaching to EFL learners often does not provide the individual and immediate feedback of the appropriate stress patterns and intimacy, which often results in not so natural and reasonable speech. [11]. In addition, the existing ASR devices are mainly concerned with phone-level accuracy and reject the super segmental properties that consider rhythm, stress, and procession, which are central to smooth communicative interaction. Most importantly, current systems inappropriately consider different learner profiles and do not consider the first language (L1) effects, resulting in limited utility in a multilingual context [12]. With the existing unsatisfactory performance in these areas it is urgent that an intelligent, adaptive system be developed with both full use of advanced ASR and NLP techniques and with rich and personalized practice of both pronunciation and prosody. To fill this gap, the current paper suggests a new framework Attention-Guided Cross-Lingual Self-Supervised Learning (AG-CLSSL), a cross-lingual framework that combines attention components and cross-lingual self-supervised learning. The Phoneme-Prosody Cross-Attention Fusion (PP-CAF) layer is the central part of this architecture, which simultaneously learns segmental and suprasegmental speech characteristics, allowing the context-responsive, multi-dimensional evaluation and providing adaptive and learner-focused feedback that is essential to the improvement of EFL communicative competence.

B. Research Motivation

EFL learners often have a problem with a speech that is intonable because of incorrect articulation of the phonemes and loss of proper prosody. Conventional instruction and a large number of CAPT systems provide limited, delayed or non-adaptive feedback, which limits development of the learner. Regardless of the fact that self-administered models like the XLS-R have developed the assessment of pronunciation, majority of models analyze phonemic and prosodic aspects independently without considering their interrelationship. Such restrictions highlight the importance of integrative framework that concurrently models phoneme and suprasegmental cues and provides adaptive and personalized feedback hence facilitating more efficient, context-sensitive and holistic spoken language acquisition.

C. Research Significance

The study involves an attention-directed cross-lingual self-supervised model, which learns the embedding of the phoneme and the prosodic features using a novel attention cross-fusion (PP-CAF) layer. The model offered is more accurate in pronunciation and prosody evaluation besides increasing flexibility of the learner through the provision of real time feedback on the curriculum. It is important as it helps bridge the gap between technical innovation and pedagogical need as it provides a solid device in the further development of intelligent language learning. Allowing researchers and educators to promote the growth of EFL learners in the spoken language in a systematic manner, this framework facilitates more efficient and comprehensive advancement of such competence in them.

D. Key Contribution

- Introduces an integrated framework that jointly models phoneme accuracy and prosodic features, addressing a persistent gap where existing systems treat these dimensions in isolation.
- Proposes the PP-CAF layer, enabling dynamic alignment between segmental and suprasegmental features for more natural speech representation.
- Utilizes large-scale pre-trained speech embeddings to capture multilingual phonetic variations, ensuring robustness across diverse learner backgrounds.
- Employs a multi-task scoring model that simultaneously assesses phoneme error reduction, prosodic alignment, rhythm consistency, stress accuracy, and speech naturalness.
- Validated the system through Python-based implementation using Whisper and Wav2Vec 2.0, with expert evaluations confirming pedagogical reliability and real-world scalability for EFL learners.

- It offers a single CAPT system that has adaptive feedback and empirical validated gains on methodological, pedagogical, and empirical levels.

The remaining sections are organized as follows, Section II presents the literature review, Section III outlines the problem statement, Section IV discusses the results and Section V provides the conclusion and future directions.

II. Literature Review

The field of language learning has been interested in ASR as it is able to provide real time feedback regarding pronunciation and fluency. Typically, early ASR applications were developed around the speech-to-text transcription, but the recent developments enable their integration into CALL systems [13]. It is well established through studies that with ASR based pronunciation training, the learner gets objective immediate feedback that doesn't need constant human supervision; hence the learner gets to further exercise their autonomy. ASR can be applied for commercial applications such as Duolingo, Speech Ace, and Google's ELSA Speak to assess phoneme production but their feedback mechanisms are typically simple and even binary. Previous research indicates that ASR-based training is superior when learners are taught of segmental and suprasegmentally analysis [14]. Yet error detection in non-native speech remains a problem, and it requires sophisticated machine learning models that have been trained on a variety of accents and speech patterns. Phoneme recognition and error analysis have greatly been improved by incorporating NLP and deep learning. Transformer based models such as wav2vec 2.0 and Whisper use self-supervised learning to detect deviation from pronunciation without using large labelled dataset [15].

