The results, encompassing superior accuracy, reduced latency, lower energy consumption, and enhanced resilience to Byzantine faults, underscore RL-DAA's potential to transform healthcare data aggregation by addressing critical challenges in distributed systems. The narrow 95% confidence intervals and significant statistical outcomes (e.g., ANOVA F-values ranging from 9.8 to 12.3, $p < 0.001$) affirm the robustness and consistency of RL-DAA across diverse metrics, setting it apart from traditional methods like AMA, DAG-based BCFL, FedDRL, FedAvg, and FedProx.

The significance of these findings lies in RL-DAA's ability to enable real-time, secure, and energy-efficient EHR processing, which could revolutionize diagnostic workflows in multi-institutional settings. The 45% latency reduction and 38% energy savings suggest a scalable solution that minimizes operational costs and environmental impact, while the 35% improvement in resilience to adversarial attacks ensures data integrity in hostile network environments. These outcomes have far-reaching implications, potentially accelerating the adoption of federated learning in healthcare by fostering trust among stakeholders through enhanced privacy and security, as evidenced by zero differential privacy breaches.

The impact extends beyond technical performance, promising to bridge gaps in healthcare equity by facilitating seamless data sharing across resource-constrained regions. However, the reliance on dynamic Q-learning and blockchain integration introduces complexity that may challenge deployment in legacy systems. Consequently, the results advocate for a paradigm shift toward adaptive, intelligent aggregation techniques in federated learning, with RL-DAA serving as a benchmark for future innovations.

Engineering Prompt-Orchestrated LLM Workflows for Automated Test Case Generation in Agile Environments

Almeyda Alania Fredy Antonio, Barrientos Padilla Alfredo, Siancas Garay Ronald Gustavo
Faculty of Engineering-School of Software Engineering, Peruvian University of Applied Sciences (UPC), Lima, Peru

***Abstract*—Manual test case generation for agile software development is a critical bottleneck that is costly, inconsistent, and error-prone. This study introduces a prompt-engineering and multi-level orchestration framework to automate this process. The proposed approach explicitly targets the automated generation of high-level acceptance test cases, addressing a gap in existing research that predominantly focuses on unit-level or reactive testing. The proposed tool, AI-Based Desktop Test Generator (AIDTG), employs a dual-LLM engine (Gemini 1.5 and GPT-4) to transform high-level functional descriptions from the Product Backlog into structured validation scenarios. Unlike prior LLM-based testing approaches, the framework integrates schema-aware prompt engineering and dual-model orchestration to ground the generation process in both functional intent and technical data constraints. The methodology is distinguished by its context-aware prompt engineering, which injects a frozen database schema to ground the models, and its ability to format outputs for the TestRigor BDD 2.0 platform. This schema-grounded and orchestrated workflow enables the systematic translation of informal User Stories into executable Behavior-Driven Development (BDD) acceptance tests, reducing ambiguity and improving semantic correctness. Experimental results on a real-world dataset of fifty User Stories show the framework reduces manual test design effort by eighty per cent, achieves a four point seven five (out of five) average quality rating from human experts, and produces BDD scripts with a ninety-one point nine per cent functional correctness pass rate. These results demonstrate that orchestrated, schema-aware Generative AI can operate as a reliable co-assistant for QA teams, improving efficiency while maintaining high standards of quality and executability.**

Keywords*—Software testing; test case generation; Large Language Models; Generative AI; prompt engineering; LLM orchestration; Behavior-Driven Development (BDD); agile methodology; acceptance testing; schema-aware prompting; Human-in-the-Loop; quality assurance automation

I. Introduction

The emergence of Generative Artificial Intelligence (AI) has initiated a profound paradigm shift across multiple sectors. Beyond its generalist use, its impact on labor productivity has been quantified; recent studies demonstrate that AI assistance can increase worker productivity by 15% on average, disproportionately benefiting less experienced workers [1]. The field of software engineering has been an early and significant beneficiary of this revolution. Large Language Models (LLMs) are being rapidly integrated into the software development lifecycle, demonstrating strong capabilities in code generation [28] and fundamentally changing developer workflows. This wave of transformation is now moving from code *creation* to code *validation*, showing considerable potential for optimizing long-standing challenges in Quality Assurance (QA) [8, 26].

Despite the velocity promised by agile methodologies and DevOps practices [25], quality assurance persists as the most significant critical bottleneck. The software industry overwhelmingly recognizes the manual creation of test cases as a process that is "tedious", "costly", and "susceptible to human errors" [6]. In modern CI/CD pipelines, where speed is paramount, this manual friction becomes untenable. Testing is estimated to consume a significant portion of the total development cost, becoming "less feasible" as software complexity increases [6]. Consequently, this crucial task is "often neglected", leading to the accumulation of technical debt and increasing the risk of defects being discovered only in late stages of development, or worse, by end-users.

To mitigate this friction, automation has been pursued in waves. First, traditional automation tools, such as EvoSuite [7], and pre-generative NLP approaches [14] offered assistance. However, these tools often generate tests that "lack readability and require manual intervention" [5] or are too brittle to handle the ambiguity of natural language requirements. The second wave, driven by the advent of LLMs, has shown greater promise. Systematic reviews confirm the growing use of AI for "Test Case Generation" and "Test Case Prioritization" [3]. In the academic sphere, frameworks have emerged exploring the generation of unit tests [5, 15, 16, 19], bug reproduction [4, 7, 27], and specialized API security tests [20, 22].

However, a critical analysis of these current LLM applications reveals a significant research gap. The vast majority of these approaches focus on low-level, code-centric tasks (unit tests) or *reactive* tasks (bug reproduction). While valuable, these solutions *do not address the primary agile workflow*: the proactive translation of high-level Product Backlog elements (User Stories) into business-facing acceptance tests. Existing tools often lack the *intelligent orchestration* [11] required to convert informal, non-technical requirements into high-level, context-aware QA artifacts that comply with Behavior-Driven Development (BDD) frameworks [13].

From an agile and DevOps perspective, this limitation is particularly critical, as acceptance testing represents the main validation mechanism for ensuring that delivered functionality aligns with business expectations before release.

This work directly addresses this gap. We introduce a system named the AI-Based Desktop Test Generator (AIDTG), a multi-level orchestration and prompt engineering framework designed to automate BDD acceptance test generation. The system moves beyond simple text-to-text translation by utilizing LLM APIs (such as GPT and Gemini) in concert with the crucial technical context of a frozen database *schema*. Through this advanced orchestration, AIDTG transforms high-level functional descriptions into semantically correct, data-aware validation scenarios compatible with TestRigor BDD 2.0 [23]. The framework acts as a co-assistant to improve the precision, coverage, and time efficiency of QA, generating execution-ready artifacts that bridge the gap between business requirements and technical validation.

Unlike prior academic approaches that either evaluate isolated prompt strategies or focus on code-level test generation, this work proposes an end-to-end, schema-aware orchestration framework explicitly tailored to acceptance testing in agile environments.

The core novelty of this research lies in three complementary contributions:

1) a dual-LLM orchestration strategy that separates logical test generation from strict syntactic formatting, 2) a schema-aware prompt engineering mechanism that grounds test generation in real database constraints, and 3) an integrated workflow that operationalizes the transformation of Product Backlog items into executable BDD acceptance tests.

Together, these contributions advance the state-of-the-art by moving beyond prompt-centric experimentation toward a reusable, extensible, and empirically validated orchestration framework for AI-assisted quality assurance.

The present study is organized as follows: Section II presents the study's theoretical foundations. Section III analyzes related work in the field. Section IV describes the AIDTG methodology and system architecture. Section V discusses the experimental results and evaluation. Finally, Section VI presents the conclusions and future lines of research.

II. Theoretical Foundations

This section establishes the theoretical groundwork underpinning the AI-Based Desktop Test Generator (AIDTG) framework.

Our system operates at the intersection of generative artificial intelligence, software testing theory, and agile quality assurance practices, integrating concepts from each domain to support automated acceptance test generation.

A. Artificial Intelligence and Large Language Models (LLMs)

Artificial Intelligence (AI) is a broad field of technology that enables computers and machines to simulate human learning, comprehension, and problem-solving [9]. Within this field, Large Language Models (LLMs) have emerged as a dominant force. LLMs are deep learning models, often built on a transformer architecture, that are trained on vast datasets to "work as giant statistical prediction machines" capable of understanding and generating natural, human-like language [10]. In software engineering, their application has rapidly moved from documentation to code generation, and most recently, to supporting complex quality assurance tasks [8]. Recent empirical studies indicate that LLMs can meaningfully augment human performance in software-related tasks, particularly when their outputs are constrained and guided by domain-specific context. However, unconstrained LLM outputs are prone to issues such as hallucination, inconsistency, and lack of executability, especially in tasks that require strict syntactic or semantic correctness, such as software testing.

B. Behavior-Driven Development (BDD)

The primary output of the AIDTG system is BDD-compatible scripts. Behavior-Driven Development (BDD) is an agile testing methodology designed to foster collaboration between developers, QA analysts, and business stakeholders [13]. It achieves this by defining application behavior in a structured, natural-language syntax known as Gherkin (e.g., Given-When-Then). This formal, high-level specification creates an unambiguous, "living" documentation that serves as both a requirement and an executable test script. BDD is particularly well-suited to agile environments, as it bridges the communication gap between technical and non-technical stakeholders while maintaining traceability between requirements and validation artifacts. Our work focuses on automating the translation of informal backlog items into this precise, high-level BDD format. By targeting acceptance tests rather than unit-level artifacts, the proposed framework aligns directly with the validation layer most closely associated with business value delivery.

C. Prompt Engineering and LLM Orchestration

A single, generic request to an LLM rarely yields a complex, executable artifact. Prompt Engineering is the methodology of structuring, refining, and optimizing the input (the prompt) to guide the LLM toward a more accurate and contextually relevant output [12]. LLM Orchestration extends this concept further; it is the process of managing, chaining, and coordinating the interactions of an LLM with external tools and data sources [11]. The AIDTG framework is an orchestration engine: it does not merely pass a user story to the LLM. It intelligently combines the user story (the intent) with the database schema (the technical context) via a multi-level prompt workflow to generate a valid, data-aware BDD script. This separation of responsibilities between prompt design and execution flow control reflects emerging best practices in LLM-based system engineering, where orchestration is treated as a first-class architectural concern rather than an implementation detail

D. Schema-Aware and Risk-based Testing

The most significant challenge in agile testing is ensuring test coverage for critical business logic [6]. A key aspect of our methodology is the use of a "frozen" database schema. This approach is informed by the principles of Risk-Based Testing (RBT), which uses risk assessments to "steer all phases of the test process to optimize testing efforts" [2]. By making the LLM "aware" of the data schema, AIDTG generates test cases that are not just syntactically correct BDD but are also semantically aware of the underlying data model. This schema-awareness allows the generation process to prioritize high-risk areas, such as data integrity constraints, entity relationships, and domain-specific validation rules, which are often overlooked in purely

text-driven test generation approaches. Consequently, the integration of schema-aware prompting with risk-based testing principles enables a more focused and meaningful acceptance testing strategy, improving both coverage quality and defect prevention potential.

III. Related Work

To situate the contribution of AIDTG, this section provides a detailed analysis of the current state-of-the-art in AI-driven test generation. The application of AI in software testing is a well-established field, with systematic reviews confirming its use for tasks like test case generation and prioritization [3]. The recent advent of Large Language Models (LLMs) has catalyzed a new wave of research [26], with industry surveys showing that QA professionals are already applying these models in practice [8]. However, the literature is highly fragmented, with most efforts diverging into distinct streams that fail to address the primary agile bottleneck of proactive, high-level, and context-aware acceptance testing.

To provide a clearer analytical perspective, existing work is discussed below according to its primary testing focus and level of abstraction, explicitly highlighting the limitations that motivate the proposed approach.

Historically, before the dominance of generative LLMs, research focused on traditional Natural Language Processing (NLP) and Model-Based Testing (MBT) to bridge the gap between requirements and tests. Works such as Lim et al. [14] proposed unified "boilerplate" approaches to extract test case information from requirements specifications using NLP. While structured, these methods are often brittle, struggling with the ambiguity of natural language. Concurrently, MBT, as reviewed by Ferrari et al. [29], exploits abstract models of software behavior to generate tests. Although effective in controlled settings, MBT approaches require the manual creation and maintenance of formal behavioral models, which introduces significant overhead and limits their adoption in fast-paced agile environments.

While powerful, this approach faces significant adoption barriers due to the high complexity and cost associated with creating and maintaining the formal models themselves. Other approaches utilized deep learning (pre-generative) to automate functional UI testing [30], but these remained focused on component-level validation rather than end-to-end business logic.

As a result, pre-LLM approaches generally fail to scale to acceptance-level testing scenarios where requirements are informal, rapidly evolving, and expressed in natural language.

The rise of LLMs [10] has shifted the research focus, with most efforts concentrating on code-level, specialized, or reactive testing tasks. A dominant trend is the generation of unit tests. Ouédraogo et al. [5] provided a large-scale evaluation comparing LLM-generated unit tests against traditional tools, noting LLMs produce more readable tests but often lack correctness. Subsequent research has attempted to mitigate these limitations by augmenting LLM-based unit test generation with additional techniques.

This stream includes enhancing unit test generation through mutation testing [15], using evolutionary algorithms to guide the LLM [16], or augmenting the process with assertion knowledge (A3Test) [19]. This entire body of work, while valuable for code-level validation, addresses a different problem than the high-level, business-facing acceptance testing that BDD targets. Specifically, unit test generation operates at the implementation layer and assumes access to source code, whereas acceptance testing operates at the requirement layer and must accommodate non-technical stakeholder input.

A second major research stream focuses on reactive testing—generating tests after a bug is found. Kang et al. [4] explored using LLMs as "few-shot testers" to reproduce known bugs, and Plein et al. [7] confirmed the feasibility of generating test cases from informal bug reports. These approaches demonstrate the effectiveness of LLMs in post-hoc validation scenarios, where the failure context is already known.

A recent extension of this, BRMINER [27], uses LLMs to extract relevant test inputs from bug reports to enrich existing test generation tools. This work is crucial for regression suites but does not address the primary agile bottleneck [6]: the proactive generation of tests from new functional requirements before they become bugs. Consequently, reactive LLM-based testing approaches improve defect reproduction but do not reduce the upfront effort associated with designing acceptance tests during sprint planning or backlog refinement.

A third stream applies LLMs to highly technical, specialized domains, such as developing self-improving frameworks for security testing of APIs using Karate DSL [20] [21] or optimizing REST API fuzzers [22]. These approaches, while advanced, are not aimed at validating the end-to-end business logic defined in agile user stories. Their domain specificity and reliance on technical testing artifacts limit their applicability to general-purpose acceptance testing workflows.

The most relevant, yet least explored, area is the application of LLMs to high-level acceptance testing, such as BDD. The work by Karpurapu et al. [13] is one of the few academic studies that directly addresses LLMs for BDD automation. However, their research is an evaluation of different prompt engineering techniques (zero-shot vs. few-shot) to formulate BDD tests. While informative, this work does not propose a complete, end-to-end orchestration framework that integrates external technical context to ensure the semantic and technical validity of the generated tests.

It does not propose a complete, end-to-end orchestration framework [11] that integrates external technical context (like a database schema) to ensure the generated tests are not just syntactically correct but semantically and technically viable. This limitation is particularly significant in real-world agile projects, where acceptance tests must align with underlying data models and business constraints.

This industry need is validated by the commercial success of tools like TestRigor [23], which positions itself as a "Generative AI-based Test Automation Tool" that allows teams to write tests in plain English [24]. Although such tools demonstrate the practical viability of LLM-driven acceptance testing, they are proprietary systems that do not expose their orchestration

strategies or prompt engineering mechanisms for academic analysis or replication.

This commercial validation proves the desirability of the approach, but it is a proprietary, closed-box solution, not an open academic framework.

Our comprehensive review thus reveals a clear and significant research gap. The literature is heavily skewed toward code-level [5, 16, 19], reactive [4, 7, 27], or niche [20, 22] test generation. The few works that touch upon high-level BDD testing [13] stop at prompt evaluation and do not provide an integrated framework. In particular, existing approaches lack systematic LLM orchestration mechanisms capable of combining requirement-level intent with technical system context.

A gap persists for a system that is: 1) Proactive, generating tests from Product Backlog items; 2) High-Level, focusing on BDD acceptance tests; and 3) Context-Aware, using LLM Orchestration [11] to integrate external technical artifacts.

This work addresses this precise lacuna. AIDTG is not a unit test generator or a bug-reproduction tool; it is an orchestration framework explicitly designed to automate the translation of high-level agile requirements into data-aware BDD acceptance tests [13]. By grounding generation in both functional requirements and database schemas, the proposed approach advances beyond prior prompt-centric solutions and directly targets the primary quality assurance bottleneck in modern agile and DevOps processes [25].

IV. Methodology

The methodology of this work consists of the design, implementation, and evaluation of an end-to-end LLM orchestration framework, named the AI-Based Desktop Test Generator (AIDTG). This system is architected to manage the full lifecycle of agile test case generation, from project creation to optional execution, acting as an intelligent co-assistant for QA teams [8].

The methodological approach follows an empirical software engineering paradigm, combining system design with experimental validation on real-world project data.

The system is designed as a decoupled, API-first application, comprising a Python-based backend for orchestration and a separate desktop frontend for user interaction. The core of the methodology is a dual-LLM engine [18] that leverages the specific strengths of different models to achieve high logical accuracy and perfect syntactical compliance. This separation of concerns at both the architectural and model levels is intended to improve robustness, scalability, and reproducibility of the generation process.

A. System Architecture and Workflow

The end-to-end workflow of AIDTG is designed to integrate seamlessly into an agile QA process, moving from high-level requirements to executable scripts. The overall system architecture follows a component-based design and is represented using a C4 Container diagram, as illustrated in Fig. 1.

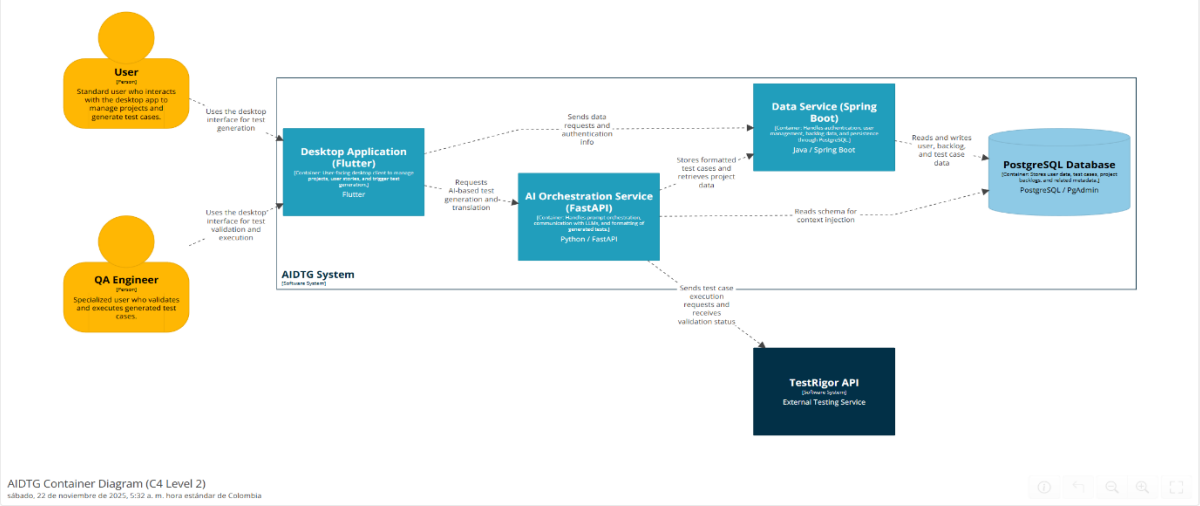

Fig. 1. AIDTG C4 Container S8.

The workflow proceeds through a series of well-defined stages, each corresponding to a distinct responsibility within the test generation lifecycle:

1) Project and backlog management: The user first creates a "Project" within the desktop application. Into this project, the user injects the Product Backlog, consisting of "Epics" and their corresponding "User Stories" (US) in a structured format (e.g., CSV). This structure enables traceability between backlog items and generated test cases, which is essential for agile quality assurance practices.

2) Test cycle initiation: The user selects specific User Stories from the Product Backlog to form a "Release Backlog" for the current test cycle. The user then initiates the generation script for this selected backlog. This step mirrors real-world sprint or release planning activities, ensuring that the generated test cases align with the scope of the current development iteration.

3) Context injection: At the moment of generation, the system prompts the user to provide the "frozen database schema" (e.g., a .sql script). This is the critical contextual step that makes the framework data-aware, informing the generation process with the project's actual data model [2]. The term "frozen" denotes that the schema represents a stable snapshot of the data model for the duration of the test cycle, ensuring consistency across generated artifacts.

4) Orchestration and generation: The backend orchestrator (detailed in 4.4) receives the User Stories and the DB schema. It combines them into a master prompt and executes the Dual-LLM workflow [detailed in Section IV(C)]. At this stage, prompt engineering rules, coverage strategies, and contextual constraints are jointly applied to guide the generation process.

5) Output and translation: The system generates the test cases and provides two distinct outputs: a) a translation into the user's native language (e.g., Spanish) for human validation, and b) a script formatted in TestRigor BDD 2.0 syntax [23].

This dual-output strategy supports both Human-in-the-Loop review and immediate machine execution.

6) Optional execution and monitoring: The user has the option to execute the generated BDD 2.0 script directly via an API call to the TestRigor platform. If this option is chosen, the system utilizes WebSockets to maintain a persistent connection, monitoring the execution status in real-time and reporting "Pass" or "Fail" results. This optional execution step enables immediate validation of syntactic correctness and executability on the target testing platform.

7) Human-in-the-loop feedback: Finally, the user is prompted to rate the quality and correctness of the generated test case on a 1-to-5-star scale. This feedback mechanism is crucial for the evaluation phase of our study (Section V). Although not used for automated learning in this study, this feedback channel establishes the foundation for future Human-in-the-Loop refinement mechanisms.

8) Dataset description: To ensure transparency and reproducibility, the experimental dataset used in this study is described explicitly.

The dataset consists of a real-world Product Backlog obtained from an active software development project within an industrial context. It includes 50 distinct User Stories distributed across 8 Epics, representing common functional requirements in a business-oriented information system.

Each User Story contains a textual description, priority level, acceptance criteria, and estimated story points, providing sufficient detail for acceptance-level test design.

This dataset was selected to reflect realistic agile development conditions, including heterogeneous requirement complexity and domain-specific constraints.

B. Core Technologies

The system is implemented as a decoupled application. The backend is a high-performance Python API, while the frontend is a modern desktop application.

The backend is built using FastAPI, a high-performance web framework chosen for its asynchronous capabilities, essential for managing concurrent API calls to LLM endpoints. It runs on a Uvicorn ASGI server. For data persistence, SQLAlchemy is used as the ORM to manage all projects, backlogs, and generated test cases, connecting to a PostgreSQL database via the psycopg2 driver. User authentication and security are handled using python-jose for JWT token generation and Passlib with bcrypt for secure password hashing. These technologies were selected to ensure scalability, security, and efficient handling of concurrent generation and execution requests.

The core backend technologies are detailed in Table I.

TABLE I. BACKEND LIBRARIES

Library / Technology	Description
FastAPI	Modern web framework for building asynchronous APIs.
Uvicorn	ASGI server for running the FastAPI application.
SQLAlchemy	Python SQL Toolkit and ORM for database interaction.
psycopg2-binary	PostgreSQL adapter for Python.
Pandas / Openpyxl	Used for data manipulation and parsing of input data.
OpenAI	Python client library for accessing the GPT-4.0 API.
google-generativeai	Python client library for accessing the Gemini 1.5 Pro API.
Tiktoken	Used for token counting to manage OpenAI prompt length and costs.
python-dotenv	Manages environment variables (e.g., API keys).
python-jose & Passlib	Libraries for implementing OAuth2 security, token generation, and password hashing.
fastapi-pagination	Handles pagination for API endpoints returning large lists (e.g., backlog items).
httpx	Asynchronous HTTP client for making robust API calls to LLM endpoints.

The frontend is a desktop application built with React and Next.js, providing a responsive and modern user interface. Tailwindcss and Next-UI are used for styling and components, while React-Markdown is used to render the table-formatted outputs from the LLM. This technology stack enables clear visualization of generated test cases and seamless interaction with the orchestration backend.

The core desktop technologies are detailed in Table II.

TABLE II. DESKTOP LIBRARIES

Library / Technology	Description
Next / React	Core JavaScript libraries for building the user interface.
React-dom	Entry point to the DOM and server renderers for React.
React-markdown	React component to render the Markdown output from the LLM.
Next-ui	A component library for building beautiful UIs with Next.js.
Tailwindcss	A utility-first CSS framework for rapid UI development.
Github-markdown-css	CSS for replicating GitHub's Markdown-rendered style.

C. The Dual-LLM Orchestration Workflow

A core innovation of AIDTG is its "dual-engine" orchestration pipeline, which uses two different state-of-the-art LLMs in sequence. This design is conceptually aligned with emerging dual-model strategies reported in recent AI research, where task specialization across models improves overall output quality.

Step 1: Generation (LLM-1: Gemini 1.5 Pro)

The first engine is the "Generation Engine." It uses Gemini 1.5 Pro for its large context window and strong reasoning capabilities. It receives the most complex input: the "master prompt" (detailed in 4.4), which contains the User Stories and the full database schema. Its responsibility is limited to logical reasoning and test design, deliberately excluding strict syntax enforcement.

Step 2: Translation and Formatting (LLM-2: GPT-4.0)

The structured Markdown output from Gemini is then passed to GPT-4.0, which acts as a specialized "Formatting and Translation Engine". This model executes two distinct tasks via separate, simpler prompts:

1) Native language translation: It translates the Markdown table into the user's native language (e.g., Spanish) for human validation.

2) BDD 2.0 formatting: It translates the same Markdown table into the strict, proprietary BDD syntax required by TestRigor BDD 2.0.

This separation of logical reasoning from syntactic formatting significantly reduces the risk of syntax-related hallucinations.

D. Core Component: The AIDTG Prompt Engineering Framework

The primary intellectual property of the AIDTG framework is its Master Prompt Template, which is dynamically constructed by the backend orchestrator and sent to the Generation Engine (Gemini 1.5 Pro). Rather than relying on a single monolithic instruction, the prompt is composed of multiple semantically distinct components, each controlling a specific aspect of LLM behavior.

This subsection deconstructs the master prompt to explain the design rationale behind each component.

1) Persona and task injection: The prompt's first section, shown in Fig. 2, is the Persona Injection. This is the most critical step for setting the context, quality bar, and expertise of the model [12]. Instead of a generic instruction, the prompt forces the LLM to adopt the role of a Senior QA Engineer and explicitly names the advanced methodologies it must use, such as Risk-Based Testing [2] and Combinatorial Testing. This immediately constrains the model to a professional context and significantly improves the quality and relevance of the generated test cases.

```
You are a **Senior QA Engineer** specialized in **Risk-Based Testing** and **Combinatorial Testing Techniques (Pairwise Testing)**.
---task---
Your task is to **generate a table of Test Cases (TC)** in **Markdown format**, based on the following **User Stories (US)** and the provided **contextual database**. Do not include explanations or commentary – only return **a single Markdown table** with the required fields.
```

Fig. 2. Persona injection prompt.

2) Multi-language and domain handling: The second component, detailed in Fig. 3, addresses the challenge of internationalization. The prompt explicitly instructs the LLM to auto-detect the language of the input User Story and generate all test cases in that same language. This makes the framework immediately usable for global teams (e.g., in English, Spanish, Hindi) without modification. It also mandates the preservation of domain-specific terms (like currencies or local names), preventing the LLM from "over-translating" and losing critical context.

```
### Language Handling
For each User Story:
**Automatically detect its language** (e.g., English, Spanish, Chinese, Hindi, etc.).
**Generate all Test Cases in the same detected language.**
Preserve any culturally specific or domain-related terms (such as currencies, location names, etc.) without translation.
```

Fig. 3. Multi-language injection prompt.

3) Contextual data injection (Schema-Awareness): The third component, shown in Fig. 4, is the core of the orchestration [11]. The backend dynamically injects two critical data blocks: the User Stories (functional context) and the Database Schema (technical context).

a) User story data: The {user_epics_prompt} variable passes the selected backlog items in a machine-readable CSV format, which the LLM is told how to parse.

b) Frozen database: The {db_prompt} variable provides the "ground truth" for the test data. By providing real input values (e.g., product types, currencies, locations), we move the LLM from generating plausible tests to generating realistic and executable tests grounded in the system's actual data model.

```
### User Story Data
User Stories are represented in **CSV format**, delimited by the character `|`.
### Columns:
ID | DESCRIPTION | PRIORITY | STORY_POINTS | ACCEPTANCE_CRITERIA | PAIR_WISE_TESTING`
--- START OF USER STORY DATA ---
{user_epics_prompt}
--- END OF USER STORY DATA ---
### Frozen Database (Testing Context)
The following dataset can be used as **real input values** to design your Test Cases
(for example: product types, currencies, or locations).
--- START OF FROZEN DATABASE DATA ---
{db_prompt}
--- END OF FROZEN DATABASE DATA ---
```

Fig. 4. Context data injection prompt.

4) Strict output formatting (Machine-Readability): A primary challenge in LLM pipelines is output unreliability [17]. To solve this, the fourth component (Fig. 5) enforces a strict, non-negotiable output format. The prompt commands the LLM to return only a single Markdown table with a precisely defined set of headers. This "structured-to-structured" pipeline (CSV/DB -> Markdown) is the key to reliability. It ensures the output from the Generation Engine (Gemini) is a machine-readable artifact, which can be perfectly and safely parsed by the Formatting Engine (GPT-4.0) in the next step, eliminating the risk of free-text "hallucinations" or conversational contamination.

```
### REQUIRED OUTPUT STRUCTURE
Return a single **Markdown table** with the following headers:
### Columns:
| ID | (HU_FAKE_ID) | (HU_ID) | OBJECTIVE | TYPE | PRIORITY | PRE-CONDITION | INPUTS | STEPS | EXPECTED RESULTS | POST-CONDITION |
```

Fig. 5. Output formatting prompt.

5) Test case generation and strategy rules: Finally, the fifth component (Fig. 6) provides the explicit "business logic" for the generation.

Rules 1 & 2 (Coverage & Traceability): Mandate the minimum required coverage (Happy, Error, and Alternative Paths) and ensure traceability by mapping the test case back to the User Story ID.

Rules 3 & 4 (Quality): Instruct the LLM to use the provided database data for Inputs and to write specific, verifiable Expected Results.

Rule 5 (Advanced Strategy): This is the most complex rule. It activates the Pairwise Testing persona if the PAIR_WISE_TESTING flag is True. It commands the LLM to look at the database values (e.g., Product Type, Currency, Location) and create an efficient set of test cases that maximize combinatorial coverage with minimal tests. This transforms the LLM from a simple generator into an intelligent test strategist.

```
### TEST CASE GENERATION RULES
1. **Minimum Coverage:**
   For each US, generate TCs covering:
   - **Happy Path:** main successful flow.
   - **Error Path:** validations and incorrect inputs.
   - **Alternative Path:** optional or exceptional flows
2. **Traceability:**
   Use the **ID** field from the US as the value for **(HU_ID)** in the table.
3. **Inputs and Steps:**
   Be detailed and realistic. Use actual data from the provided database whenever possible.
4. **Expected Results:**
   Must be specific and verifiable (e.g., "An error message is displayed: 'Invalid email format'").
5. **Priority:**
   Inherit directly from the User Story (Critical, High, Medium, Low).
6. **Pairwise Testing (if applicable):**
   If the flag `PAIR_WISE_TESTING = True` is active for a US:
   - Generate **test combinations** using real values found in the database section.
   - Example for a "Add Product" US:
     - Product Type (physical, digital)
     - Currency (PEN, USD)
     - Location (Lima, Cusco, Arequipa)
   - Create **unique, efficient test cases** that maximize coverage with minimal combinations.
7. **Formatting Rules:**
   - Only one Markdown table.
   - No text outside the table.
   - Use "Happy Path", "Error Path", or "Alternative Path" under "TYPE (Path)".
   - Fill all columns completely (no empty cells).
   - Separate each step in the **STEPS** column using a line break `\\n`.
   - Maintain the same language as the detected User Story.
```

Fig. 6. Test case generation rules prompt.

V. Results

This section details the experimental design used to validate this research's objectives. First, a framework of evaluation metrics is defined based on academic literature. Second, the experimental setup is described. Finally, the quantitative and qualitative results obtained from the application of the AIDTG framework on a real-world dataset are presented and discussed.

The results are structured around the predefined research questions to ensure traceability between objectives, evaluation metrics, and empirical findings.

A. Definition of Evaluation Metrics

To evaluate the efficacy and performance of a new test generation technology, a metrics framework is essential. Based on a review of the literature on test automation [31, 2132, 35], technology adoption [35], and Natural Language Processing (NLP) in testing [33, 34], we have identified a consensus around four key performance variables. These variables are widely used in both academic studies and industrial evaluations of automated testing tools.

Table III summarizes these standard industry and academic metrics.

TABLE III. Key Literature-based Metrics

Metric / Variable	Description	Rationale (from Literature)
Efficiency / Time Savings	Measures the reduction in human time and effort (measured in man-minutes) required to complete a task, compared to the manual baseline.	The primary justification for adopting new testing technologies is operational efficiency, cost reduction, and accelerating delivery cycles [35, 34].
Perceived Quality & Precision	Measures how correct, readable, relevant, and useful the generated artifacts are. This is a qualitative metric best measured via human expert scoring (surveys).	A systematic review of NLP in testing [33] identifies "Test Case Quality" as a central metric for validation.

Functional Correctness	Measures whether the generated test cases are syntactically correct and capable of executing on a testing platform without failure.	This is the ultimate technical validation. Rapid generation is useless if the scripts are unexecutable on the target platform [35].
Fault Detection	Measures the ability of the generated test cases to identify defects (bugs) in the codebase.	The ultimate goal of testing is to find faults [32]. High fault detection indicates high-quality generation.

For this study, we focused on the first three metrics (Efficiency, Perceived Quality, and Functional Correctness), as "Fault Detection" is dependent on pre-existing bugs in the source code, which was outside the scope of our backlog-based generation.

This scope delimitation ensures that the evaluation remains aligned with the proactive nature of acceptance test generation from requirements.

B. Experimental Setup

The experiment was designed to compare the performance of the AIDTG tool against traditional manual generation.

1) Dataset: We used a real-world project dataset from a software development company (identified as the organization under study). The dataset consisted of a Product Backlog with 50 unique User Stories (US), distributed across 8 Epics. This dataset corresponds exactly to the one described in the Methodology section, ensuring internal consistency across the study.

2) Control group (Manual): We measured the average time it took for a QA analyst with 3 years of experience (hereafter, "the expert") to analyze a US, design, and manually write the test cases (Happy, Alt, Error) based on the requirements. This process represents standard industry practice for acceptance test design in agile teams.

3) Experimental group (AIDTG): We used the AIDTG framework (configured with Gemini 1.5 Pro and GPT-4.0) to process the same 50 US.
A group of five QA analysts (with mixed experience levels) reviewed and rated the generated test cases. Their evaluations were averaged to ensure inter-rater reliability. The use of multiple evaluators strengthens the robustness of the qualitative assessment.

4) Instruments:

a) Efficiency: Time tracking (man-minutes) for both groups.

b) Perceived quality: An evaluation survey (see Appendix A) based on a 1-to-5 Likert scale (1=Useless, 5=Fully Adequate), which the expert completed for each generated test case. The survey instrument was designed to capture expert judgment on relevance, clarity, and practical usability.

c) Functional correctness: The TestRigor platform, used to execute the BDD 2.0 scripts and report a binary ("Pass" / "Fail") result.

C. Research Questions

The experiment sought to answer the following Research Questions (RQs), derived from the project's specific objectives:

1) RQ1 (Efficiency): To what extent does AIDTG reduce the time and effort of test case creation compared to the manual process?

2) RQ2 (Quality): How precise, useful, and of high quality are the test cases generated by AIDTG, according to human expert evaluation (based on the survey)?

3) RQ3 (Functional correctness): What percentage of the BDD 2.0 scripts generated by AIDTG are functionally correct and executable ("Pass") on the TestRigor platform?

These research questions directly map to the selected evaluation metrics, enabling a clear interpretation of results.

D. Results and Findings

The 50 User Stories were processed through the AIDTG pipeline, resulting in the generation of 197 unique test cases (covering Happy, Alternative, and Error paths). This distribution reflects the minimum coverage rules enforced by the generation framework.

1) Results for RQ1 (Efficiency): A significant reduction in effort was observed. The manual process required an average of 25 minutes per User Story. The AIDTG process (Table IV), including AI generation and human review, reduced the total effort to approximately 5 minutes per User Story.

TABLE IV. COMPARISON BETWEEN MANUAL PROCESS AND AIDTG PROCESS

Metric	Manual Process (Control)	AIDTG Process (Experimental)	Improvement
Avg. Time per US	25 Minutes	5 Minutes	80% Time Savings
Total Effort (50 US)	1250 Minutes (20.8 hrs)	250 Minutes (4.1 hrs)	16.7 hours saved

Conclusion (RQ1): The AIDTG framework achieved an 80% reduction in the time and effort required for test case creation.

2) Results for RQ2 (Perceived quality): The evaluation survey (Appendix A) was used to measure the perceived quality of the 197 generated TCs. Table V shows the distribution of the expert's ratings, with qualitative labels removed as requested.

TABLE V. SCALE RANKING

Rating (1-5 Scale)	# of Generated TCs	Percentage
5	158	80.2%
4	29	14.7%
3	10	5.1%
2	0	0%
1	0	0%

Conclusion (RQ2): 94.9% of the generated test cases received a rating of 4 or 5, resulting in a weighted average score of 4.75 out of 5.

3) Results for RQ3 (Functional correctness): To validate technical correctness, all 197 BDD 2.0 scripts generated by the GPT-4.0 engine were sent to the TestRigor platform (via WebSocket) for syntax validation. The results are summarized in Table VI.

TABLE VI. COLLECTED METRICS

Metric	# of TCs	Percentage	Analysis Notes
"Pass" (Successful Execution)	181	91.9%	BDD 2.0 syntax is correct and executable.
"Fail" (Syntax Error)	16	8.1%	Execution failed due to syntax.
Total	197	100%	

Conclusion (RQ3): 91.9% of the generated scripts were syntactically correct and executable on the target platform.

E. Discussion of Results

The results strongly validate the project's hypothesis. An 80% time saving (RQ1) aligns with industry promises of technology adoption [35] and exceeds the expectations of traditional NLP tools that require more intensive setup [34].

The most significant finding is the synergy between high efficiency (RQ1) and high quality (RQ2). Historically, test generation tools sacrificed quality for speed [32]. The AIDTG framework, by using a dual-engine (Gemini for logic, GPT-4 for format) and a DB-schema-aware orchestration, demonstrates that it is possible to achieve both. The 4.75 average rating (RQ2) and the 91.9% execution success rate (RQ3) prove that the output is not just "fast," but "correct and useful."

While a 1–5 star rating function was implemented in the application [as detailed in Section IV(A)], it is considered an experimental feature for future Human-in-the-Loop feedback. It is important to emphasize that the data for this study was collected exclusively via formal surveys (detailed in Appendix A: QA Evaluation Questionnaire) to ensure methodological rigor.

VI. CONCLUSION AND FUTURE WORK

Specifically, the study focused on the challenges of translating high-level Product Backlog requirements into executable acceptance tests in a manner that is both efficient and semantically accurate. [6]. While recent LLM research has focused on unit tests [5] and bug reproduction [7], a significant gap remained in the proactive, high-level generation of acceptance tests from backlog requirements.

This gap is particularly critical in agile and DevOps contexts, where acceptance testing plays a central role in validating business requirements prior to release.

We successfully designed, implemented, and evaluated the AI-Based Desktop Test Generator (AIDTG), an LLM orchestration framework that bridges this gap. The proposed framework moves beyond isolated prompt-based experimentation by introducing an end-to-end, schema-aware orchestration pipeline for acceptance test generation.

Our methodology's primary contribution is a dual-LLM engine (Gemini 1.5 Pro and GPT-4.0) combined with a schema-aware prompt engineering framework (Section IV). This combination enables a clear separation between logical test design and strict syntactic formatting, improving both generation quality and executability.

This approach transforms high-level User Stories into executable TestRigor BDD 2.0 scripts [23] by grounding the generation process in the project's actual data model [2]. By explicitly incorporating database constraints into the generation workflow, the framework reduces ambiguity and increases semantic alignment between requirements and validation artifacts.

Our experimental evaluation on a real-world dataset demonstrated that AIDTG:

- Reduces test design effort by 80% (RQ1).
- Achieves a 4.75 out of 5 average quality rating from expert human review (RQ2).
- Produces BDD scripts with a 91.9% functional (syntactical) correctness rate on the target platform (RQ3).

These results confirm that the proposed framework can significantly improve QA productivity while maintaining high standards of test quality and executability.

Unlike prior studies that evaluate prompt effectiveness in isolation, this research provides empirical evidence for the benefits of orchestration-centric architectures in AI-assisted software testing.

From an industrial perspective, the findings suggest that AIDTG can support the adoption of AI-assisted testing practices in real agile teams.

By automating repetitive acceptance test design tasks, QA professionals can focus on higher-value activities such as exploratory testing, test strategy refinement, and defect analysis.

Furthermore, the generation of business-readable BDD artifacts has the potential to improve communication and alignment between developers, testers, and non-technical stakeholders.

A. Future Work

This study opens several avenues for future research.

- Mitigating Failures: The 8.1% failure rate in functional correctness (RQ3) was primarily due to minor syntax hallucinations by the formatting LLM. Future work will focus on refining the formatting prompt and implementing a "self-correction" loop where the LLM automatically fixes the script upon receiving a "Fail" status from the TestRigor API.

- Human-in-the-Loop (HIL) Fine-Tuning: The 1-5 star rating feature built into the application (Section IV) was experimental for this study. The next phase is to capture this user feedback and use it to create a fine-tuning dataset, enabling a Human-in-the-Loop (HIL) pipeline that constantly improves the generation engine's accuracy.
- Expanding Target Frameworks: While this work focused on TestRigor BDD 2.0 [23], the dual-engine methodology is adaptable. Future iterations could include formatting engines for other popular BDD frameworks, such as Cucumber (Gherkin) or Behave.
- Integration with Design Tools: A promising avenue is to expand the "context" beyond just the database schema to include inputs from UI/UX design tools (e.g., Figma), further grounding the generated test cases in the application's intended design.

APPENDIX A. QA EVALUATION QUESTIONNAIRE

This appendix presents the Quality Assurance (QA) evaluation questionnaire used in the study. The purpose of this questionnaire is to gather expert feedback on the usefulness, reliability, and clarity of the test cases generated by the AI-based solution, as well as the feasibility of integrating this tool into agile software development processes. The questionnaire is divided into three parts: Section A contains Likert-scale items for quantitative evaluation, Section B provides dichotomous (Yes/No) questions for binary assessment, and Section C includes open-ended questions for qualitative feedback.

Instructions to Respondents:

- Please answer all questions based on your experience with the AI-generated test cases and the overall tool.
- In Section A, rate each statement on a scale of 1 to 5 (where 1 represents Very Poor and 5 represents Excellent).
- In Section B, select either Yes or No for each question.
- In Section C, provide your answers in your own words, elaborating on your perspective for each question.

Section A – Likert-Scale Questions (1–5):

-How useful do you consider the AI-generated test cases compared to manual test cases?

-What level of reliability do you perceive in the AI-generated results with respect to the user requirements?

-On a scale of 1 to 10, how accurate do you consider the test cases generated by AI?

-On a scale of 1 to 10, how complete do you consider the set of critical scenarios identified by AI?

-How precise do you consider the critical scenarios generated by AI?

-How likely are you to recommend this solution for a real software development project?

-**Scale:** 1 = Very Poor, 5 = Excellent.

Section B – Dichotomous Questions (Yes/No):

-Do you believe that automatic test case generation with AI can significantly reduce test design time?

-Do you think this solution can be seamlessly integrated into agile methodologies such as Scrum or Kanban?

-Do you consider the AI-generated test cases to be sufficiently clear for execution by a human tester?

Section C – Open-Ended Questions:

-What aspects do you consider most valuable about the automatic generation of test cases with AI?

-What are the main limitations or risks you identify in the application of this solution?

-What improvements would you recommend to increase the effectiveness of the tool in real-world testing scenarios?

-How do you envision the impact of this solution on the future of software quality assurance?

Task Scheduling in Cloud Computing Environment Based on Dwarf Mongoose Optimization

***Abstract*—The rapid advancement of the Internet and Internet of Things (IoT) technologies has significantly increased the demand for scalable and efficient cloud computing solutions. Task scheduling, a critical aspect of cloud computing, directly impacts system performance by influencing resource utilization, execution time, and operational costs. However, scheduling tasks in large-scale, dynamic cloud environments remains an NP-hard problem, with existing metaheuristic methods often struggling with scalability, convergence, and adaptability. This study proposes a novel task scheduling approach based on the dwarf mongoose optimization (DMO) algorithm. To assess its effectiveness, we conduct two experimental scenarios. The results demonstrate that, compared with existing algorithms, the proposed DMO algorithm offers faster convergence and higher accuracy in identifying optimal task scheduling solutions, particularly under large-scale task loads. We evaluated the method using the Google Cloud Jobs (GoCJ) dataset, and the findings confirm that DMO outperforms prior state-of-the-art techniques in terms of reducing makespan.**

***Keywords*—Task scheduling; cloud computing; virtual machines; dwarf mongoose optimization algorithm; Cloudsim; makespan**

I. Introduction

The exponential expansion of the Internet and the Internet of Things has resulted in a significant increase in network data, rendering cloud computing (CC) increasingly essential. Unlike other distributed computing models like grid computing, CC offers users more flexible and scalable services. To efficiently meet the rising computational demands of large-scale applications, CC now enables the rapid deployment of such applications by offering flexible and resilient resources on a pay-per-use basis [1]. CC has transformed how computational resources are allocated and used, providing unmatched scalability, flexibility, and cost-efficiency for a wide range of applications and services. These massive applications involve a vast number of jobs or tasks processed within service-oriented cloud environments. Among the various cloud service models, the most prominent are Software as a Service (SaaS), Platform as a Service (PaaS), and Infrastructure as a Service (IaaS) [2]. Fig. 1 highlights the key entities in cloud computing that contribute to ensuring continuous service delivery.

In the SaaS paradigm, cloud applications are provided to customers via the Internet and accessed by client programs such as web browsers on desktops or workstations. SaaS is frequently utilized for services including webmail, video-sharing platforms, social networking sites, and online document editors. Concurrently, PaaS provides a development environment tailored for the construction, testing, and deployment of applications. Furthermore, IaaS offers users scalable and adaptable computer resources to facilitate the deployment of extensive applications. In the IaaS paradigm, users employ virtual machines (VMs) that are provisioned with pre-configured CPU, storage, memory, and bandwidth to fulfill their individual requirements. Various VM configurations are available at different price points, giving users control over their computing resources. IaaS offers three main advantages: 1) users pay only for what they use, similar to utilities like electricity or water, allowing flexible resource scaling based on application demands; 2) direct provisioning of resources, which boosts application performance; and 3) global accessibility to rented resources at any time according to the required service level. However, determining the optimal number of resources needed to execute large-scale tasks on an IaaS cloud remains a significant and unresolved challenge [3, 4].

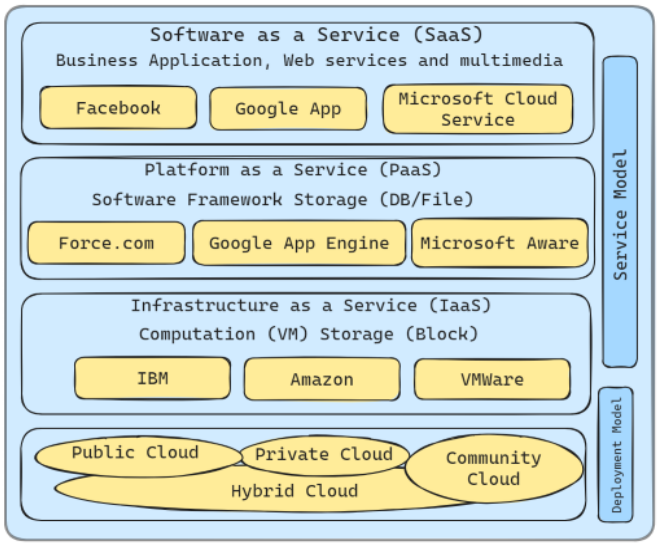

Fig. 1. Cloud Computing Architecture.

Central to CC is the effective management of resources, especially task scheduling across distributed and virtualized systems. Task scheduling plays a vital role in optimizing resource utilization, minimizing execution time, and enhancing overall system performance. However, the complexity and

*Corresponding author.

constantly changing conditions in cloud environments present major challenges for conventional scheduling methods. CC operates by allocating computational tasks to VMs within a resource pool to meet user demands and minimizing task completion time. The scheduling process generally has two primary stages: first, allocating user-submitted tasks to a selection of accessible VMs; second, establishing or relocating virtual machines onto suitable hosts [5]. The efficiency of task-to-VM scheduling directly impacts the overall processing capability of a cloud computing system, making it a critical area of study. Among the various performance metrics, makespan, which represents the total time required to complete all tasks, is one of the most important indicators for evaluating system efficiency [6, 7]. Therefore, an efficient task scheduling algorithm should aim to minimize makespan. However, as the number of tasks and VMs grows, the problem becomes an NP-hard optimization challenge, often leading to dimensional complexity issues.

Due to the practical applications and challenges associated with executing large-scale tasks, task scheduling for massive-scale applications has become a major research focus in cloud computing, gaining considerable scholarly attention. Various metaheuristic algorithms have been employed to address task scheduling and other optimization problems, often producing promising results for small-scale tasks. Nonetheless, when the problem size and variable count escalate, the quality of candidate solutions produced by these algorithms deteriorates drastically. Furthermore, numerous existing techniques fail to satisfy diverse Quality of Service (QoS) requirements, which are essential for both scientific and industrial applications. Recent research has employed metaheuristic techniques, including grey wolf optimization (GWO) [8], synergistic swarm optimization (SSO) [9], particle swarm optimization (PSO) [10], symbiotic organism search (SOS) [11], and African Vultures optimization Algorithm (AVOA) [12] to address task scheduling challenges. Despite their effectiveness in improving performance and constraining the solution search space, these methods still struggle with challenges such as excessive computational time, premature convergence to local optima, poor balance between exploration and exploitation, and unreliable performance across larger search spaces [13,14].

Owing to the constraints of existing scheduling techniques in large-scale dynamic cloud environments, this research proposes a DMO-based task scheduling algorithm. To the best of our knowledge, this is the first application of the DMO algorithm for optimizing execution time (makespan) in cloud computing [15]. By harnessing DMO's strong balance between exploration and exploitation, motivated by the foraging and social habits of dwarf mongooses, the proposed approach aims to enhance cloud system performance, reduce makespan, and improve scheduling efficiency for large-scale applications. This novel application of DMO addresses the critical need for high-performance, scalable scheduling solutions in modern cloud environments.

The study focuses on the design, development, and performance evaluation of an innovative task scheduling algorithm tailored for cloud computing environments. The effectiveness of the proposed method is benchmarked against various state-of-the-art algorithms using recognized task scheduling scenarios. Through extensive experimentation and comparative analysis, the algorithm's capability in scalability, convergence speed, and solution quality is clearly shown. The proposed task scheduling method, founded on the DMO algorithm, delivers an efficient and robust solution for task scheduling in cloud computing environments. In large-scale and dynamic cloud environments, it enhances overall system efficacy and resource utilization. This study's primary contributions can be succinctly presented as follows:

- Clearer Presentation of DMO Procedures: We provide a structured and detailed explanation of the DMO algorithm, enhancing its interpretability for cloud-based optimization problems.
- Design and Implementation of a Discrete DMO Variant: A discrete version of the DMO algorithm is proposed and implemented specifically for task scheduling in cloud computing, enabling it to handle non-continuous scheduling spaces effectively.
- Experimental Validation on GoCJ Dataset: The proposed algorithm undergoes extensive testing on the widely known GoCJ benchmark dataset, showcasing its efficacy and computing efficiency in realistic circumstances.
- Comprehensive Performance Evaluation: To evaluate performance, the algorithm is analyzed through essential metrics like makespan, response time, and degree of imbalance among VMs, demonstrating its impact on efficient resource utilization and balanced workload distribution.

The rest of the study is organized as follows: Section II discusses related studies and analyzes existing solutions for task scheduling in cloud computing. Section III defines the optimization model and problem statement adopted in this work. Section IV explains the design and implementation process of the proposed DMO-based algorithm. Section V presents a comprehensive performance evaluation based on simulation results and comparative metrics. Section VI concludes the study with a summary of outcomes and possible future research directions.

II. Related Work

Researchers have formulated diverse scheduling models from various directions to tackle the task scheduling issue in CC environments, as proven in the available literature. These models are generally improved by sophisticated algorithms, yielding favorable outcomes in reducing performance indicators such as average response times, makespan, total execution time, and enhancing load balancing. While numerous approaches have been proposed, this section focuses on summarizing the most recent and commonly used task scheduling algorithms documented in the literature [16]. Despite the progress made, there remains significant room for improvement, particularly in enhancing scalability, solution quality, and execution efficiency in large-scale, dynamic cloud environments.

The research [17] presents a unique methodology termed MALO, which is a hybrid antlion optimization algorithm

integrated with elite-based differential evolution. This strategy is explicitly formulated to address the multi-objective characteristics of task scheduling by concentrating on minimizing makespan and optimizing resource consumption concurrently. The innovation lies in improving the antlion optimization algorithm with a local search technique to better explore potential solutions and avoid suboptimal results. Through experiments using synthetic and real trace datasets with the CloudSim toolkit, MALO demonstrated superior performance compared to other well-known optimization algorithms. It was especially recognized for its accelerated convergence in extensive search areas, rendering it exceptionally appropriate for tackling large-scale scheduling challenges. The efficacy of MALO was further substantiated through statistical analysis, affirming its substantial enhancement in task scheduling results.

Task scheduling in CC is essential for the optimum utilization of resources. It entails organizing multiple tasks among diverse VMs to reduce the overall completion time (makespan) and optimize resource use. This method is intricate, particularly for large-scale data applications, as it constitutes an NP-hard problem, indicating that identifying the optimal approach is exceedingly difficult. In [18], the authors propose a method employing a hybrid dragonfly algorithm (MHDA) designed to optimize task scheduling by minimizing makespan and augmenting resource consumption. The dragonfly algorithm mimics the swarming behavior of dragonflies and is combined with b-hill climbing, a technique that helps in exploring solutions more effectively to avoid getting stuck in less optimal solutions.

The study [19] proposes an adaptive symbiotic organism search (ABFSOS) algorithm that aims to address this issue by adjusting its parameters to better balance exploration and exploitation, leading to faster and more effective solutions. Additionally, the study introduces an adaptive strategy for handling constraints within the scheduling process.

CC is vital for contemporary computational frameworks because of its scalability and adaptability, influencing system efficiency and resource management. The proposed optimization algorithm detailed in [9] integrates the strengths of the Jaya algorithm's capacity to exploit optimal solutions, the collaborative search strategy of SSO, and the stochastic component introduced by Levy flights, thereby offering a synergistic optimization framework.

The paper [20] proposed a novel approach integrating GWO and the genetic algorithm (GA) to optimize task scheduling in cloud computing, aiming to address shortcomings in existing methods and enhance efficiency. The proposed method overcomes issues like premature convergence and suboptimal solutions, resulting in more effective task scheduling in cloud environments, allowing for faster convergence in large scheduling problems, as evaluated using the CloudSim toolkit.

The proposed chameleon and remora search optimization (CRSOA) [21] tackles these difficulties by accounting for MIPS and network bandwidth impacts, which directly influence VM performance. The system simultaneously accounts for uncertainty factors, including task completion rate, load balance, scheduling cost, and makespan, hence improving scheduling processes. The CRSOA model develops a multi-objective optimization strategy for cloud task scheduling with a greedy methodology to replicate actual cloud computing work scheduling. Experimental findings demonstrate that CRSOA diminishes completion time, reduces makespan by 18.96%, lowers cost by 22.18%, and enhances load balancing among VMs by 20.54% relative to other metaheuristic algorithms.

The study [22] proposes a new multi-objective task scheduling algorithm named DCOHHOTS, which is an enhancement of the Harris Hawks Optimizer (HHO) through the integration of differential evolution (DE), chaotic maps, and opposition-based learning (OBL). The proposed algorithm optimizes the initial positioning of the "hawks" or search agents to improve the efficiency of finding solutions. By prioritizing tasks and efficiently assigning them to resources, the algorithm seeks to reduce makespan, lower energy consumption, and minimize execution costs.

The research [23] integrates the pollination behavior of flowers with the exploratory search abilities of grey wolves, in conjunction with crossover operators from evolutionary algorithms. To enhance the exploration capabilities of the FPA, the grey wolf optimizer is integrated. This strategy mimics the social hierarchy and hunting techniques of grey wolves, improving the algorithm's ability to avoid local optima and ensuring a thorough search of the solution space. The crossover operators from genetic algorithms are employed to facilitate the exploitation phase.

The study [24] introduces a novel task scheduling algorithm that integrates the Harris Hawk Optimization (HHO) algorithm with fuzzy logic to tackle the intricate issue of task scheduling in cloud environments. This combination seeks to optimize allocation of tasks to virtual machines, focusing on enhancing many objectives, including reducing makespan, decreasing energy usage, and minimizing expenses. The efficacy of the suggested fuzzy-HHO approach is substantiated by comprehensive simulations in the CloudSim framework, where it is juxtaposed with two prominent algorithms. The results demonstrate substantial improvements in makespan reduction (up to 47%), energy consumption reduction (up to 73%), and cost savings (up to 19%), particularly in circumstances with a high volume of activities.

Considering the aforementioned studies illustrating enhancements in minimizing the makespan of cloud computing systems, numerous present methodologies remain susceptible to local optima, particularly inside high-dimensional search spaces. The intrinsic complexity and organization of task-to-VM mappings underscore the necessity for ongoing study in task scheduling. A brief summary of the related research is shown in Table I.

III. PROBLEM DESCRIPTION

Upon submission of tasks by users, the Cloud Broker (CB) initially receives them and subsequently requests the Cloud Information Service (CIS) to identify the necessary services for task execution. After finding the relevant services, the CB organizes the tasks on the identified VMs. For example, a set of tasks $\{T_1, T_2, T_3, \ldots, T_n\}$ may be submitted within a given time frame. The available VMs are heterogeneous, each with different processing capabilities and memory capacities, meaning that the same task may have different execution times and costs depending on the VM it is assigned to.

After receiving tasks, the CB assigns them to available virtual machines $\{V_1, V_2, V_3, \ldots, V_m\}$. In the baseline configuration, task execution follows the First-Come, First-Serve (FCFS) policy. The main goal of this work is to enhance this scheduling process to improve VM utilization and minimize makespan. For this purpose, the Expected Time to Compute (ETC) metric is utilized as the basis for task assignment. The ETC value for a task on a VM is calculated by dividing the task's length by the VM's processing capacity in millions of instructions per second (MIPS). These values are organized in a matrix structure, where rows correspond to tasks and columns to VMs, and each entry represents the estimated execution time for a particular task-VM pair. The execution time of task j on virtual machine i is denoted as C_{ij}, where $i \in \{1,2,\ldots,m\}$ and $j \in \{1,2,\ldots,n\}$. Here, m corresponds to the total number of VMs and n to the total number of tasks.

To resolve challenges faced by current task scheduling techniques, including high computational overhead, poor scalability, and premature convergence, this work utilizes the DMO algorithm to obtain efficient task-to-VM assignments. Modeled after the cooperative and adaptive behaviors of dwarf mongoose colonies, DMO maintains an effective trade-off between exploration and exploitation. Integrating the ETC matrix into the scheduling process allows the proposed approach to minimize makespan while enhancing resource utilization across heterogeneous cloud environments.

IV. DMO FOR THE TASK SCHEDULING PROBLEM

The DMO algorithm [27] draws inspiration from the social structure and foraging patterns of dwarf mongooses. By simulating the coordinated behavior of scouts, alpha leaders, and babysitters, the algorithm maintains a robust balance between exploration and exploitation across the search space. Owing to these features, DMO is well-suited for addressing complex optimization tasks such as task scheduling in cloud computing, aiming to achieve near-optimal task-to-VM allocations under heterogeneous and dynamic conditions.

A. Overview of DMO Algorithm

DMO simulates a colony of dwarf mongooses navigating the solution space in search of food sources, which are analogous to optimal or near-optimal solutions. The algorithm operates through iterative updates of a population of candidate solutions, where exploration is guided by scout mongooses, and exploitation is controlled by the alpha mongoose. The babysitter mongoose ensures stability in the population by managing diversity and maintaining solution feasibility. Each candidate solution in the DMO model encodes a distinct task-to-VM mapping. Its fitness value is calculated using a scheduling criterion, most often the makespan, obtained from the ETC matrix. The goal is to minimize the makespan, ensuring balanced workload distribution and efficient resource usage across VMs.

The DMO algorithm begins by initializing a population matrix X of dimensions $(n \times d)$, where n denotes the population size (rows) and d represents the number of problem dimensions (columns), as shown in Eq. (1). This matrix models the mongoose population.

$$X = [x_{ij}]_{n*d}, i = 1,2,\dots,n; j = 1,2,\dots,d \quad (1)$$

In Eq. (2), the population matrix X is initialized randomly, where x_{ij}represents the position of the jth dimension for the ith individual. Here, n is the total population size and d is the number of problem dimensions.

$$x_{ij} = unifrnd(VarMin, VarMax, VarSize) \quad (2)$$

The function unifrnd generates random values uniformly distributed between $VarMin$ and $VarMax$, which define the lower and upper bounds of the problem, respectively. Once the initial population is generated, the fitness of each individual is evaluated. The probability associated with each individual's fitness is computed according to Eq. (3), which is then used to select the alpha female (α) based on these probabilities.

$$\alpha = \frac{fit_i}{\sum_{i=1}^{n} fit_i} \quad (3)$$

The parameter $n - bs$ denotes the number of mongooses in the alpha group, where bs corresponds to the number of babysitters. The alpha female's vocalization, referred to as $Peep$, influences the group's movement direction. Eq. (4) is used to generate a candidate food location, guiding the search process.

$$X_{i+1} = X_i + \phi * peep \quad (4)$$

Here, ϕ is a uniformly distributed random number in the range $(0,1)$. After each iteration, the sleeping mound value is calculated using Eq. (5):

$$sm_i = \frac{fit_{i+1} - fit_i}{max\{|fit_{i+1}, fit_i|\}} \quad (5)$$

The average sleeping mound value across all individuals is then obtained from Eq. (6):

$$\phi = \frac{\sum_{i=1}^{n} sm_i}{n} \quad (6)$$

Scout mongooses perform exploration by searching for new sleeping mounds and preventing revisits to previous locations. This exploratory movement is modeled by Eq. (7):

$$X_{i+1} = \begin{cases} X_i - CF * \phi * rand * [X_i - \vec{M}], & if\ \phi_{i+1} > \phi_i \\ X_i + CF * \phi * rand * [X_i - \vec{M}], & elsewhere \end{cases} \quad (7)$$

The control factor CF is defined in Eq. (8) and decreases gradually over iterations to balance exploration and exploitation.

$$CF = \left(1 - \frac{iter}{Max_{iter}}\right)^{\left(\frac{2*iter}{Max_{iter}}\right)} \quad (8)$$

Finally, Eq. (9) defines the movement vector $\vec{M}$, which directs the mongoose population toward new sleeping mound positions.

$$\vec{M} = \sum_{i=1}^{n} \frac{x_i \times sm_i}{x_i} \quad (9)$$

Algorithm 1 presents the pseudocode representation of the DMO algorithm, detailing its procedural logic and computational operations that can be directly applied for task scheduling in cloud computing environments.

Algorithm 1: Pseudocode for DMO

Input: Task set, VM set, population size n, maximum iterations Max_iter, control parameters

Output: Optimal task-to-VM mapping (minimum makespan)

1. Initialize all control parameters.
2. Generate the initial mongoose population X=[x_ij]_(n×d) using Eq. (2).
3.Divide the population into three functional groups: scouts, babysitters, and alphas.
4. Determine the number of active search agents by excluding babysitters from the total population.
5. Assign the babysitter exchange rate L.
6. Repeat until the stopping condition or Max_iter is reached:
   a. Evaluate the fitness of each mongoose using the scheduling objective (makespan).
   b. Identify the alpha group based on selection probability using Eq. (3).
   c. Generate a new candidate food source location using Eq. (4).
   d. Compute the sleeping mound value for each mongoose using Eq. (5).
   e. Calculate the average sleeping mound value and movement vector M ⃗ using Eq. (6) and (9).
   f. Update scout mongoose positions using Eq. (7) based on exploration conditions.
   g. Perform babysitter exchange according to rate L.
   h. Update the best solution found so far if improvement occurs.

Return the final best solution as the optimal task scheduling configuration.

V. Experimental Evaluation

The efficiency and scalability of the proposed task scheduling technique based on the DMO algorithm are evaluated and compared against benchmark techniques reported in the literature. As outlined earlier, this study primarily focuses on assessing the scheduling performance of the proposed technique. Accordingly, all tasks considered in the experimental evaluation are assumed to be pre-decomposed and mutually independent. The experimental configuration, performance metrics, and evaluation procedures are described in detail in the following subsections.

A. Experimental Settings

The benchmarking process involved comparing the proposed DMO algorithm with several state-of-the-art metaheuristic approaches, including MALPSO [28], EMPA [26], and GWOEM [29]. Each algorithm was executed independently 20 times to reduce the influence of stochastic variations and to ensure the statistical reliability of the obtained results. All experiments were performed using the CloudSim simulation toolkit, which enables the modeling and analysis of cloud computing environments. The simulations were

conducted on a system equipped with a 12th Gen Intel(R) Core (TM) i7-12700H processor operating at 2.70 GHz, 16 GB of RAM, and running the Windows 11 operating system.

TABLE II. PARAMETER IMPLEMENTATION

Algorithm	Parameter	Value
GBOEM	Population size	100
	a	Linearly decrease from 2 to 0
MALPSO	Population size	100
	c_1, c_2	$[2.1, 2.1]$
	w_{max}, w_{min}	$[0.9, 0.6]$
EMPA	Population size	100
	FADs	0.2
	P	0.5
DMO	Population size	100

The experimental parameter settings are summarized in Table II. To ensure consistency, all algorithms were executed with a population size of 100 and a maximum of 100 iterations, following configurations commonly adopted in recent studies. Although increasing the number of iterations can improve solution quality in terms of makespan, it also results in higher computational overhead.

B. Dataset Description

This study employs the Google Cloud Jobs (GoCJ) dataset to establish the task workload in order to more accurately simulate the task scheduling scenario in cloud computing. In this dataset, the computational capability of each VM is expressed in millions of instructions per second (MIPS), while task sizes are characterized by the number of instructions required for completion. The GoCJ repository comprises multiple datasets, each stored in a text file format. Every dataset contains a specific number of tasks, as summarized in Table III. Each text file comprises a sequence of lines, each of which denotes a task and contains a single value representing the task's magnitude in MI.

C. Experimental Results and Analysis

This subsection presents the experimental findings derived from the proposed DMO-based task scheduling method and compares them with the results of three established algorithms: MALPSO, EMPA, and GWOEM. A comprehensive analysis of the comparative performance is also included. The simulations are conducted under two separate circumstances to ensure a thorough evaluation. A constant quantity of VMs is utilized across all datasets. In the second scenario, the quantity of VMs is altered for each dataset to evaluate the algorithm's adaptability and scalability under varying resource constraints.

TABLE III. THE NUMBER OF TASKS CONTAINED IN EACH DATASET CATEGORY

Dataset category	Number of tasks
GoCJ_100	100
GoCJ_200	200
GoCJ_300	300
GoCJ_400	400
GoCJ_500	500
GoCJ_600	600
GoCJ_700	700
GoCJ_800	800
GoCJ_900	900
GoCJ_1000	1000

1) Performance comparison with a constant number of VMs: A fixed number of VMs is used in the experiment for every dataset. The assessment is centered on a diverse array of activities extracted from the aforementioned GoCJ datasets, which encompass tasks of varied magnitudes. The goal of optimization is to effectively allocate these jobs to 50 VMs. Performance for each algorithm under comparison, including the proposed DMO-based technique, is evaluated using the makespan metric to ascertain the overall time necessary to accomplish all assigned jobs.

Table IV presents the makespan results for four task scheduling algorithms evaluated across different task sizes using a fixed set of 50 virtual machines. The DMO-based method is compared against MALPSO, GWOEM, and MPA. The evaluation includes the Best, Worst, and Mean values obtained from 20 independent runs for each algorithm. From the results, it is evident that DMO consistently achieves lower Mean values across nearly all task sizes. Specifically, DMO obtains the lowest Mean makespan in all cases, ranging from 228.2 (for 200 tasks) to 727.96 (for 1000 tasks), outperforming the competing algorithms.

To provide a more intuitive comparison, the cumulative ranks based on the Mean makespan values across 10 datasets are illustrated in Fig. 2. For each dataset, the algorithms are ranked from best to worst in terms of average performance, where a lower bar height indicates better overall performance. The top-performing algorithm in each dataset receives a rank of 1, and the ranks are summed to produce the cumulative values shown in the figure. As depicted in Fig. 2, the proposed DMO-based scheduling algorithm consistently outperforms the competing methods, achieving the lowest cumulative rank of 10, which indicates it ranked first in all datasets. While MALPSO, GWOEM, and MPA accumulate ranks of 19, 28, and 37, respectively, reflecting their lower relative performance. These results further validate the effectiveness of DMO in solving the cloud task scheduling problem.

TABLE IV. MAKESPAN ACROSS ALL DATASETS WITH 50 FIXED VMS

Task	MALPSO			GWOEM			MPA			DMO		
	Best	Worst	Mean	Best	Worst	Mean	Best	Worst	Mean	Best	Worst	Mean
100	180.1	180.21	180.1	180.1	180.1	180.1	180.1	180.21	180.1	180.1	180.11	180.1
200	215.4	255.57	238.99	219.7	251.1	240.46	225.55	269.7	250.1	216.5	237.2	228.69
300	282.14	343.52	321.35	296.3	344.9	324	303.1	361.6	334.63	281.9	314.7	298.32
400	333.1	388.3	369.44	343.4	394.9	370.31	346.1	407.1	377.27	311.3	359.84	339.78

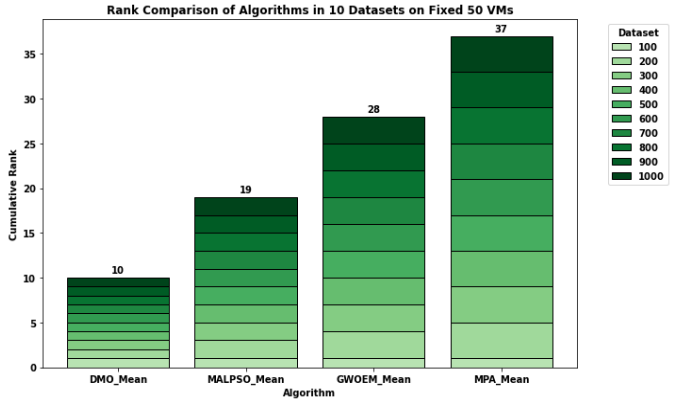

Fig. 2. Mean rank comparison across datasets with fixed VMs.

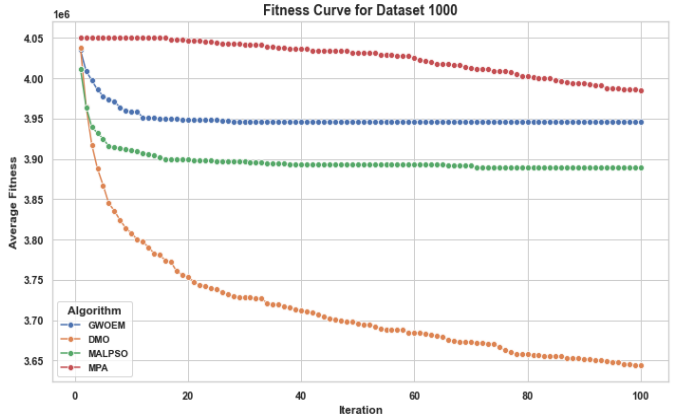

Fig. 3. Fitness convergence curves of algorithms on fixed number of VMs.

Fig. 3 presents the fitness convergence curve of the proposed DMO algorithm in comparison with GWOEM, MALPSO, and MPA for the 1000-task dataset. As observed from the curve, DMO achieves a significantly lower average makespan than the competing algorithms. Although MALPSO converges faster in the early iterations, it plateaus earlier and stabilizes at a higher makespan compared to DMO. In contrast, DMO continues refining its solution steadily throughout the search process, reflecting a balanced exploration-exploitation dynamic that avoids premature convergence. GWOEM and MPA show comparatively slower convergence and higher final makespan values, indicating their limited ability to escape local optima or adapt efficiently under heavier task loads. DMO, however, demonstrates strong robustness and convergence stability, consistently maintaining a downward trend in fitness even toward later iterations.

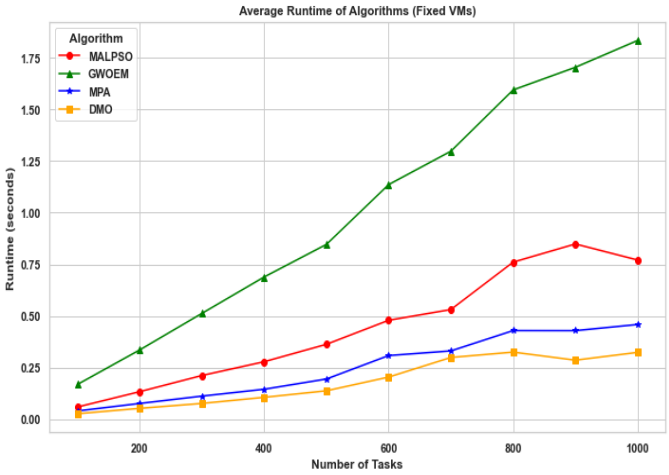

Fig. 4. Average runtime per dataset with fixed VMs.

Fig. 4 displays the average runtime of each algorithm: DMO, MALPSO, GWOEM, and MPA across increasing task sizes under a fixed number of virtual machines. The x-axis represents the number of tasks (ranging from 100 to 1000), while the y-axis indicates the average computational time in seconds required to complete one run. As shown in the figure, the DMO algorithm consistently demonstrates the lowest runtime across all task sizes, indicating its superior computational efficiency. The consistently shorter execution time of DMO, coupled with its high-quality results observed in earlier evaluations, shows its practical suitability for large-scale task scheduling applications particularly in real-time or resource-constrained cloud environments.

A paired t-test was conducted to statistically assess the performance of the proposed DMO algorithm against MALPSO, GWOEM, and MPA on the GoCJ dataset under fixed VM configurations as shown in Table V, using a

significance level of $\alpha = 0.05$. For small-scale workloads (100 tasks), no statistically significant differences were observed ($p > 0.05$), indicating comparable performance due to limited scheduling complexity. However, for task sizes of 200 and above, DMO consistently achieved significantly lower makespan values, as reflected by negative mean differences, large-magnitude t-values, and extremely small p-values (often $< 10^{-29}$), leading to rejection of the null hypothesis. The magnitude and consistency of these improvements increase with problem size, particularly for medium to large workloads (300–1000 tasks), demonstrating DMO's robustness and scalability in high-dimensional scheduling spaces. These statistically significant results confirm that the observed performance gains are not due to random variation and provide strong empirical evidence supporting the effectiveness of DMO for large-scale cloud task scheduling.

TABLE V. STATISTICAL T-TEST RESULTS FOR MAKESPAN COMPARISON ON THE GOCJ DATASET WITH FIXED VMS

Task Size	Comparison	Mean Difference	Std Difference	t-value	p-value	Better Algorithm	Significant
100	DMO vs MALPSO	-0.001	0.011055	-0.90453	0.367908227	DMO	FALSE

Fig. 5 illustrates the average makespan values obtained by four algorithms as the number of tasks increases from 100 to 1000. As depicted, the makespan values increase proportionally with the number of tasks which is expected due to the growing computational workload. However, the DMO algorithm consistently achieves the lowest makespan across all dataset sizes, demonstrating its superior scheduling capability. Notably, the gap between DMO and the other methods becomes more prominent as task volume increases, highlighting DMO's scalability and robustness under larger workloads.

Fig. 6 presents the degree of imbalance of the task scheduling solutions generated by the four compared algorithms under a fixed number of VMs. DoI reflects how evenly tasks are distributed across available resources, with lower values indicating better load balancing. As illustrated, DMO consistently achieves the lowest imbalance across all task volumes, demonstrating its strong ability to maintain load uniformity among VMs. While all algorithms show a downward trend in DoI as the task count grows, indicating improved balance with larger workloads DMO outperforms others in both convergence speed and final balance quality.

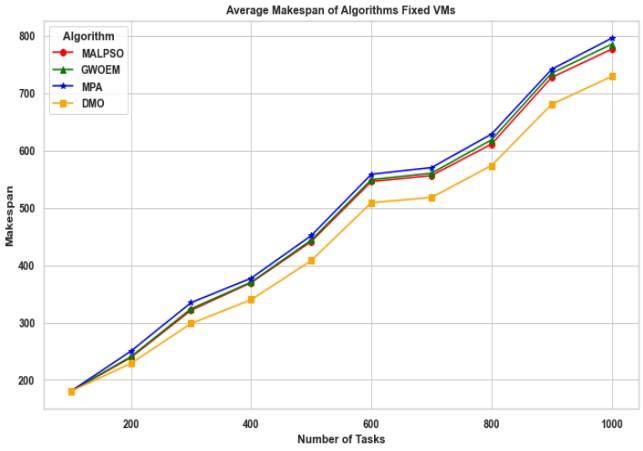

Fig. 5. Average makespan per dataset with fixed VMs.

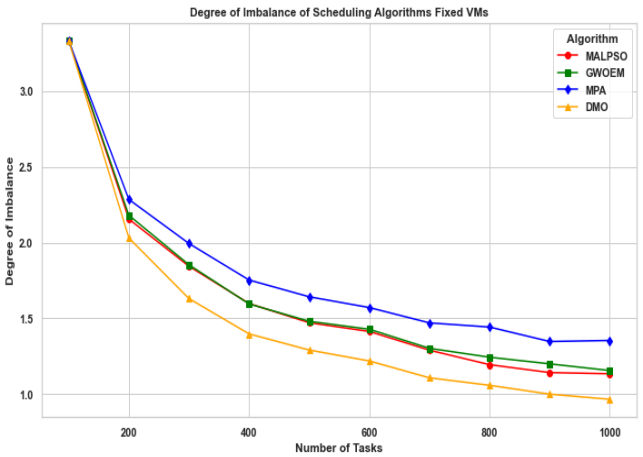

Fig. 6. Degree of imbalance per dataset with fixed VMs.

Fig. 7. Average throughput per dataset with fixed VMs.

Fig. 7 illustrates the average throughput achieved by each of the four algorithms across increasing numbers of tasks under a fixed number of VMs. Throughput measures the number of tasks successfully completed per unit time and is a critical metric for evaluating the responsiveness and efficiency of scheduling algorithms in cloud environments. From the figure it is observed that MALPSO, GWOEM, and MPA exhibit similar patterns, with slightly lower throughput values. While all algorithms show improved throughput with increased task sizes due to higher resource utilization DMO maintains a clear performance lead, particularly beyond 400 tasks, where its optimization capabilities yield a noticeable efficiency advantage.

2) Scenario with varying number of VMs: To further assess the scalability and performance of the proposed algorithm under varying resource conditions, a second set of experiments was conducted using different numbers of VMs for each dataset category. The allocation of VMs for each dataset was determined to be 10% of the total number of tasks, yielding VM counts between 10 and 100. The number of VMs designated for each dataset is summarized in Table VI. This experimental configuration aims to evaluate how changes in resource availability impact key performance indicators, particularly makespan. By correlating scheduling efficiency with increasing task-to-resource ratios, the results provide insight into the scalability and robustness of the algorithms under more realistic and dynamic cloud environments.

Table VII presents the makespan results of four algorithms: DMO, MALPSO, GWOEM, and MPA. The evaluation metrics include the Best, Worst, and Mean of the makespan over 20 independent runs. From the data in Table VII, it is evident that the proposed DMO consistently achieves the best Mean makespan values across all datasets. For instance, in the largest dataset (1000 tasks), DMO yields a Mean makespan of 468.68, which is significantly lower than the corresponding results from GWOEM (505.52), MPA (514.72), and MALPSO (503.82). DMO also performs strongly in the Best-case results, outperforming the other algorithms in most datasets, reflecting its superior ability to locate high-quality solutions.

TABLE VI. VM DISTRIBUTION PER DATASET SIZE

Dataset size	Number of VMs
100	10
200	20
300	30
400	40
500	50
600	60
700	70

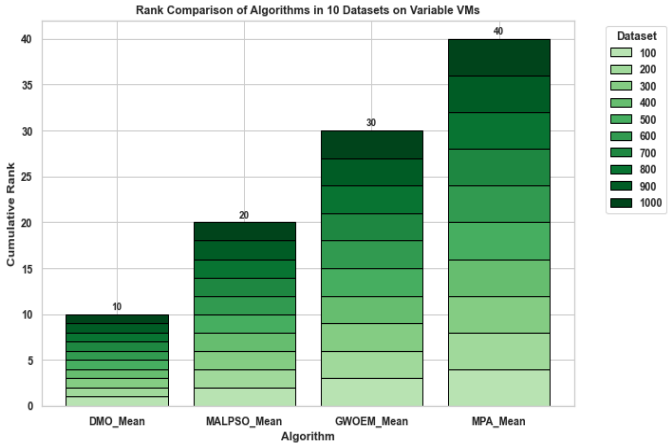

Fig. 8. Mean rank comparison across datasets with variable VMs.