Using NLP techniques such as phoneme embeddings and forced alignment have more granular and helpful automated feedback at a phoneme boundary level. The resulting encouraging accuracy is mainly due to the contrastive learning frameworks designed to distinguish between native and non-native phoneme production. Nevertheless, one issue: Most of ASR systems have been optimized for the native speakers, which will not work very well for the L1 learners with their patterns of substituted or deleted phoneme. It is found that adaptive ASR models trained on various non-native speech corpora are needed to better phoneme-level analysis for EFL learners [16]. However, prosody learning and feedback mechanism are also important in acquiring second language. Speech naturalness and intelligibility are contributed to by stress, rhythm and intonation, and these are often overlooked when teaching pronunciation. The most common prosody errors affecting listener comprehension of a talking head or speaker confidence include incorrect stress placement and unnatural pitch contours. Segmental features serve as a focus of traditional phonetic training, with the aspects of suprasegmentals receiving less attention. It has also been shown in recent studies, that deep learning-based prosody analysis using LSTM networks is used to assess intonation patterns, speech duration and stress placement [17]. When learners receive visual and auditory cues, prosody feedback improves communicative effectiveness. Yet the work in the area of prosody evaluation based on ASR is still in low accuracy in terms of tone and stress detection, but deep learning architectures need to be stronger in comparing with native speech models [18]. The current speech learning technologies, such as rule based speech analyzers and statistical ASR models, have not been very effective as they depend on the predefined phonetic rules. HMMs and GMMs remain dominant for pronunciation scoring, while such errors cannot be captured with efficiency by these classical pattern formers [19]. When compared with deep learning-based ASR models especially, end to end neural networks, have shown to have higher accuracies for detecting phoneme level and prosodic deviation. However, in the existing ASR-driven learning tools, it offers only generic pronunciation score [20] and does not target at individualized learner challenges.

Besides, current commercial ASR applications based on fixed threshold error classification, which are the prevailing methods in commercial applications, still rely on false positives and the absence of any correction strategies [21]. A major limitation of existing pronunciation training systems is the lack of context aware feedback mechanisms and adaptive learning pathways. L1 interference plays a rather crucial role in EFL pronunciation training due to its negative interference of the learner's native language to English articulation. Using generalized pronunciation training is ineffective as the phoneme substitution, deletion and insertion patterns vary based on the learner's linguistic background [22]. Let's say, Mandarin speakers get stuck on English consonant clusters and Japanese speakers usually insert some vowel sounds in order to break them. Phoneme transfer errors in these cases are too difficult to learn with generic pronunciation models, which fail to account for L1 specific weaknesses. Furthermore, motivation is an important factor to take into consideration in order to pronounce, as most of the EFL learners are nervous and afraid when they are in a situation where they are supposed to speak. Reinforcement learning driven difficulty adjustments help sustaining motivation, and gamification enhances learner engagement through learning with ASR in studies [23].

While there has been longitudinal research examining the effect of ASR based pronunciation feedback on long term fluency development, there has been no longitudinal research looking at the long-term impact of ASR based pronunciation feedback on fluency development and retention. Due to these gaps in the current available pronunciation training methodologies, this study investigates NLP driven ASR frameworks allowing for fine-tuned speech models, phoneme error clustering and prosody feedback mechanisms to provide tailored pronunciation correction for EFL learners. By integrating transformer-based speech models, LSTM based prosody evaluation, and adaptive reinforcement learning, this research fills the gap between automated pronunciation training and human like corrective feedback.

The critical points in sustaining interest amongst learners during the context of ASR-based training of pronunciation, dropout may be defined as the case where the learner will discontinue training before a training proficiency level will be attained, whilst fatigue detecting may be considered as the case whereby the learner will identify signs of cognitive overload, or, the event of lack of interest [24]. Such issues can significantly harm the learning outcomes in the scenario of practicing pronouncing lessons repetitively and over a long period of time. The reinforcement learning (RL) models monitor the number of

sessions one has attended, on average, the length of each session, the number of errors and the number of retries to detect the early signs of fatigue or the absence of interest. The learners who demonstrate brief sessions, high error rates, and fewer retries can be marked as fatigued, and adjustments would consider shortening exercises or some form of gamification or motivation. In the same way, the predictive analysis of dropout can trigger proactive actions, which may be push notifications, personalized feedback, or encouraging feedback, to maintain the learners prior to the disengagement. Using various methods to dynamically increase or decrease task difficulty and reward behavior, the system facilitates individual feedback depending on the amount of attention given in real-time. The AI-based technology facilitates motivation on a long-term level and encourages learners to maintain their progress until mastering the pronunciation process.