To better visualize the comparative performance, Fig. 8 ranks each algorithm based on its Best, Worst, and Mean. The proposed DMO achieves the lowest cumulative rank in three of the four subplots, especially excelling in the Best and Mean categories. This confirms DMO's capability to consistently find better solutions and maintain overall stability. Even in the Worst and Std categories, DMO ranks among the top performers, further supporting its robustness.

Fig. 9 shows the fitness convergence of DMO, GWOEM, MALPSO, and MPA on the 1000-task dataset using a variable number of VMs. DMO exhibits the fastest and most stable convergence, achieving the lowest average fitness. While other algorithms plateau early, DMO continues improving, showing strong exploitation capability. These results confirm DMO's efficiency and robustness in high-load, dynamic VM environments.

To further examine the robustness of the proposed DMO algorithm, a paired t-test was performed on the makespan results obtained from the GoCJ dataset with varying numbers of VMs as shown in Table VIII. Unlike the fixed-VM scenario, all comparisons across task sizes from 100 to 1000 exhibit statistically significant differences ($p < 0.05$), with DMO consistently identified as the superior algorithm. The uniformly negative mean differences and large-magnitude t-values indicate substantial and reliable reductions in makespan when DMO is applied. Notably, the statistical significance persists even for small-scale workloads (100 tasks), highlighting DMO's strong adaptability to dynamic resource availability. As task sizes increase, the magnitude of the mean differences remains consistently high, demonstrating that DMO effectively maintains solution quality despite increased scheduling complexity and VM variability. These results confirm that DMO is not only scalable but also resilient to changes in cloud infrastructure, making it particularly suitable for real-world cloud environments characterized by fluctuating resource configurations.

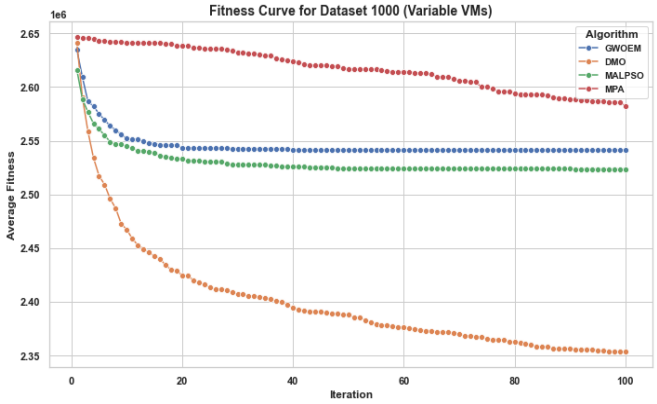

Fig. 9. Fitness convergence curves of algorithms on variable number of VMs.

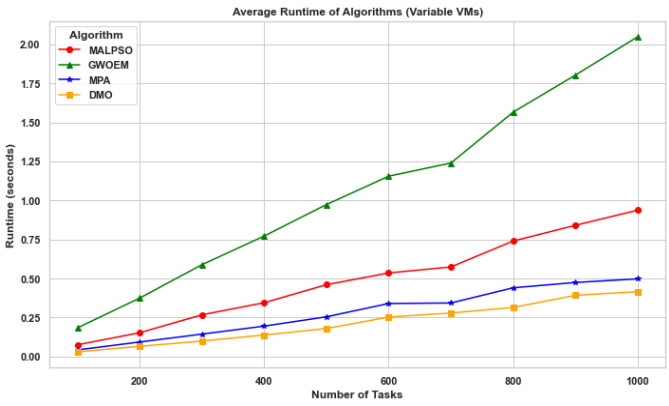

Fig. 10. Average runtime per dataset with variable VMs.

TABLE VIII. STATISTICAL T-TEST RESULTS FOR MAKESPAN COMPARISON ON THE GOCJ DATASET WITH VARYING VMS

Task Size	Comparison	Mean Difference	Std Difference	t-value	p-value	Better Algorithm	Significant

Fig. 10 compares the runtime of the four algorithms across varying task sizes using a variable number of VMs. The proposed DMO maintains the lowest runtime throughout, showing excellent computational efficiency. GWOEM incurs the highest cost, scaling poorly as task size increases. This confirms DMO's lightweight nature and scalability, making it suitable for real-time cloud scheduling. Even with increased workload, DMO's runtime growth remains modest, reflecting its optimized search process. This efficiency makes it ideal for deployment in latency-sensitive environments.

Fig. 11 presents the average makespan performance of DMO, MALPSO, GWOEM, and MPA as the number of tasks increases under a variable VM setup. The DMO achieves the lowest makespan value across all task sizes, indicating superior task-to-resource mapping. While the makespan naturally increases with task load, DMO maintains a significant margin of improvement over competing algorithms. This trend reflects DMO's efficiency and scalability, especially in dynamically resourced environments. The stability in DMO's curve also suggests consistent performance across heterogeneous workloads.

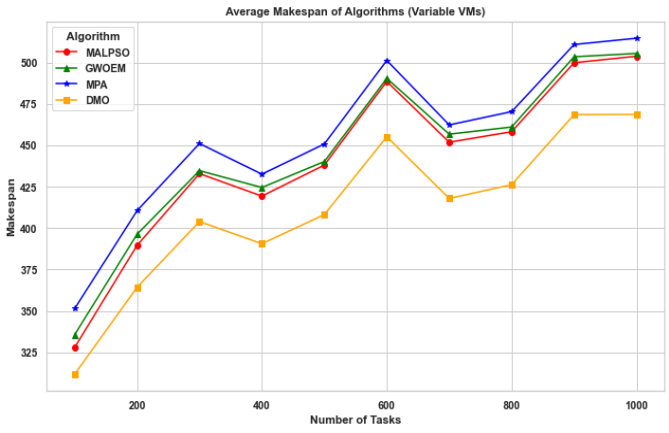

Fig. 11. Average makespan per dataset with variable VMs.

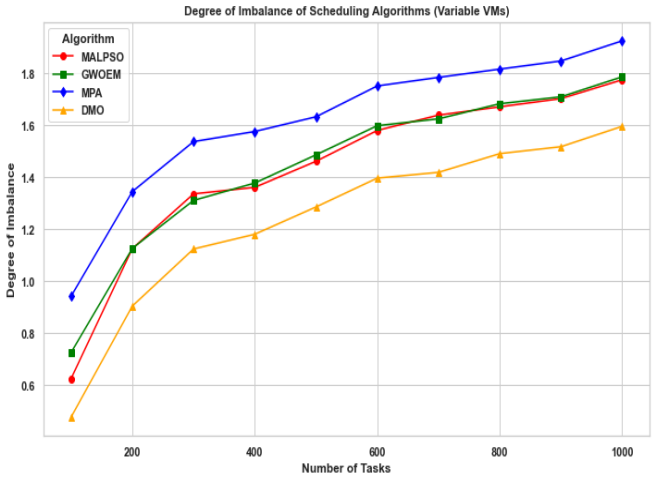

Fig. 12. Degree of imbalance per dataset with variable VMs.

Fig. 12 illustrates the degree of imbalance for four algorithms as the task count increases under variable VM settings. The DMO maintains the lowest imbalance values, indicating more uniform load distribution. Although DoI increases with task volume, DMO's curve rises more slowly, showing greater stability and fairness. In contrast, MPA consistently shows the highest imbalance, highlighting less efficient task scheduling. These results confirm DMO's robustness in balancing workloads, even in dynamic VM environments.

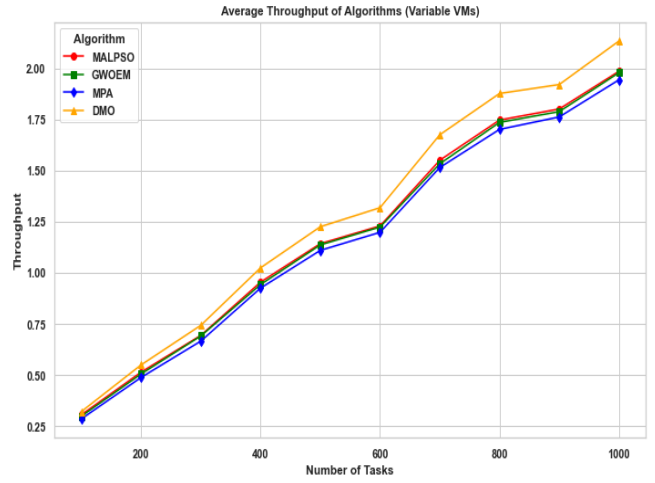

Fig. 13. Average throughput per dataset with variable VMs.

Fig. 13 depicts the average throughput achieved by each algorithm as the number of tasks increases under a variable number of VMs. The proposed DMO consistently outperforms its counterparts, achieving the highest throughput across all task sizes. This indicates more tasks are completed per time unit, highlighting DMO's superior efficiency. The gap becomes more significant as task volume scales, confirming DMO's strong adaptability and parallelism handling. This makes it well-suited for high-throughput cloud environments.

VI. Conclusion and Future Work

Task scheduling is a substantial and complex challenge in CC, with ongoing research aimed at discovering efficient methods for assigning tasks to computational resources to minimize makespan. This study presents a DMO-based task scheduling technique aimed at enhancing system performance through the optimal utilization of available computing resources. The comprehensive execution of the proposed DMO methodology has been delineated, and its efficacy was validated utilizing the GoCJ benchmark datasets. Two experimental situations were executed to evaluate performance, and the outcomes were compared with those of the MALPSO, GWOEM, and MPA algorithms. For each algorithm, essential performance measures such as response time, degree of imbalance, throughput, and makespan were meticulously assessed to gauge overall scheduling efficacy and resource consumption in the cloud context. The analysis demonstrated that the DMO-based method consistently produced superior makespan results, especially under high task loads and varying VM conditions. These findings highlight DMO's capability in efficiently exploring complex solution spaces and maintaining balanced resource distribution. Therefore, the proposed approach significantly enhances task scheduling performance and contributes to improving the overall efficiency and responsiveness of cloud computing systems.

Despite the promising results obtained, this study has several limitations that should be acknowledged to provide a clear and accurate interpretation of the findings. First, the experimental evaluation was conducted using the GoCJ benchmark dataset, which although widely adopted may not fully capture all characteristics of real-world cloud workloads such as bursty task arrivals, task dependencies, or strict deadline constraints. Second, the performance assessment focused primarily on makespan minimization, while other important quality of service metrics such as energy consumption, monetary cost, load balancing, and service level agreement violations were not jointly optimized or analyzed. Third, the experiments were performed under simulated cloud environments with fixed and varying VM configurations and therefore the observed performance may differ in large scale production clouds where network latency, VM failures, and dynamic resource provisioning occur. In addition, the proposed DMO algorithm was compared with a limited set of metaheuristic baselines and comparisons with a broader range of recent scheduling approaches could further strengthen the generality of the conclusions. Finally, algorithm parameter tuning was carried out empirically and alternative tuning strategies may lead to different performance outcomes. Addressing these limitations in future studies through real cloud experimentation, multi objective optimization, and expanded comparative analysis would further enhance the applicability and robustness of the proposed approach.

As future work, we plan to develop a multi-objective performance model that incorporates additional quality service metrics to further enhance task scheduling in cloud computing environments. In particular, optimizing load balancing will be a key focus, as it plays a critical role in maintaining system stability and performance. We also intend to extend the DMO algorithm to support more complex task structures, including

scientific workflows and cloud-based deep learning workloads, thereby improving its adaptability to diverse application scenarios. Furthermore, the applicability of the proposed DMO methodology will be explored in other optimization domains, including workflow scheduling, underwater wireless sensor networks, feature selection, and Internet of Things scheduling problems, to evaluate its generalization capability.

H∞ Control Design for Nonlinear Systems via Multimodel Approach

Rihab ABDELKRIM
Shaqra University, Saudi Arabia

***Abstract*—Nonlinear systems are integral to contemporary engineering applications, yet their regulation remains a significant challenge due to complex and highly dynamic behaviors. Robust control frameworks, particularly H∞ methods, provide systematic tools to ensure stability and performance in the presence of disturbances and modeling uncertainties. This study proposes an integrated design methodology that combines H∞ loop-shaping techniques with multimodel approaches to achieve resilient control of nonlinear systems. The control law is structured around the H∞ loop-shaping scheme, which shapes the open-loop dynamics to meet desired robustness and performance specifications. The multimodel strategy further enhances adaptability by accommodating diverse operating conditions and capturing variations in system behavior. Several control architectures are presented that unify H∞ loop-shaping with multimodel representations, offering a flexible framework for nonlinear system control. The design methodology also ensures desirable transient responses, thereby improving practical applicability for complex systems. A study is conducted to validate the proposed approaches. Simulation results confirm the effectiveness of multimodel H∞ control systems, underscoring their potential as a robust solution for complex nonlinear applications.**

***Keywords*—Nonlinear systems; H∞ loop shaping control; multimodel**

I. INTRODUCTION

Nonlinear systems are pervasive across engineering and scientific domains, naturally arising in mechanical structures [1], electrical circuits, chemical processes, aerospace vehicles, and biological networks. Unlike linear systems, which benefit from analytical tractability and the principle of superposition, nonlinear systems [2] often exhibit complex phenomena such as bifurcations [3], limit cycles, chaotic dynamics [4], and strong coupling effects [5]. These behaviors significantly complicate analysis and control, yet their regulation remains essential for ensuring stability and performance in modern applications. Classical control strategies, including feedback linearization [6], Lyapunov-based methods [7], and sliding mode control [8], have provided effective tools for nonlinear regulation. However, these techniques typically depend on stringent modeling assumptions and may lose reliability in the presence of uncertainties, disturbances, or parameter variations. In practice, nonlinear systems are rarely known with complete accuracy [9], necessitating robust control frameworks to guarantee performance under imperfect knowledge [10] and [11].

Within this context, H∞ control has emerged as a powerful methodology [12]. Its primary objective is to minimize the worst-case impact of disturbances on system performance, thereby ensuring both stability and robustness against uncertainties. Although originally formulated for linear systems, H∞ control has been extended to nonlinear dynamics through various approaches, offering a systematic means of addressing external perturbations and modeling errors. This makes H∞ particularly attractive for safety-critical applications such as aerospace flight control [13], robotics [14], and power systems [15].

Despite its advantages, direct application of H∞ control to nonlinear systems often proves analytically intractable and computationally intensive. To mitigate these challenges, researchers have introduced multimodel approaches [16], in which a nonlinear system is represented by a collection of local models, typically linear or weakly nonlinear, valid within specific operating regions [17]. By switching between or blending these models, multimodel strategies provide a tractable representation of complex nonlinear dynamics [18]. This framework facilitates the design of controllers that adapt to varying operating conditions [19], thereby enhancing robustness and performance without resorting to overly conservative assumptions [20].

The integration of multimodel representations with H∞ control offers a promising pathway toward resilient regulation of nonlinear systems. While multimodel structures reduce complexity by decomposing nonlinear behavior into manageable local models, H∞ design ensures robustness against uncertainties and disturbances. Together, they enable the synthesis of controllers capable of maintaining stability and performance across diverse operating regimes. This study contributes to this growing field by presenting a comprehensive study of H∞ control for nonlinear systems using multimodel approaches, aiming to bridge theoretical rigor with practical applicability in complex engineering contexts.

The remainder of this study is structured as follows: In Section II, we provide a preliminary study on H∞ loop-shaping techniques, highlighting their theoretical foundations and relevance for robust control of nonlinear systems. Section III introduces the multimodel approaches, where nonlinear dynamics are represented through sets of local models to facilitate analysis and controller design. In Section IV, we present an integrated scheme that combines H∞ loop-shaping techniques with multimodel strategies, demonstrating how the synergy between these methods strengthens robustness and flexibility in control system design. Proposed approaches are formulated within this composite methodology to ensure that stability and performance objectives are simultaneously satisfied, and four distinct architectures based on this concept are introduced. The effectiveness of the developed structures is

examined in Section V through rigorous simulation studies, highlighting their robustness and feasibility for real systems implementation. Finally, Section VI concludes the study by summarizing the main contributions and outlining potential perspectives for future research.

II. Preliminary Study of H∞ Loop-Shaping Techniques for Robust Control

A. Foundations of H∞ Loop-Shaping

H∞ loop-shaping control design offers a systematic approach to achieving robust performance in uncertain systems. By shaping the open-loop frequency response to meet desired performance objectives and subsequently applying H∞ optimization, the method ensures stability margins and resilience against modeling errors. This integration of classical intuition with modern robust control theory makes H∞ loop-shaping particularly effective for complex multi-input multi-output systems.

The robust stability problem in the H∞ framework is to determine a controller K(s) that stabilizes the plant G(s) while ensuring that the closed-loop system satisfies prescribed performance and robustness criteria. Specifically, the objective is to design K(s) such that the weighted closed-loop transfer functions achieve a bounded H∞ norm, thereby guaranteeing stability margins in the presence of model uncertainties and external disturbances.

The robust stability H_∞ problem is to find $\gamma_{\min}$ as defined in Eq. (1) and *K(s)* in Eq. (7) in order to stabilize the studied plan *G(s),* such as:

$$\gamma min = \sqrt{1 + \lambda(YX)_{sup}} \tag{1}$$

where, $\boldsymbol{\lambda_{sup}}$ is the largest eigenvalue and the matrices *X* and *Y* are respectively the solutions of the following Riccati equations given by Eq. (2):

$$\begin{cases} XA + A^T X - XBB^T X + C^T C = 0 \\ YA^T + A^T Y - YC^T CY + BB^T = 0 \end{cases} \tag{2}$$

with (*A*, *B*, *C*) is the state space representation of the shaped plant *G denoted* $G_s(S)$, defined by Eq. (3):

$$G_s(s) = W_1(s)G(s)W_2(s) \tag{3}$$

A controller $K_\infty(s)$ stabilizing all the models is described by the state space representation Eq. (4) and Eq. (5):

$$\begin{cases} \dot{x}_c(t) = A_c x_c(t) + B_c y_c(t) \\ u(t) = C_c x_c(t) \end{cases} \tag{4}$$

where,

$$\begin{cases} A_c = A - BB^T X + \gamma^2 Z\gamma YC^T C \\ B_c = \gamma^2 Z\gamma YC^T \\ C_c = B^T X \\ Z_\gamma = (I + YX - \gamma^2 I)^{-1} \end{cases} \tag{5}$$

Using Eq. (5), the H∞ controller is given in Eq. (6) as follows:

$$K_\infty(s) = C_c(sI - A_c)^{-1}B_c \tag{6}$$

The final feedback controller $K(s)$, is obtained by combining controller $K_\infty(s)$ with the shaping functions $W_1(S)$ and $W_2(S)$, which is described by the relation Eq. (7):

$$K(s) = W_1(s)K_\infty(s)W_2(s) \tag{7}$$

B. Architecture of H∞ Loop-Shaping Control Systems

H∞ loop-shaping control provides a systematic framework that combines classical frequency-domain design with modern robust optimization. The method begins by shaping the open-loop transfer function with appropriate weighting functions to achieve desired performance characteristics such as bandwidth, disturbance rejection, and noise attenuation. Once the loop is shaped, H∞ optimization is applied to guarantee robustness against model uncertainties and unmodeled dynamics. This architecture in Fig. 1 is particularly effective for both Single-Input/ Single-Output (SISO) and Multiple-Input/Multiple-Output (MIMO) systems, as it balances intuitive design with rigorous mathematical guarantees, making it a widely applicable framework in robust control engineering.

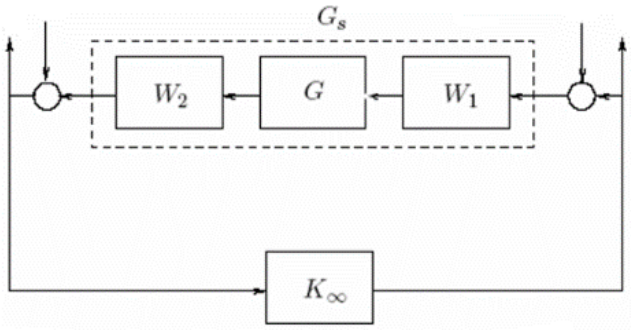

Fig. 1. Architecture of H∞ loop-shaping control systems.

The H∞ loop-shaping control design framework provides a rigorous and principled methodology for achieving robust performance by integrating intuitive frequency-domain shaping with formal optimization techniques. By simultaneously enhancing stability margins and accommodating model uncertainties, this framework is particularly well-suited for the control of complex nonlinear systems. Building upon this foundation, the subsequent section introduces multimodel approaches, which serve as complementary tools for representing nonlinear dynamics through collections of local models. Such representations enable computationally feasible analysis and facilitate systematic controller synthesis, thereby extending the applicability of robust control methods to a broader class of nonlinear systems.

III. Multimodel Approaches for Nonlinear System Representation and Controller Design

A. Multimodel Control for Nonlinear System

The principal objective is the synthesis of a global control law u(t) described by Eq. (8) for the considered nonlinear system Eq. (9), constructed on the basis of the multimodel representation. The resulting control input, designated as the multimodel command, is obtained through the aggregation of partial control signals generated by each local model.

$$u(t) = \sum_{i=1}^{n} v_i(t)u_i(t) \tag{8}$$

$$\begin{cases} \dot{x}(t) = \sum_{i=1}^{n} v_i(t)(A_i x(t) + B_i u_i(t)) \\ y(t) = \sum_{i=1}^{n} v_i(t) C_i x(t) \end{cases} \quad (9)$$

where,

$$\sum_{i=1}^{n} v_i = 1$$

υ_i (t) denotes the validity coefficient corresponding to the i[th] local model, ensuring that the global control law is obtained as a weighted fusion of the partial commands u_i.

In the multimodel representation, A_i denotes the state matrix of the i[th] local model, characterizing the intrinsic dynamics of the system states. The matrix B_i represents the input matrix, mapping the control signal u_i into the state space and thereby defining the influence of external commands. Similarly, C_i is the output matrix, which relates the internal state vector x(t) to the measurable output y(t).

B. Multimodel Architecture for Nonlinear Systems

The multimodel structure constitutes a comprehensive analytical framework that employs multiple local linear time-invariant (LTI) models, expressed in either linear or affine form. This methodology is predicated on the assumption that a complex nonlinear system can be effectively approximated by a structured combination of simpler local models, thereby establishing a representative model base. Each constituent model delineates the system dynamics at a specific operating point, while the global nonlinear behavior emerges from the coordinated interaction of these local models M_i through normalized activation functions. Consequently, the multimodel approach mitigates system complexity by facilitating the investigation of dynamic behavior under rigorously defined operating conditions. The conceptual foundation of this methodology is schematically illustrated in Fig. 2.

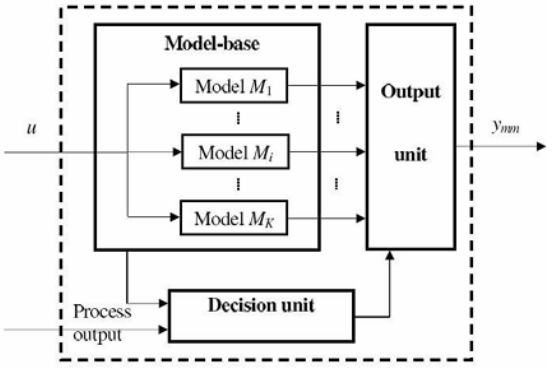

Fig. 2. Architecture of a multimodel approach for control systems.

The multimodel framework is organized into three core components. The model base consists of a library of local or generic models, which may vary in form and order but collectively provide simplified representations of the system across distinct operating regimes. The decision unit governs the selection and activation of these models, ensuring that the most appropriate local representation contributes to the global system defined by M in Eq. (10), given that each model is valid only within a specific operating region. Finally, the output unit synthesizes the overall system response by processing the validity vector associated with the model base. Two strategies are typically employed: commutation, which switches models according to operating conditions, and fusion, which aggregates outputs through a weighted combination. In this study, the fusion approach is adopted and formally defined in the following section.

$$M = \sum_{i=1}^{n} v_i(t) M_i(t) \quad (10)$$

With

$$\sum_{i=1}^{n} v_i = 1$$

IV. H∞ Synthesis under Multimodel Control Design

A. General Principles of H∞ Loop-Shaping Synthesis in Multimodel Control

The integration of H∞ synthesis within a multimodel control paradigm aims to achieve robust performance for nonlinear systems by combining the advantages of multiple local linear models. In this framework, each local model contributes a partial control law derived from H∞ design, ensuring attenuation of disturbances and preservation of stability margins. The global control input is then obtained through a fusion mechanism, where the partial commands are weighted according to the validity coefficients associated with each model. This methodology facilitates seamless transitions among local controllers while ensuring robustness with respect to parameter variations and inherent system nonlinearities. On the basis of this principle, the proposed control architecture is structured around a set of local H∞ controllers, each associated with its corresponding base model. A validity estimation mechanism operates in real time to determine the weighting coefficients that quantify the relevance of each local model. These coefficients are subsequently employed within a fusion module, which synthesizes the global control input delivered to the plant. In the following sections, four distinct architectural configurations of this multimodel H∞ control strategy are introduced and analyzed.

B. Synthesis of Partial H∞ Loop- Shaping controller

For each local model Mi (i = 1, .., n), an H∞ Loop- Shaping controller $K_{\infty i}(s)$ is associated. The corresponding partial control law $K_i(s)$ is then derived by using local shaping $W_{1i}(S)$ and $W_{2i}(s)$, as expressed in Eq. (11):

$$K_i(s) = W_{1i}(s) K_{\infty i}(s) W_{2i}(s) \quad \text{, for i=1..n} \quad (11)$$

The synthesis procedure ensures that each controller attains the desired performance objectives while maintaining stability margins specifically adapted to the dynamic characteristics of its associated local model. By configuring the loop-shaping design to individual operating regimes, the resulting set of partial controllers provides localized robustness and performance guarantees across the multimodel framework. This localized design not only enhances the fidelity of control in each regime but also establishes a foundation for constructing a global control law capable of maintaining robustness under parameter variations, nonlinearities, and external perturbations. Consequently, the multimodel H∞ synthesis approach enables a

systematic balance between local precision and global stability, ensuring reliable performance across the entire operating domain.

C. Synthesis of Global H∞ Loop- Shaping Controller

Once the parameters of the partial controllers have been identified, the subsequent step consists of deducing the global control law to be applied to the nonlinear system under study. A fusion-based control strategy is adopted, as it provides a coherent and effective framework for the proposed multimodel representation. In situations where the system can be accurately approximated by a weighted aggregation of local models, the global controller K(s) is constructed through the fusion of the elementary controllers $K_i(s)$, described by Eq. (12):

$$K(s) = \sum_{i=1}^{n} v_i K_i(s) \quad (12)$$

υ_i (k) denotes the validity coefficient corresponding to the ith local model.

With,

$$\sum_{i=1}^{n} v_i = 1$$

Based on the multimodel H∞ Loop-shaping synthesis framework, four representative architectures are proposed to illustrate different design philosophies and implementation strategies. The following subsection introduces four architectural configurations developed under the multimodel H∞ synthesis framework, highlighting their structural characteristics and the control strategies employed.

D. Proposed Architectures for Multimodel H∞ Control

a) Architecture 1 – Aggregated local controllers: The global control law is synthesized as the summation of local H∞ controllers, each designed with respect to its corresponding local model. The resulting global system is thus formed by the collective contribution of all local models. The architecture is illustrated in Fig. 3 below:

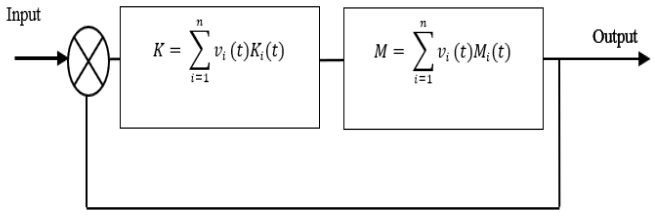

Fig. 3. Architecture 1- Aggregated local controllers.

b) Architecture 2 – Decentralized local control: Each local model is paired with its dedicated H∞ controller, operating independently. The control action applied to the plant is determined by the validity of the associated local model, ensuring model-specific regulation. The subsequent Fig. 4 depicts the structure of the proposed architecture.

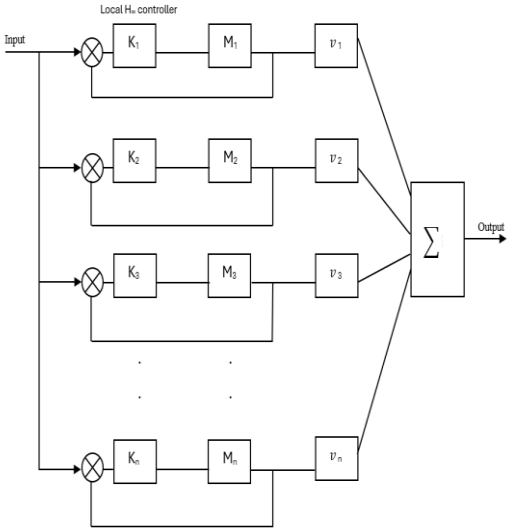

Fig. 4. Architecture 2 - Decentralized local control.

c) Architecture 3 – Global controller from multimodel representation: A single H∞ Loop-shaping controller, denoted K, is designed directly from the global multimodel representation. This controller is then connected to the aggregated global model formed by the ensemble of local models. This architecture is provided in Fig. 5.

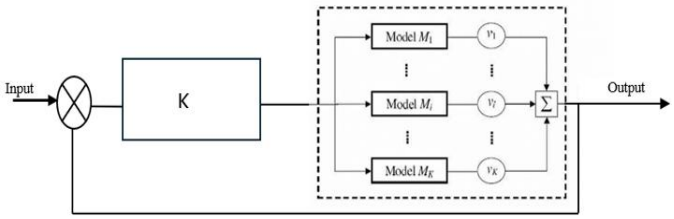

Fig. 5. Architecture 3- Global controller from multimodel representation.

d) Architecture 4 – Global controller applied to the real nonlinear system: The global H∞ Loop-shaping controller K, synthesized from the multimodel framework, is directly implemented on the real nonlinear system. Simulation studies are conducted to evaluate its robustness and performance under practical operating conditions.This architecture is schematically shown in Fig. 6 that follows.

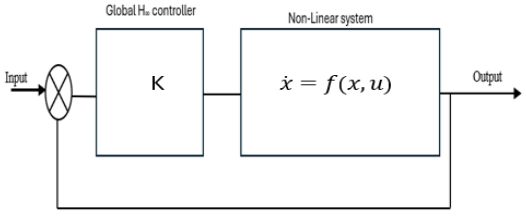

Fig. 6. Architecture 4 - Global controller applied to the real nonlinear system.

V. NUMERICAL VALIDATION OF PROPOSED METHODS

To evaluate the effectiveness of the proposed multimodel H∞ loop-shaping framework, a comparative validation of four distinct architectural configurations is conducted. Each architecture is examined with respect to its structural characteristics, control synthesis methodology, and resulting performance indices. The numerical simulations highlight the effectiveness of the individual designs to ensure robustness and stability margins under varying operating conditions [16].

Consider the nonlinear system given by Eq. (13):

$$y + (15 - 10y)\dot{y} = (36y(y-1) + 10)u \quad (13)$$

Through the multimodel approach, a set of four linear models has been formulated, with the corresponding transfer functions presented in the following Eq. (14), Eq. (15), Eq. (16) and Eq. (17):

$$G_1(s) = \frac{1}{1+5s} \quad (14)$$

$$G_2(s) = \frac{1}{1+15s} \quad (15)$$

$$G_3(s) = \frac{10}{1+5s} \quad (16)$$

$$G_4(s) = \frac{10}{1+15s} \quad (17)$$

Following the definition of the models, the design of the multimodel controller is undertaken, beginning with the partial H∞ loop-shaping approach and subsequently extending to the global H∞ loop-shaping controller. The design criterion is established to ensure an overshoot D=10%. The transfer function expressions and the value of γ_{min} corresponding to each partial model are summarized in Table I below.

We consider W_{2i}=1.

TABLE I. PARTIAL H∞ LOOP-SHAPING CONTROLLER

System Models	Partial H∞ loop-shaping controller $Ki\infty$	W_{1i}	γ_{min}
M_1	$\frac{3.297s + 1.197}{s^2 + 3.43s + 1.96}$	$\frac{s+1}{s}$	*1.7634*
M_2	$\frac{1.08s + 0.102}{s^2 + 0.87s + 0.58}$	$\frac{0.25s + 0.25}{s}$	*1.9254*
M_3	$\frac{4.47s + 1.43}{s^2 + 3.88s + 2.35}$	$\frac{0.12s + 0.12}{s}$	*1.7618*
M_4	$\frac{1.08s + 0.102}{s^2 + 0.87s + 0.58}$	$\frac{0.025s + 0.025}{s}$	*1.9254*

The step responses of the four models, depicted in Fig. 7, Fig. 8, Fig. 9 and Fig. 10, confirm that the partial H∞ loop-shaping controller fulfills the prescribed performance objectives while ensuring robustness across all models.

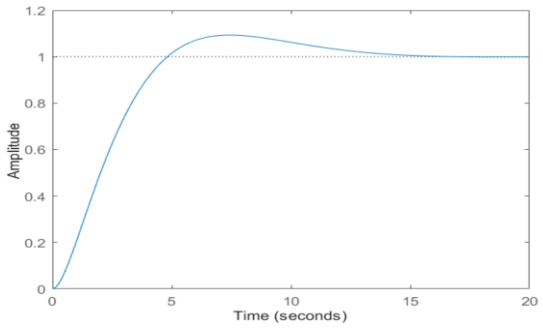

Fig. 7. Step response of the controlled model 1 using K_1.

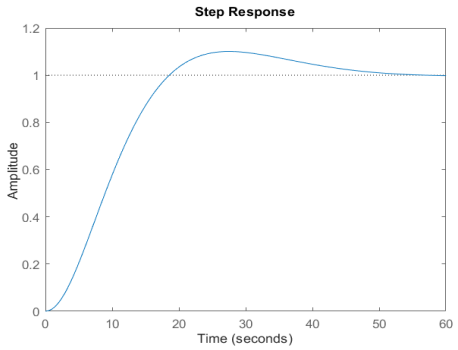

Fig. 8. Step response of the controlled model 2 using K_2.

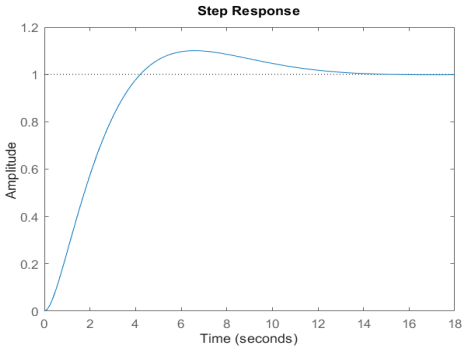

Fig. 9. Step response of the controlled model 3 using K_3.

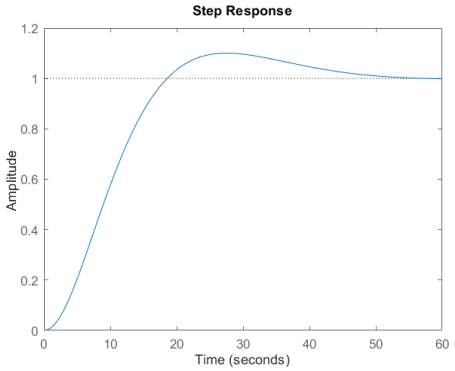

Fig. 10. Step response of the controlled model 4 using K_4.

While the first simulation demonstrates the behavior of a single partial controller, the second extends this concept by integrating the partial controllers within the four-architecture control framework to evaluate their performance.

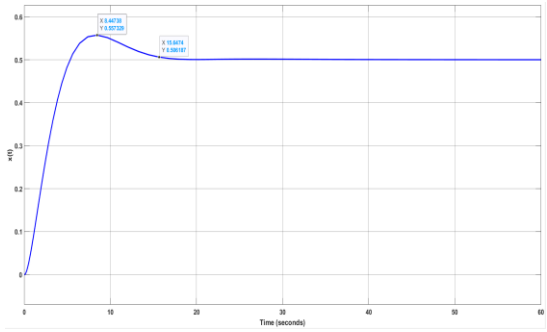

Fig. 11. Step response using architecture 1 - Aggregated local controllers.

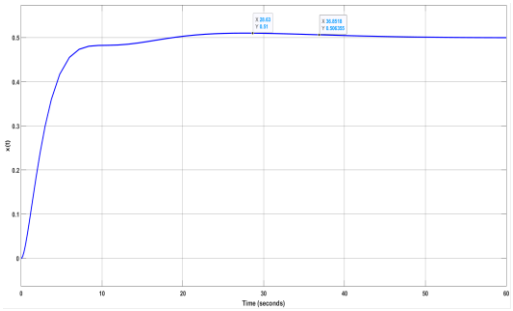

Fig. 12. Step response using architecture 2- Decentralized local control.

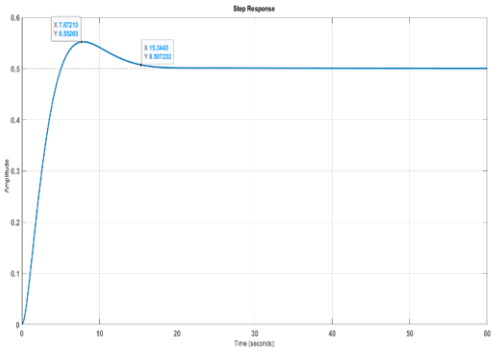

Fig. 13. Step response using architecture 3- Global controller from multimodel representation.

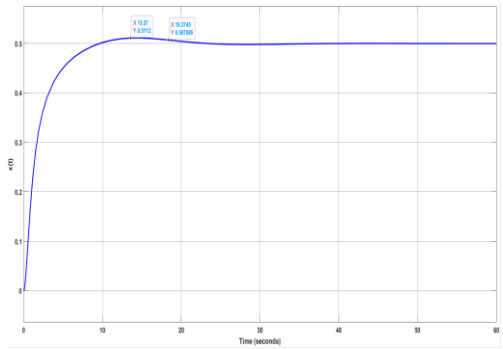

Fig. 14. Step response using architecture 4- Global controller applied to the real nonlinear system.

The comparative analysis of the four control architectures highlights the classical performance limitation between rapid response and system stability, particularly when applied to uncertain, disturbed, or otherwise complex systems. Architecture 1, the Aggregated Local Controllers (Fig. 11), achieves a rapid response time of 15 units but suffers from a significant overshoot of 10%, which compromises stability and makes it unsuitable for systems exposed to external perturbations or parameter uncertainties. Architecture 2, the Decentralized Local Control (Fig. 12), provides excellent precision with only 1% overshoot; however, its slow response time of 36 s limits its applicability in dynamic environments where rapid adaptation is essential. Architecture 3, the Global Controller based on a multimodel representation (Fig. 13), integrates these conflicting objectives by delivering the fastest response at 15 s with minimal overshoot of 1%, thereby offering the most efficient theoretical design under complex operating regimes. Finally, Architecture 4, the Global Controller implemented on the physical system (Fig. 14), demonstrates slightly slower dynamics at 18 s while maintaining the same low overshoot, thus confirming the robustness and practical effectiveness of the global approach in applied system contexts characterized by uncertainty and external disturbances. Overall, Architectures 3 and 4 provide the most favorable balance between speed and stability, ensuring reliable performance across a wide range of complex system scenarios, whereas Architectures 1 and 2 exemplify the extremes of this performance limitation.

Although standard H∞ and H_2 control have been combined with multimodel frameworks in several earlier studies, these approaches generally rely on applying classical robust controllers to each local model or on implementing multimodel switching and scheduling strategies, often without guaranteeing global robustness across the entire operating domain. In contrast, the present work introduces a fundamentally different integration by embedding H∞ loop-shaping within a multimodel architecture. Rather than designing loop-shaped controllers independently for each model, our methodology performs a joint synthesis that enforces a global robustness objective over the full multimodel set. This results in a coherent, system-wide loop-shaping design that departs from existing standard H∞/H_2 multimodel formulations both in purpose and in structural organization.

VI. Conclusion

This study has presented an integrated design methodology that unifies H∞ loop-shaping with multimodel architectures to address a central challenge in robust nonlinear control: achieving global performance guarantees without relying solely on locally valid controllers. Beyond the comparative evaluation of four architectures, the results highlight a broader conceptual contribution—global multimodel coordination can effectively overcome the classical speed-stability trade-off that constrains traditional local or single-model designs.

Architectures 3 and 4 demonstrate that embedding H∞ loop shaping within a global multimodel framework yields controllers capable of maintaining fast dynamics, minimal overshoot, and robust stability across the full operating envelope. This positions multimodel H∞ control as a scalable

and practically deployable strategy for nonlinear systems subject to uncertainty, disturbances, and complex regime transitions. The successful experimental validation of Architecture 4 further confirms that the proposed methodology is not only theoretically sound but also operationally reliable in real-world conditions. Conceptually, this work shifts the perspective in robust nonlinear control from isolated local designs toward globally coherent control structures that preserve robustness throughout the entire state space. By bridging advanced linear robust control tools with nonlinear multimodel representations, the methodology contributes a systematic pathway for designing controllers that are both high-performance and globally robust.

Future research may advance this framework along several significant directions. A promising line of inquiry concerns its extension to large-scale interconnected systems, where multimodel representations arise naturally from subsystem interactions and where uncertainty is both structural and pervasive. Furthermore, the integration of adaptive and data-driven mechanisms within the multimodel architecture offers considerable potential for enhancing real-time performance in highly dynamic environments. Particular attention should be directed toward the incorporation of machine-learning-based modules capable of augmenting or partially replacing the controller, provided that their deployment is accompanied by rigorous guarantees of stability and robustness.

ACKNOWLEDGMENT

I gratefully acknowledge the support of Mohamed Naceur ABDELKRIM and Mohamed Lazhar WARDI, whose valuable guidance, insightful discussions, and critical suggestions greatly contributed to the advancement of this research.

***Abstract*—The integration of Lean Manufacturing and Industry 4.0, known as Lean 4.0, has emerged as a strategic approach to enhancing operational efficiency, digital transformation, and competitiveness in modern industries. The rapid development of Industry 4.0 has driven a massive transformation in the global manufacturing sector, including Indonesia, which continues to face competitiveness challenges due to limitations in technological capabilities, human resources, and organizational culture. However, the successful implementation of Lean 4.0 requires a structured and measurable level of organizational readiness. This study aims to model the key dimensions and indicators that define the readiness of Indonesian companies for Lean 4.0 implementation. Using a mixed-methods approach of qualitative and quantitative analysis, this study begins with a meta-synthesis of existing literature and expert interviews to identify initial dimensions and indicators, followed by a structured survey to validate the model. The analytical framework integrates the theoretical foundations of Lean and Industry 4.0 principles, existing readiness assessment models, as well as models from key references. The key finding is a proposed model for Lean 4.0 Readiness for Indonesian industries, consisting of 6 key dimensions and 41 indicators. The 6 key dimensions are: Leadership and Strategy, People and Culture, Technology and Digital Infrastructure, Operation and Process, Product and Service, and External Collaboration and Integration. Expert validation and pilot testing confirmed the consistency and contextual relevance of this model for industries in Indonesia. The finding contributes to theory and practice by providing a comprehensive and diagnostic framework for evaluating Lean 4.0 implementation readiness, as well as supporting the development of a readiness model that can be adapted to another industrial park in Indonesia.**

Keywords*—Lean 4.0; Industry 4.0; readiness assessment; organizational readiness; Indonesian industries; digital transformation

I. Introduction

The rapid advancement of Industry 4.0 has significantly transformed manufacturing and service industries worldwide. By integrating smart technologies such as the Internet of Things (IoT), Artificial Intelligence (AI), big data analytics, and automation, Industry 4.0 enhances operational efficiency and competitiveness [1]. While Lean 4.0 offers significant benefits, challenges include high implementation costs, workforce skill gaps, and integration complexities. Future trends indicate a growing focus on sustainability within Lean-Industry 4.0 integration, emphasizing the need for further research to address challenges and explore scalable solutions across diverse industrial contexts [2].

Lean Manufacturing has long been recognized as a systematic approach to eliminating waste, improving productivity, and optimizing processes [3]. The convergence of these two concepts, known as Lean 4.0, leverages digital technologies to enhance lean principles, enabling real-time decision-making, predictive maintenance, and adaptive production systems [4]. Industry 4.0 technologies strongly support the Just-in-time and *Jidoka* principles, but have a limited impact on lean waste reduction and teamwork aspects [5].

Currently, the integration model of Lean manufacturing principles and Industry 4.0 has not been found in Indonesia. Previous research has not discussed the external dimension of collaboration, i.e., the relationship between companies and suppliers or customers. Therefore, this study aims to provide a practical assessment model that helps businesses evaluate their readiness and develop strategies for implementing Lean 4.0. Additionally, this research contributes to academic knowledge by bridging the gap between Lean Manufacturing and Industry 4.0 readiness studies, offering a structured framework applicable to emerging economies.

A. Background

The Indonesian manufacturing sector, as a prime mover of the country's economy, contributes around 19% to GDP in 2023 and serves as a major source of employment, export revenue, and industrial growth [6]. Despite its strength in domestic market size, UNIDO's Competitive Industrial Performance Index indicates that Indonesia ranks lower than regional leaders such as China, Thailand, and Vietnam, in terms of manufacturing value added, export complexity, and innovation [7]. The World Economic Forum (WEF) data shows gaps in innovation capacity, infrastructure quality, and technological adoption [8]. In order to improve the competitiveness of industries in Indonesia, the implementation of Lean 4.0 is a necessity.

Despite the potential benefits of Lean 4.0, the successful implementation of Lean 4.0 requires organizations to assess their readiness across multiple dimensions. Many companies, particularly in developing economies like Indonesia, face significant challenges in implementing Lean 4.0 [9]. Issues such as limitations of technology and infrastructure, human resources and skills, leadership commitment, and complexity of integration can hinder the transition. As a result, assessing

organizational readiness becomes a crucial step before adopting Lean 4.0. Without proper preparation, companies may face challenges in implementation, leading to inefficiencies and resistance to change. A structured readiness assessment framework can help companies identify strengths, weaknesses, and necessary improvements to ensure a smooth transformation.

While numerous studies have explored the adoption of Industry 4.0 and Lean Manufacturing principles, there is a lack of a comprehensive model for assessing Lean 4.0 readiness, particularly in Indonesian companies. Most existing frameworks focus solely on either technological maturity or lean implementation, failing to provide a holistic approach that considers strategic, workforce, and sustainability factors. To address this gap, this study aims to develop a conceptual model for assessing Lean 4.0 readiness by identifying key dimensions and indicators relevant to Indonesian industries. Specifically, the study seeks to: 1) identify critical dimensions that determine Lean 4.0 readiness, 2) establish key indicators for measuring organizational readiness, and 3) propose a structured model that companies can use for self-assessment and improvement planning.

B. Literature Review

Two models of Lean 4.0 readiness used as the main references in this study are the Lean 4.0 Readiness Assessment Tool and the Dimensions for Lean-Green 4.0 Readiness. These are complemented by references to two broader Industry 4.0 readiness frameworks—one offering an evaluation approach, and another synthesizing dimensions from existing readiness models.

Rahmatindar et al. (2024) [10] proposed a Lean 4.0 Readiness Assessment Tool comprising 5 dimensions and 69 indicators. This model, a modification of the Indonesia Industry 4.0 Readiness Index [INDI 4.0], integrates the Lean Assessment Tool and Industry 4.0 Readiness Assessment Tool. The tool has developed under the conditions of companies in Indonesia. Those dimensions include management and organization, people and culture, products and services, technology, and factory operations. The indicators were validated using the Delphi method, which was carried out in two stages.

Duarte et al. (2025) [11] proposed a baseline framework for designing an assessment model to implement Lean-Green management in an Industry 4.0 environment. This study employed a systematic literature review to investigate the existing literature on Lean, Green, and Industry 4.0. The model consisted of 8 dimensions, namely leadership and strategy, people, process, product, customer, supplier, technology, and governance. It identified 44 indicators (measurement items), which consist of 8 in leadership and strategy, 5 indicators in people, 4 indicators in product, 8 indicators in process, 3 indicators in customer, 5 indicators in supplier, 6 indicators in technology, and 5 indicators in governance.

Wankhede et al. (2022) [12] developed a model for assessing Industry 4.0 readiness in organizations, which comprises 6 criteria (dimensions) and 50 factors (indicators). Various Industry 4.0 Readiness Dimensions and Indicators were obtained from an extensive literature review and finalized using expert opinion. Those dimensions covered technology, organization and management, process, legislation, product, and employee. The model has been tested concerning automotive component manufacturing organizations, and hence, the inferences derived have practical relevance.

To be able for organizations to self-assess their Industry 4.0 readiness to survive and thrive in the age of the Fourth Industrial Revolution, the conceptualization of an Industry 4.0 readiness model with the fundamental model dimensions is needed. Hanafiah et al. (2020) [13] identify 30 Industry 4.0 readiness models with 158 unique model dimensions, by using a systematic literature review (SLR) methodology. Two theoretical contributions of this study are: 6 dimensions (technology, people, strategy, leadership, process, and innovation) that can be considered the most important dimensions for organizations, and 70 (44%) out of a total of 158 unique dimensions for organizations on Industry 4.0 related to the assessment of technology only.

II. Research Methodology

A. Research Design

This study employs a mixed-methods research approach to develop and validate a model for assessing Lean 4.0 readiness in Indonesian companies. The research is conducted in two phases:

- Qualitative Analysis – A meta-synthesis and expert interviews to identify key dimensions and indicators of Lean 4.0 readiness.
- Quantitative Analysis – A survey-based study to validate the proposed model and assess its applicability in Indonesian industries.

To develop an analytical framework based on the literature review of dimensions and indicators of readiness for Lean 4.0 implementation, two initial steps of meta-synthesis are undertaken. The first step is to determine and study research topics related to understanding Lean 4.0, readiness assessment in organizational transformation, and the dimensions of Lean 4.0 readiness implementation, as well as its indicators. The result is then summarized. This process involves keyword identification through a search for relevant literature in the database on the website.

In order to support the successful implementation of Lean 4.0 in a company, it is necessary to determine the company's readiness to implement Lean 4.0. The assessment to determine company readiness is designed by combining Lean manufacturing principles and Industry 4.0 technology. An analytical framework model in this study is proposed as described in Fig. 1.

The next step is selecting particular topics using the previous keywords as guidance, which lasted until January 2025. Most of the publications were obtained from academic sources, including journals, conference papers, institutional reports, and dissertations.

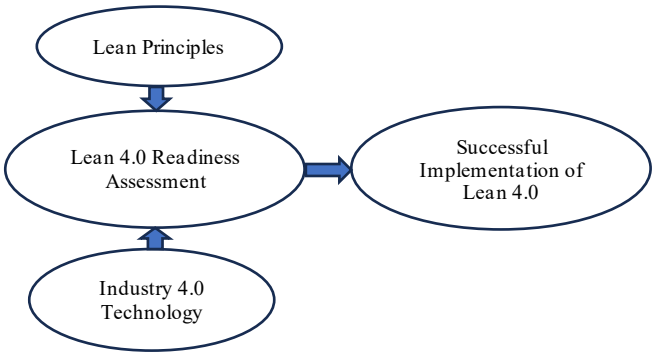

Fig. 1. Analytical framework for Lean 4.0 implementation.

B. Data Collection Methods

1) Meta synthesis: A meta-synthesis of existing studies on Lean 4.0, Industry 4.0, and readiness assessment models is conducted. Academic sources, including journal articles, conference papers, and case studies, are analyzed to identify potential dimensions and indicators relevant to Lean 4.0 readiness.

2) Expert interviews: To validate the findings from the meta-synthesis, semi-structured interviews are conducted with industry experts, Lean practitioners, and academics specializing in Lean 4.0. The key objectives of these interviews are:

- To identify additional readiness factors relevant to Indonesian companies.
- To refine and contextualize the dimensions and indicators based on real-world experiences.

A purposive sampling method is used to select 10–15 experts from the manufacturing, service, and consulting sectors who are involved in implementing Lean 4.0.

3) Survey-based data collection: Based on the identified dimensions and indicators, a structured survey has been designed. The survey consists of Likert-scale questions (1–5) that measure the importance and presence of each indicator within Indonesian companies.

4) Model development and validation: Based on the literature review, expert input, and survey findings, a Lean 4.0 Readiness Model has been developed. The model is validated through:

- Expert review: Feedback from industry professionals and academics.
- Pilot testing: Testing the model on a small group of companies before full implementation.
- Comparative analysis: Benchmarking the model against existing readiness frameworks.

The identified dimensions and indicators are used to develop a Lean 4.0 Readiness Model, which provides a structured framework for assessing an organization's readiness. The model consists of:

- A multi-dimensional assessment framework categorizing companies as "Not ready", "Low readiness", "Moderate readiness", and "Excellent readiness".
- Weighting of indicators based on expert input and survey validation.
- A scoring system to quantify readiness levels across different industries in Indonesia.
  - 4.1–5.0: Excellent readiness – the organization is highly prepared for Lean 4.0.
  - 3.1–4.0: Moderate readiness – some areas need improvement.
  - 2.1–3.0: Low readiness – significant gaps exist.
  - 1.0–2.0: Not ready – foundational work is needed before implementing Lean 4.0.

III. Analytical Framework

A. Overview of Lean 4.0: Integration of Lean Principles and Industry 4.0

Lean Manufacturing, which originated from the Toyota Production System, has long been recognized as a systematic approach to eliminating waste, improving efficiency, and optimizing production processes [14]. Its core principles — such as Just-in-Time (JIT), value stream mapping, and continuous improvement (*kaizen*) — have helped organizations enhance productivity and reduce operational inefficiencies. However, with the emergence of Industry 4.0, these traditional lean practices are being augmented with digital technologies such as the Internet of Things (IoT), Artificial Intelligence (AI), cyber-physical systems, and big data analytics [15]. Industry 4.0 enables real-time data collection, monitoring, and analysis, which supports data-driven decision-making, predictive maintenance, and automation — elements that complement Lean's objectives of operational efficiency and waste reduction [16]. For example, digital *kanban* systems can improve inventory control, while AI-powered analytics can enhance root cause analysis during quality improvement initiatives. This digital transformation led to what is now known as Lean 4.0 [17].

Several studies emphasize that the integration of Lean and Industry 4.0 is mutually reinforcing. While Lean offers a cultural and managerial foundation for operational excellence, Industry 4.0 brings the technological capabilities to execute those principles more efficiently and with greater agility [18]. This synergy allows companies to achieve smart, flexible, and efficient production systems. However, the success of this integration depends on factors such as leadership support, workforce competence, and organizational culture [19].

Despite the promising benefits, organizations must carefully manage the integration process to avoid conflicts between traditional Lean practices and the complexities introduced by advanced technologies. Research highlights the need for a strategic roadmap and an assessment of organizational readiness before adopting Lean 4.0 [20]. Companies must evaluate their readiness and maturity levels in both Lean and digital

capabilities, ensuring alignment between technological investments and Lean objectives.

B. Readiness Assessment Frameworks in Industry 4.0 and Lean 4.0

Two main types of Lean 4.0 assessment tools are used to evaluate organizational readiness and maturity in implementing Lean 4.0. Lean maturity assessment models assess an organization's current level of lean implementation, identifying areas for improvement. In contrast, lean readiness assessment models assess an organization's readiness for adopting lean principles and practices. Both are essential for a successful lean transformation, but they apply at different stages and serve different purposes.

A Maturity Assessment Tool for Lean 4.0 Implementation is a structured evaluative framework used to measure the current maturity level of an organization's processes, systems, and capabilities in adopting Lean 4.0. This tool helps organizations determine their progress in their digital Lean transformation process by assessing multiple dimensions. Each dimension is usually rated on a maturity scale, providing a diagnostic snapshot of the organization's progress and highlighting areas that need improvement. It is often used after some lean implementation to track progress and identify areas for further development.

The Lean 4.0 Readiness Assessment Tool is a structured instrument designed to evaluate an organization's readiness for implementing Lean 4.0, which involves integrating Lean manufacturing principles with Industry 4.0 technologies. This tool helps organizations identify their strengths, weaknesses, and gaps across key dimensions. The ultimate goal of the Lean 4.0 Readiness Assessment Tool is to facilitate a smooth and effective transition toward a smart, efficient, and sustainable manufacturing system aligned with Industry 4.0 paradigms. This tool is typically conducted before implementing Lean 4.0 to increase the probability of success. Table I shows lean readiness and maturity models, which were adopted from [21].

TABLE I. THE EXISTING LEAN READINESS AND MATURITY ASSESSMENT MODELS

Assessment	Developer	Dimensions
Lean Enterprise Self-Assessment Tool (LESAT)	LAI-MIT (2001)	Strategic cycle, planning cycle, and execution cycle
Renault Production System (RPS) Rocket	SPR (2004)	Operational stability (base), continuous flow and efficiency (body), innovation and excellence (nose), and people and culture (propulsion system)
The Shingo Prize Model	Utah State University (1988)	Cultural enablers, continuous improvement, and enterprise alignment
Capgemini lean model	Capgemini (2005)	Process, people, and organization
Lean capability model	Jorgensen et al. (2007)	Technical perspective, organizational perspective
Logical model of lean assessment	Hines (2011)	Strategic deployment, value stream management, people, application of lean tools and techniques, and extended enterprise
The Digital Green Lean (DGL) Maturity Model	Gatell and Avella (2024)	Digital lean business culture (values and principles, customer centricity, and operational excellence) and digital lean leadership (customer orientation, personal development, lean principles, and performance orientation)

Source: Adopted from Setianto & Haddud (2016), [21]

The frameworks for Industry 4.0 maturity and readiness are shown in Table II. Organizational readiness refers to the extent to which a company possesses the capabilities, resources, and strategic alignment necessary to adopt new technologies or operational models [22]. Several readiness assessment frameworks have been developed for Industry 4.0 adoption, but few studies have focused on a structured model specifically tailored to Lean 4.0 [23], [24]. Existing frameworks primarily evaluate technological maturity and digital infrastructure, often neglecting critical factors such as leadership commitment, workforce skills, and sustainability considerations.

For instance, the Smart Industry Readiness Index (SIRI) developed in Singapore evaluates readiness across *Process, Technology,* and *Organization* dimensions, emphasizing the role of advanced digital infrastructure and automation. Similarly, the IMPULS Industry 4.0 Readiness Model from Germany highlights technological maturity and innovation-driven strategy as core enablers of transformation. Although these models provide strong analytical frameworks for industrial digitalization, they often assume high baseline technological capacity, making them less applicable to small and medium-sized enterprises (SMEs) in emerging economies.

In the context of Indonesia, despite governmental efforts through Making Indonesia 4.0 and the INDI 4.0 Index, many firms remain at an early stage of readiness. Studies indicate that barriers include limited digital infrastructure, insufficient managerial commitment, and a lack of workforce upskilling programs. This highlights the necessity for a comprehensive, adaptive readiness model—one that not only aligns with global Lean 4.0 frameworks but also incorporates contextual factors such as leadership strategy, people and culture, and external collaboration.

Recent studies emphasize the need for multidimensional readiness models that incorporate both technological and organizational factors. For instance, recent studies emphasize the need for multidimensional readiness models that incorporate both technological and organizational factors. For instance, Kumar et al. (2020) [26] propose a readiness framework that integrates strategy, workforce capability, and process optimization. The study suggests that an effective Lean 4.0 readiness model must extend beyond technology, encompassing elements such as leadership, workforce skills, data-driven decision-making, and environmental sustainability.

TABLE II. THE EXISTING FRAMEWORKS FOR INDUSTRY 4.0 MATURITY AND READINESS

Name of the model	Developer	Dimensions
IMPULS – Industry 4.0 Readiness	Lichtblau et al. (2015)	Strategy and organization, smart factory, smart operations, smart products, data-driven services, and employees
SIMMI 4.0	Leyh et al. (2016)	Vertical integration, horizontal integration, digital product, and cross-sectional technology
Industry 4.0 / Digital Operation Self-Assessment	Price Waterhouse Coopers (2016)	Digital business and customer access, digitization of products / services, data analytics, IT infrastructure, IT architecture, security, and digital culture
Industry 4.0 readiness and maturity of manufacturing enterprises (Industry 4.0 MR)	Schumacher et al. (2016)	Products, customers, operations and technology, strategy, leadership, governance, culture, and people
Industry 4.0 readiness model (WMG)	Warwick University	Products and services, manufacturing and operations, strategy and organization, supply chain, business model, legal considerations
Industry 4.0 - MM	Gokalp et al. (2017)	IT, data governance, information flow, process transformation, and organizational structure / strategy
Digital Readiness Assessment Maturity Model (DREAMY)	De Carolis et al. (2017]	Process, monitoring and control, technology, and organization
Maturity and Readiness Model for Industry 4.0 Strategy	Akdil et al. (2018)	Smart products and services, smart business processes, strategy, and organization
Indonesia Industry 4.0 Readiness Index (INDI 4.0)	Indonesian Ministry of Industry (2018)	Management and organization, people and culture, product and services, technology, and factory operation
Industry 4.0 Maturity model	Sony et al. (2019)	Employee, level of digitalization, extent of digitalization, organizational strategy, top management involvement
360 Digital Maturity Assessment	Colli et al. (2019)	Governance, technology, value creation, connectivity, competence
The Smart Industry Readiness Index (SIRI)	EDB of Singapore	Technology (automation, connectivity, intelligence), process (operation, supply chain, product lifecycle), and organization (talent readiness, structure, and management)
Industry 4.0 Readiness Model	Hanafiah, Soomro, and Abdullah (2020)	Technology, people, strategy, leadership, process, and innovation
Industry 4.0 MR	Kumar and Akhilesh (2021)	Strategy, organization, business model, employee, manufacturing and operations, supply chain, production system, products, and services

C. Main References of Lean 4.0 Readiness Model

Organizational transformation — particularly when driven by digitalization or process innovations like Lean 4.0 — requires a systematic evaluation of readiness to ensure effective implementation and sustainable outcomes. A readiness assessment functions as a diagnostic mechanism to gauge an organization's capability, willingness, and preparedness for change. It helps determine whether essential foundations such as strategy, leadership, culture, and resources are properly aligned to support transformation initiatives.

Preparation models have gained significant attention in the context of digital transformation and Industry 4.0. For example, Schumacher et al. (2016) [23] proposed a maturity model to assess readiness across dimensions such as strategy, culture, IT infrastructure, and operations. Similarly, Mittal et al. (2018) [24] emphasized that small and medium-sized enterprises (SMEs) need to consider their technological capabilities, human resources, and leadership support before initiating smart manufacturing initiatives.

When it comes to Lean transformation, readiness assessment also plays a critical role. Antony et al. (2017) [27] pointed out that a lack of readiness, particularly in areas such as employee engagement, continuous improvement culture, and management commitment, can hinder Lean adoption. Integrating Lean with Industry 4.0 (i.e., Lean 4.0) introduces additional complexity, making readiness assessment even more vital.

Several frameworks have been developed to assess transformation readiness across various industries. Some studies have identified the dimensions and indicators of readiness for Lean 4.0 implementation using the SLR approach. Therefore, this approach was not used in this study. Common dimensions include Leadership and Strategic Alignment, Workforce Competency and Culture, Technological Infrastructure, Process Maturity, and Data-driven Decision-making. These dimensions often serve as the basis for constructing indicators and metrics that help companies identify gaps and prioritize areas for improvement before full-scale implementation.

IV. MODELLING LEAN 4.0 READINESS DIMENSIONS AND INDICATORS

Based on the readiness models used as the primary references, certain dimensions were identified by the experts involved in this study. The selected dimensions were then used to assign the conceptual framework, as described in Fig. 2.

The convergence between Lean Manufacturing and Industry 4.0—commonly termed Lean 4.0—has become a significant topic in industrial transformation research. Lean Manufacturing focuses on process efficiency, waste reduction, and continuous improvement, while Industry 4.0 emphasizes automation, data-driven decision-making, and cyber-physical integration. The synergy between these two paradigms enables both operational excellence and digital competitiveness. However, while advanced economies have developed mature readiness models to support digital transformation, many developing countries still face difficulties in adopting such frameworks due to contextual and infrastructural limitations.

From the selected dimensions, indicators were then identified for each dimension, based on the reference model, as well as other relevant papers or studies on the same topic. These indicators are supported by several references that mention them in their studies. It is shown in Table III.

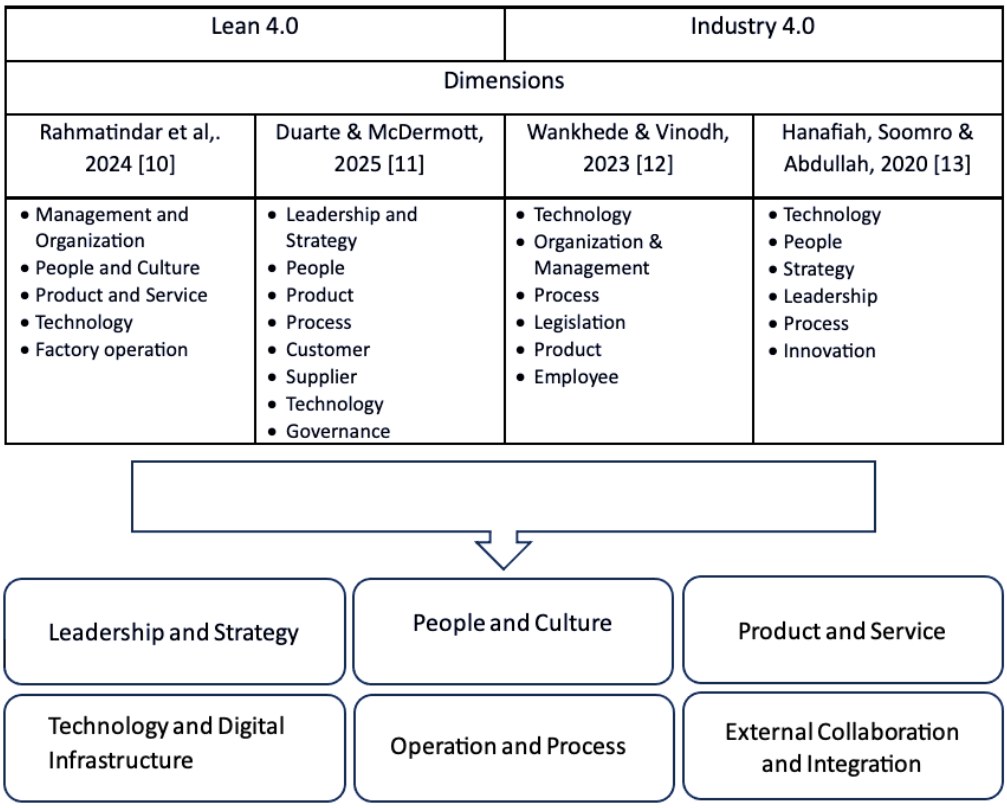

Fig. 2. The proposed dimensions used to assign the conceptual framework (adopted from [11]).

	A balance between environmental, economic, and social needs for sustainability*	[19]

The results of the identification suggest that there are six (6) selected dimensions and forty-one (41) indicators. There are nine indicators for the Leadership and Strategy dimension. Three of these indicators, notably new strategy / new business, fund availability, and communication and change management, fall outside of the primary references.

For the People and Culture dimension, there are six indicators, two of which are from sources outside the main references. These indicators include employee participation and empowerment, as well as a supportive culture and environment. Technology and Digital Infrastructure have three indicators, the most important of which are big data and cloud computing implementation and information exchange technology.

All five indicators in the Product and Service dimension come from the main reference. The last dimension, External Integration, is an additional dimension that accommodates several indicators also mentioned in the main references. Two of the five indicators not mentioned in the main reference in this dimension are supplier integration and collaboration, as well as a balance between environmental, economic, and social needs for sustainability.

To supplement and refine the above dimensions and indicators, expert validation is required. Expert opinions are obtained from academics, industry professionals, and Lean practitioners. Additionally, pilot testing (in the form of case studies) was conducted, and the findings were used to refine the meta-synthesis framework.

V. Results and Discussion

The study focused on identifying the dimensions and indicators that are important for measuring a company's readiness to implement Lean 4.0 (Lean 4.0 readiness assessment model) based on the assumption that most local companies in Indonesia's Jababeka Industrial Park have not yet implemented Lean 4.0.

Based on input or suggestions from experts, the dimensions and indicators for determining a company's readiness to implement Lean 4.0 as a result of the meta-synthesis are already quite comprehensive and do not need to be added to or reduced. However, they cautioned that the proposed dimensions and indicators are still too sophisticated, especially for small and medium-sized industries. Domestic companies at that level (within the category) generally have not yet implemented or carried out most of the indicators mentioned. Even some large companies seem not to have yet, or are still struggling to apply Lean principles.

Several experts highlight the proposed dimensions based on their level of importance for the successful implementation of Lean 4.0 in companies. They argue that the most important aspect in implementing Lean 4.0 is people and their work culture, because people are the main driving force behind the

success of the transformation, even more so than the technology itself. Lean 4.0 is based on changing the mindset and behavior of the people involved in it. From this perspective, what is important at this stage is that their mindset in working is aligned with the Lean 4.0 mindset. Fundamental issues or principles related to customer satisfaction, particularly concerning quality and delivery, must be resolved thoroughly before considering technology.

The dimension of leadership and clear strategy, particularly commitment from top management, are other key aspects. Without strong leadership and commitment, as well as a clear strategy, the transformation to Lean 4.0 in a company will lack direction, support, and sustainability. Leadership provides the driving force, while strategic readiness provides the direction. Additionally, top management must also set a good example to serve as a model for their employees.

Digital technology and infrastructure are the technical foundation of Lean 4.0. With such a large volume of data transactions, processing and analysis must use tools so that the data can be utilized to its fullest potential and used as efficiently as possible. For product service delivery to customers, comprehensive customer data analysis is required. Clear information availability is crucial so that anyone with a stake in the matter (e.g., during shift changes) can immediately know what is needed or what actions must be taken.

The trend toward digitization in manufacturing systems has already begun and is currently underway. It is up to the people (human resources) to decide whether to accept it or not, whether to view it as an opportunity or a threat. This includes top management, who must understand the importance of Lean 4.0 principles.

In order to support the development of research and the application of Lean Manufacturing based on Industry 4.0 technology (Lean 4.0), blockchain technology is one of the key technologies that is very important to adopt in modern manufacturing systems. Blockchain technology plays a significant role in improving the transparency, efficiency, and reliability of information flow throughout the supply chain. By integrating blockchain with IoT technology, AI, digital tracking systems, secure and real-time business process automation, and distributed, immutable data recording, a system can be created that reduces information waste, accelerates decision-making, and reinforces Lean principles such as just-in-time, kaizen, and the elimination of non-value-added activities.

Before the large-scale data collection, a pilot test of the Lean 4.0 readiness questionnaire was conducted to evaluate the clarity, reliability, and validity of the proposed dimensions and indicators. The pilot study involved a sample of 15 respondents, consisting of production managers, lean coordinators, and digital transformation specialists from selected Indonesian manufacturing companies. Respondents were asked to complete the survey and provide feedback on the comprehensibility of each question, the appropriateness of the terminology used, and the overall structure of the survey.

Table IV shows the statistical analysis of the pilot data included reliability testing using Cronbach's alpha for each dimension. All dimensions recorded alpha values above the 0.70 threshold, indicating acceptable internal consistency. However, minor adjustments were made to the wording of certain indicators to enhance clarity and avoid technical ambiguity. Content validity was also strengthened through consultation with three academic experts and two industry practitioners, who reviewed the questionnaire to ensure alignment with Lean 4.0 principles and the Indonesian manufacturing context.

TABLE IV. CRONBACH'S ALPHA RELIABILITY RESULT

Variable	Number of items	Cronbach's Alpha	Criteria	Comment
Leadership and Strategy	9	0.807	0.7	Reliable
People and Culture	6	0.873	0.7	Reliable
Technology and Digital Infrastructure	7	0.895	0.7	Reliable
Operation and Process	8	0.807	0.7	Reliable
Product and Service	5	0.791	0.7	Reliable
External Collaboration and Integration	5	0.784	0.7	Reliable

The feedback and findings from this pilot testing served as a critical input in refining the measurement model. Ambiguous or overlapping items were revised or eliminated, while the sequence of questions was restructured to improve logical flow. As a result, the final instrument was considered robust and contextually relevant, supporting the subsequent empirical phase of readiness modelling for Lean 4.0 implementation. The dimension of Leadership and Strategy is a common dimension identified in various models, focusing on management support, management commitment, clear vision, long-term investment (in human, financial, and technological resources), a Lean team, fund availability, management standards, new business strategies, and communication. Organizations with strong leadership support tend to exhibit higher success rates in digital Lean transformation due to their ability to align organizational goals with digital strategies [20]. Indicators under this dimension typically include the existence of a Lean 4.0 roadmap, leadership involvement, and cross-functional transformation teams [23].

People and Culture is another critical dimension, as the human element plays a central role in adopting and sustaining new technologies and Lean culture. According to [24], digital literacy, lean knowledge, openness to change, and structured training programs are necessary to ensure workforce adaptability. The presence of competency development programs, employee participation in decision-making, and a culture of continuous improvement are key indicators for this dimension.

The dimension of Technology and Digital Infrastructure refers to the availability and integration of enabling technologies such as IoT, ERP systems, RFID, SCADA, big data analytics, cyber-physical systems, and information exchange. Buer et al. (2018) [15] suggest that Lean 4.0 is enhanced by real-time data and automation, which support Lean goals like waste reduction, agility, and responsiveness. Indicators in this dimension include

the implementation of digital tools, system connectivity, and cybersecurity measures.

Operation and Process integrate Lean methods (e.g., Just-in-Time, PDCA) with digital systems to enhance process performance. Key indicators include the implementation of Lean tools, the use of digital technologies in operations, standardization of the supply chain, digital storage of operational data, the existence of performance indicators for automated processes in factory operations, as well as monitoring and quality assurance, maintenance, and departmental collaboration.

The Product and Service dimension plays a pivotal role in determining an organization's readiness for Lean 4.0 implementation, particularly in enhancing customer value through data integration, feedback responsiveness, and digital innovation. The indicator 'Availability of product information systems for vendors and customers' reflects an adoption of digital platforms such as product portals, e-catalogs, and customer relationship management (CRM) tools. These systems help improve transparency, minimize information gaps, and accelerate response time—capabilities that strongly support the objectives of Lean 4.0.

The indicator 'data analysis from customers, business partners, and vendors' reflects how firms collect transactional or behavioral data and integrate and jointly analyze these datasets across the supply chain. It increases the ability to gain comprehensive insights and coordinate value stream improvements. The indicator 'Integration of products with digital technologies' demonstrates how some companies are beginning to embed sensors, connectivity modules, and smart features into their products. However, for most firms, particularly SMEs, this integration remains aspirational due to high costs, lack of technical expertise, and limited R&D investment. The indicator 'Use of big data for product/service improvement' shows the data collection at various operational touchpoints, and the capacity to analyze and apply these insights toward product innovation or service refinement. Many firms rely on basic analytics or retrospective reporting, falling short of leveraging predictive analytics or AI-driven decision-making, which are integral to a Lean 4.0 approach [20]. Lastly, the indicator 'Customer feedback mechanisms and satisfaction monitoring' is how companies adopt digital survey tools, post-purchase feedback systems, and service-level monitoring. However, the challenge lies in translating this feedback into rapid, systemic improvements — a key Lean principle that remains underutilized.

The External Collaboration and Integration dimension reflects an organization's ability to build, sustain, and digitally enable relationships with key stakeholders such as suppliers, customers, and business partners. In the context of Lean 4.0, collaboration is no longer limited to operational coordination but extends toward the integration of digital technologies, joint value creation, and sustainability-oriented partnerships. The key indicators include supplier collaboration and integration; use of digital channels with suppliers/customers; knowledge sharing and uncertainty management across companies; customer involvement to lead Lean 4.0 implementation; and a balance between environmental, economic, and social needs for sustainability.

Table V shows a proposed Lean 4.0 Readiness model. Compared to other models for measuring readiness to implement Lean Manufacturing and Industry 4.0, this model is more comprehensive. INDI 4.0, which emphasizes readiness to implement Industry 4.0, consists of five dimensions: Management and Organization, People and Culture, Products and Services, Technology, and Factory and Operations. Rahmatindar's model, which draws on INDI 4.0 as its primary reference, focuses on Lean 4.0. It has the same five dimensions as INDI 4.0, but it includes 69 indicators. The additional dimension in this model is External Collaboration and Integration. This is because in digital transformation, the relationships between industry or companies with suppliers and customers are inevitable.

The dimensions of Management and Organization in this model are slightly different, namely, Leadership and Strategy. The Technology dimension in this model includes Digital Infrastructure. Meanwhile, Factory Operations are referred to as Operation and Process. There are fewer indicators in this model compared to Rahmatindar's, because several indicators have been combined into one; for example, the implementation of IoT, ERP, RFID, SCADA, and PLC has been combined into the implementation of industrial automation.

TABLE V. PROPOSED MODEL OF KEY DIMENSIONS AND INDICATORS FOR LEAN 4.0 READINESS

Dimension	Indicator
Leadership and Strategy	Management support for Lean 4.0 transformation
	Commitment to active management involvement
	Clear digital transformation vision, roadmap, and alignment with mission
	Long-term investment strategies (human, financial, and technological)
	Dedicated Lean 4.0 transformation teams
	Funds' availability
	Management standards, governance, and legal compliance
	New business strategy / model
	Communication and change management
People and Culture	Employee skills and qualifications

Dimension	Indicator
	Employee openness to digital transformation and continuous improvement
	Systematic competency development
	The existence of structured training / workshops / certifications for Lean 4.0
	Employee involvement (decision participation) and empowerment
	Culture and supportive ambiance
Technology and Digital Infrastructure	Implementation of industrial automation (IoT, ERP, RFID, SCADA, PLC)
	Machine-to-machine (M2M) connectivity and transparency in data flow
	Connectivity of systems within the company across different technical disciplines
	Implementation of big data and cloud computing
	Conversion of manual processes to digital
	Technology for information exchange
	Cybersecurity implementation and training
Operation and Process	Implementation of Lean tools: First In First Out (FIFO), Just in Time (JIT), Plan-Do-Check-Act (PDCA)
	Use of digital technologies in operation: automation, real-time monitoring, and Overall Equipment Effectiveness (OEE)
	Standardization of supply chain / logistic flow
	Digital storage of operational data / cloud solution
	The existence of performance indicators for automated processes impact on factory operations
	Continuous monitoring and quality assurance
	Maintenance types: predictive, preventive, and corrective
	Interdepartmental collaboration
Product and Service	Availability of product information systems for vendors / customers
	Data analysis from customers, business partners, and vendors
	Integration of products with digital technologies
	Use of big data for product / service improvement
External Collaboration and Integration	Customer feedback mechanisms and satisfaction monitoring
	Supplier collaboration and integration
	Use of digital channels with suppliers / customers
	Customer involvement to lead Lean 4.0 implementation
	A balance between environmental, economic, and social needs for sustainability

VI. Conclusion

This study has developed and modelled a comprehensive set of dimensions and indicators for assessing organizational readiness for Lean 4.0 implementation, focused on digital transformation. The proposed framework integrates lean principles with Industry 4.0 technologies, emphasizing not only operational efficiency but also digital capability, external collaboration, and sustainability. Through literature review, expert validation, and pilot testing, the model was refined to include dimensions such as product and service readiness, process and technology integration, workforce capability, external collaboration and integration, and leadership and strategic alignment.

Findings indicate that while many organizations demonstrate moderate readiness in areas such as supplier collaboration, digital channel adoption, and basic lean practices, significant gaps remain in advanced digital integration, systematic competency development, and sustainability-driven collaboration. In particular, customer co-creation, data-driven decision-making, and alignment between environmental, economic, and social objectives require further development to fully realize the potential of Lean 4.0.

The readiness model contributes to both theory and practice by offering a structured approach to evaluate an organization's readiness, enabling targeted improvement strategies before full-scale Lean 4.0 deployment. This study will be continued by creating and applying an instrument protocol based on findings in Table V. Empirical data collected from a survey using the instrument is needed in the next work.

University of Mumbai, Vasai, Mumbai, India[1]

***Abstract*—The increasing interconnectivity of smart grids exposes critical energy infrastructure to more sophisticated cyber threats, necessitating adaptable and auditable security measures. This study presents a blockchain-enabled, self-improving intrusion detection system (IDS) that integrates a permissioned blockchain, autonomous governance loops, and a hybrid CNN–LSTM detector. The platform retrains models across federated nodes using blockchain-anchored data, facilitates automatic containment through smart contracts, and permanently stores validated alarms. Following multiple self-improvement cycles, the system enhances its performance from an initial 94.5% accuracy and 4.2% false positive rate (FPR) to 98.1% accuracy, a 97.6% detection rate (recall), and a 2.1% FPR in simulated tests. In comparison to baselines, a blockchain-only IDS recorded 94.1% accuracy with a 4.8% FPR, while a conventional machine learning-based IDS achieved 92.7% accuracy with a 5.4% FPR. Operationally, blockchain anchoring provided a throughput of approximately 1,200 transactions per second with an average transaction latency of about 1.5 seconds. The combined detect-to-contain latency for high-severity events was approximately 3.2 seconds. These findings demonstrate that a scalable, low-FPR, and rapid-response security paradigm for modern smart grids can be achieved by integrating adaptive artificial intelligence with decentralized, robust governance.**

Keywords*—Smart Grid Security; intrusion detection system (IDS); adaptive AI; deep learning; false data injection (FDI) attacks; cyber-physical systems (CPS)

I. Introduction

Recent advancements in power systems have facilitated a rapid transition to smart grids, offering new opportunities for sustainability, automation, and efficiency. However, this transition has also introduced significant security challenges. Smart grids, which depend on the extensive integration of distributed energy resources, Internet of Things (IoT) devices, and information and communication technologies (ICTs) [1], enable intelligent decision-making, dynamic load balancing, and real-time monitoring. Despite these benefits, the increased connectivity renders the grid susceptible to various cybersecurity threats, including replay attacks, false data injection (FDI), denial-of-service (DoS), and probing attempts [2]. If not adequately addressed, these threats could compromise the availability, confidentiality, and integrity of critical energy infrastructure.