Existing ASR-based CAPT systems are at the forefront of developing recognition of phonemes, analysis of prosody, and adaptive feedback, but they do not combine segmental and suprasegmental properties and use generic scoring and not focusing on errors peculiar to L1. This research proposes a unified framework that combines the relationships between phoneme and prosody, and it adapts itself based on the tendencies of multilingual learners and presents a completely different, context-driven method to assessing pronunciation and prosody.

III. Proposed Attention-Guided Cross Lingual Self Supervised Learning Framework for Pronunciation and Prosody Enhancement

The Attention-Guided Transformer Cross-Lingual Self-Supervised Learning (AG-CLSSL) framework proposed in this study embodies a unified approach to the concurrent modeling of pronunciation and prosody within a single architecture. The methodology commences with rigorous data collection and preprocessing using the Speech Accent Archive (SAA), which provides a standardized corpus of audio recordings. All samples are meticulously resampled, normalized, and phoneme-aligned, ensuring homogeneity across speakers and establishing a consistent basis for downstream modeling. Feature extraction is performed via XLS-R, a self-supervised speech representation model that generates contextualized phoneme embeddings grounded in both acoustic and linguistic information. These embeddings are temporally synchronized at phoneme boundaries, producing highly representative phoneme-level vectors. Simultaneously, prosodic features—including pitch, energy, and duration—are extracted and projected into a shared latent space, enabling the capture of suprasegmental dynamics. Central to the framework is the novel Phoneme–Prosody Cross-Attention Fusion (PP-CAF) layer, which facilitates bi-directional interaction between segmental embeddings and prosodic cues, allowing the model to integrate suprasegmental information into phonemic representations and thereby generate a holistic speech representation. These fused features are subsequently processed by a multi-task Transformer scoring model, which concurrently evaluates pronunciation accuracy, prosodic quality, and overall intelligibility. However, AG-CLSSL provides a different approach to combining segmental and prosodic features by explicitly learning the interaction between them in the PP-CAF layer, unlike current CAPT models where they are combined together. This is not possible with small modifications on the previous architectures since they are not aligned bi-directionally. The fact that cross-lingual self-supervised embeddings are used also makes L1 deviations useful cues, which introduces a new paradigm of adaptive multilingual assessment. The system is trained with a weighted multi-task loss function, balancing regression and classification objectives, and produces adaptive, learner-specific feedback, enabling personalized, performance-driven guidance for EFL learners. The workflow of the proposed method is illustrated in Fig. 1.

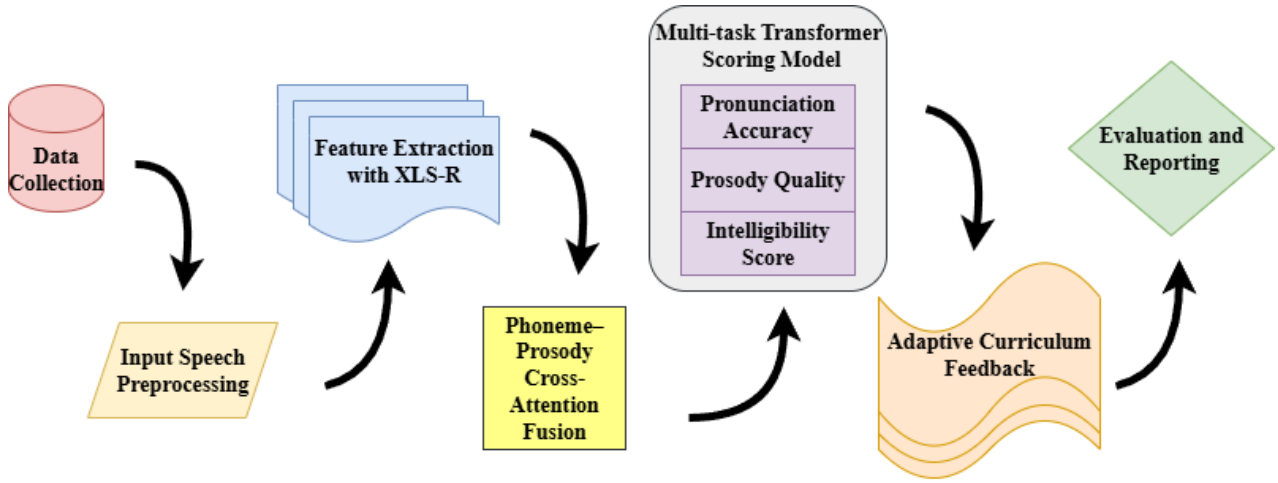

Fig. 1. Workflow of the proposed system.