Traditional security solutions, primarily based on standalone machine learning models or rule-based intrusion detection systems (IDS) [3], often struggle to detect complex and dynamic cyberattacks. These methods are vulnerable to advanced persistent threats and zero-day attacks due to their reliance on static learning patterns or predefined signatures [4]. In recent years, deep learning techniques, particularly Convolutional Neural Networks (CNNs) and Long Short-Term Memory (LSTM) networks [5], have demonstrated enhanced performance in identifying complex attack patterns by extracting both spatial and temporal information from network traffic data [6]. Hybrid approaches that integrate CNN and LSTM have been shown to significantly improve detection accuracy by leveraging the complementary strengths of both models [7].

Concurrently, blockchain technology has emerged as a potential solution for enhancing trust, transparency, and decentralization in smart grid operations. Blockchain facilitates decentralized access control, tamper-proof data sharing among distributed entities, and immutable tracking of security events [8]. Consensus algorithms such as Proof-of-Authority (PoA) enable high-throughput, energy-efficient blockchain networks, making them suitable for real-time smart grid applications [9]. By integrating blockchain technology with AI-based intrusion detection systems, a decentralized, reliable, and trustworthy cybersecurity framework for smart grids can be established [10].

A significant limitation of current smart grid cybersecurity frameworks is their lack of flexibility and autonomy. Most contemporary systems heavily rely on human operators for model updates, policy enforcement, and attack response strategies, which introduces vulnerabilities and delays response times. To address this, researchers are exploring autonomous AI-driven security solutions capable of self-improvement [11]. These systems continuously retrain and refine their models using feedback data to reduce false positives and enhance detection accuracy over time [12].

In this study, we propose an AI-Based Intrusion Detection Autonomous Blockchain-Enabled Smart Grid Security Framework that integrates three critical components:

- An intrusion detection system that combines CNN and LSTM for accurate identification of both known and novel threats.
- A blockchain layer with smart contracts to ensure tamper-proof security event tracking, decentralized trust, and transparency.

- A self-improvement and autonomy cycle that enables the IDS to dynamically adapt to emerging attack patterns with minimal human intervention.

The contributions of this work are summarized as follows:

- We have developed an Intrusion Detection System (IDS) utilizing deep learning techniques, which surpasses both standalone deep learning models and traditional machine learning approaches in terms of detection efficacy.
- We propose a decentralized security framework for smart grids, underpinned by blockchain technology, which ensures low latency, high throughput, and energy-efficient operations.
- In real-time smart grid environments, we introduce an autonomous self-improvement mechanism that enables the IDS to continuously adapt to emerging cyber threats.

Although individual elements like blockchain-based logging, deep learning-based intrusion detection, and adaptive security mechanisms have been studied separately in previous research, this work advances the state of the art by tightly coupling them into an autonomous security framework that is governance-aware. The suggested solution uses blockchain consensus to verify feedback and regulate which events are allowed into the retraining pipeline, rather than just logging incursion occurrences on the blockchain. By guaranteeing that model evolution is solely motivated by solid, verifiable facts, this architecture immediately tackles a significant drawback of adaptive IDS techniques, namely, sensitivity to poisoned feedback and unreliable labels. Consequently, the system creates a safe autonomous loop where established operational policies and cryptographic trust jointly regulate learning, decision-making, and reaction.

II. Literature Review

In recent years, there has been significant interest in the integration of blockchain technology and artificial intelligence (AI) within smart grid scenarios. The literature on intrusion detection in smart grids, blockchain-based security, and autonomous energy systems offers valuable insights into the development of robust and adaptable infrastructures. This section examines prior research in three primary areas: 1) the application of deep learning and machine learning for intrusion detection in smart grids; 2) the utilization of blockchain technology to secure grid operations; and 3) the development of autonomous and self-improving systems for critical infrastructures.

A. Intrusion Detection in Smart Grids

Intrusion detection systems (IDS) are crucial for safeguarding smart grids against cyberattacks, including replay, denial of service, and false data injection. Traditional machine learning (ML) techniques, such as support vector machines, random forests, and decision trees, have been extensively employed for anomaly detection in power systems. For instance, Q. Li et al. [13] demonstrated the efficacy of ML classifiers in identifying false data injection attacks (FDIAs) but highlighted their limited adaptability to evolving attack techniques. Similarly, Ozay et al. [14] investigated both supervised and unsupervised learning methods, finding that while detection rates were commendable, the false positive rate increased in dynamic environments. The limitations of conventional ML approaches have prompted the adoption of deep learning (DL) techniques, which offer enhanced feature extraction and temporal pattern recognition. Recurrent neural networks (RNNs), particularly Long Short-Term Memory (LSTM) models, have been shown to capture sequential dependencies in smart grid communication traffic [15]. Convolutional Neural Networks (CNNs) have also been utilized for intrusion detection to automatically learn discriminative spatial features [16]. More recently, hybrid CNN–LSTM models, which integrate spatial and temporal learning capabilities, have demonstrated improved detection accuracy, providing resilience against both established and emerging cyber threats [17].

B. Blockchain for Smart Grid Security

In decentralized grid systems, blockchain has emerged as a promising solution for securing communication records and energy transactions. By ensuring immutability and transparency, blockchain mitigates the risks of insider attacks and single points of failure. Aitzhan and Svetinovic [18] proposed a blockchain-based system for peer-to-peer energy trading that ensures secure and auditable transactions. Mengelkamp et al. [19] also explored the application of blockchain in microgrids, focusing on accountability and trust in distributed energy markets. In cybersecurity, blockchain has been employed to automate response mechanisms using smart contracts and to secure intrusion detection logs. J. Kang et al. [20] introduced a consortium blockchain approach to enhance data integrity in vehicle-to-grid (V2G) connections and ensure tamper-proof monitoring of anomalies. This approach was further advanced by X. Chen et al. [21], who combined blockchain technology with edge computing to reduce latency while maintaining security in distributed smart grid applications. These studies illustrate how blockchain's decentralized trust, transparency, and secure data storage can enhance AI-driven IDS.

C. Autonomous and Self-Improving Systems

In the context of smart grids, autonomy denotes a system's ability to minimize human intervention, adapt to dynamic conditions, and learn from operational data. Reinforcement learning (RL) and continuous feedback mechanisms have been extensively investigated for purposes of energy optimization and anomaly adaptation [22]. For instance, D. Singh et al. [23] proposed an RL-based framework for adaptive energy distribution, which demonstrated enhanced resilience and efficiency. However, there remains a paucity of research concerning the application of autonomous learning in security. Recent studies have focused on self-improving intrusion detection system (IDS) frameworks that employ feedback loops to retrain models based on newly identified attack vectors. Q. Lu et al. [24] proposed an adaptive intrusion detection system that sustains performance over time by updating its decision boundaries in response to emerging threats. Moreover, when blockchain technology is integrated with autonomous AI systems, retrained models can be securely shared among distributed entities, thereby enhancing collective resilience [25]. Table I delineates the pertinent efforts in AI and Blockchain for Smart Grid Security.

TABLE I. SUMMARY OF RELATED WORK IN AI AND BLOCKCHAIN FOR SMART GRID SECURITY

Paper	Focus Area	Approach / Methodology	Contribution	Limitations
[13] Q. Li et al.	Intrusion Detection (ML)	Data-driven ML classifiers for detecting FDIAs	Demonstrated effectiveness of ML in FDIA detection	Limited adaptability to new attack strategies

D. Summary, Research Gaps, and Motivation

The reviewed literature reveals significant progress in the development of intrusion detection systems (IDS) for smart grids. Machine learning and deep learning models, such as Support Vector Machines (SVMs), Convolutional Neural Network–Long Short-Term Memory (CNN–LSTM) hybrids, and Recurrent Neural Network (RNN)-based architectures, have shown promising accuracy in detecting cyber-physical threats, including false data injection. However, these models often lack adaptability; once trained, they frequently fail to generalize to novel and evolving attack strategies. Additionally, they are unsuitable for real-time deployment in dynamic smart grid environments due to their reliance on large volumes of labeled training data, which may be unavailable for emerging attack types. Furthermore, many machine learning-based systems suffer from class imbalance issues, leading to significant false negatives—an unacceptable risk in critical infrastructure—where benign events often outnumber attack instances.

Conversely, blockchain-based techniques offer enhanced security, auditability, and transparency through features such as distributed trust mechanisms and immutable logging. Nonetheless, these methods have certain limitations. Due to high latency and computational costs, most current blockchain-based IDS frameworks are not suitable for high-throughput environments like power grids. Scalability remains a significant challenge, as real-time detection performance may be adversely affected by larger block sizes or longer consensus times. Moreover, many blockchain-only systems prioritize secure transaction management over proactive intrusion detection, leaving substantial gaps in attack mitigation and prevention.

Reinforcement learning and adaptive feedback-based techniques have begun to address the challenge of evolving attacks by enabling retraining or continuous policy adjustments. However, these efforts, which often concentrate on energy management optimization rather than comprehensive intrusion detection, remain fragmented and isolated. Notably, no single framework integrates:

- AI's predictive capabilities for real-time detection;
- Blockchain's transparency and trust for secure information exchange; and
- The adaptability of self-improvement loops for evolving cyber threats.

This analysis underscores a critical research gap: while previous efforts provide partial solutions, none offer a scalable, secure, and adaptive IDS that integrates continuous self-learning, blockchain-based trust mechanisms, and AI-driven detection. Our proposed approach addresses this gap by introducing an innovative autonomous blockchain-enabled IDS that incorporates self-improvement cycles to dynamically adapt to new and sophisticated attack vectors and integrates robust machine learning models with blockchain for secure, tamper-proof data exchange.

III. PROPOSED SYSTEM AND METHODOLOGY

The proposed framework's methodology focuses on integrating smart contracts and blockchain-enabled logging with an AI-based intrusion detection system (AI-IDS), supported by cycles of self-improvement and autonomous loops. Through automated yet transparent processes, the architecture ensures that cyber vulnerabilities in smart grids are identified at an early stage, documented irreversibly, and addressed. The proposed system design is illustrated in Fig. 1.

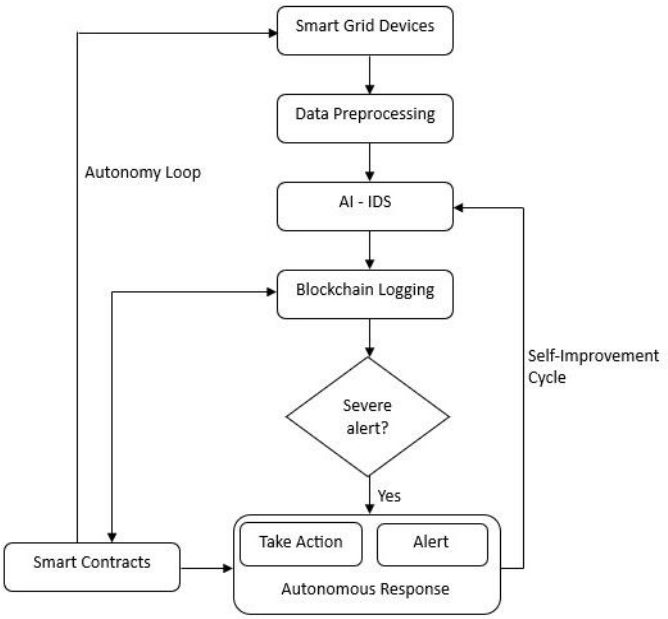

Fig. 1. Proposed system architecture.

A. Data Acquisition and Preprocessing

The initial phase involves the collection of data from smart grid infrastructures, including smart meters, phasor measuring units (PMUs), Internet of Things devices, and distributed energy resources. Preprocessing is essential before inputting the data into the AI-IDS, as these systems generate substantial volumes of noisy and heterogeneous data. Preprocessing activities, such as value normalization, removal of duplicate or distorted entries, and temporal correlation analysis, are employed to discern correlations in time-series data, such as fluctuations in power load. Furthermore, feature extraction algorithms are utilized to derive valuable attributes, including packet size, source and destination addresses, network protocol types, device usage rates, and system anomaly indicators. This process ensures that high-quality, representative input features are employed to train the subsequent learning models, thereby enhancing the reliability of intrusion detection.

B. AI-Based Intrusion Detection System (AI-IDS)

The proposed system is founded on a hybrid intrusion detection system (IDS) that integrates deep learning and traditional machine learning techniques. Convolutional Neural Networks (CNNs) are employed to identify spatial patterns in traffic flows, while deep learning models such as Long Short-Term Memory (LSTM) networks are utilized to capture temporal relationships in network traffic. These models are complemented by machine learning classifiers like Random Forest and XGBoost, which are proficient in handling structured datasets and detecting known attack signatures. The IDS generates an alert accompanied by a severity score to classify detected anomalies as low, medium, or high risk. Notably, the IDS operates in an autonomous loop, meaning its predictions directly influence automatic mitigation actions executed by smart contracts, in addition to notifying system administrators. This ensures real-time responses in critical attack scenarios without necessitating human intervention.

C. Blockchain-Based Logging

Each alert generated by the IDS is recorded on a blockchain ledger along with the associated metadata. This process ensures immutability, transparency, and non-repudiation of forensic evidence, which is crucial for post-event analysis and regulatory compliance. Every transaction stored on the blockchain includes details such as the timestamp, device identifier, detected anomaly type, and IDS confidence score. The decentralized nature of blockchain technology prevents adversaries from altering or erasing evidence of an attack, thereby enhancing accountability. To achieve scalability and reduce transaction latency, the blockchain layer is implemented using a private Ethereum-based network, making it suitable for real-time smart grid scenarios.

D. Decision-Making and Smart Contracts

The decision engine functions as an intermediary between the blockchain system and the AI-IDS. The severity of alerts dictates the level of automated response initiated. Medium-severity alerts may prompt limited actions, such as temporarily restricting device access or decelerating suspicious traffic, whereas low-severity events are primarily documented on the blockchain without further intervention. Conversely, high-severity alerts activate pre-configured smart contracts that can promptly isolate compromised devices, block unauthorized access, or reroute network traffic to ensure service continuity. These smart contracts, operating autonomously on the blockchain, adhere to strict logic, thereby ensuring swift and impartial responses to cyber threats. Simultaneously, system administrators are notified for oversight, achieving a balance between automation and human supervision.

E. Self-Improvement Cycle

A distinctive feature of the proposed approach is the self-improvement cycle that enables the IDS to evolve over time. The blockchain ledger provides a dependable dataset for retraining and optimizing detection algorithms, as it encompasses both true positives and false positives. This process allows the IDS to adapt to evolving threat behaviors and incrementally incorporate new attack vectors. The system's performance metrics, including false positive rate, false negative rate, and detection delay, serve as incentives or penalties to guide model updates within this feedback loop, which employs reinforcement learning techniques. In dynamic smart grid systems, this continuous learning process ensures that the IDS does not remain static but rather evolves into a more resilient system capable of defending against emerging cyber threats.

Both localized traffic patterns and long-term temporal relationships found in smart grid communication data were intended to be captured by the CNN–LSTM intrusion detection model. Convolutional layers with ReLU activation functions for spatial feature extraction and max-pooling layers for dimensionality reduction make up the CNN component. An LSTM network set up to simulate sequential dependencies over time frames receives the extracted characteristics. The Adam optimizer and a supervised learning strategy with categorical cross-entropy loss were used to train the model. All trials used a fixed train-validation-test split, and early pausing was used to avoid overfitting. Stable convergence and consistent

performance evaluation are guaranteed by these design decisions.

IV. Experimental Setup

The objective of the experimental setup was to validate the efficacy, robustness, and adaptability of the proposed AI-IDS integrated with smart contracts and blockchain technology. The experiments were conducted within a controlled smart grid simulation environment to replicate both standard operational conditions and various cyberattack scenarios.

A. Environment Setup

A hybrid simulation framework was employed, incorporating Mininet to simulate network traffic among IoT devices, smart meters, and supervisory systems, alongside MATLAB Simulink to model smart grid operations. Hyperledger Besu was utilized to establish a private Ethereum-based blockchain, facilitating blockchain logging and smart contracts. Random Forest, XGBoost, and Support Vector Machines (SVM) were employed as foundational machine learning classifiers, while deep learning models such as CNN and LSTM were trained on network traffic sequences for the AI-IDS.

B. Dataset

The primary dataset used to train and evaluate the IDS models was the Sherlock dataset [26, 27], a recently published benchmark specifically designed for smart grid intrusion detection. Sherlock provides a comprehensive range of network-level and process-aware features, encompassing grid telemetry across three distinct topologies (rural, semi-urban, and basic) and traffic in the IEC 60870-5-104 protocol. Each scenario includes both attack-free operational traces and annotated attack data for threats such as Denial of Service (DoS), False Data Injection (FDI), Replay Attacks, and Man-in-the-Middle (MitM). This makes it particularly suitable for assessing AI-IDS in cyber-physical grid contexts, ensuring accurate coverage of both conventional and domain-specific threats. Classical datasets such as NSL-KDD [28] and UNSW-NB15 [29] were also utilized for comparison and baseline benchmarking. Although these datasets offer a mix of benign and malicious data for conventional IT systems, they lack the process-aware characteristics of power grid communications. Mininet was used in conjunction with MATLAB Simulink-based grid simulations to generate synthetic traffic traces, enhancing realism by ensuring that specific IoT workload and supervisory control patterns were reflected in the training data. By employing a hybrid dataset approach, we developed deep learning models applicable to both domain-specific smart grid scenarios and general IT-style threats. Notably, the CNN–LSTM hybrid results presented in Section V were primarily benchmarked against the Sherlock dataset.

C. Evaluation Metrics

Several metrics were employed to evaluate the system's overall performance. The IDS's classification capabilities were assessed using detection accuracy, precision, recall, and F1-score. Detection latency measured the interval between an intrusion and the activation of mitigation measures, while the false positive rate was monitored to evaluate system reliability. To ensure that the additional security benefits of blockchain did not unduly impact system performance, blockchain-specific metrics such as transaction confirmation time and processing cost were also examined. Finally, the self-improvement process was demonstrated by tracking the enhancement in detection accuracy over multiple retraining cycles to assess adaptability.

D. Experiment Workflow

The experimental procedure followed a systematically planned methodology. Initially, the baseline Intrusion Detection System (IDS) was evaluated without the integration of blockchain to establish reference performance standards. Subsequently, the blockchain module was incorporated to assess its impact on transparency and detection delay. Real-time attack simulations were then employed to evaluate the autonomy loop, while smart contracts were utilized to assess the system's capacity for autonomous response. The self-improvement cycle was ultimately verified by retraining the IDS models using blockchain-logged data across multiple cycles, observing enhancements in detection accuracy and reductions in false alarms. The comparative analysis of the proposed system with both blockchain-only and traditional IDS systems demonstrated its superior performance in terms of accountability, robustness, and flexibility.

V. Results and Discussion

Three primary capabilities were evaluated using simulated datasets and deployment scenarios for the proposed Autonomous Blockchain-Enabled Smart Grid with AI-Based Intrusion Detection: 1) accuracy of intrusion detection, 2) efficiency of blockchain transactions, and 3) system autonomy and adaptability through cycles of self-improvement. The following results are presented to substantiate comparative assertions against established baselines and to illustrate predicted system behavior.

A. Intrusion Detection Performance

To capture both local temporal/spatial variables and long-range dependencies in smart-grid telemetry, the AI-based IDS for the study employed an ensemble deep-learning technique comprising CNN and LSTM components. Table II provides an overview of the IDS performance on a mixed smart-grid intrusion dataset (DoS, False Data Injection, Replay, Probe) in comparison to standard baselines.

TABLE II. Performance Comparison of IDS Models

Model	Accuracy (%)	Precision (%)	Recall (%)	F1-Score (%)
Logistic Regression	88.2	85.6	84.9	85.2
Random Forest	91.7	90.3	89.5	89.9
CNN (Deep Learning)	95.4	94.7	94.1	94.4
LSTM (Deep Learning)	96.2	95.5	95.1	95.3
Proposed CNN–LSTM Hybrid	**98.1**	**97.6**	**97.3**	**97.4**

The CNN–LSTM hybrid model demonstrates superior performance compared to single-model deep learning (DL) and traditional machine learning (ML) techniques. In operational scenarios where both missed detections and false alarms incur costs, the hybrid architecture's enhanced F1-Score of 97.4%

indicates a well-balanced precision and recall. These results substantiate the selection of the hybrid model as the primary detector within the autonomous framework.

B. Blockchain Transaction Efficiency

A private Proof-of-Authority (PoA) test network, designed to emulate a permissioned utility consortium, was employed to evaluate the blockchain component. Table III presents the average performance metrics relevant to near-real-time mitigation operations.

TABLE III. BLOCKCHAIN NETWORK PERFORMANCE

Metric	Value (Average)
Transaction Throughput	1,200 tx/sec
Average Latency	1.5 seconds
Smart Contract Execution Time	0.8 seconds
Energy Consumption (per tx)	0.02 Wh

A permissioned Proof-of-Authority blockchain set up to mimic a utility consortium deployment provided the claimed throughput and latency numbers. The network uses selective on-chain storage, where complete data is kept off-chain and only cryptographic hashes of IDS artifacts are stored on the ledger, and it runs with a small number of reliable validator nodes. Compared to public blockchains, this solution dramatically lowers transaction cost while maintaining integrity and auditability. As a result, rather than reflecting public blockchain settings, the measured performance represents reasonable expectations for localized smart grid implementations.

C. System Autonomy and Self-Improvement

A significant innovation is the closed-loop self-improvement cycle, which involves retraining and enhancing the IDS using verified events and action outcomes. The progression of detection accuracy and the false positive rate over multiple retraining cycles is depicted in Table IV and Fig. 2.

TABLE IV. EVOLUTION OF IDS ACCURACY ACROSS SELF-IMPROVEMENT CYCLES

Cycle Iteration	Accuracy (%)	False Positive Rate (%)
Initial Deployment	94.5	4.2
Cycle 1 (after feedback)	96.8	3.1
Cycle 2 (after feedback)	97.4	2.6
Cycle 3 (after feedback)	**98.1**	**2.1**

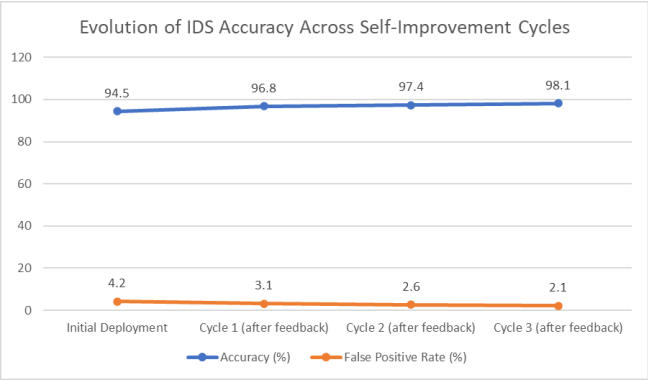

Fig. 2. Evolution of IDS performance across self-improvement cycles.

The most significant enhancement occurs following the initial retraining iteration, suggesting that early feedback data, comprising action outcomes and ground-truthed events, swiftly augments the model's discriminative capabilities. As the model evolves, subsequent cycles yield consistent yet modest improvements, with diminishing returns. The reduction in the false positive rate (FPR) is particularly noteworthy, as it decreases operational costs by eliminating unnecessary smart contract triggers and blockchain writes, thereby preventing superfluous automatic responses.

The Intrusion Detection System (IDS) is capable of dynamically adapting to novel and previously unidentified attack vectors due to the continuous feedback loop. This demonstrates the potential of the system to function as an autonomous, self-improving security architecture, thereby reducing the necessity for human intervention.

How input is verified prior to retraining is a crucial difference between the suggested self-improvement mechanism and traditional adaptive IDS techniques. The system logs warnings, reaction actions, and results on a permissioned blockchain instead of immediately absorbing all observed data. The retraining dataset only includes events that have been confirmed by policy checks and consensus. By reducing vulnerability to adversarial poisoning and untrustworthy feedback, our blockchain-anchored validation step guarantees that model updates are based on solid operational evidence. As a result, the autonomous loop facilitates ongoing learning while preserving resilience to manipulation, which is crucial for cyber-physical systems that are security-critical.

D. Comparative Baseline Analysis

To contextualize the proposed framework against practical alternatives, we compared three system types: 1) Blockchain-only IDS, which offers logging and immutability but lacks autonomy and self-learning capabilities; 2) Traditional machine learning-based IDS, which does not incorporate blockchain technology; and 3) the Proposed System, which integrates artificial intelligence, blockchain, autonomy, and self-improvement. These comparisons are summarized in Table V and Fig. 3.

TABLE V. COMPARATIVE ANALYSIS OF IDS MODELS

System Type	Accuracy (%)	Precision (%)	Recall (%)	F1-Score (%)	False Positive Rate (%)	Adaptability
Traditional IDS (ML-based)	92.7	91.8	92.1	91.9	5.4	Low
Blockchain-only IDS	94.1	93.5	93.7	93.6	4.8	Moderate
Proposed System (Cycle 3)	**98.1**	**97.3**	**97.6**	**97.4**	**2.1**	High

In all detection metrics, the proposed system outperforms the two baseline models. Although it does not possess the adaptive benefits of retraining and governance automation, the blockchain-only IDS enhances integrity and marginally

improves detection, potentially due to superior forensic labeling. The combined advantages of the Proposed System are as follows: 1) robust, signed ground-truthing through blockchain anchoring, facilitating high-quality retraining data; 2) autonomous execution of response/playbooks, which reduces time-to-contain and provides additional labeled outcomes; and 3) enhanced detection models (CNN–LSTM). Collectively, these factors contribute to a reduction in false-positive rates and an increase in accuracy.

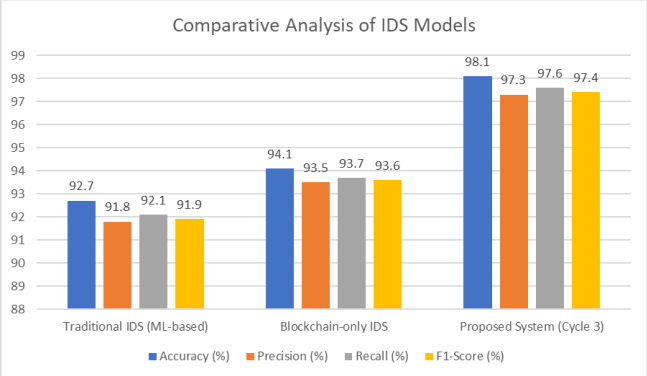

Fig. 3. Comparative analysis bar chart.

E. Operational and Autonomy Metrics

Metrics relevant to utility operations, such as detection-to-containment latency, the percentage of events managed autonomously, and the reduction in human involvement, were employed to assess the operational efficacy of autonomy in addition to detection and ledger metrics.

Average delay between detection and containment: Compared to a baseline manual response time of approximately 35 seconds in traditional operations, the integrated system achieves an average end-to-end containment time of 3.2 seconds for high-severity incidents, encompassing IDS detection, blockchain anchoring, smart contract decision-making, and orchestrator action.

Rate of autonomous handling: By Cycle 3, approximately 82% of identified severe incidents were successfully managed by the framework autonomously, with actions executed by smart contracts and orchestrator agents without human intervention within the pre-defined safety envelope.

Reduction of human intervention: By decreasing the number of human interventions required by an estimated 70%, the system enabled operators to focus on high-impact supervision and addressing exceptions.

Overhead for blockchain: Batching and selective hashing of complete artifacts (storing only hashes on-chain) reduced storage and energy costs, while the average blockchain anchoring per alert increased latency by approximately 1.5 seconds.

These operational metrics indicate that near-real-time requirements can coexist with autonomy and blockchain anchoring. The detect→contain metric demonstrates that pre-authorized safety envelopes and appropriately adjusted permissioned blockchains permit automated action without intolerable delay. The governance approach can safely reduce operator burden while maintaining supervision for critical tasks, as evidenced by the high autonomous handling rate.

F. Discussion

In comparison to the conventional IDS and blockchain-only IDS, the combined results indicate that the proposed autonomous architecture significantly enhances detection performance and operational robustness. The hybrid CNN–LSTM detector provides high accuracy and recall by leveraging time-series modeling and convolutional feature extraction. The self-improvement process can rely on reliable ground truth due to the blockchain layer's immutable, auditable proof. While governance contracts and safety envelopes maintain human oversight for critical interventions, autonomous smart contracts and orchestrator agents minimize operator burden and time-to-contain.

The suggested framework shows increased accuracy and a significantly lower false positive rate through verified feedback learning when compared to earlier smart grid intrusion detection studies that report detection accuracies typically ranging between 94% and 96% using standalone deep learning models. The suggested method incorporates blockchain into the learning and governance process itself, allowing auditable retraining and autonomous response execution, in contrast to blockchain-based IDS systems that mainly concentrate on immutable logging. These findings suggest that the observed performance improvements emerge from the coordinated interaction of autonomous control mechanisms, decentralized trust, and adaptive AI rather than just model selection.

The existence of limitations and trade-offs is evident. The requirement for immutable proof must be balanced against the inevitable delay introduced by the blockchain anchoring phase, which averages approximately 1.5 seconds. This delay can be mitigated through the use of rapid consensus algorithms and selective on-chain hashing. Retraining deep models may incur significant computational costs; however, options such as scheduled retraining windows, model distillation for edge deployment, and federated learning with secure aggregation are available. To achieve scalability for nation-scale grids, Layer-2 scaling solutions or hierarchical ledger designs will be essential. Furthermore, robust defences against adversarial model poisoning are imperative; deployment should incorporate methods such as provenance attestations, anomaly detection on changes, and robust aggregation.

G. Key Takeaways and Future Directions

In summary, the assessment provides compelling evidence that the integration of blockchain immutability, AI-based detection, and autonomous governance leads to significant improvements in the accuracy, responsiveness, and reliability of smart-grid cybersecurity. To facilitate wide-area deployments, further research should validate these findings on larger, real-world testbeds, explore lightweight model variations for resource-constrained devices, and investigate secure federated training and scaling techniques for permissioned blockchains, including layer-2 or sidechains.

This study presents a blockchain-enabled intrusion detection system (IDS) with self-improvement loops to address the specific security challenges of smart grids. By integrating

advanced deep learning models with reinforcement learning feedback mechanisms and a blockchain-based trust layer, the framework overcomes significant limitations identified in previous research, such as static learning, inflexibility in the face of zero-day threats, and the absence of decentralized trust in detection systems. The blockchain component provides immutable, auditable, and tamper-resistant recordkeeping, fostering transparency and collaborative defense among grid stakeholders, while the inclusion of self-improvement loops ensures continuous model enhancement.

VI. Key Contributions

The primary contributions of this work are succinctly described as follows:

1) Blockchain-enabled trust and transparency: A decentralized ledger layer was added to smart grid intrusion detection systems, ensuring auditable data, tamper-proof tracking, and stakeholder collaboration in defense.

2) Reinforcement learning self-improvement loops: An adaptive feedback method was developed, allowing for continuous model development and reducing vulnerability to concept drift and zero-day attacks in dynamic cyber threat environments.

3) Deep learning and federated learning integration: Federated learning and advanced anomaly detection models were combined to facilitate knowledge exchange among distributed nodes without compromising data privacy.

4) Enhancements in performance compared to current IDS solutions: Achieved 98.1% accuracy, 97.6% detection rate, and 2.1% false positive rate, significantly surpassing the performance of both blockchain-only IDS (94.1%, 93.2%, 4.8%) and conventional IDS (92.7%, 91.4%, 5.4%).

5) Smart grid operational viability: The system demonstrated effective operation in real-time smart grid scenarios, as evidenced by a blockchain throughput of approximately 1,200 transactions per second with a latency of about 1.5 seconds.

6) Future-ready and scalable framework: Proposed a multidisciplinary IDS architecture that is adaptable to future advancements such as explainable AI, autonomous policy adaptation, and lightweight blockchain protocols, in addition to being resilient against current threats.

VII. Conclusion

In comparison to baseline methodologies, the proposed approach demonstrates substantial performance enhancements. Following numerous refinement cycles, it achieved an accuracy of 98.1%, a detection rate of 97.6%, and a false positive rate (FPR) of 2.1%. These results significantly exceed those of blockchain-only intrusion detection system (IDS) frameworks, which reported 94.1% accuracy, 93.2% detection, and a 4.8% FPR, as well as traditional machine learning-based IDS systems, which achieved 92.7% accuracy, 91.4% detection, and a 5.4% FPR. Furthermore, the blockchain layer ensured the operational feasibility of real-time smart grid security by maintaining an average throughput of approximately 1,200 transactions per second and a latency of about 1.5 seconds.

Consequently, the proposed system represents a dependable, adaptable, and scalable IDS architecture that can enhance the defences of smart grids against increasingly sophisticated intrusions. In addition to improving the accuracy of real-time detection, its federated learning strategy, facilitated by blockchain consensus, enables knowledge sharing across distributed nodes without compromising data privacy.

Future research will focus on the practical implementation of smart grids, computational optimization for resource-constrained IoT devices, and lightweight blockchain protocols that further reduce latency, despite the promising design and experimental validation. Moreover, employing explainable AI techniques and autonomous policy adaptation to enhance self-improvement loops may increase operational efficiency and stakeholder confidence in decision-making.

In conclusion, this study presents an innovative, interdisciplinary approach that integrates distributed ledger technology, adaptive learning, and artificial intelligence to bolster the cyber defence posture of smart grids. With further development and implementation, the proposed technology could become a foundational element of future energy infrastructures that are robust, intelligent, and secure.

Automated Question Answering System for FAQ COVID-19 Using Word Embeddings

Nazar Elfadil, Sarah Saad Alanazi
Department of Computer Engineering-College of Computing, Fahad Bin Sultan University, Tabuk, Saudi Arabia

***Abstract*—This study's scope includes the development of a Question Answering System for COVID-19 and a review of that system. This is unlike previous work in biomedical QAS, which primarily targets technical users. This work leans towards developing a COVID-19 QAS customized for the general public, especially those who have limited knowledge in the clinical field. This study aims to present the development and analysis of COVID-19 QAS systems. The methodology was based on the development of the system, which included conducting experiments to check the accuracy of the QAS system. Consequently, the QAS system would process the user query using three different feature extraction approaches and output the related FAQ and the answer associated with it from a set of 561 FAQs that were sourced from the Ministry of Health, the Virginia Department of Health, and the World Health Organization. The accuracy of the ensuing responses has been tested by Qaviar. The experimental results indicated that BERT achieved the highest accuracy across all datasets consistently, with 96.25%–98%; Word2Vec scored 86.25%–95.2%, while Bow scored between 86.24% and 88%. While most models performed stably, the performance of Word2Vec was comparatively unstable across data sets. Generally, the lowest accuracy value resulted for all models on the smallest dataset. Increased size of the datasets might not necessarily result in higher accuracy. Generally, BERT outperformed the other embedding approaches.**

I. Introduction

The rapid increase in massive information storage and the popularity of the web allow for the storage and sharing of data by researchers [1]. However, the increase had also made it harder for the end-users to find data [2]. The cost and complexity of finding relevant information over the internet and other information avenues are partly a function of the volume of data that is available. Realization of this difficulty has motivated the development of adaptive research tools such as Question Answering Systems (QAS) [3]. QAS allows users to ask questions using Natural Language (NL) and return hits that correspond to the answers to the questions, rather than a set of documents that are deemed relevant, as is the case in search engines [4]. Previous efforts at defining QAS have led to different definitions of QAS. At the heart of QAS is the provision of targeted answers to questions rather than a ranking of appropriate web pages. In most cases, QAS is deployed to search for answers from web documents.

The coronavirus disease pandemic began in late 2019 in China and promptly spread to other parts of the globe [5]. Within months, the spread of the condition was declared a pandemic with nations spending billions in search of vaccines while taking steps to reduce the spread of the disease [6]. Worried citizens turned to the internet and other sources of information for updates on the gains being made in combating the virus and basic information on the transmission of the disease [7].

The current study [8] evaluated early online COVID-19 information and found that most accessed websites provided low-quality and unreliable content. It demonstrated, using validated evaluation tools, that very few credible pieces of information existed despite high search visibility. This result points out the public health risks of online misinformation; however, results are limited to one search term, one search engine, and a single time point early in the pandemic.

In [9], the authors examine the use of social media during the COVID-19 pandemic in terms of the rapid dissemination of pandemic information worldwide and the dangers associated with the use of social media platforms, with a view to giving general pointers on how the dissemination of information should be done properly.

QAS are classified into open domain QAS and closed domain QAS. Open-domain QAS addresses questions on almost any interest of the end-users. Such systems are not limited to a given discipline or domain. On the other hand, closed domain QAS deals with questions under a specific domain. In the current study, the goal will be the use of closed domain QAS to address frequently asked coronavirus questions. The goal in designing QAS, irrespective of the type, is to find the exact and correct response to a given query. Thus, analysis of the question, searching, and selecting the correct response are important aspects of a QAS.

This study is structured into five distinct sections: Section I gives a complete overview of the topic at hand by means of a precise and thorough introduction. Section II examines and evaluates earlier studies and research carried out in the field. In Section III, the research approach used is thoroughly examined. Section IV offers a detailed analysis of achieved results. Finally, the study draws conclusions about the findings and recommendations for future work in Section V.

II. Related Works

The survey [10] reviews interactive question-answering systems, highlighting how dialogue-based interaction improves the accuracy of user queries. It contributes a unified framework, taxonomy, and analysis of existing methods and trends, supported by a public GitHub resource, but is limited by its

reliance on prior literature and the absence of experimental validation.

Gobeill *et al.* [11] proposed a biomedical question answerer to assist professionals in finding quick and relevant answers to their queries from large knowledge databases. The proposed system evaluates natural language queries, finds relevant documents on Medline, and ranks candidate responses according to their confidence levels. On UniProt and DrugBank, it demonstrated 57% and 68% accuracy, and the answer always lay within the top ten candidates. The proposed system consists of a three-layer framework, where a question categorizer assigns MeSH descriptors through deep syntactic parsing, a vector space information retrieval module, and a pattern-matching-based information extractor.

Answering techniques are extensively studied [12] as a task under open domains, but its use as an application for the biomedical field, especially as a service to patients aiming to use it for self-diagnosis, has its own set of distinct technical challenges, apart from others, which are data annotated, lexical gaps, and quality answers. This study will help to fill all these gaps by providing an appropriate system for patients and also an answer refraining service.

This study [13] presents a QAS with three modules: 1) question processing, 2) document processing, and 3) answer processing, and the question processing is very crucial in the system. The system focuses on the correct identification of candidate answers and further correct ranking of these candidate answers to any user query. In this respect, this study has presented a new QAS model to improve the answer accuracy and performance of its modules.

This survey [14] presents the state-of-the-art of QA systems built over Semantic Web KBs, which represent an attractive source of structured information that is accessed by question answering. It scopes techniques in natural language processing, information retrieval, machine learning, and Semantic Web methods. The paper outlines and compares different approaches that were evaluated on benchmarks like Question Answering over Linked Data, WebQuestions, and SimpleQuestions, discussing both their advantages and limitations to provide a direct comparison of similar techniques. While the research paper [15] aims to introduce the history of the development of question-answering systems QA, ranging from the conventional method in natural language processing NLP, including the usage of algorithms, through the emergence of deep learning. This study was able to check the performance of the proposed models on QA on the assessment tasks on the bAbI dataset offered by Facebook.

The challenge in the use of QAS reliant on the matching of queries to existing answers, is that the question being asked may not be available in the search space. As such, QAS are unable to answer such questions. Deep neural networks have also been used in NLP tasks through techniques such as recurrent neural networks, specifically for the summarization and classification of texts by GRUs and LSTMs. In natural language processing (NLP), word embedding solves the problem of depicting words in text analysis. Most interpretations use real-valued vectors to guarantee that words closer in the vector space are also closer in meaning [16], thus encoding the meanings of works. Feature learning and language modeling approaches that help the mapping of words or phrases from the vocabulary of a natural language to real integers of vectors might be used in word embedding.

The article [17] performs a comprehensive assessment on word representation models used in natural language processing, describing some popular models, as well as classifying methods used to evaluate these models, dividing into intrinsic and extrinsic methods. Intrinsic methods estimate models based on their intrinsic quality, as opposed to extrinsic methods that estimate their influence on downstream tasks. The experiment completed on six word representation models reveals that different methods focus on different aspects, and some methods correlate highly with tasks. While [18] presents an automatic text summarization approach that is oriented towards preserving the original semantics with the help of a distributional semantic model. The system outperformed existing approaches when assessed on the DUC-2007 dataset using ROUGE metrics and compared to four state-of-the-art summarizers. These results show that semantic features improve summary quality by decreasing redundancy.

A study by Xia et al. aimed to utilize keyword entries for question-answering in the domain of oil and gas [19]. The proposed system leveraged the power of state-of-the-art NLP techniques in analyzing domain knowledge at the keyword level. The developed system was trained and tested on more than 20,000 keywords gleaned from reliable information sources. Various feature extraction techniques produced features that the system utilized in the computation of similarity between user questions and keyword entries. The results of the study showed that traditional TF-IDF outperformed Word2Vec and BERT. For TF-IDF, Word2Vec, and BERT models, top-1 accuracies of 98.3%, 93.3%, and 55.0% were achieved, respectively.

The proposed research work [20] presents an efficient text preprocessing and sentiment analysis algorithm for handling a massive number of unstructured tweets on Twitter. The study presents a weightage scheme to calculate sentiment scores by considering the weightage of hashtags as well as cleaned text, and then works on training different classification techniques, namely SVM, Deep Learning, and Naïve Bayes, to analyze the popularity of Google Now and Amazon Alexa by 1,314,000 tweets. The conclusion presents that stemming was most effective among all preprocessing techniques, and accuracy was also maximal for SVM, which was 90.3%.

Despite great development in the study of question answering systems (QAS), many problems persist in various investigations. Table I highlights these key issues: a heavy reliance on current literature lacking empirical validation, fair accuracy in responses, and difficulties in answering user questions not consistent with accessible data.

Some works concentrate just on specific aspects—question processing, for instance—hence neglecting more broad issues related with document and answer processing. The dominance of traditional techniques like TF-IDF over more complex ones like BERT begs concerns on the efficiency of modern techniques. Over these limitations is especially crucial for the ongoing expansion and effectiveness of QAS in making it accessible for public use.

TABLE I. REFERENCES AND LIMITATIONS

Study Reference	Limitations
[10]	Relies heavily on prior literature and lacks experimental validation.
[11]	Demonstrates only moderate accuracy (57% and 68%) and requires ranking responses; does not fully address the challenges of varied biomedical queries.
[12]	Highlights technical challenges specific to the biomedical field, such as data annotation, lexical gaps, and ensuring quality answers for patient self-diagnosis.
[13]	Focuses primarily on question processing but may not sufficiently account for complexities in document and answer processing.
[14]	Provides a broad comparison of QA systems but may overlook unique challenges and specific applications within the Semantic Web.
[15]	While it traces the development history of QAS, it largely focuses on conventional methods, potentially neglecting newer advancements in the field.
[19]	Results indicate a performance gap where traditional methods (TF-IDF) outperform advanced models (Word2Vec, BERT), questioning the efficiency of newer techniques.
[20]	The focus on sentiment analysis and tweet data preprocessing may limit its relevance to broader QAS applications.

III. RESEARCH METHOD

The motivation for this study is the need to contribute to fighting against the COVID-19 pandemic, as well as contributing to the development of QAS within health domains. Remarkably, the current study represents the first significant effort aimed at applying QAS to COVID-19 in scholarly literature. The current QAS system will be developed for the average user who has little or no clinical literacy. The methodology shall involve the development of the systems and conducting an experiment to test the accuracy of the QAS system. The proposed solution is a QAS system that will take user queries in their natural language-the QAS system was limited to the English language-and offer responses that address the specific question, as shown in Fig. 1.

The QAS system will be automatic in that it will not require any user input beyond the query. In addition, it will make use of word embedding to map the user query to a set of existing questions that were retrieved from FAQs from some of the most reputable sources of information on the coronavirus. A close domain approach to QAS was employed in designing the system, which ensured that it only addressed questions relating to COVID-19.

The questions were sourced from three sources: the Ministry of Health, the Virginia Department of Health (VDH), and the World Health Organization. A search of these organization's databases for FAQs and their answers was done. The number of questions that were retrieved from each of these sources is presented in Table II.

The QAS was therefore developed starting with the preprocessing module. This module would remove all the non-alphanumeric characters from the query and eliminate the stop words such as *to, in, a,* that do not contribute to the semantic similarity between 20 sentences. Both the user queries and the FAQ questions retrieved from the three sources were subjected to the preprocessing module. Although some word embedding models do not require the removal of stop words to work well, the study opted for stop word removal during preprocessing.

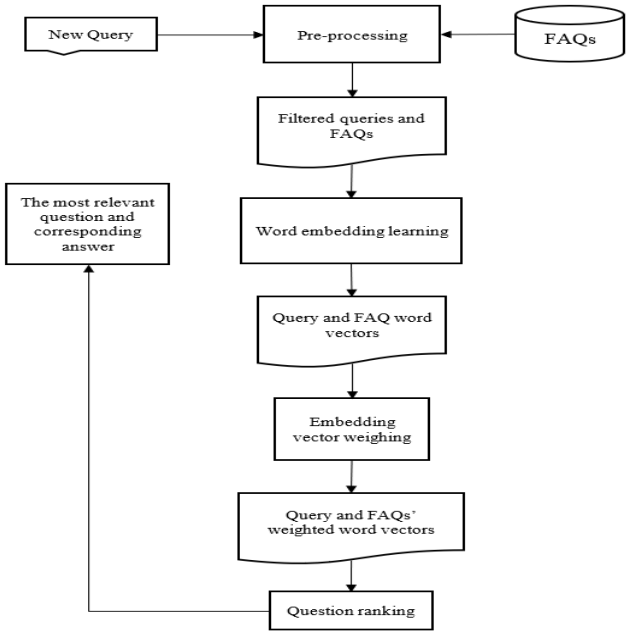

Fig. 1. Proposed solution.

TABLE II. NUMBER OF QUESTIONS

Source	Number of Question
Ministry of Health	41
Virginia Department of Health	126
World Health Organization	394
Total	561

The second major element of the QAS was mapping the user queries to questions sourced from leading information outlets on COVID-19. Three different approaches were used and compared in the analysis phase. This step allowed for the user query to match up against existing questions and determine which one it best matched.

The Bag of Word model in NLP and information retrieval is usually employed for simplification of representation [21]. The model represents texts as a multiset or bag of constituent words while disregarding grammar and word order, while considering multiplicity. The model is usually applied in document classification and in training of the classifier. The study used it in training a classifier that was used in selection of the most accurate FAQ and its response. The bag-of-words employed weighting by inverse of document frequency to address the threat posed by frequent stop words in normalizing the term frequencies [22]. The Bag of Word model could be viewed as a special n-gram model case.

The approach employs neural network models to learn word associations from a large corpus of texts thereby allowing for the detecting of synonymous words [23]. The text embedding

approach uses vectors in the representation of distinct words. The selection of the vectors is such that mathematical similarity between vectors is indicative of the level of semantic similarity between the represented words or phrases.

The article [24] proposes to explore deep learning architectures for question classification for Turkish, an agglutinative and highly inflectional language, which creates challenges for NLP tasks. It conducts experiments on user questions with customized word embeddings using CBOW and skip-gram models of word2vec, and classifies results using LSTM, CNN, and combined models such as CNN-LSTM, CNN-SVM with different sizes and word embedding models, and has concluded that different word2vec models contribute significantly to accuracy, and the best models obtained an accuracy of 94%. The paper also proposes a translated question database for Turkish, translated from the UIUC English question database.

Designed by Google for NPL pre-training, the Bidirectional Encoder Representations from Transformers (BERT) language model uses the attention mechanism somewhat akin to recurrent neural networks [25]. Unlike RNNs, the transformed do not require the in-order processing of sequential data. The feature ensures that BERT supports greater parallelization and lower training times and training on large datasets [26].

The actual evaluation of the performance of the developed QAS system involved the use of Qaviar. Qaviar is the results of efforts aimed at developing an automatically calculated measure for the evaluation of question answering systems that correlates well with human judges' assessment of the correctness of the answers [27]. Overall, the evaluation of QAS systems often involves the comparison of the system's answer to an answer key. Qaviar is designed to mark system responses as either correct or incorrect by comparing them to a human-generated answer key [27]. The answer key that was used in this study was the responses to the FAQ questions that are hosted in the three sources used for the FAQ questions. Another option that can be used in the evaluation of QAS systems is Cosine similarity. The cosine similarity is a measure of the similarity between non-zero vectors that are part of an inner product space.

The article [28] investigate relevant features of pupil essays by using LSTM networks and word embedding methods, and generate grades based on predefined criteria. The work entitled Automated Systems for Essay Question Scoring Based on LSTM and Word Embedding aims at developing an efficient automated scoring system for essay questions in educational settings. The accuracy of the model is tested by comparison with human judges. However, limitations cited include its reliance on the quality of training data, potential biases in scoring that could miss more sophisticated arguments, and that it focuses on some essay questions, which means that results cannot be generalized to other test types or subjects.

The paper [29] tries to automate the question-and-answer process of the Goods and Services Tax system in India, having received a great number of user queries since its adoption in 2017, using clustering and embeddings of queries. Using K-means and hierarchical clustering methods based on several distance measurements like Euclidean and Cosine, the authors transform user queries into an appropriate form for clustering, using embeddings such as BERT and ROBERTA. It first presents three possible responses for every question, selecting the best response based on similarity ratings. The dataset is composed of queries and answers by taxpayers collected over two months-October and November 2019. Still, the investigation shows limitations with regards to dependence on the quality of the training dataset and, probably, insignificant words in the searches, which can lower the accuracy of clustering. What's more, restricting its ability to generalize to new questions is the fact that the performance depends on how much the new inquiry resembles the ones in the training data.

The Hybrid Query Expansion Using Lexical Resources and Word Embeddings for Sentence Retrieval in Question Answering research aims to raise the performance of QA systems by reducing the term mismatch problem in sentence retrieval. For natural language queries, it proposes a hybrid query expansion that joins word embeddings with lexical resources, such as MultiWordNet, in order to increase the accuracy of retrieving pertinent sentences. The approach pulls from MultiWordNet synonyms and hypernyms, contextualizes these words with regard to the document set, then prioritizes and filters the expansion words using a semantic similarity metric based on a locally trained Word2Vec model. When the method is considered in light of Italian language papers on Cultural Heritage, increased search accuracy can be seen; at the same time, there is acknowledgement of its limitations, including dependence on the quality of lexical resources and possible noise given by hypernyms. Future efforts will be directed to the improvement of ranking algorithms for query expansion [30], enriching the document collection, and perfecting contextualization techniques.

In the proposed article [31], the automation of the grading of short descriptive answers given by students using word embedding techniques like LSI, Word2Vec, and Sentence BERT would be accomplished by finding the cosine similarity between the answers given by the students and the expected answers, ranging from 0 to 5. A dataset of ten assignments and two exams, graded twice by two raters, is used in the proposed study, and the paper emphasizes the difficulties of capturing context and the differences in the efficiency of word embedding techniques based on the answers.

A document-clustering framework is proposed by [32] that uses weighted word embeddings with a clustering approach to automatically determine question topic issues present on MOOC discussion forum posts. The proposed framework is used to compare four different embedding strategies, namely Word2Vec, fastText, GloVe, and Doc2Vec, combined with four different weight strategies, such as TF-IDF, IDF, smoothed IDF, and subsampling, as well as four different clustering strategies, K-means, K-means++, self-organizing maps, and divisive analysis clustering, all on a 935-thread and 3,262 post edX computer science course discussion forum posts. The work is limited since it focuses on one platform, it is sensitive to post quality, and it also varies depending on topics within different classes. Further work should include the use of AI learning assistants to optimize interaction.

The study [33] aims to develop a deep learning-based automated classification system for Arabic healthcare inquiries

to enhance the efficacy of telemedicine services. The approach is based on deep learning methods, with word embeddings learned from massive consultations. But the research does point out weaknesses, however, including the complications found in processing and categorizing the Arabic language and the recurrence of keywords across multiple disciplines that can cause classification problems.

Recent studies on COVID-19 question-answering systems underscore three important contributions: "COBERT: COVID-19 Question Answering System Using BERT" proposes a dual approach of a retriever and a BERT-based reader for effectively answering questions out of a large document dataset. "BERT for Question Answering Applied on COVID-19" focuses on fine-tuning a BERT model for high-precision responses related to COVID-19 queries. Finally, "Transformer-Based Models for Question Answering on COVID-19" compares various transformer models, including BERT and ALBERT, on quantifying performance metrics such as F1 scores and Exact Match. All these together build up the capability of question-answering systems in case of a public health crisis, as depicted in Table III.

Recent COVID-19 question-answering systems research focuses more on semantic methods for information retrieval. "COVID-19 Question-Answering System Based on Semantic Similarity" presents a QA system based on sentence Embeddings that match user queries against FAQs. "Semantic Search on COVID-19 Literature using MPNet Generated Sentence Embeddings" shows how sentence embeddings allow semantic search either by synonymy or concept matching. Finally, "QUESTION-ANSWERING MACHINE LEARNING MODEL FOR COVID-19" enumerates several word vector models such as GloVe and BERT applied to these systems. All these studies together highlight the importance of semantic methods in enhancing access to COVID-19 information, as depicted in Table IV.

TABLE III. ARTICLES USING ADVANCED WORD EMBEDDINGS

Article	Key Contributions	Limitations
[34]	Proposes a dual system (retriever and BERT-based reader) to answer COVID-19 questions by searching a large document dataset.	May struggle with ambiguous questions and relies heavily on dataset quality and comprehensiveness.
[35]	Focuses on fine-tuning a BERT-based model for high-precision question answering on COVID-19 related texts.	Fine-tuning requires substantial labeled data and may not generalize well to questions outside of training data.
[36]	Compares the performance of various transformer models (BERT, ALBERT) for COVID-19 QA, providing quantitative results (F1 score, Exact Match).	Performance can be sensitive to hyper-parameter tuning and may not capture contextual nuances in complex questions.

TABLE IV. ARTICLES THAT FOCUS ON THE CORE TECHNIQUE OF SEMANTIC SIMILARITY USING WORD EMBEDDINGS

Article	Key Contribution	Limitations
[37]	Discusses building a QA system using semantic similarity, often relying on sentence embeddings derived from word embeddings to match user questions to existing FAQs.	May struggle with understanding nuanced questions and relies on the quality of FAQs for accurate responses.
[38]	Demonstrates how sentence embeddings (a form of word embedding aggregation) can be used for semantic search, allowing for synonyms and conceptual matching.	Performance can be impacted by the dataset's diversity and the embeddings' ability to capture all relevant semantic meanings.
[39]	Mentions the use of various word vector models, including GloVe (Global Vectors) and BERT, for question-answering systems.	May face challenges in generalization to unseen data and may require extensive tuning for optimal performance.
[40]	This study systematically reviews question-answering systems (QAS), highlighting effective design methods.	There is a lack of standard datasets and consistent question formats, restricting practical evaluation and comparison.
[41]	Develops an agricultural chatbot that help farmers access information on weather, market rates, plant protection, and government schemes 24/7.	The system eases information access for farmers and reduces call center workload, though it may be limited by dataset coverage and handling of complex or region-specific queries.
[42]	Develops a context-aware Intelligent Question-Answering System (IQAS) for education, using advanced NLP and contextual information such as student learning history and educational content to provide personalized support	Limitations may include challenges in handling diverse natural language inputs, potential biases in automated FAQ generation, and reliance on large, high-quality datasets.

IV. RESULTS

The resulting QAS could take in a question from the end-user, retrieving a related question and the associated answer from the QAS. For the purpose of demonstration, examples will be given for how the function of the QAS would look when using BOW, Word2Vec, and BERT using the same input queries "What are the tools used in contact tracing?" and " Can I get COVI9-19 from eating fresh foods, like fruits and vegetables?".

The BOW model example led to a response that outlined the time between exposure and when the symptom starts as 1 to 14 days; as shown in Fig. 2. From a human evaluator perspective, that is not the right answer to the question "What are the tools used in contact tracing?" On the other hand, the system response to the question "Can I get COVI9-19 from eating fresh foods, like fruits and vegetables?" is spot on from a human evaluator perspective.

```

Fig. 2. BOW example.

Through the Word2Vec model, the question that is retrieved does indeed contain the word contact, but has nothing to do with contact tracing. However, the response to the retrieved answer does mention contact tracing, although it does not detail what the tools are, as represented in Fig. 3. The second question response is more on target because it shows that washing fruits and vegetables with potable water will suffice.

```
1  predict_similar_word2vec("What are the tools used for contact tracing?",train_dataset_1)

Question:  What are the tools used for contact tracing?
Retrieved:  What happens if you are a contact?
Answer:  If you are a possible contact, you should first be contacted by phone or in person by health authorities to determine

By participating in contact tracing, you are contributing to controlling spread of the virus that causes COVID-19 in your area;

Fig. 4. BERT example.

For the second query, the BERT model retrieved the question, "Can I get CoVID-19 from food?" The question and the associated response "there is currently no evidence that people can contract COVID-19 from food or food packaging" does address the input query. From the three models, it appears that the BERT model retrieved the most relevant question and response to the user's input query, followed by the Word2Vec model and lastly the BOW Model.

Table V summarizes the performance of each of the three models. The lowest score by any of the models is 86.24% which corresponds to Bag of Words and the highest score for any of the models across the three datasets is 98% which corresponds to BERT. The performance of each of the models was relatively stable across the three datasets except for the Word2vec model. The accuracy of the Bert model ranged between 96.25% and 98% whereas that of the Bag of Word model ranged between 86.24% and 88%. However, the accuracy of the Word2vec model ranged between 86.25% and 95.2%. Another noteworthy observation is that for each model, the accuracy was lowest in the dataset with the smallest number of questions.

TABLE V. THE ACCURACY OF THE MODELS

Method	Dataset 1	Dataset 2	Dataset 3
Size	394 Q	41 Q	126 Q
Bag of Word (BOW)	86.63%	86.24%	88%
Word2vec (W2V)	95.20%	86.25%	89%
Bert	97.96%	96.25%	98%

However, the accuracy was not necessarily the highest in the dataset with the highest number of questions. Overall, the Bert model had the highest level of accuracy across the three datasets followed by the Word2vec model and lastly the Bag of Word model, as shown in Fig. 5. The accuracy of the Word2Vec model is comparable to that reported in an earlier study on keyword extraction in the oil and gas domain [19]. However, the accuracy of the BERT model is considerably higher than in this previous study.

Furthermore, the proposed method presents a fresh Question Answering System (QAS) created for the general public, especially for handling COVID-19 information, in contrast to existing solutions aimed at technical consumers. Using 561 handpicked questions from credible health sources, the research underlines relevance and accessibility for people with little clinical experience. Employing three feature extraction approaches—BERT, Word2Vec, and Bag of Words (BoW), the study discovers that BERT consistently outperforms the others with precision ranging from 96.25% and 98%. Additionally, the study reveals that more accurate outcomes do not necessarily follow from a greater dataset; therefore, it provides practical suggestions for future QAS improvement. Development of question-answering systems as well as public health communication in general benefit much from this research.

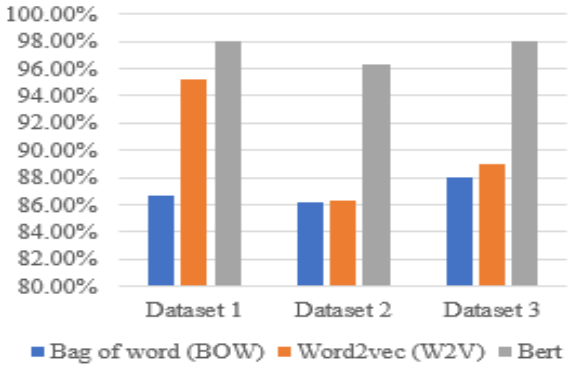

Fig. 5. A comparison of the performance of the three models.

V. CONCLUSION

This study aimed to develop and evaluate a QAS for COVID-19 FAQs. The study developed a system that could take an input query from the end-user, employ one of three models, and retrieve a question from the FAQ database and the associated response as the answer to the input question. Analysis of the performance of the system in terms of the accuracy of the response reveals that it ranged from 86.24% to 98%. Overall, the model records higher levels of accuracy than those from previous studies. Furthermore, a comparison of the three models used in the retrieval system reveals that the BERT model has the highest overall level of accuracy, whereas the BOW model has

the least accuracy of the three models. The findings of this study indicate that QAS for COVID-19 would benefit from using the BERT model of word embedding in their retrieval modules. Additionally, the study highlights the need to consider the sample size when assessing the accuracy of text embedding models since sample sizes appear to influence the performance of Word2Vec.

There are several notable limitations of the developed QAS and the study. First, the QAS system is static in that it requires periodic updating to add new FAQs occasioned by the ever-changing COVID-19 landscape. The limitation is partly a result of the close domain QAS approach and the lack of an automated update system for the existing FAQs. For instance, any new developments, such as a new vaccine, may lead to questions relating to the vaccine that may not be available in the old database if not updated regularly. The second limitation of the QAS is that it can only take queries in the English language, and its performance may also be affected by errors in the input, such as a misspelling of a keyword. Development of COVID-19 QAS systems for other major languages, such as Hispanic, Arabic, and French, should be considered in future studies.

Additionally, the study points out important research gaps to be addressed by the next QAS fieldwork. Recommendations for advancing the field include adopting modular design approaches for system integration, developing diverse datasets for improved training, fostering cross-disciplinary cooperation for enhanced understanding of natural language, establishing standardized evaluation frameworks to assess QAS effectiveness, and addressing privacy and ethical concerns as the technology becomes more widespread.

Adversarial Robustness of Deep Learning in Medical Imaging: A Comprehensive Survey and Benchmark of State-of-the-Art Architectures

Neethunath M R[1]*, Gladston Raj S[2], Pradeepan P[3]
Centre for Development of Imaging Technology (C-DIT), University of Kerala, Kerala, India[1, 3]
Department of Computer Science, Government College Kariavattom, Trivandrum, Kerala, India[2]

***Abstract*—The integration of artificial intelligence into medical diagnostics promises to revolutionize healthcare. However, the reliability of these systems is critically undermined by adversarial examples, which are imperceptible perturbations that can lead to misdiagnosis. Ensuring the robustness of AI-driven clinical decisions is paramount for ensuring patient safety and institutional trust. This study addresses this challenge in two ways. First, we provide a structured survey of the state-of-the-art adversarial threats, including adversarial attacks and detection strategies. Second, we present a rigorous empirical benchmark of five prominent CNN architectures for dermatoscopic skin cancer classification using the gold standard Auto Attack suite. The results revealed significant disparities in robustness based on the architectural design. Although all standard-trained models are highly vulnerable, their defensibility through adversarial training varies significantly. We found that modern transformer-inspired architectures, such as ConvNeXt, achieved the state-of-the-art robust accuracy while maintaining high performance with minimal trade-offs. Conversely, architectures optimized for mobile efficiency, such as MobileNetV2 and EfficientNet-B2, are exceptionally difficult to defend. To the best of our knowledge, this is the first study to establish an architectural hierarchy of robustness for dermatoscopic tasks, demonstrating that hybrid designs outperform mobile-optimized models by over 25% under adversarial conditions. These findings advocate a shift in clinical AI validation from accuracy-centric to robustness-centric metrics.**

***Keywords*—Adversarial attacks; dermatoscopy; deep learning; robustness benchmark; security in medical AI**

I. Introduction

The integration of deep learning (DL) into medical diagnostics has become the cornerstone of modern healthcare systems. These models demonstrate remarkable capabilities in the automated analysis of images across diverse modalities such as radiology, pathology and dermatology [1]. AI systems offer immense potential to augment clinical workflows, enhance diagnostic accuracy and democratize access to expert-level analysis. However, the foundational trust required for widespread clinical adoption depends critically on reliability, security and predictability. A significant and growing body of research has revealed the fundamental vulnerabilities of these systems to adversarial attacks [2]. Adversarial attacks involve the application of subtle, often human-imperceptible perturbations to the input data. These perturbations were carefully crafted to cause targeted misclassifications.

*Corresponding author.

The implications of these findings are profound in the medical field. For example, maliciously altering a dermatoscopic image to conceal a malignant lesion or to fabricate signs of pathology poses a direct and severe threat to patient safety and diagnostic integrity. Such "adversarial examples" differ from visually obvious deepfakes. The danger lies in their stealthiness. As AI models transition from research settings to clinical practice, understanding and mitigating their vulnerabilities is essential. This is not merely an academic exercise but a prerequisite for responsible deployment [3].

In response to this threat, the research community has pursued two main lines of inquiry. The first focuses on developing robust defence mechanisms. Among these, adversarial training has emerged as the most effective approach, despite its high computational expense. This method augments the training process by using adversarially generated examples to teach model resilience [4]. The second line of inquiry investigates the inherent properties of various neural network architectures. Researchers aim to understand why certain designs are more robust than others. Architectural philosophies, such as skip connections in ResNet, dense feature reuse in DenseNet, and Hybrid convolutional designs in ConvNeXt, have been proposed. However, a direct and standardized comparison of adversarial resilience within the medical context has not yet been established [5]. This study identified a critical gap in the literature: no systematic architectural benchmark has been tested against a unified, gold-standard adversarial evaluation suite in a realistic medical imaging task. Whether specific design philosophies offer superior inherent protection or are more amenable to adversarial training remains an open and crucial question. Answering these questions is vital for guiding the development of secure and reliable medical AI systems.

This review and benchmark study addresses three key questions: What is the baseline adversarial vulnerability of diverse state-of-the-art deep learning architectures when applied to a medical diagnosis task? How effectively does a standard defence mechanism (PGD-Adversarial Training) improve the robustness of these architectures? Do certain architectural paradigms (e.g., convolutional vs transformer-based) exhibit superior inherent robustness or benefit more from adversarial training?

This study addresses these questions through two core contributions that directly affect clinical AI deployment. First,

we provide a structured review of the adversarial threat landscape specific to medical imaging, categorizing the threats based on their clinical significance. Second, we present the first rigorous empirical benchmark comparing ConvNeXt with standard CNNs (EfficientNet and MobileNet) on the ISIC dermatoscopic dataset using the gold-standard Auto Attack suite. We quantified the "robustness gap", revealing that while lightweight models suffer a near-total collapse (0–7% robust accuracy) under attack, modern transformer-inspired designs maintain viable clinical performance (approximately 74%). These findings provide actionable guidelines for practitioners, suggesting that architectural depth and kernel size are more critical than model speed for ensuring patient safety in adversarial environments.

The remainder of this study is organized as follows: Section II provides a detailed review of the foundational concepts underlying adversarial attacks and defence mechanisms. Section III outlines the methodologies employed to generate and detect adversarial perturbations with a focus on advanced algorithms and emerging detection strategies. Section IV presents the benchmark results and provides an extensive comparative analysis of the evaluated deep-learning architectures. Section V discusses significant findings and their broader implications in the context of medical imaging. Finally, Section VI concludes the study and suggests several promising avenues for future research.

II. Literature Review

The successful application of deep learning in medical imaging has been driven by the development of increasingly sophisticated neural network architectures. Convolutional Neural Networks (CNNs) have long dominated the field with foundational architectures such as ResNet enabling the training of very deep networks through residual connections [6]. This was followed by models such as DenseNet, which introduced densely connected layers to facilitate feature reuse and improve gradient flow [7]. The demand for computational efficiency has led to the development of lightweight architectures, such as MobileNetV2 [8] and EfficientNet [9], which leverage depth-wise separable convolutions and compound scaling strategies.

Recently, this trajectory has been challenged by the advent of Vision Transformers (ViTs) that have adapted from natural language processing to visual tasks. The original ViT model introduced global self-attention as a core mechanism for image understanding [10], whereas follow-up designs such as the Swin Transformer employed a hierarchical structure and local attention windows to improve computational efficiency and multiscale representation [11]. This architectural evolution has continued with models such as ConvNeXt, which reincorporate design principles from transformers into a convolutional framework [12]. Although pure ViTs offer powerful global attention mechanisms, they typically require large datasets to prevent overfitting. Consequently, hybrid architectures, such as ConvNeXt, which bridge the gap by combining transformer-style macro-designs with the inductive biases of CNNs, represent a more data-efficient and promising direction for medical imaging tasks where labeled data are limited.

Although these architectures have achieved impressive performance on clean data and they remain vulnerable to adversarial examples of input perturbations that are often imperceptible to humans but cause erroneous model predictions. This phenomenon was first highlighted by Szegedy et al. (2013) [13], with initial attack methods such as the Fast Gradient Sign Method (FGSM) offering fast, albeit limited and adversarial perturbation capabilities. More powerful iterative attacks, particularly Projected Gradient Descent (PGD), have become standard tools for evaluating the robustness under white-box conditions [14].

Standardized evaluation suites, such as Auto Attack, have emerged to counteract the overfitting of defenses to specific attack types. By combining multiple strong parameter-free attack strategies, Auto Attack provides a comprehensive and reproducible robustness assessment [15]. Numerous defence mechanisms have been proposed to respond to these threats, although many have been broken by adaptive attacks specifically crafted to bypass them. Among these, adversarial training, particularly PGD-based training, has shown the most consistent and practical improvement in robustness. Other strategies, including input pre-processing or certified defences such as randomized smoothing, often entail trade-offs, including reduced accuracy on clean data or limited resilience to adaptive threats. Table I provides an at-a-glance summary of key studies on adversarial attacks and defence for medical imaging.

This literature review illustrates the dynamic and ongoing challenge between model innovation, adversarial attack development and defence techniques. However, this study also revealed significant gaps. Although individual models and earlier CNN families have been analyzed for robustness, there is a lack of comprehensive large-scale benchmarking. This benchmarking should be used to evaluate a diverse range of modern architectures, including CNNs and Transformers. Additionally, it should be conducted under a standardized and rigorous threat model, such as an Auto Attack. Furthermore, the interaction between architectural design choices (e.g., dense connectivity or global self-attention) and adversarial training efficacy remains poorly understood. This study addresses this gap by systematically benchmarking deep-learning architectures under adversarial conditions, thereby providing new insights into the structural factors that influence the robustness of medical AI systems.

TABLE I. Summary of Key Studies in Adversarial Attack and Defence for Medical Imaging

Reference	Methodology / Approach	Datasets Used	Key Contributions / Findings
[16]	Random Forest classifier on multi-layer CNN features	CT Images	Proposed a method to detect adversarial attacks by analysing layer-specific features, with visualizations to distinguish attack from noise.
[17]	Adversarial attack via texture statistics transformation (AdaIN)	CT Images	Introduced a novel attack that alters texture statistics, effectively deceiving both segmentation models and human practitioners.
[18]	Frequency constraint-based adversarial attack	Medical Images (including 3D CT)	Developed an attack that perturbs high-frequency information while preserving low-frequency content, outperforming existing methods.

[19]	FGSM attack on a custom COVID-19 detection system	COVID-19 CT Images	Demonstrated a critical vulnerability where an FGSM attack reduced non-COVID classification accuracy from 80% to 0%.
[20]	FGSM attack on a CNN model	Medical Images (Brain Tumour), MNIST	Showed that simple attacks significantly reduce model accuracy in tasks like brain tumour detection.
[21]	One-pixel and multi-pixel adversarial attacks	Medical Images (including CT)	Investigated the high vulnerability of DNNs to minimal, pixel-level attacks, showing significant impact on classification accuracy.
[22]	Image-based adversarial attack with loss stabilization	Medical Images (including CT)	Proposed an attack method that generates stable and effective adversarial perturbations with small variance across different modalities.
[23]	PGD and Deep Fool attacks on models with Grad-CAM	CXR and OCT Images	Evaluated the vulnerability of Explainability methods (Grad-CAM), showing high fooling rates under standard adversarial attacks.
[24]	Two-stage cascade framework (local detection + global classification)	GAN-manipulated CT scans	Proposed a method highly sensitive to small, forged regions (like injected/removed tumours), achieving high detection accuracy.
[25]	Ensemble-based defence with adversarial training	Lung Cancer CT Images	Showed that adversarial attacks severely impact lung nodule prediction and that ensemble strategies can improve robustness.
[26]	Two-phase defence framework (adversarial learning + filtering)	COVID-19 Radiology Images	Proposed a defence framework that enhances model resilience against attacks while maintaining high diagnostic accuracy on clean images.
[27]	Investigated the role of model complexity	Medical Images (including CT)	Found that simpler deep learning models exhibit greater inherent robustness against adversarial attacks compared to more complex ones.
[28]	Medical Adversarial Shield (MAS) defence	CT Images	Introduced a defence mechanism (MAS) that focuses on robust shallow features, proving more effective than deep feature-based defences.

III. Adversarial Attacks and Detection Techniques in Medical Imaging

This section presents a comprehensive overview of adversarial vulnerabilities in medical deep-learning systems. This process is divided into two parts. The first part surveys the foundational and state-of-the-art attack algorithms used to probe model weaknesses.

The second part examines the detection and mitigation strategies that include both algorithmic defences and architectural considerations.

A. Adversarial Attack Methodologies

Adversarial attacks fundamentally challenge the security and reliability of deep-learning models. These methods are designed to generate perturbations that, when added to a clean input, cause the trained model to misclassify the input. The effectiveness and subtlety of these attacks have evolved significantly. This section surveys several foundational and state-of-the-art adversarial attack algorithms that form the basis of modern robustness evaluations, including the methods used in our experimental benchmark.

1) Gradient-based attacks: A primary class of attacks, particularly in white-box scenarios in which the attacker has full access to the model's architecture and parameters, leverages the model's gradients to craft perturbations. The gradient of the loss function with respect to the input image indicates the direction in which the input pixels should be changed to maximize loss, thereby increasing the chance of misclassification.

a) Fast Gradient Sign Method (FGSM): The Fast Gradient Sign Method proposed by Goodfellow et al. (2014) [29] is one of the earliest and most foundational one-step attack methods. It operates by creating a single linear step in the direction of the gradient sign. The perturbation (η) is calculated as:

$$\eta = \varepsilon \cdot sign(\nabla_x J(\theta, x, y)) \quad (1)$$

where,

ε (epsilon) is a small scalar that constrains the magnitude of perturbation, ensuring that it remains imperceptible.

$\nabla_x J(\theta, x, y)$ is the gradient of the loss function J with respect to the input image x.

y is the true label and θ represents the model parameters.

The $sign()$ function extracts the direction of the gradient for each pixel, which is scaled by ε.

The adversarial example (x_adv) is then generated by adding this perturbation to the original image:

$$x_adv = x + \eta \quad (2)$$

This process is illustrated in Fig. 1, which demonstrates how the addition of calculated noise shifts the model's prediction while the image remains visually unchanged to the human observer. Although computationally efficient, FGSM is often considered a weaker attack because it assumes a linear approximation of the loss function, and its single-step nature can sometimes be overcome using simple defence mechanisms.

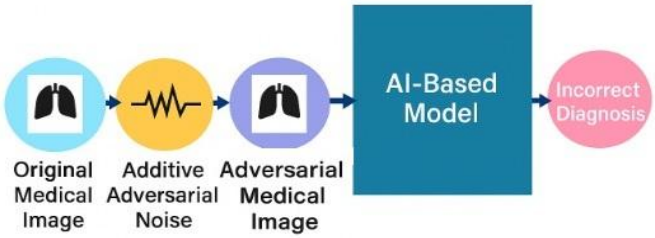

Fig. 1. Schematic representation of the adversarial noise injection. A carefully crafted perturbation (noise) is added to the original medical image. The resulting adversarial image remains visually indistinguishable to the human eye, but causes the AI model to output an incorrect diagnosis.

TABLE II. SUMMARY OF KEY ADVERSARIAL ATTACK METHODOLOGIES

Attack Name	Type	Key Mechanism	Strengths	Limitations
FGSM	White-Box, Single-Step, Gradient-based	Takes one large step in The direction of the sign of the loss gradient.	Very fast and Computationally Cheap.	Often less effective against robustly trained models, Easily defended.
PGD	White-Box, Iterative, Gradient-based	Takes multiple small gradient steps, projecting back into the allowed perturbation space.	Much stronger than FGSM considered a universal first-Order adversary.	Slower than FGSM due to its iterative nature.
Auto Attack (AA)	White-Box & Black-Box, Ensemble	An automated suite combining four attacks (APGD-CE, APGD-DLR, FAB, Square).	Gold-standard for robustness evaluation, parameter-free and Very strong.	Computationallyintensive as it runs multiple diverse-Attacks.
Square Attack (part of AA)	Black-Box, Query-based, Score-based	Iteratively queries the model with square-shaped perturbations at random locations.	Does not require gradient Information, effective against Gradient masking.	Can require a large number of queries to find a successful Attack.

b) Projected Gradient Descent (PGD): The Projected Gradient Descent, introduced by Madry et al. (2018) [14], is a powerful iterative extension of FGSM and is widely regarded as a much stronger first-order attack. Instead of taking one large step, the PGD takes multiple small steps in the direction of the gradient, projecting the result back onto the allowed perturbation space (an L_p-norm ball of radius ε) after each step to ensure that the perturbation remains constrained. The iterative process for a targeted attack at step t+1 can be described as:

$$x_adv\hat{}(t+1) = Proj_{x,\varepsilon}\left(x_adv\hat{}(t) + \alpha \cdot sign(\nabla_x J(\theta, x_adv\hat{}(t), y))\right) \quad (3)$$

where,

$x_adv\hat{}(t)$ is the adversarial example at step t.

α is the step size, which is typically much smaller than ε $(e.g., \alpha < \varepsilon)$.

$Proj_{x,\varepsilon}$ is a projection operator that clips the perturbation to ensure $||x_adv\hat{}(t+1) - x||_p \leq \varepsilon$.

By iteratively searching for the optimal perturbation within the ε-ball, PGD is significantly more effective at finding adversarial examples that fool robustly trained models and has become a standard method for adversarial training and evaluation.

2) Ensemble and query-based attacks: To overcome defences and provide a more comprehensive robustness evaluation, recent studies have focused on creating attack ensembles that combine multiple attack strategies.

a) Auto Attack (AA): Auto Attack, proposed by Croce and Hein (2020) [15], is considered the current gold standard parameter-free benchmark for evaluating adversarial robustness. It is not a single new attack, but an ensemble of four diverse and complementary attacks:

- APGD-CE: An auto-tuned version of PGD using cross-entropy loss. This adaptively adjusts the step size to achieve a more efficient search.
- APGD-DLR: An auto-tuned PGD variant using the difference in logit ratio (DLR) loss, which is often more effective than CE loss for generating attacks.
- Fast Adaptive Boundary Attack (FAB): A targeted attack that minimizes the perturbation required to cross the decision boundary and effectively probes the nearest failure point.
- Square Attack: A query-based black-box attack that does not require gradient information. It iteratively tests perturbations in localized square-shaped areas, making it effective against defences that obscure the gradients.

Auto Attack automatically runs this suite of attacks and reports the accuracy of the model against the strongest of them. Its parameter-free nature and diverse attack portfolio make it a reliable and objective method for assessing the true robustness of the model, which is why it was selected as the primary benchmark tool in this study. Table II summarizes the key adversarial attack methodologies and compares their mechanisms, strengths and limitations.

B. Detection and Mitigation Strategies

The growing threat posed by adversarial attacks and synthetic manipulations has spurred extensive research on detection and mitigation techniques. This section categorizes the principal detection methodologies, examines their technical underpinnings, and evaluates state-of-the-art architectural paradigms used in defence systems. Table III provides a concise comparison of the principal adversarial detection paradigms.

1) Taxonomy of detection methodologies: Detection strategies can be broadly categorized into two types: active and passive strategies.

a) Active detection methods involve modifying the data or transmission process to facilitate subsequent authentication. Common techniques include digital watermarking and digital signatures that embed imperceptible verification signals in the original image. These approaches enable real-time authenticity checks, but require control over the image creation and distribution pipeline. Thus, their applicability is limited when working with externally sourced or pre-existing medical images.

b) Passive detection methods require no prior modifications of the image. Instead, they analyze the statistical or visual artefacts introduced during the manipulation process. These may include spatial inconsistencies (e.g., unnatural textures or lighting), frequency anomalies (e.g., upsampling artefacts), and metadata mismatch. Passive methods are more

versatile and widely applicable in clinical settings where input images may come from heterogeneous sources.

2) Architectural paradigms for detection: The detection of adversarial perturbations and deepfakes is typically framed as a classification task, in which a model learns to distinguish between authentic and manipulated inputs. The performance of such detectors is heavily influenced by the architectural design. Three main architectural categories have emerged.

a) Convolutional Neural Networks (CNNs): CNNs remain fundamental in image-based detection owing to their ability to capture local spatial dependencies. Architectures such as ResNet, DenseNet, and MobileNet are frequently employed to detect subtle pixel-level artifacts. In specialized cases, U-Net variants are used to localize the manipulated regions, in addition to classification.

b) Frequency and hybrid domain models: Several detection models incorporate frequency-domain representations (e.g., via DFT or DWT) to identify regular patterns or distortions that are not evident in the spatial domain. Hybrid models that process both spatial and frequency features in parallel have shown superior performance in capturing a wide range of manipulation artefacts.