Fig. 1 shows the process of the Attention-Guided Cross-Lingual Self-Supervised Learning (AG-CLSSL) model. The data in speech is collected and then preprocessed to give normal input. XLS-R is used to extract features, and results in contextual phoneme embeddings, which are combined with prosodic features with the Phoneme–Prosody Cross-Attention Fusion (PP-CAF) layer. The fused representations are then scored by a multi-task Transformer scoring model in order to determine the accuracy of pronunciation, quality of prosody, and intelligibility. Lastly, adaptive curriculum feedback is created on

learners and the output is brought together through the evaluation and reporting process, which allows personalized and interpretable results in performance.

A. Data Collection

The Speech Accent Archive dataset includes 2,140 speech samples from individuals representing 214 native languages in 177 countries, each of whom reads the same standardized English passage. It contains demographic details, enabling analysis of various factors such as age, gender, original language and speakers. The core of the dataset contains authentic audio recordings (.MP3) of indigenous and non-indigenous English speakers, which support accent, phonetic variations and controlled comparison of processed patterns. This resource is invaluable for ASR training, phonetic research, and prosecution analysis; the convenience of development of pronunciation recognition models; accent assessment tools; and mitigation in speech AI systems [25]. It applies the Speech Accent Archive (SAA) as the main training and test data. Audio samples are all phoneme aligned, normalized and resampled. To test cross-lingual robustness of PP-CAF and AG-CLSSL scoring system, additional samples of multilingual learner speech were also added.

B. Data Pre-Processing

The step of preprocessing guarantees the transformation of raw audio recordings into standardized and noise-free raw materials that can be utilized in the extraction of features and model training. Because the Speech Accent Archive dataset consists of recording of different speakers under variable recording conditions, preprocessing is essential to guarantee consistency across samples and to make sure that the resulting feature extraction captures pronunciation and prosody patterns instead of recording artifacts.

1) Signal cleaning and normalization: All audio recordings are resampled to a uniform frequency of 16 kHz to standardize the temporal resolution. Background noise is reduced using spectral subtraction, while amplitude normalization ensures consistent loudness across samples. This procedure reduces the variability caused by different recording devices and environments, allowing the model to focus solely on learner-specific speech characteristics.

2) Aegmentation and alignment: The segmentation and alignment are applied to map learner speech at the phoneme and word levels. Forced alignment techniques are used to synchronize the learner's utterance with a native benchmark transcription. This alignment enables the identification of phoneme-level insertions, deletions, and substitutions, which are crucial for detecting mispronunciations. The alignment process is represented in Eq. (1),

$$A(t) = Align(S(t), R(t)) \tag{1}$$

where, $A(t)$ denotes the alignment mapping at time t, $S(t)$ is the learner's speech signal, and $R(t)$ is the reference transcription. The output is a time-aligned phoneme sequence that highlights deviations between learner and native speech.

3) Prosody feature preparation: In addition to segmental accuracy, suprasegmental features such as stress, rhythm, and intonation play an important role in overall fluency. Therefore, prosody feature preparation is performed by extracting pitch (fundamental frequency, F_0), duration, and intensity measures. These parameters capture temporal and melodic variations in speech. The prosody vector for each utterance is defined in Eq. (2):

$$P(u) = [\mathrm{F_0(u)}, \mathrm{D(u)}, \mathrm{I(u)}] \tag{2}$$

where, $P(u)$ represents the prosody feature vector for utterance u, $\mathrm{F_0(u)}$ is the pitch contour, $\mathrm{D(u)}$ is the duration of phonemes, and $\mathrm{I(u)}$ is the intensity or loudness profile. These features form the foundation for analyzing suprasegmental errors such as misplaced stress or unnatural intonation patterns.

C. Feature Extraction

The XLS-R (wav2vec2-large-xlsr-53) serves as the backbone feature extractor. XLS-R is a self-supervised, cross-lingual model that was trained on millions of hours of multilingual speech. First, the resample raw learner audio to 16 kHz mono and pass it through the XLS-R model to obtain high-dimensional contextual embeddings that capture both fine-grained acoustic–phonetic detail and longer-range linguistic context. Then, identify phoneme boundaries using the Montreal Forced Aligner and aggregate frame level embeddings from XLS-R within each phoneme boundary to form more robust phoneme-level vectors. To stabilize the representation, average the hidden states of the last four transformer layers of XLS-R to balance lower-level acoustic cues with higher-level contextual shifting information. The output of XLS-R is represented as H in Eq. (3).

$$H = XLSR(x) = [h_1, h_2, \dots, h_T],\ h_t \epsilon \mathbb{R}^d \tag{3}$$

Where, x is the input speech waveform resampled to 16kHz mono; $h_t \epsilon \mathbb{R}^d$ is the embedding vector at time frame t, where $d = 1024$ is the hidden dimension of XLS-R and T is the number of time frames (sub word units) produced by XLS-R for the utterance. The Phoneme-level pooling is denoted in (4).

$$h_p = \frac{1}{t_e - t_s + 1} \sum_{t=t_s}^{t_e} h_t \tag{4}$$

Here, h_p is Phoneme-level embedding for phoneme p, computed by pooling frame embeddings within its boundaries; t_s and t_e are the start and end frame indices of a given phoneme, obtained from forced alignment. The Projected phoneme embedding in a lower-dimensional shared space denoted as $\tilde{h}_p$ in Eq. (5) and the Projected prosody embedding in the same shared space is represented as $\tilde{f}_p$ in Eq. (6):

$$\tilde{h}_p = W_p h_p + b_p,\ \ \tilde{h}_p \epsilon \mathbb{R}^d \tag{5}$$

$$\tilde{f}_p = W_f h_f + b_f,\ \ \tilde{f}_p \epsilon \mathbb{R}^d \tag{6}$$

where, W_p is the learnable projection parameters for transforming phoneme embeddings, and W_f is the earnable projection parameters for prosody features.

Fig. 2 illustrating the self-supervised pre-training stage and supervised fine-tuning stage. In the self-supervised stage, raw audio is processed by a convolutional feature encoder, masked prediction, and a Transformer network, which produces

contextualized speech embeddings, with quantization as a technique for improving stability of the representation learning process. The supervised fine-tuning stage adopts these pre-trained embeddings with learner specific data, enabling the transfer of knowledge to distinguish pronunciation and prosody-based features. The outputs are incorporated into a personalized feedback module, which supports adaptive and targeted feedback for learners to improve the segmental and suprasegmental components of speech. After obtain the phoneme embeddings, map the embeddings into 512-dimensional space to reduce computational efficiency, then feed the representations into the intended PP-CAF Layer, where embeddings are dynamically aligned with prosodic features (pitch, energy, and duration). By grounding phoneme representations in acoustic detail and suprasegmental cues, XLS-R serves as powerful backbone that provides the proposed framework to evaluate pronunciation and prosody simultaneously with improved representation of the learner and hence improved performance over traditional concatenating features or one stream processing.

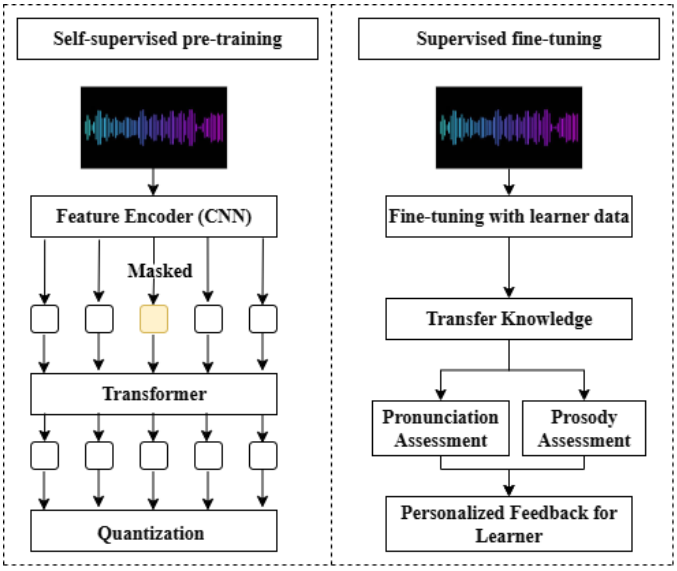

Fig. 2. Architecture of the proposed framework.