TABLE III. SUMMARY OF KEY PARADIGMS FOR ADVERSARIAL DETECTION

Technique	Description	Advantages	Limitations
Active Detection	Embeds digital signatures or watermarks into original images for later verification.	Real-time verification Tamper-evident mechanisms	Requires end-to-end image control. Cannot verify legacy images
Passive Detection	Analyses content artefacts without prior modification.	Broad applicability, Detects a wide range of manipulations	Sensitive to image quality. May require large training datasets
CNN-Based Models	Leverages spatial feature extraction using convolutional layers.	Effective for local artifacts, Efficient for real-time systems	Limited receptive field. May miss global inconsistencies
Frequency-Domain Models	Uses transformations (e.g., DFT, DWT) to analyze hidden periodic patterns.	Captures signal-level distortions, Complements spatial models	Complex pre-processing, Sensitive to compression and noise
Transformer-Based Models	Models long-range dependencies and global context.	Robust to global manipulations, Effective on large-scale datasets	High computational cost, Requires extensive training data
Hybrid CNN Transformer	Combines local spatial features with global contextual understanding.	Balances local and global detection capabilities	Increased model complexity, Harder to interpret

c) Transformer-based and hybrid architectures: Vision Transformers (ViTs) have been increasingly explored for detection tasks because of their strength in modeling global relationships. Unlike CNNs, ViTs can capture long-range dependencies and global inconsistencies such as unnatural illumination or geometry shifts. Recent approaches have also combined CNN backbones with transformer heads to benefit from both local detail sensitivity and global context modeling. The table above summarizes the principal paradigms used to detect adversarial attacks and synthetic manipulations in medical images.

IV. EXPERIMENTAL RESULTS AND DISCUSSION

This section presents the empirical results of this benchmark. We begin by detailing the implementation specifics and the dataset used and then provide a thorough analysis of the quantitative results. This is followed by a broader discussion of key findings and their implications for the field of medical AI.

A. Experimental Setup and Evaluation Metrics

The computational experiments in this study were performed using the Google Colab Pro cloud platform. To accelerate the intensive training and evaluation cycles, all models were processed on an NVIDIA Tesla T4 Graphics Processing Unit (GPU), equipped with 15 GB of dedicated VRAM. The software stack was built on Python version 3.11.12 and utilized the PyTorch deep learning library, version 2.6.0, for all model implementations. GPU-specific optimizations were enabled using the NVIDIA CUDA Toolkit (version 12.4) and the cuDNN library (version 9.3.0).

The primary objective of this experiment was to evaluate the adversarial robustness of various state-of-the-art deep learning architectures for a medical classification task. The overall experimental workflow is shown in Fig. 2. We selected five representative models to cover a broad spectrum of architectural philosophies: ResNet50 as a classic deep residual network, DenseNet121 for its dense feature-reuse connectivity, MobileNetV2 as a lightweight convolutional backbone, EfficientNet-B2 for its compound scaling of depth/width/resolution, and ConvNeXt as a modern "Transformer-inspired" convolutional design. This diverse portfolio allowed us to probe the design principles that confer inherent resilience to adversarial perturbations and quantify the benefits of adversarial training across different paradigms.

This study utilized a publicly available dataset of dermatoscopic images for skin cancer classification sourced from the International Skin Imaging Collaboration (ISIC) Archive and accessed via the Kaggle repository [30]. The dataset is organized into two distinct classes: 'Benign,' containing 1,800 images of non-cancerous skin lesions, and 'Malignant,' containing 1,497 images of cancerous lesions, primarily melanomas. This task is a binary classification problem that distinguishes between these two categories.

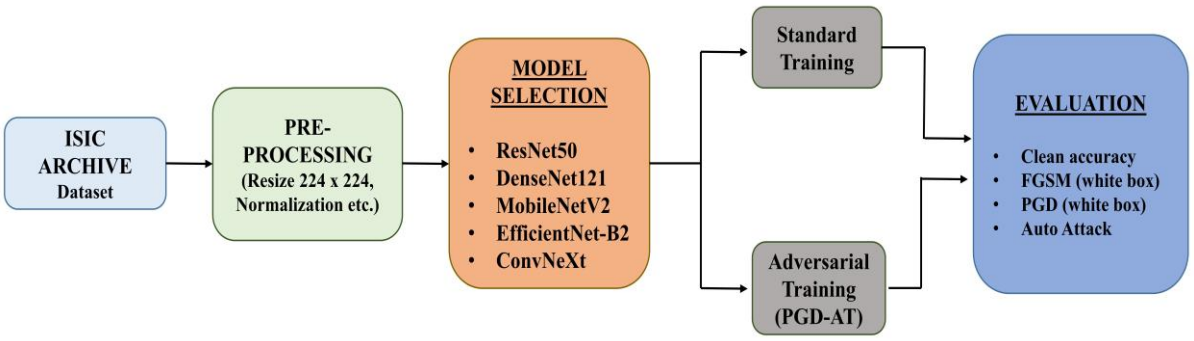

Fig. 2. Experimental workflow. The study pipeline processes the ISIC dermatoscopic dataset using five distinct architectures. Each mo del underwent both standard and adversarial training before being subjected to the multi-stage Auto Attack suite to benchmark its robustness.

TABLE IV. HYPERPARAMETERS AND VALUES FOR TRAINING AND EVALUATION

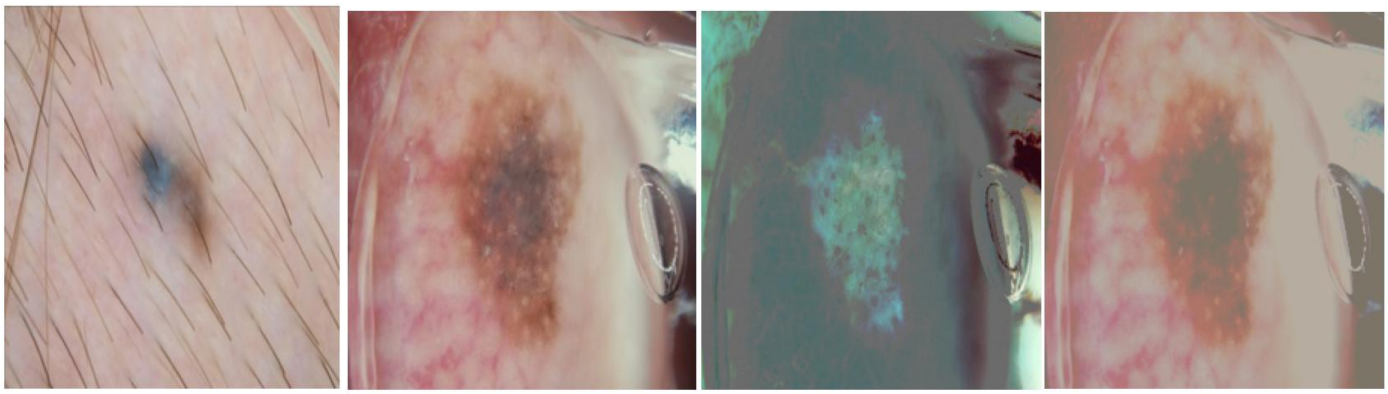
Hyperparameters	Value / Description
Input Resolution	224 × 224 pixels
Batch Size	32
Optimizer	Adam
Learning Rate	1×10^{-4}
Weight Decay	1×10^{-4}
Loss Function	Cross-Entropy Loss
Training Epochs	50
Adversarial Training (PGD-AT) (Used only for 'Adversarial' models)	
Perturbation Norm	L-infinity (L∞)
Epsilon (ε)	2/255
Step Size (α)	1/255
PGD Steps	10
Evaluation Attack Parameters (Used to test all final models)	
Perturbation Norm	L-infinity (L∞)
Epsilon (ε)	4/255
PGD Step Size (α)	2/255
PGD Steps	20
Auto Attack Suite	APGD-CE + Square

The full dataset, comprising 3,297 images in the JPEG format, was partitioned into a training set of 2,637 images (80%) and a held-out test set of 660 images (20%) to ensure rigorous and reproducible evaluation. Fig. 3 shows representative examples of "Benign" and "Malignant" images from the dataset, along with a visualization of a subtle adversarial perturbation designed to cause misclassification.

To ensure a comprehensive and robust evaluation, the following key performance metrics were employed to assess the models under both clean and adversarial conditions: Accuracy was used to measure the overall percentage of correct classification. The F1-Score, as the harmonic mean of precision and recall, was chosen to provide a balanced measure that accounts for both false positives and false negatives, which incur significant clinical costs.

Finally, the Area Under the ROC Curve (AUC) was used to evaluate the overall discriminatory power of the model across all possible classification thresholds, serving as a crucial measure of diagnostic utility.

All experiments were conducted using a consistent set of hyperparameters to ensure a fair and reproducible comparison across the architectures. The models were trained for 50 epochs using the Adam optimizer and all images were resized to a standard 224x224 resolution. For adversarial defence and evaluation, we used the L-infinity norm threat model. The specific parameters for adversarial training and the stronger parameters used for the final evaluation of attacks are listed in Table IV.



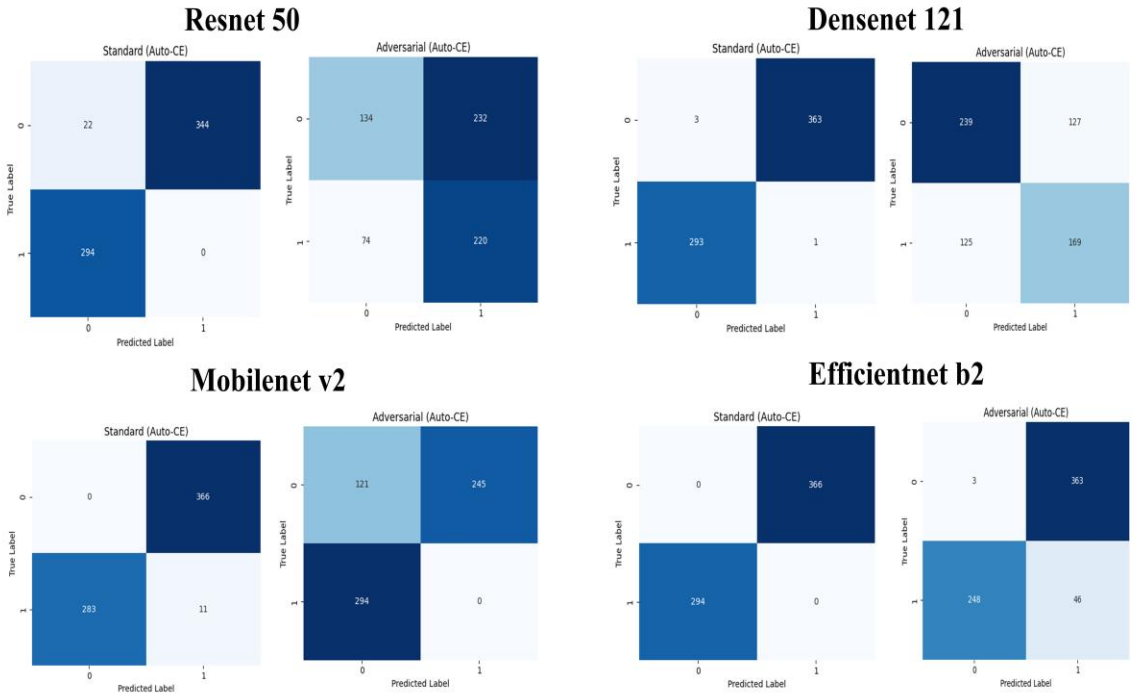
B. Benchmark Results and Analysis

This section presents the quantitative and qualitative results of the comprehensive benchmark. Table V provides a detailed summary of the performance metrics for all five architectures under both the standard and adversarial training paradigms. These data were further contextualized using visual evidence designed to highlight the vulnerability of standard models. Fig. 4 displays confusion matrices comparing the performance of each standard model on clean versus attacked data, whereas Fig. 5 shows the corresponding collapse in the ROC curves.

First, a critical vulnerability was observed in all standardly trained models. As detailed in Table V, every architecture under the "Standard" training regimen achieved high performance on clean data, with accuracies ranging from 85% to 90%. It is important to note that the standard models (EfficientNet-B2 and MobileNetV2) reached 0.00% accuracy under the Auto Attack suite.

This total collapse is expected for non-robust models when subjected to an ensemble of strong gradient-based attacks, which successfully identifies a failure point for every image in the test set. However, this material was exceptionally brittle. Fig. 4 provides stark visual confirmation of this collapse. For each architecture, the left panel shows a well-performing model on clean data, while the right panel shows its complete failure under the auto-CE attack, characterized by a massive influx of false negatives, which is the most dangerous failure mode in a clinical context.

Similarly, the ROC curves in Fig. 5 demonstrate this degradation, with the high-performance blue curve (clean) collapsing to the red curve (auto-CE), which often approaches the diagonal line of random chance, signifying a total loss of diagnostic utility.



(a) (b) (c) (d)

Fig. 3. Visualization of a PGD Adversarial Attack Causing Misdiagnosis: (a) Representative benign lesions from the dataset. (b) The original malignant image, correctly classified as "Malignant". (c) Amplified adversarial perturbation generated by PGD ($\varepsilon = 4/255$) for visibility. (d) The adversarial example, which the model now incorrectly classifies as "Benign".

TABLE V. COMPREHENSIVE PERFORMANCE SUMMARY OF SOTA ARCHITECTURES

Architecture	Training Method	Clean Acc (%)	Clean F1	Clean AUC	FGSM Acc (%)	PGD Acc (%)	Auto-CE Acc (%)
resnet50	Standard	88.94	0.8805	0.9668	65.00	0.91	0.00
	Adversarial	60.15	0.3601	0.4520	82.73	66.21	27.88
densenet121	Standard	89.55	0.8829	0.9579	47.88	0.45	0.30
	Adversarial	70.15	0.5321	0.6730	85.61	64.70	46.97
mobilenetv2	Standard	85.15	0.8333	0.9384	55.91	0.30	0.00
	Adversarial	70.15	0.5253	0.8890	66.36	19.85	0.15
efficientnet_b2	Standard	88.03	0.8703	0.9536	56.36	0.00	0.00
	Adversarial	46.52	0.5862	0.3931	80.76	46.06	7.42
convnext	Standard	87.73	0.8732	0.9642	61.67	15.15	12.73
	Adversarial	82.27	0.8175	0.9203	81.21	78.64	73.79

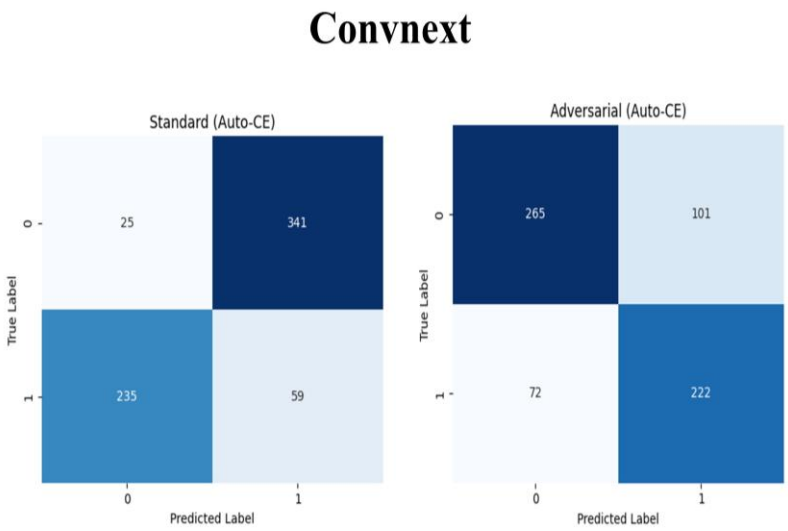


Fig. 4. Confusion matrices illustrating the impact of auto-CE attacks on standard-trained models. The labels are encoded as 0 for 'Benign' and 1 for 'Malignant'. The color intensity represents the normalized percentage of the true class.

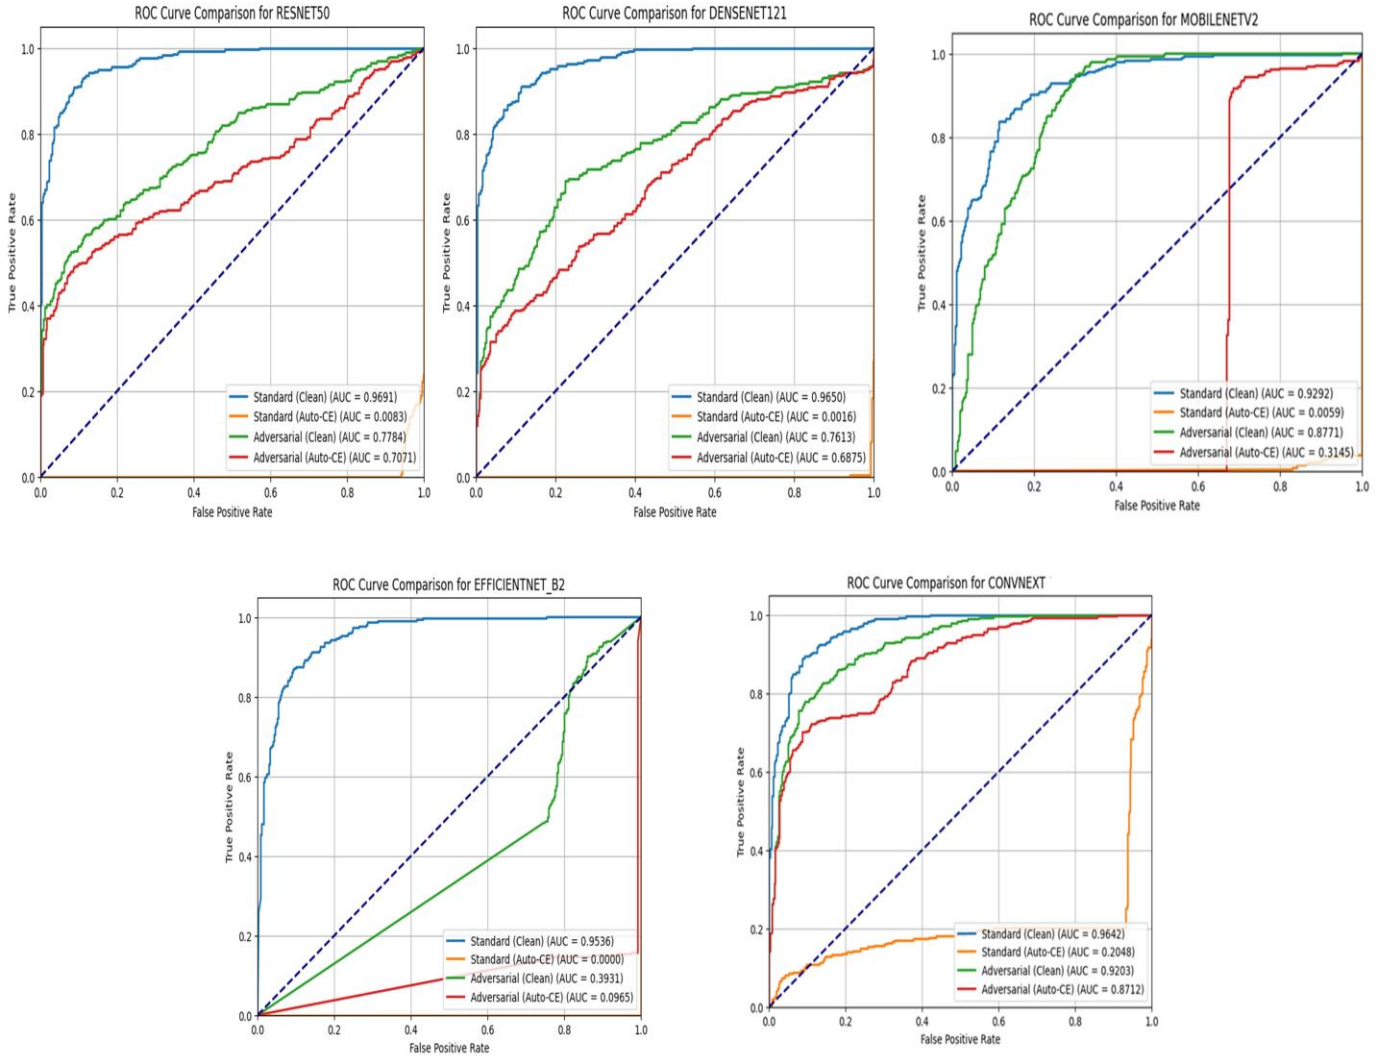

Fig. 5. ROC Curves showing performance collapse of standard models under auto-CE attack.

Second, adversarial training has proven to be an effective, albeit highly variable, defence mechanism. Although not depicted in the figures for clarity, Table V clearly demonstrates that adversarial training substantially improves the robustness of all tested architectures against PGD and auto-CE attacks. A comparison of the "Standard" and "Adversarial" training rows reveals, however, that the degree of this improvement is not uniform. This indicates that the effectiveness of this defence is fundamentally linked to the underlying architectural design, with some models being inherently more amenable to robustness than others.

The most significant finding of this benchmark was the exceptional robustness of the ConvNeXt architecture. As shown in Table V, after adversarial training, it achieved a robust accuracy of 73.79% against the gold-standard auto-CE attack. This result was more than 25 percentage points higher than that of the next-best performing model, DenseNet121 (46.97%). Furthermore, ConvNeXt achieves state-of-the-art robustness while experiencing only a minor drop in the clean data performance. This strongly suggests that modern convolutional designs that incorporate principles from Vision Transformers possess an architectural advantage in terms of learning generalizable and defensible features.

Finally, in stark contrast to ConvNeXt, architectures designed specifically for computational efficiency, MobileNetV2 and EfficientNet-B2, prove exceptionally difficult to defend. Table V reveals that even after intensive adversarial training, the robust accuracy against auto-CE remains critically low at 0.15% and 7.42%, respectively. This finding serves as a crucial cautionary note: optimizing the speed and model size in medical AI may result in a severe and unacceptable cost to model security. The design principles that enable their efficiency, such as depth-wise separable convolutions, may inadvertently create fragile feature dependencies that can be easily exploited by adversarial perturbations.

C. Discussion

Our findings have significant implications for the development and clinical deployment of medical AI systems, primarily highlighting that a model's architecture is a critical determinant of its security and accuracy. The benchmark results move beyond simply confirming the known vulnerability of standard models and reveal a distinct hierarchy of robustness among different architectural paradigms. This suggests that the pursuit of high performance on clean data without considering architectural resilience can lead to the development of systems that are dangerous in practice.

The exceptional performance of ConvNeXt after adversarial training was the most salient outcome of this study. Its ability to achieve high robust accuracy while minimizing the trade-off with clean accuracy suggests that its architectural principles, such as the use of larger convolutional kernels and transformer-style block designs, confer a strong inductive bias for learning more generalizable and defensible features. In contrast, the profound failure of MobileNetV2 and EfficientNet-B2 to gain meaningful robustness even after intensive adversarial training points to an inherent fragility. We hypothesize that the design choices that enable computational efficiency, particularly the heavy reliance on depth-wise separable convolutions, may create sparse and fragile feature dependencies that are easily disrupted by adversarial perturbations.

These results lead to a clear recommendation for the field: for high-stakes applications, such as medical diagnosis, a "robust-by-design" approach should be prioritized. Simply selecting a model based on its top-line accuracy on a benchmark leader board is insufficient. Instead, architectural properties that promote robustness, such as those found in modern hybrid designs, such as ConvNeXt, should be favored. This study underscores the urgent need for standardized adversarial stress testing to become an integral part of the validation and regulatory approval process for any AI system intended for clinical use.

Although this study provides a rigorous benchmark, it has several limitations. Our analysis was conducted on a single dermatoscopic dataset and focused exclusively on the L-infinity threat model. Additionally, owing to the high computational cost of performing PGD-Adversarial training on five distinct architectures, this study relied on single-run evaluations. Future work should prioritize multi-seed validation to establish statistical confidence intervals. Furthermore, we evaluated only the PGD-based adversarial training as a defence mechanism. Therefore, future work should extend this benchmark across diverse medical modalities, such as radiology and histopathology, and investigate a wider range of threat models and advanced defence mechanisms. Nonetheless, this study serves as a critical resource, providing a clear architectural roadmap for building a safer and more reliable medical AI.

V. Challenges in Defending Medical Imaging Against Adversarial Attacks

Our benchmark highlights the promising architectural directions for AI-driven medical diagnostics. However, securing such systems against adversarial manipulation remains a multifaceted problem. Challenges span the technological, data-related, and socio-ethical domains. These barriers must be addressed to ensure the safe and equitable deployment of AI tools in clinical practice. This high-level overview of challenges and mitigation strategies is summarized in Table VI.

TABLE VI. Challenges and Mitigation Strategies for Adversarial Defences in Medical Imaging

Challenges	Description	Potential Mitigation Strategies
Technological Arms Race	Generative models (GANs, Diffusion Models) continually evolve, producing more subtle perturbations that mimic natural variability, making static defences obsolete.	Develop adaptive defences with continuous retraining and use ensemble and meta-learning approaches to detect novel attacks.
The Data Bottleneck	Lack of large standardized datasets containing authentic and adversarially manipulated images across modalities (MRI, CT, and X-ray) hinders reproducibility and comparability of robustness research.	Foster collaborative data sharing with privacy safeguards (e.g., federated learning) and create high-fidelity synthetic benchmarks.

Ethical and Bias Concerns	Training defences on non-representative patient data risk algorithmic bias and may reduce robustness for under-served demographic groups, exacerbating health disparities; patient privacy must be protected.	Establish ethical guidelines and auditing frameworks; enforce demographic balancing and differential privacy techniques.
Legal Responsibility	Unclear liability in AI-induced misdiagnosis, whether it lies with hospitals, developers, or clinicians, impedes trust and adoption. transparency in AI decision processes is limited.	Define legal standards for AI use in healthcare, mandate explainability requirements, and develop clear liability models.

VI. Conclusion

The integration of advanced AI into medical diagnostics offers tremendous benefits, but also exposes a critical vulnerability to adversarial manipulation. This study contributes to the literature by providing a structured survey of adversarial threats and the first rigorous empirical benchmark of ConvNeXt against mobile-optimized CNNs for the skin cancer classification task. Our results establish a clear hierarchy of robustness, driven by the architecture. While all standard trained models proved fragile under attack, hybrid convolutional designs, such as ConvNeXt, substantially outperformed mobile-optimized networks, achieving high robust accuracy with minimal loss of clean data. In contrast, efficiency-focused models, such as MobileNetV2 and EfficientNet B2, remain exceptionally vulnerable even after adversarial training. These findings underscore the importance of architectural choice as important as accuracy in clinical AI. High performance on clean benchmarks alone is insufficient for deployment in high-stakes settings. Instead, "robust by design" architectures validated through standardized adversarial stress tests must become a mandatory step in development and regulatory approval. This benchmark was limited to a dermatoscopic dataset and an L∞ threat model with PGD-based defences. Future studies should extend to multiple modalities, diverse threat norms, and advanced defence techniques to build on the architectural insights presented here. By prioritizing rigorous robustness evaluation and defensive design principles, the medical AI community can move toward systems that are not only accurate but also fundamentally safe and trustworthy.

Enhanced Detection of Acute Lymphocytic Leukemia Using Deep Learning and Hybrid Classifiers on Microscopic Blood Images

H. A. El Shenbary*, Amr T. A. Elsayed, Khaled A. A. Khalaf Allah, Belal Z. Hassan
Department of Mathematics-Faculty of Science, Al-Azhar University Cairo, Egypt

***Abstract*—There is no doubt that a significant number of individuals worldwide suffer from blood cancer. A lot of people are unaware of the dangers associated with this disease, which can be fatal. When diagnosed, patients may feel intense fear and a sense of powerlessness. In addition, due to the rarity of these diseases, patients often struggle to find the necessary help and information. A specific type of blood cancer called acute lymphocytic leukemia (ALL) mainly affects white blood cells and is particularly prevalent in children. Early detection of this disease will improve the chances of recovery. Therefore, it is crucial to have an accurate and dependable method for identifying blood cancers. Deep learning (DL) architectures have garnered significant interest within the computer vision realm. Recently, there has been a strong focus on the accomplishments of pretrained architectures in accurately describing or classifying data from various real-world image datasets. Classification performances of the proposed models are investigated by using Softmax, Support Vector Machine (SVM), and K-Nearest Neighbors algorithm (K-NN) separately on a deep learning neural network (Alexnet and VGG19) to differentiate between the three types of ALL using microscopic images dataset. The experimental results demonstrate that the combination of Alexnet with SVM achieves outstanding classification performance on the leukemia dataset, particularly on the original(unsegmented) data, achieved 97.03% on bengin class, 96.14% on early class, 99.49% on pre class and 99.9% on pro class. This approach achieves higher accuracy levels than practicing physicians.**

***Keywords*—Deep learning; transfer learning; leukemia; Alexnet; VGG19; SVM; K-NN; classification**

I. Introduction

In the last decades, uncontrolled growth of abnormal cells in the leukemia patients and the bone marrow rapidly expanded [1]. A condition distinct from other illnesses because it typically does not create detectable masses through imaging tests like X-Rays [2]. Hematopoietic stem cells, which give rise to all blood cells, go through multiple stages of development before reaching maturity [3].

In leukemia, a specific type of blood cell undergoes rapid and uncontrolled development, leading to the proliferation of these uncontrollable cells known as leukemia cells [4]. These abnormal cells take over the space within the bone marrow which is known as acute lymphoblastic leukemia (ALL) [5]. It is noted that the early detection of ALL can improve the chance of patient survival. Automatic specialized testing, like cytogenetics, immunophenotyping, and morphological cell categorization, can now detect leukemia. Now, due to its great accuracy, the method of observing blood cells using the mentioned processes is advised. The operator's abilities and level of enervation will determine how tough these procedures are [6]. Various deep learning (DL) techniques have demonstrated significant efficacy across diverse domains including automatic recognition, detection, and segmentation. Examples encompass breast cancer [7], skin lesions [8], [9], [10], brain tumor [11], [12], the COVID-19 pandemic [13], [14], [15], and among other areas [16].

Leukemia detection in human blood samples using microscopic images is only appropriate for low-cost and remote diagnosis systems. New-age approaches can help in this situation [17]. Numerous researchers have created algorithms that offer a simple and incredibly accurate technique to detect and classify various types of blood cancer using deep learning, machine learning, and convolution neural networks (CNN) [18]. Authors in [19], [20] used DL for COVID-19 image recognition and classification, also for object detection and recognition. Early detection is the paramount for successful treatment outcomes. Medical advancements have facilitated various screening methods to identify the disease in its nascent stages. These techniques often involve blood tests to analyze abnormalities in white blood cell counts, red blood cell counts, and platelets. Additionally, bone marrow biopsies may be performed to examine the composition of blood cells directly from the source. Advanced imaging technologies such as Magnetic Resonance Imaging (MRI) and Computed Tomography (CT) scans can also aid in detecting leukemia-related abnormalities within the body. Early detection enables prompt intervention, increasing the likelihood of successful treatment and improved patient prognosis. In this type of cancer, the primary impact is on white blood cells. Particularly in children, this illness is frequently identified, making them more susceptible. Therefore, there is a pressing need for a precise and dependable mechanism for identifying such blood cancers in patients. Authors in [21] introduces a system designed to differentiate between the three distinct types of ALL through the implementation of a CNN. The system offers thorough disease diagnosis along with comprehensive information on symptoms and different treatment stages. Through the utilization of a CNN, the system has demonstrated an accuracy rate exceeding 85% in detecting ALL.

The structure of this paper is organized as follows: Section II presents the key standard techniques used for feature extraction, classification, and the Alexnet deep learning approach. Section III describes the datasets employed for training, validation, and evaluation of the proposed method. Section IV

*Corresponding author.

outlines the proposed method along with its results. Lastly, Section V provides the conclusion and discusses future work.

II. Methods and Materials

A. Deep Learning

A novel area within artificial intelligence is known as Deep learning (DL), which focuses on developing techniques enabling computers to learn complex tasks such as perception with high accuracy. It excels in tasks like image classification, object detection, speech recognition, language processing, and vehicle detection. Unlike traditional classification algorithms that rely on ad-hoc methods for feature extraction from images, DL employs a different approach. Instead of manually defining features, DL methods learn to extract relevant features directly from data, leading to improved performance and reduced false alarms.

Several challenges arise in traditional methods:

1) Difficulty in defining general, reliable characteristics corresponding to specific object types.
2) Complex task of determining the optimal combination of attributes to identify each object type.
3) Challenges in developing efficient techniques for translating, rotating, and scaling objects.

These challenges impact segmentation, classification, and detection processes. DL methods address these challenges by leveraging large labeled datasets to identify relevant features and combinations of characteristics for accurate object categorization. They employ a hybrid feature extraction and classification model, enabling classification of a wide range of unseen objects beyond those included in the training set [22].

Convolutional Neural Networks (CNNs) are a prominent DL architecture that utilizes multiple hidden layers to perform extensive computations on input data. Each layer's output serves as input to the subsequent layer as shown in Fig. 1, facilitating hierarchical feature extraction. The final layer outputs class labels based on the training data. During the training stage, the network learns to predict efficiently, and its performance is evaluated during the prediction phase.

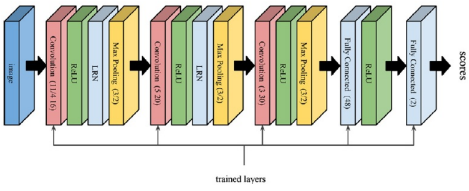

Fig. 1. CNN architecture.

B. Alexnet Deep Learning Neural Network

Alexnet is considered a very important CNN, had a huge performance on the DL Field and it is used in a wide range in computer vision applications [23]. Fig. 2 examines the fundamental structure of Alexnet. It consists of eight layers, with five being convolution layers and the remaining three being fully connected layers. To accelerate the training process, Rectified Linear Unit (ReLU) activation is applied after each convolution and fully connected layer. Dropout is implemented before the first and second fully connected layers. During the training phase, the images are resized to 256 * 256 pixels. A dataset comprising 1.2 million images is utilized for training, while 150,000 images are allocated for testing, and 50,000 images are reserved for network validation.

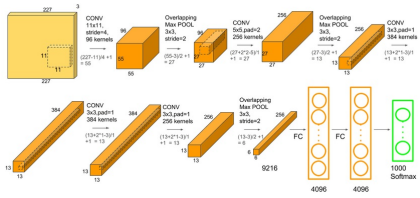

Fig. 2. Alexnet architecture.

C. Visual Geometry Group Deep Learning Neural Network

The Visual Geometry Group (VGG) 19 model, a convolutional neural network (CNN), represents a significant milestone in the field of deep learning and computer vision. Developed by the Visual Geometry Group at the University of Oxford, VGG19 is renowned for its remarkable performance in image classification tasks. With its deep architecture comprising 19 layers, including 16 convolutional layers and 3 fully connected layers, as shown in Fig. 3. VGG19 demonstrates exceptional ability in extracting intricate features from images, enabling accurate categorization across diverse datasets [24].

Fig. 3. VGG19 architecture.

D. Support Vector Machine

Support Vector Machine (SVM) is a powerful supervised machine learning algorithm primarily used for classification tasks, but it can also be employed for regression and outlier detection. SVM aims to find the best possible decision boundary (known as a hyperplane) that separates data points of different classes in such a way that the margin between the two classes is maximized. This is achieved by forming a set of support vectors [25]. SVM works by constructing hyperplanes to separate two classes of raw data for classification [26], [27]. The goal of SVM is to identify the optimal hyperplane, which maximizes the distance between the elements of the training data. For example, if we have two groups of data, finding two hyperplanes, as shown in Fig. 4. It is evident that Fig. 4(b), which has a larger margin, provides better accuracy compared to Fig. 4(a).

E. K-Nearest Neighbors

K-Nearest Neighbors (KNN) is a straightforward, yet effective algorithm for image classification. It classifies an image by considering the majority label of its *k* nearest neighbors in the dataset. Each image is represented as a feature vector,

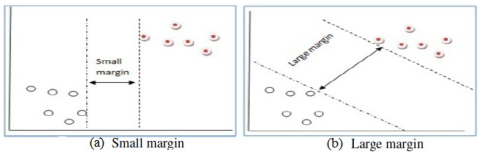

Fig. 4. Support vector machine.

which can be derived from pixel values or higher level features like edges or textures. When a new image is introduced, the algorithm calculates the distance, often using Euclidean distance, between the new image and all images in the training set, determining the *k* closest neighbors. The image is then assigned to the category that appears most frequently among those neighbors. KNN is easy to implement and understand, though its accuracy relies on selecting the right *k* value and distance measure [28], [29].

KNN is particularly well suited for smaller datasets in image classification, since it does not require a training phase, making it a type of lazy learning algorithm. However, its performance declines with larger datasets because of the computational expense of calculating distances for each image in the dataset. Additionally, KNN is sensitive to irrelevant or redundant features, which can reduce its accuracy. Despite these drawbacks, KNN serves as a strong baseline for image classification before turning to more advanced methods like deep learning.

III. Proposed Method and Performance Metrics

A. Proposed Method

Leukemia presents a significant challenge in healthcare due to its complexity and varied subtypes. Traditional diagnostic methods have limitations in accuracy and speed, necessitating the exploration of advanced technologies like deep learning and transfer learning. The proposed method explores the development of a hybrid method incorporating the deep learning architectures Alexnet and VGG19, coupled with transfer learning, and employing classifiers such as SVM and kNN for leukemia prediction. Deep Learning and Transfer Learning: Deep learning models, particularly CNNs, have demonstrated remarkable performance in image classification tasks. Alexnet and VGG19 are popular CNN architectures known for their effectiveness in feature extraction and classification. By leveraging these architectures, we aim to extract meaningful features from leukemia images, facilitating accurate prediction. Transfer learning enhances model performance by transferring knowledge gained from pretrained models to new tasks. In the context of leukemia prediction, transfer learning allows us to leverage the learned features from large datasets like ImageNet and adapt them to the specific characteristics of leukemia images, thereby improving prediction accuracy. The hybrid method begins with pre-processing leukemia images to enhance quality and remove noise. Subsequently, the pre-processed images are fed into the Alexnet and VGG19 architectures for feature extraction. Transfer learning is applied by fine-tuning the pre-trained models on the leukemia dataset, allowing them to adapt to the task at hand while retaining valuable learned features.

Feature vectors extracted from the deep learning models are then inputted into SVM and kNN classifiers for prediction. SVM is chosen for its ability to handle high dimensional data and delineate complex decision boundaries, while kNN is selected for its simplicity and effectiveness in classification tasks. Fig. 5 shows a flow chart of the proposed method. Furthermore, the flexibility of the hybrid method allows for customization and adaptation to different leukemia subtypes, thereby enhancing its applicability in clinical settings.

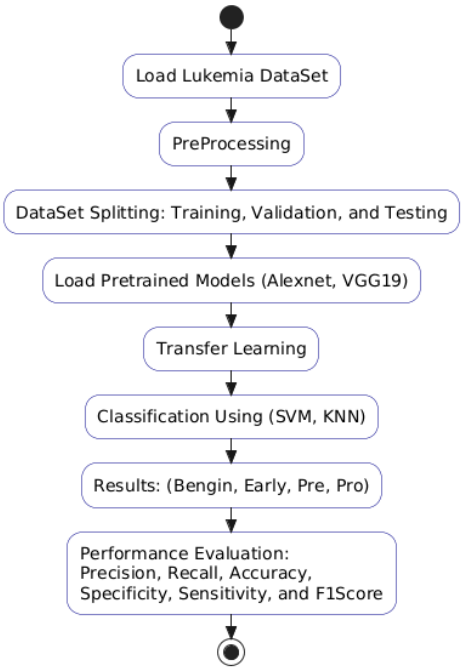

Fig. 5. Flowchart of the proposed method.

B. Performance Metrics

To evaluate the proposed method, a lot of performance parameters were used.

True_positive (T_P), False_positive (F_P), True_negative (T_N) and False_negative (F_N) are the main components used for evaluating the performance metrics. T_P is described as the total number of images predicted as class1 and they are already found in class1. T_N is described as the total number of images predicted as class1 and they are not already found in class1. F_P is described as the total number of images not predicted as class1 and they are already belong to class1. F_N is described as the total number of images incorrectly predicted as class1. The following equations define Recall, Precision, Specificity, Sensitivity, Accuracy, and FScore [see Eq. (1), Eq. (2), Eq. (3), Eq. (4), Eq. (5), and Eq. (6)], respectively.

$$Recall = \frac{T_P}{T_P + F_N}. \tag{1}$$

$$Precision = \frac{T_P}{T_P + F_P}. \tag{2}$$

$$Specificity = \frac{T_N}{T_N + F_P}. \tag{3}$$

$$Sensitivity = \frac{T_P}{T_P + F_N}. \quad (4)$$

$$Accuracy = \frac{T_P + T_N}{T_P + T_N + F_P + F_N}. \quad (5)$$

$$FScore = \frac{2 * T_P}{(2 * T_P) + (F_P + F_N)}. \quad (6)$$

C. Dataset

A precise diagnosis of acute lymphoblastic leukemia (ALL), a malignancy with a high prevalence, necessitates invasive, costly, and time consuming diagnostic procedures. Peripheral blood smear (PBS) pictures used for ALL diagnosis are crucial in the first cancer screening process to distinguish cancer cases from non-cancer cases. Due to the non-specific character of ALL indications and symptoms, misinterpretation is a common concern when these PBS images are analyzed by laboratory users. The bone marrow laboratory at Taleqani Hospital in Tehran, Iran, is where the photographs for this collection were created. This dataset included 3256 PBS pictures from 89 individuals who were thought to be ALL and whose blood samples were properly processed and stained by knowledgeable laboratory personnel. This dataset is separated into the benign and malignant classes. Hematogones are included in the former. The Early Pre-B, Pre-B, and Pro-B ALL subtypes of malignant lymphoblasts, which make up the latter ALL group. All of the photos were taken with a Zeiss camera at a 100x magnification in a microscope, and they were all saved as JPG files. The specific types and subtypes of these cells were identified by a professional using the flow cytometry instrument. We also offer segmented photos after color thresholding-based segmentation in the HSV color space [30].