D. Phoneme–Prosody Cross-Attention Fusion

The analysis presents the PP-CAF Layer that directly combines segmental and suprasegmental cues via cross-attention as opposed to concatenation. Embeddings of phonemes, pooled at XLS-R outputs across the boundaries between phonemes, are attended to by projected prosodic features, and yield the resultant enriched vectors, which integrate the phonemic accurateness with the prosodic appropriateness. These combined representations are then processed through a multi-task Transformer scorer to perform consonant, vowel, and consonant together predicting pronunciation, prosody, and intelligibility. The, PP-CAF allows articulation and prosody to interact modelling only those cases where phonemes themselves are correct but are stressed or intonated in the wrong way, providing a more holistic and context-relevant view of the speech of a learner than has been previously possible. The PP-CAF layer implements scaled dot-product cross-attention is expressed in Eq. (7).

$$A_p = softmax\left(\frac{\tilde{h}_p W_q (\tilde{f}_p W_k)^T}{\sqrt{d_k}}\right) \quad (7)$$

where, W_q, W_k $\epsilon \mathbb{R}^{d' \times d'}$ are learnable projection matrices, and d_k is the attention dimension. The enriched phoneme-prosody vectors are passed into the multi-task Transformer scorer.

E. Scoring Model with Multi-task Transformer

The integrated representations emitted from the PP-CAF layer are funneled into a multi-task Transformer-based scoring model that evaluates pronunciation accuracy, prosody quality, and overall intelligibility concurrently. Each phoneme–prosody vector is first input into the positional encoding layer, then into a 6-layer Transformer encoder that captures dependencies across phonemes and syllables in an utterance. This architecture allows the model to consider local errors (e.g., phoneme substations) and global structures (e.g., stress and rhythm across a phrase) at the same time. Two multi-task output heads are then implemented on top of the common Transformer encoder. The first output head predicts whether each phoneme was pronounced correctly, and this classification is compiled as the score for pronunciation accuracy. The second output head scores prosody regression, predicting the stress and rhythm alignments with reference scores to compute a prosody quality score. The third output head use regression to obtain an intelligibility assignable with the 1-5 scales of human experts. To train / tune the model, collect and apply a weighted multi-task loss function to the three tasks. It is represented in Eq. (8):

$$L = \alpha L_{pron} + \beta L_{prosody} + \gamma L_{intell} \quad (8)$$

where, L_{pron} is a cross-entropy loss for phoneme correctness classification, $L_{prosody}$ is a mean squared error loss for prosody scoring, and L_{intell} is an L1 regression loss for intelligibility. The weights α, β and γ are tuned empirically on the validation set to ensure balanced learning across tasks.

Algorithm 1: Attention-guided Cross-Lingual Self-Supervised Learning

Input:
- Speech utterance x (16 kHz mono)
- Reference transcript T
- Forced alignment boundaries B = {b1, b2, …, bn}

Preprocess input audio (resample, trim silence, normalize).

Extract contextual embeddings H = XLS-R(x).

For each phoneme boundary (ts, te) in B:
- Pool XLS-R embeddings → phoneme vector hp

Extract prosody features for each phoneme:
- Pitch (YAAPT), Energy (RMS), Duration (MFA)
- Project features into embedding space fp

Apply PP-CAF:
- Fused representation up = Attention (hp, fp)

Feed fused representations U = {u1, u2, …, un} into Transformer encoder.

Apply task-specific output heads:
- Pronunciation head → accuracy score
- Prosody head → stress/rhythm score

Intelligibility head → 1–5 rating
Compute total loss:
$L = \alpha L_{pron} + \beta L_{prosody} + \gamma L_{intell}$
Output:
Pronunciation accuracy score
Prosody quality score
Intelligibility score
Adaptive feedback for learner

Algorithm 1 outlines the Attention-guided Cross Lingual Self Supervised Learning framework presented in this study, which combines pronunciation and prosody assessment in a single learning pipeline. The system initially preprocesses the audio of the learner and derives phonemically embedded XLS-R as well as prosodic (pitch, energy, duration, etc.) features. The PP-CAF layer combines these two streams into a single stream generating better representations that are more segmental and suprasegmental. Fused vectors are then fed into a multi-purpose Transformer in order to concurrently predict pronunciation accuracy, prosody quality, and intelligibility. The weighted loss function leads to model training and in the course of the study, adaptive curriculum scheduler offered customized multimodal feedback as a support to robust assessment as well as to learner advancement. The sensitivity analysis involved a parameter sensitivity analysis in the learning rate, weights of the PP-CAF fusion, and multi-task loss coefficients. Findings depict that the fusion weight (α) is a powerful predictor of prosody accuracy and loss weight (λ) is a powerful predictor of stability in scoring pronunciation. Any slight differences in learning rate caused very little performance variation.

The suggested procedure combines both segmental and suprasegmental speech analysis in one learning path, which is a novel concept in the pronunciation evaluation. The homophonic characteristics of the traditional tools pay attention to phoneme-level accuracy most, with prosody being a secondary characteristic, in some cases limited to length. The interaction of phoneme embeddings with prosodic cues, such as pitch, energy and duration, is possible with the PP-CAF layer allowing a more thorough framework to be presented to cover the instances of phonemes being pronounced correctly but the prosody being unnatural. The method will make use of XLS-R self-supervised embeddings, which offer multilingual capabilities, encode finer-grained phonemic and contextual features and are resistant to learners with varying language backgrounds. A multi-task Transformer scoring model is used to process these enriched representations and makes joint predictions of the accuracy of the pronunciation, the quality of the prosody and the intelligibility. The methodology, which simulates the interaction between articulation and suprasegmental features, provides a holistic and context-sensitive measurement of the spoken language which is superior to other conventional assessment which considers segmental and prosodic information independently.

IV. Results and Discussion

The suggested Attention-guided Cross-Lingual Self-Supervised Learning model significantly increased a performance of learners in spoken English at all levels of proficiency. The framework generated more detailed speech representations, with the addition of phoneme embeddings and prosodic cues via the PP-CAF layer, which allowed learners to perform phonemic articulation more accurately and had a manufacturing speech that was more understandable and fluent and easier to comprehend. Prosodic aspects were strengthened, and there was the increased natural stress placement, less stumbling rhythm, and regular intonation patterns of the entire speech. Adaptive feedback of the framework offered a real time, customized feedback and gave learners the opportunity to rectify articulation and prosodic mistakes in real time when conversing. The feedback was provided in a multimodal way - visual pitch contours, auditory examples, and textual hints, which enhanced the activity of learners and the intensity of their practice. The participants expressed increased confidence, less anxiety, and increased motivation to engage in future verbal communication activities. Altogether, the framework promoted a comprehensive enhancement in the areas of pronunciation, fluency and prosody, as well as the establishment of a conducive, interactive and encouraging learning atmosphere.

Table I shows the Simulation parameters used in the application of the proposed framework. The table presents a summary of the experimental design applied to guarantee similar preprocessing, feature extraction, model setup, and training procedures. These parameters were set to guarantee good reproducibility and computational stability and reliable results for assessing performance of the proposed framework for all case studies.

TABLE I. Simulation Parameter Table

Parameter	Value
Sampling rate	16 kHz
Frame length (for prosody / F0)	25 ms
Frame hop	10 ms
Alignment granularity	phoneme-level
Pitch frame step	10 ms
XLS-R checkpoint	wav2vec2-large-xlsr-53
Projected phoneme dim (d′)	512
Prosody embedding dim	512
Encoder layers	6
Model dim	512
Feed-forward dim	2048
Attention heads	8
Positional encoding	sinusoidal or learned
Pronunciation head	phoneme-level classification
Batch size	16 (adjust to GPU mem)
Epochs (head training)	20–30
Warmup steps	2,000
Weight decay	0.01
Gradient clipping	max-norm = 1.0
Dropout	0.1
Random seeds	{42, 123, 2024}
GPU	NVIDIA V100 / A100 recommended
Validation split	speaker-independent val set (10–15%)

A. Experimental Outcome

The Experimental outcome of the proposed framework yielded significant improvement in learner speech production, including more precise phoneme production, more fluid rhythm, and more natural intonation. Learners were able to adapt quickly to the new system, participated actively with the multimodal feedback, and increased their self-awareness of errors as they corrected them during practice. The adaptive curriculum models provided a personalized practice journey for each participant that allowed for more balanced training progress. Participants also expressed increases in confidence, motivation, and willingness to communicate in spoken English.

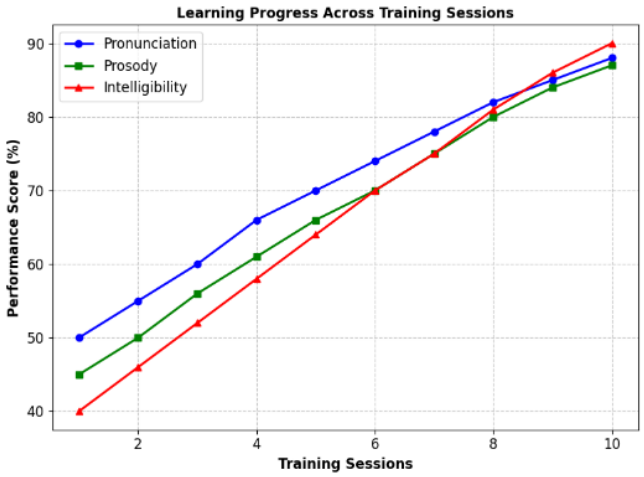

Fig. 3. Learning progress across training sessions.

Fig. 3 shows continuous and marked improvements in pronunciation accuracy, prosody quality and overall intelligibility across the ten sessions. Each of the three dimensions showed a consistent and positive growth trajectory, indicating that the system supported improved performance on multiple aspects of spoken English for individual learners simultaneously.

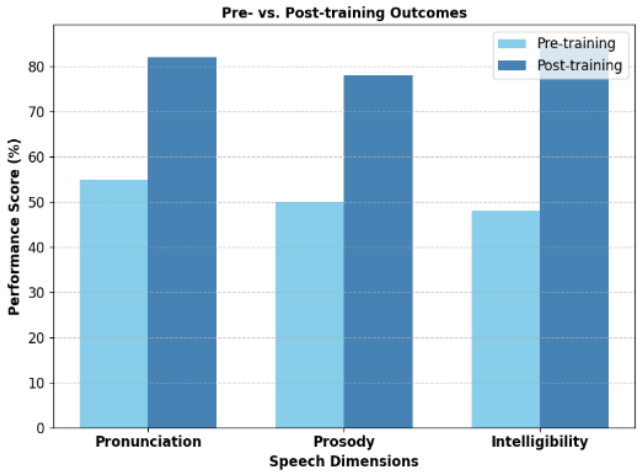

Fig. 4. Pre vs. Post training outcomes.

Fig. 4 depicts clear differences across three dimensions – pronunciation, prosody, and intelligibility – after training, with the differences persisting and consistent following the training period. The increased performance across the three dimensions indicates that the framework is effective in developing and enhancing both segmental and suprasegmental features of speech.

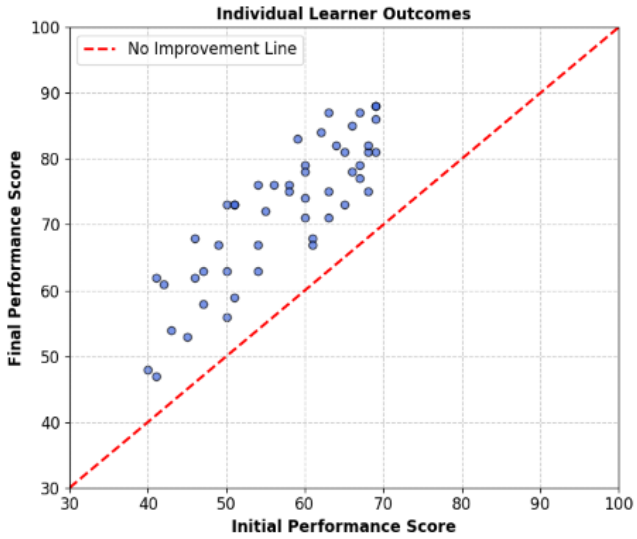

Fig. 5. Individual learner outcome.

Fig. 5 illustrates the individual learner outcomes before and after training with the proposed framework. Each point represents a learner's original and final score for performance. Most points are above the diagonal reference line indicating that the vast majority of learners improved their pronunciation, prosody and overall intelligibility, while using the proposed framework.

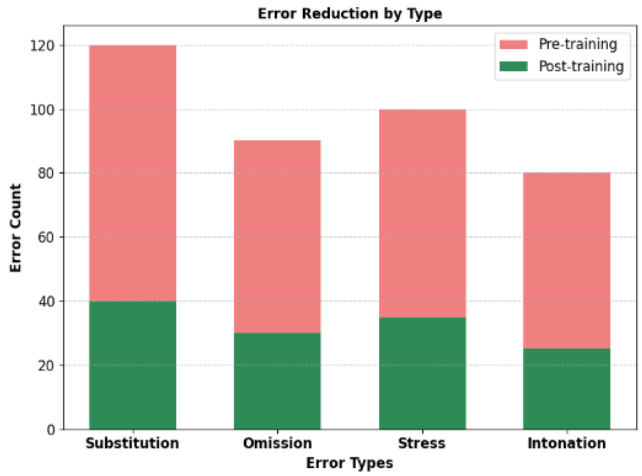

Fig. 6. Error reduction by type.

Fig. 6 demonstrating reduction of errors by type after training with the Attention-guided Cross Lingual Self Supervised Learning framework. The number of errors demonstrated a decrease in the following categories: substitution, omission, stress, and intonation, illustrating an overall improved balance of precision in articulation and prosody.

Fig. 7 depicting learner development at levels of proficiency over time in training using the proposed framework. Each group,