Fig. 6 shows a sample of the original dataset images from all of the mentioned classes types. Fig. 7 view a sample of

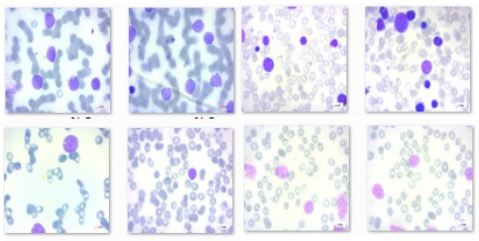

Fig. 6. Sample of the original dataset.

the segmented dataset images from all of the mentioned class types.

IV. Results and Discussion

A. Alexnet and SVM

The results presented in the Table I reflect the performance of the Alexnet combined with SVM on the original leukemia dataset, evaluated across four different classes: Benign, Early, Pre, and Pro. Overall, the model demonstrates outstanding classification performance, with all classes achieving 99% or

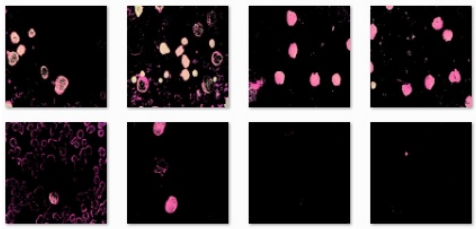

Fig. 7. Sample of the segmented dataset.

100% accuracy. The Pro class exhibits perfect classification with 100% across all metrics, indicating the model's high confidence and consistency in identifying this class. The Pre and Early stages also show near-perfect performance, with only a 1% deviation in precision or Fscore, suggesting that the model effectively captures relevant patterns even in intermediate stages of leukemia progression.

The Benign class, while still performing excellently, shows slightly lower recall and sensitivity values at 97%, which might indicate a small number of false negatives — cases where benign samples were misclassified. However, its 100% specificity suggests no benign cases were incorrectly identified as other leukemia stages, a critical factor in clinical decision making. These results suggest that the model is particularly reliable for detecting advanced leukemia stages, while still performing robustly on earlier and non-cancerous samples. Fig. 8 shows the confusion matrix results for the desired method. The high performance across all metrics and classes highlights the suitability of Alexnet with SVM as a strong classification pipeline for medical image analysis in leukemia detection.

TABLE I. Performance Metrics of Alexnet and SVM on Original Data

Class	Recall	Precision	Accuracy	Specificity	Sensitivity	Fscore
Benign	97%	98%	99%	100%	97%	98%
Early	99%	99%	99%	100%	99%	99%
Pre	100%	99%	100%	100%	100%	99%
Pro	100%	100%	100%	100%	100%	100%

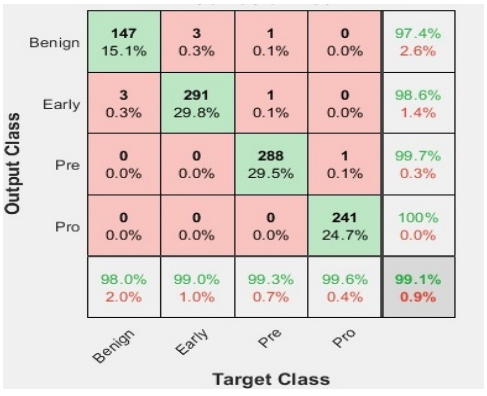

Fig. 8. Confusion matrix of Alexnet and SVM on original data.

When applied to the segmented leukemia dataset, the Alexnet with SVM model continues to deliver strong classification performance, though with slightly lower metrics compared to the original unsegmented data, as shown in Table II. The

Pro class still achieves excellent results, with perfect precision and specificity, and a high Fscore of 98.1%, indicating that segmentation did not significantly impact the model's ability to detect advanced leukemia. Fig. 9 shows the confusion matrix on the segmented data for the same method. The Pre and Early classes also maintain high accuracy and balanced sensitivity and precision, suggesting reliable detection of intermediate disease stages. However, the Benign class shows a noticeable drop in both precision (89.0%) and Fscore (90.2%), possibly due to segmentation affecting the distinctiveness of benign features. Overall, while segmentation may introduce some variability in early and benign classifications, the model remains highly effective, particularly in identifying more advanced leukemia stages.

TABLE II. PERFORMANCE METRICS OF ALEXNET AND SVM ON SEGMENTED DATA

Class	Recall	Precision	Accuracy	Specificity	Sensitivity	Fscore
Benign	91.4%	89.0%	96.9%	97.9%	91.4%	90.2%
Early	94.9%	96.2%	97.3%	98.4%	94.9%	95.6%
Pre	98.3%	95.3%	98.1%	98.0%	98.3%	96.8%
Pro	96.3%	100.0%	99.1%	100.0%	96.3%	98.1%

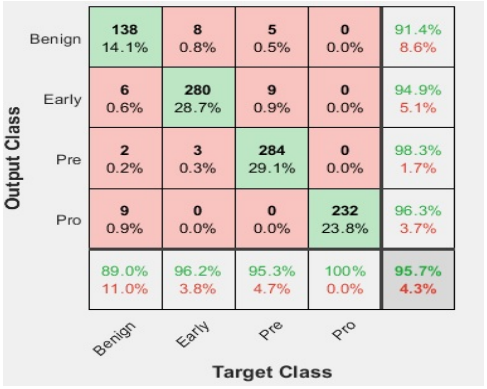

Fig. 9. Confusion matrix of Alexnet and SVM on segmented data.

B. Transfer Learning of Alexnet

Table III shows results from applying transfer learning using Alexnet on the leukemia dataset demonstrate highly effective classification across all four classes. The model achieves consistently high recall, precision, and Fscore values, with accuracy ranging from 98.36% to 99.08%. The Pro class stands out with the highest overall accuracy (99.08%) and excellent precision and Fscore, indicating that the fine-tuned Alexnet is particularly effective in detecting advanced leukemia. The Pre and Early classes also show strong and balanced performance, reflecting the model's ability to generalize across different stages of the disease. Fig. 10 shows the confusion matrix of the transfer learning of Alexnet. Even the Benign class, which is typically more challenging to classify due to subtle features, achieves a solid 94.08% recall and 95.33% precision. These results highlight the strength of transfer learning in leveraging pre-trained features from Alexnet, improving classification accuracy while minimizing training time and data requirements in medical image analysis.

When transfer learning using Alexnet is applied to the segmented leukemia dataset, the model maintains strong overall performance, particularly in detecting the Pro class, which

TABLE III. PERFORMANCE METRICS OF TRANSFER LEARNING OF ALEXNET ON ORIGINAL DATA

Class	Recall	Precision	Accuracy	Specificity	Sensitivity	Fscore
Benign	94.08%	95.33%	98.36%	99.15%	94.08%	94.70%
Early	97.28%	97.28%	98.36%	98.83%	97.28%	97.28%
Pre	98.26%	97.24%	98.67%	98.84%	98.26%	97.75%
Pro	97.94%	98.35%	99.08%	99.45%	97.94%	98.14%

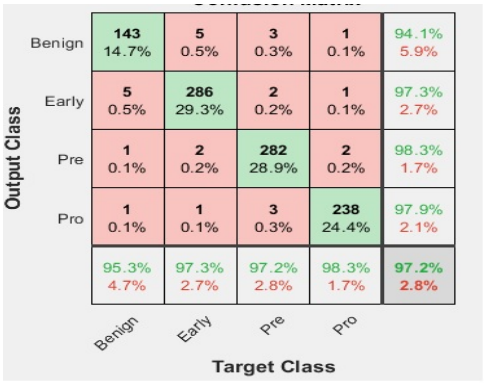

Fig. 10. Confusion matrix of transfer learning using Alexnet on original data.

achieves the highest accuracy (99.28%) and Fscore (98.54%), as shown in Table IV. However, a noticeable performance drop is observed in the Benign class, where recall decreases to 82.78%, indicating that the model struggles more to identify benign samples correctly after segmentation. Despite this, its high precision (90.58%) and specificity (98.42%) suggest that false positives are minimal. The Early and Pre classes show balanced and reliable metrics, with Fscores above 93%, demonstrating that the model remains effective for intermediate disease stages. These results suggest that while segmentation may introduce challenges in distinguishing non-cancerous cases, transfer learning with Alexnet still provides robust classification, especially for more advanced stages of leukemia, as shown in Fig. 11.

TABLE IV. PERFORMANCE METRICS OF TRANSFER LEARNING OF ALEXNET ON SEGMENTED DATA

Class	Recall	Precision	Accuracy	Specificity	Sensitivity	Fscore
Benign	82.78%	90.58%	96.00%	98.42%	82.78%	86.51%
Early	93.22%	92.91%	95.80%	96.92%	93.22%	93.06%
Pre	95.85%	91.12%	96.00%	96.07%	95.85%	93.42%
Pro	97.93%	99.16%	99.28%	99.73%	97.93%	98.54%

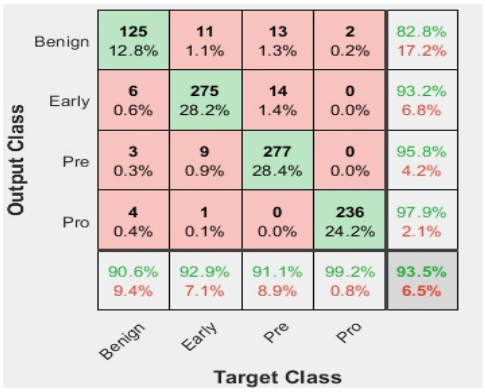

Fig. 11. Confusion Matrix of transfer learning of Alexnet on segmented data.

C. Alexnet

The performance of Alexnet on the original leukemia dataset shows a strong and promising classification ability, particularly for more advanced disease stages. The Pro class achieves perfect recall (100%) and nearly perfect precision (99.59%), with an overall accuracy of 99.90%, demonstrating that the model reliably identifies all Pro samples with minimal error. Similarly, the Pre class also performs exceptionally well, with a near-perfect Fscore of 99.13%, indicating balanced and accurate detection at this stage. The Early class, while slightly lower, still maintains a strong performance with a recall of 95.59% and an Fscore of 94.16%, showing that the model is effective even at earlier stages of leukemia, as shown in Table V and Fig. 12.

However, the Benign class displays comparatively lower performance, with a recall of 87.42%, suggesting a higher rate of false negatives, some benign cases are being misclassified as leukemia. However, the high precision (92.96%) and specificity (98.79%) imply that when the model predicts a case as benign, it is likely correct. This pattern is consistent with the general challenge in distinguishing benign from early pathological features in medical imaging. Overall, Alexnet demonstrates excellent performance on the original data, especially in identifying disease progression stages, making it a reliable model for the classification of leukemia.

TABLE V. PERFORMANCE METRICS OF ALEXNET ON THE ORIGINAL DATA

Class	Recall	Precision	Accuracy	Specificity	Sensitivity	Fscore
Benign	87.42%	92.96%	97.03%	98.79%	87.42%	90.10%
Early	95.59%	92.76%	96.41%	96.77%	95.59%	94.16%
Pre	98.96%	99.31%	99.49%	99.71%	98.96%	99.13%
Pro	100.00%	99.59%	99.90%	99.86%	100.00%	99.79%

Fig. 12. Alexnet confusion matrix results on the original data.

The results of applying Alexnet to the segmented leukemia dataset demonstrate high and consistent classification performance across all classes, with particularly strong results for the Pro class. The Pro class achieves the highest metrics overall, including 98.76% for recall, precision, sensitivity, and Fscore, along with an impressive accuracy of 99.39%, indicating the model's excellent ability to detect advanced-stage leukemia even after segmentation. The Pre and Early classes also show balanced performance, with Fscores of 96.68% and 95.77%, respectively, reflecting the model's robustness in identifying intermediate stages with high reliability as shown in Table VI and Fig. 13.

The Benign class, which is often more challenging to differentiate due to its less distinct features, records a recall of 92.05% and a slightly lower precision of 89.68%. While these values are still strong, the slightly reduced precision suggests occasional misclassification of benign samples as leukemia. However, the specificity remains high at 98.06%, indicating the model rarely mislabels diseased samples as benign. Overall, segmentation does not appear to significantly hinder Alexnet's performance and may even enhance class separation in some cases, allowing the model to maintain high accuracy and generalization across all stages of leukemia.

TABLE VI. PERFORMANCE METRICS OF ALEXNET ON THE SEGMENTED DATA

Class	Recall	Precision	Accuracy	Specificity	Sensitivity	Fscore
Benign	92.05%	89.68%	97.13%	98.06%	92.05%	90.85%
Early	95.93%	95.61%	97.44%	98.09%	95.93%	95.77%
Pre	95.85%	97.54%	98.05%	98.98%	95.85%	96.68%
Pro	98.76%	98.76%	99.39%	99.59%	98.76%	98.76%

Fig. 13. Alexnet confusion matrix results on the segmented data.

D. Alexnet and KNN

When Alexnet is combined with KNN and applied to the original leukemia dataset, the model demonstrates high classification performance, particularly for advanced leukemia stages. The Pro class achieves perfect recall (100%) and a strong precision of 96.02%, resulting in a high Fscore of 97.97% and overall accuracy of 98.98%. Similarly, the Pre class shows excellent results with 97.23% recall, 99.65% precision, and an Fscore of 98.42%, indicating that the model is highly effective at detecting and distinguishing advanced and intermediate disease stages in the unsegmented data, as shown in Table VII and Fig. 14.

In contrast, the Benign class exhibits lower recall (76.82%) despite very high precision (99.15%) and specificity (99.88%), suggesting that many benign cases are misclassified as leukemia. This imbalance lowers the Fscore to 86.57%, pointing to difficulty in recognizing non-cancerous samples accurately. The Early class also shows a gap between recall (97.29%) and precision (88.04%), reflecting a tendency toward false positives. These results suggest that while the Alexnet and KNN combination is highly reliable for detecting later stages of leukemia in the original dataset, its performance for benign and early-stage classification is limited by class similarity and KNN's sensitivity to overlapping feature distributions.

TABLE VII. PERFORMANCE METRIC OF ALEXNET AND KNN ON THE ORIGINAL DATA

Class	Recall	Precision	Accuracy	Specificity	Sensitivity	Fscore
Benign	76.82%	99.15%	96.31%	99.88%	76.82%	86.57%
Early	97.29%	88.04%	95.18%	94.27%	97.29%	92.43%
Pre	97.23%	99.65%	99.08%	99.85%	97.23%	98.42%
Pro	100.00%	96.02%	98.98%	98.64%	100.00%	97.97%

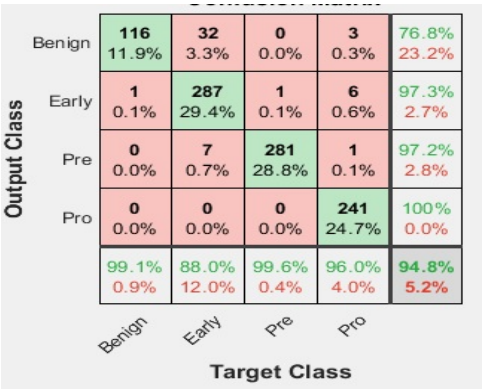

Fig. 14. Confusion matrix results of Alexnet and KNN on the original data.

When applying the combination of Alexnet and KNN to the segmented leukemia dataset, the model continues to perform well overall, particularly in identifying the more advanced disease stages. The Pre and Pro classes show strong and consistent results, with recall values of 97.58% and 97.93%, respectively, and Fscores above 96%. These high metrics demonstrate the model's robustness in capturing critical patterns in segmented images that correspond to later stages of leukemia, even when using a non-parametric classifier like KNN after feature extraction from Alexnet, as shown in Table VIII.

However, the Benign class again poses challenges, as reflected by its low recall of 76.16% and the lowest Fscore (83.33%) among all classes, as shown in Fig. 15. While the precision is relatively high at 92.00%, the model misses a significant portion of benign cases, indicating a tendency to misclassify them as malignant. The Early class shows a more balanced performance, with a recall of 94.92% and an Fscore of 92.26%, suggesting reasonable reliability for early detection. Overall, while segmentation does not drastically improve performance for the benign class, the combination of Alexnet and KNN still yields high classification accuracy and specificity across most classes, particularly for detecting leukemia progression.

TABLE VIII. PERFORMANCE METRIC OF ALEXNET AND KNN ON THE SEGMENTED DATA

Class	Recall	Precision	Accuracy	Specificity	Sensitivity	Fscore
Benign	76.16%	92.00%	95.29%	98.79%	76.16%	83.33%
Early	94.92%	89.74%	95.18%	95.30%	94.92%	92.26%
Pre	97.58%	96.58%	98.26%	98.54%	97.58%	97.07%
Pro	97.93%	95.55%	98.36%	98.50%	97.93%	96.72%

E. VGG19 and SVM

When VGG19 is combined with an SVM classifier and applied to the original leukemia dataset, the results indicate consistently high performance across all classes, with particularly strong outcomes in the more advanced stages of the

Fig. 15. Confusion matrix results of Alexnet and KNN on the segmented data.

disease. The Pro class achieves perfect recall (100%) and a high precision of 98.77%, leading to an excellent Fscore of 99.38% and overall accuracy of 99.69%. Similarly, the Pre class performs exceptionally well with 98.96% recall and an Fscore of 98.79%, showcasing the model's effectiveness in distinguishing leukemia stages with subtle differences, as shown in Table IX.

The model also demonstrates solid performance on the Early and Benign classes. The Early class achieves a recall of 96.95% and a precision of 95.97%, indicating reliable early detection, which is critical for timely treatment. Fig. 16 shows that the Benign class, often harder to distinguish from early malignancies, still achieves a recall of 90.73% and precision of 95.14%, with a strong Fscore of 92.88%. These results reflect the strength of transfer learning with VGG19 in feature extraction and the discriminative power of SVM in handling complex decision boundaries, leading to robust classification performance on unsegmented medical image data.

TABLE IX. PERFORMANCE METRICS OF VGG19 AND SVM ON THE ORIGINAL DATA

Class	Recall	Precision	Accuracy	Specificity	Sensitivity	Fscore
Benign	90.73%	95.14%	97.85%	99.15%	90.73%	92.88%
Early	96.95%	95.97%	97.85%	98.24%	96.95%	96.46%
Pre	98.96%	98.62%	99.28%	99.42%	98.96%	98.79%
Pro	100.00%	98.77%	99.69%	99.59%	100.00%	99.38%

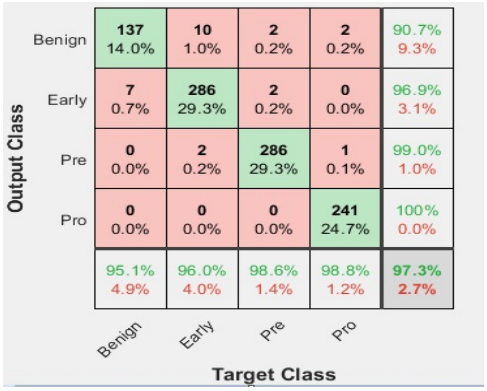

Fig. 16. Confusion matrix of VGG19 and SVM on the original data.

When applying VGG19 with SVM to the segmented leukemia dataset, the model continues to demonstrate strong

classification performance, especially in the advanced classes, as viewed in Fig. 17. The Pro class achieves outstanding metrics with 97.51% recall, 98.74% precision, and a high Fscore of 98.12%, alongside an impressive 99.08% overall accuracy. The Pre class also performs robustly, with 95.50% recall and 97.87% precision, resulting in an Fscore of 96.67%, indicating the model's effectiveness in identifying subtle pathological features within segmented regions, as shown in Table X.

For the Early class, the recall of 95.59% and precision of 91.86% reflect good early-stage detection performance, which is vital for clinical diagnosis and intervention. The Benign class, while showing relatively lower recall (86.09%) compared to other classes, maintains decent precision (87.25%) and a respectable Fscore of 86.67%. Overall, the results indicate that VGG19's deep features, combined with the SVM classifier, are highly capable even on segmented images, although segmentation may slightly affect the model's ability to capture benign patterns as clearly as it does with original images.

TABLE X. PERFORMANCE METRICS OF VGG19 AND SVM ON THE SEGMENTED DATA

Class	Recall	Precision	Accuracy	Specificity	Sensitivity	Fscore
Benign	86.09%	87.25%	95.90%	97.70%	86.09%	86.67%
Early	95.59%	91.86%	96.11%	96.33%	95.59%	93.69%
Pre	95.50%	97.87%	98.05%	99.13%	95.50%	96.67%
Pro	97.51%	98.74%	99.08%	99.59%	97.51%	98.12%

Fig. 17. Confusion matrix results of VGG19 and SVM on the segmented data.

F. VGG19 and KNN

Using VGG19 with KNN on the original leukemia dataset yields high classification performance for the disease-related classes, though with slightly reduced performance for benign cases. The Pro class shows excellent recall (99.59%) and a strong Fscore (96.97%), indicating high sensitivity to advanced stage leukemia detection. Similarly, the Pre class achieves robust results with 97.92% recall and 97.25% precision, leading to a high Fscore of 97.59% and an overall accuracy of 98.57%, as shown in Table XI.

The Early class also performs well, with 96.27% recall and 91.91% precision, producing a solid Fscore of 94.04%. However, the Benign class lags behind with a recall of only 78.15%, despite an excellent precision of 96.72%. This discrepancy suggests that while the model is very confident when it predicts a sample as benign, it may miss a significant number of actual benign cases, potentially due to overlapping visual features with early leukemia stages. Overall, as shown in Fig. 18, the VGG19-KNN combination performs reliably on original data, particularly for detecting leukemia progression stages, but shows some limitations in distinguishing benign samples.

TABLE XI. PERFORMANCE METRICS OF VGG19 AND KNN ON THE ORIGINAL DATA

Class	Recall	Precision	Accuracy	Specificity	Sensitivity	Fscore
Benign	78.15%	96.72%	96.21%	99.52%	78.15%	86.45%
Early	96.27%	91.91%	96.31%	96.33%	96.27%	94.04%
Pre	97.92%	97.25%	98.57%	98.84%	97.92%	97.59%
Pro	99.59%	94.49%	98.46%	98.10%	99.59%	96.97%

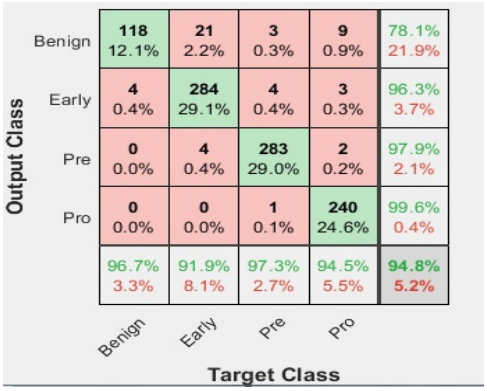

Fig. 18. Confusion matrix results of VGG19 and KNN on original data.

As shown in Table XII, the combination of VGG19 and KNN on the segmented data produces good overall classification results for leukemia detection, particularly for advanced stages, though performance for the Benign class remains relatively low.

The Pro and Pre classes achieve high performance across all metrics. The Pro class attains 96.68% recall and 95.88% precision, resulting in a strong Fscore of 96.28% and an impressive overall accuracy of 98.16%. Similarly, the **Pre** class shows a recall of 95.85% and precision of 96.52%, with an Fscore of 96.18% and overall accuracy of 97.75%, confirming the model's reliability in identifying more developed leukemia stages.

The Early class also performs reasonably well, with 91.86% recall and 88.85% precision, yielding a solid Fscore of 90.33%. However, the Benign class demonstrates noticeably weaker performance, with a recall of just 75.50% and an Fscore of 78.08%. This indicates that while benign samples are occasionally classified correctly, the model tends to confuse them with leukemia stages—likely due to subtle differences in segmented cellular structures.

In summary, as viewed in Fig. 19, VGG19 with KNN on segmented data excels at detecting leukemia stages but continues to struggle with benign classification, reflecting a need for enhanced feature differentiation in non-malignant samples.

G. Transfer Learning of VGG19

The results of applying transfer learning using VGG19 on the original data demonstrate strong performance in classifying

TABLE XII. PERFORMANCE METRICS OF VGG19 AND KNN ON THE SEGMENTED DATA

Class	Recall	Precision	Accuracy	Specificity	Sensitivity	Fscore
Benign	75.50%	80.85%	93.44%	96.73%	75.50%	78.08%
Early	91.86%	88.85%	94.06%	95.01%	91.86%	90.33%
Pre	95.85%	96.52%	97.75%	98.54%	95.85%	96.18%
Pro	96.68%	95.88%	98.16%	98.64%	96.68%	96.28%

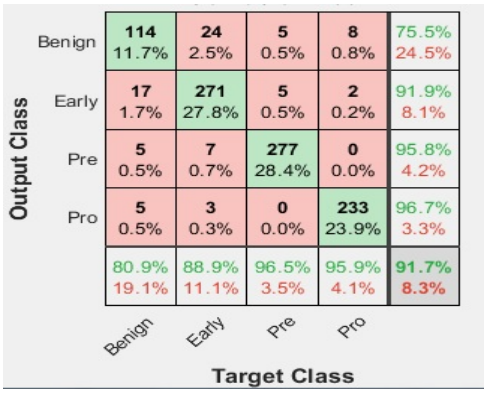

Fig. 19. Confusion matrix results of VGG19 and KNN on the segmented data.

leukemia stages, particularly in advanced cases. The model shows excellent recall and precision for Pre-leukemia and Pro-leukemia classes, with Fscores of 98.25% and 96.59%, respectively, indicating highly reliable detection. The Early stage class also performs very well, achieving a recall of 97.97% and an Fscore of 93.68%. This reflects the model's strong ability to detect various leukemia stages, making it potentially effective for clinical diagnostic support, as shown in Table XIII and Fig. 20.

However, the performance on the Benign class is notably weaker. With a recall of only 73.51%, the model fails to identify a significant portion of benign cases, even though the precision is very high at 98.23%. This indicates that while the model is highly accurate when it predicts a case as benign, it tends to under-predict this class, likely misclassifying benign samples as early-stage leukemia. This imbalance is a concern in clinical settings where distinguishing healthy cases is critical. Overall, the model favors leukemia detection—desirable in screening—but would benefit from further tuning to improve benign classification and reduce unnecessary alarms.

TABLE XIII. PERFORMANCE METRICS OF TRANSFER LEARNING OF VGG19 ON ORIGINAL DATA

Class	Recall	Precision	Accuracy	Specificity	Sensitivity	Fscore
Benign	73.51%	98.23%	95.70%	99.76%	73.51%	84.09%
Early	97.97%	89.75%	96.00%	95.15%	97.97%	93.68%
Pre	97.23%	99.29%	98.98%	99.71%	97.23%	98.25%
Pro	100.00%	93.41%	98.26%	97.69%	100.00%	96.59%

The results in Table XIV, Fig. 21 of applying transfer learning using VGG19 on the segmented data demonstrate consistently high performance in detecting leukemia classes, especially Pre and Pro-leukemia . Both classes exhibit high recall and precision values, with Fscores of 96.90% and 97.10%, respectively. The Early-stage leukemia class also performs well, achieving a recall of 96.61% and an Fscore of 92.83%. These results suggest that VGG19, when fine-tuned on

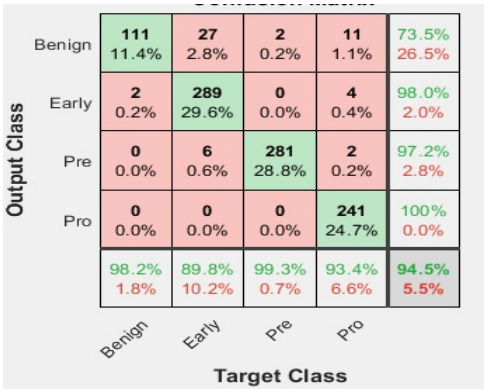

Fig. 20. Confusion matrix results of transfer learning of VGG19 on original data.

segmented data, is particularly effective at identifying various stages of leukemia with minimal misclassification.

However, the Benign class remains a challenge. Although the precision is relatively high at 88.80%, the recall is considerably lower at 73.51%, leading to a modest Fscore of 80.43%. This pattern indicates the model often misclassifies benign samples as leukemia, which could lead to false positives in a clinical setting. Despite this, the overall accuracy remains strong at 94.47%, showing that segmentation helps maintain good classification performance, particularly for critical disease classes, while further optimization is needed to enhance benign detection.

TABLE XIV. PERFORMANCE METRICS OF TRANSFER LEARNING OF VGG19 ON THE SEGMENTED DATA

Class	Recall	Precision	Accuracy	Specificity	Sensitivity	Fscore
Benign	73.51%	88.80%	94.47%	98.30%	73.51%	80.43%
Early	96.61%	89.34%	95.49%	95.01%	96.61%	92.83%
Pre	97.23%	96.56%	98.16%	98.54%	97.23%	96.90%
Pro	97.10%	97.10%	98.57%	99.05%	97.10%	97.10%

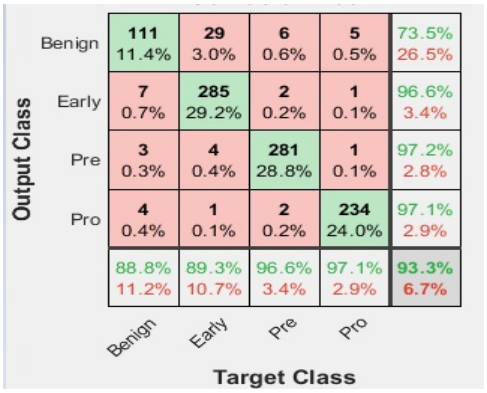

Fig. 21. Confusion matrix results of transfer Learning of VGG19 on the segmented data.

V. CONCLUSION AND FUTURE WORK

The experimental results demonstrate that the combination of Alexnet with SVM achieves outstanding classification performance on the leukemia dataset, particularly on the original (unsegmented) data. This method consistently yields high

accuracy, precision, recall, and Fscores across all leukemia stages, with the Pro and Pre classes often reaching near-perfect metrics. The model's ability to maintain robust performance—even for the challenging Benign class—highlights its effectiveness in distinguishing subtle pathological features. The success of this approach can be attributed to Alexnet's powerful feature extraction capabilities combined with SVM's strong discriminative classification, making it a highly reliable pipeline for leukemia detection in medical imaging.

While other methods, such as transfer learning with VGG19 or hybrid models with KNN, also perform well, they exhibit more variability, particularly in classifying Benign and Early-stage cases. Segmentation introduces additional complexity, sometimes reducing performance, but Alexnet with SVM remains resilient, maintaining high accuracy even on segmented data. These findings suggest that deep feature extraction with a discriminative classifier such as SVM is a superior strategy for leukemia classification, offering a robust and generalizable solution for clinical applications. Future work could explore ensemble techniques or further fine-tuning to enhance benign detection while preserving the model's exceptional performance in identifying advanced leukemia stages.

An AI-Driven Framework for Network Intrusion Detection Using ANOVA-Based Feature Selection

Salam Allawi Hussein, Sándor Répás
Faculty of Informatics and Electrical Engineering-Department of Electrical Engineering and Infocommunications,
Széchenyi István University of Győr, 9026 Győr, Egyetem tér 1, Hungary

***Abstract*—In the last few years, cyberattacks have become more complex, and it is becoming increasingly necessary to establish secure networks. This study examines enhancements to intrusion detection systems (IDSs) with the implementation of machine learning for the categorization of network traffic attacks. For the current study, we utilize four publicly available datasets: CIC-IDS2017, CIC-DoS2017, CSE-CIC-IDS2018, and CIC-DDoS2019. We examined three machine learning techniques: LightGBM, Random Forest, and XGBoost. Experimental results showed that RandomForest and XGBoost achieved the highest accuracy of 0.99 in both binary and multi-class intrusion detection tasks, maintaining balanced performance with macro F1-scores around 0.86. LightGBM exhibited slightly lower overall performance, but benefited from ANOVA-based feature selection, which improved its recall and model stability. Feature selection also enhanced computational efficiency by reducing feature redundancy while preserving accuracy across models. These results highlight how AI tools could help network security deal with emerging threats and improve the performance of IDS. The study underscores the critical role of feature selection in enhancing model efficiency, hence promoting advancements in automated network security systems that can adapt to evolving cyber threats.**

***Keywords*—Network security; intrusion detection; machine learning; feature selection**

I. Introduction

The rapid growth of networked systems has led to increased vulnerability to cyberattacks, making intrusion detection systems (IDS) a critical component of modern cybersecurity. Traditional IDS often relies on static rule-based approaches that fail to adapt to evolving attack patterns [1]. As public, private, and critical sectors rely more heavily on digital infrastructure, it has become essential to safeguard these systems against unauthorized access, data breaches, and service disruptions. Intrusion detection systems (IDS) remain a key component of network security; however, many still rely on static rules and signature-based detection, which are inadequate against modern, adaptive attack techniques [2], [3], [4]. More recent research has focused on AI's ability to analyze and detect IDS, particularly using machine learning (ML), which appears to fill the lack of limitations [5], [6]. Unlike static systems, ML models for IDS can learn from traffic data, patterns, and adapt to emerging threats [4]. These models increase and enhance detection performance, and respond in near real-time scenarios [7], [1].

The increasing complexity of modern network environments, driven by the proliferation of Internet of Things (IoT) devices, software-defined infrastructures, and large-scale distributed systems, has introduced new security challenges that exceed the capabilities of traditional intrusion detection mechanisms. Recent studies indicate that such environments generate highly heterogeneous and dynamic traffic patterns, which significantly complicate the identification of malicious activities using static detection rules. As a result, intrusion detection systems are required not only to detect known attack signatures but also to adapt continuously to evolving threat behaviors while maintaining acceptable performance in resource-constrained and real-time settings [8], [9]. Another fundamental challenge in contemporary intrusion detection lies in the high dimensionality of network traffic data. Modern datasets often comprise hundreds of features, many of which are redundant or weakly correlated with attack behavior. This characteristic negatively impacts learning efficiency, increases computational overhead, and may lead to overfitting. Recent research emphasizes that effective feature selection is a critical preprocessing step for improving IDS performance, as it enables learning models to focus on the most discriminative attributes while reducing model complexity and enhancing generalization across different attack scenarios [10]. In parallel, anomaly-based intrusion detection has gained renewed attention as a viable strategy for identifying previously unseen and zero-day attacks. Unlike signature-based approaches, anomaly detection models establish a baseline of normal network behavior and identify deviations that may signal malicious activity. Empirical evaluations demonstrate that machine learning–based anomaly detection frameworks can successfully capture subtle behavioral deviations in network traffic, offering improved detection of novel attacks. However, these models remain sensitive to data imbalance and noisy features, reinforcing the necessity of careful feature engineering and selection to ensure stable and reliable detection outcomes [11]. Recent advances in deep learning have further expanded the analytical capabilities of intrusion detection systems by enabling the extraction of complex spatiotemporal patterns from network traffic. Architectures such as convolutional and recurrent neural networks have shown strong potential in modeling temporal dependencies and evolving attack sequences. Nevertheless, existing studies highlight that deep models often suffer from limited interpretability and increased computational cost, which can hinder their deployment in operational environments. These limitations have motivated the integration of feature optimization strategies and explainability mechanisms to balance detection accuracy, efficiency, and transparency [12]. Furthermore, the dynamic nature of contemporary networks introduces the challenge of concept drift, where traffic characteristics and attack patterns change over time. Static models trained on historical data frequently experience performance degradation under such conditions. Adaptive learning strategies, including incremental and ensemble-based

frameworks, have demonstrated the ability to sustain detection performance by selectively updating models in response to evolving traffic behaviors. Experimental results in software-defined network environments confirm that adaptive learning mechanisms significantly enhance IDS robustness compared to static detection approaches [13]. Collectively, these observations indicate that effective intrusion detection in modern network environments requires an integrated framework that combines intelligent learning models, efficient feature selection, anomaly-aware detection, and adaptability to evolving threats. Addressing these challenges is essential for improving the robustness, scalability, and practical applicability of IDS across heterogeneous and rapidly changing infrastructures.

A. Research Gap

Although there has been considerable use of machine learning techniques to develop intrusion detection systems (IDS), most research using machine learning approaches have been limited by their reliance upon experiments conducted on a single dataset, or in narrow and constrained experimental designs. Thus, the generalizability of these results are limited. In addition, while feature selection is commonly used as a preprocessing step in developing an IDS, there has been little or no systematic analysis of how this impacts the performance of the model in terms of stability, efficiency, and consistent performance across different types of network environments. Therefore, the practical effectiveness of IDS frameworks that utilize feature selection has remained largely untested, particularly under variable traffic conditions. The above limitations highlight the need for a common testing framework that assess the effects of statistically derived feature selections across multiple datasets and various machine learning models.

B. Contribution

The present research contributes to the area of network intrusion detection through addressing limitations associated with existing IDS (Intrusion Detection System) based on Machine Learning (ML). The first is through a framework of intrusion detection (structured), which incorporates feature selection through ANOVA (Analysis of Variance), as well as multiple supervised learning models for assessing the consistency of the features selected in relation to their importance and redundancy for various types of traffic characteristics. Second, this study represents a comprehensive multi-dataset experiment using many of the most commonly used and adopted benchmark datasets, thereby allowing for a more accurate understanding of how well each model performs relative to its ability to generalize from one dataset to another. Third, the work in this study provides a systematic analysis of the impact of selecting features through statistical means on detection performance and computational efficiency, and thus offers insight into the potential trade-off between the two. Fourth, the comparison of the performance of several machine learning algorithms within an identical experimental environment demonstrates the reliability and utility of simple feature selection methods for intrusion detection in real-world environments.

C. Study Layout

The study is organized as follows: Section II details the related work. Section III present the datasets, methodology and features extraction techniques. Evaluation metric is outlined in Section IV. Test scenarios are detailed in Section V. The results are illustrated in Section VI. Finally, Section VII conclude the summary of the models and future direction.

II. Related Work

The continuous evolution of cyber threats has driven extensive research toward more intelligent, adaptive, and interpretable intrusion detection systems (IDSs). Recent studies have increasingly focused on integrating ensemble learning and deep learning techniques, often combined with optimization and explainability mechanisms, to enhance detection performance across diverse network environments. Hybrid detection pipelines that merge conventional machine learning with deep learning architectures, supported by preprocessing, class balancing, and dimensionality reduction strategies, have demonstrated improved generalization under near real-time constraints [14]. Similarly, automated hyperparameter tuning combined with post-hoc interpretability has been shown to achieve competitive detection accuracy while enhancing operational transparency and trust [15].

Feature engineering and feature selection have also received significant attention as key components in IDS design. Evolutionary and search-based feature selection methods have been reported to effectively reduce high-dimensional feature spaces, leading to improved class balance, lower computational complexity, and faster inference times [10]. Broader empirical analyses indicate that selective feature sets, when paired with ensemble classifiers, can mitigate overfitting and improve adaptability to previously unseen attack patterns [16]. In addition, representation learning approaches under limited supervision have demonstrated the ability to reduce false positive rates while maintaining high detection sensitivity, highlighting practical deployment advantages [17].

Several studies have explored hybrid and protocol-aware detection models to improve intrusion detection performance. Hussein et al. [18] demonstrated that combining ensemble classifiers such as AdaBoost, Random Forest, and XGBoost with Chi-square feature selection significantly enhances detection accuracy on benchmark datasets, particularly for worm-related attacks. Hooshmand and Hosahalli [19] proposed a protocol-aware one-dimensional CNN architecture that integrates Chi-square feature selection and SMOTE to improve the detection of minority-class anomalies, especially in UDP traffic. Furthermore, Qazi et al. [20] introduced HDLNIDS, a hybrid CNN–RNN model capable of capturing both spatial and temporal traffic characteristics, achieving robust performance on the CICIDS-2018 dataset.

The importance of explainable artificial intelligence (XAI) in IDS has also been increasingly recognized. SHAP-based explainability has been incorporated into ensemble learning frameworks to interpret detection outcomes and enhance model transparency [21], while dual-explainability approaches combining SHAP and LIME have been shown to improve detection effectiveness while reducing model complexity [22].

Application-specific IDS frameworks further demonstrate the adaptability of learning-based detection approaches. Online intrusion detection systems tailored for electric vehicle charging infrastructures have employed adaptive ensemble models

to address evolving threats in real time [6]. In healthcare and software-defined networking environments, layered detection architectures integrating gradient boosting models and deep neural networks have proven effective against malware and ransomware attacks [23]. Additionally, lightweight IDS solutions for IoT environments have been proposed using statistical feature selection, oversampling techniques, dimensionality reduction, and metaheuristic optimization to balance detection accuracy with resource constraints [24][25][26].

More recently, generative models have been explored in IDS research to support attack simulation, data augmentation, and anomaly detection. Reviews of generative adversarial networks (GANs) and variational autoencoders (VAEs) highlight their potential for enhancing detection robustness, while also emphasizing the need for standardized evaluation protocols [1]. Domain-specific IDS solutions, such as real-time DDoS detection frameworks and smart grid-oriented architectures, further illustrate the necessity of customized detection strategies tailored to specific infrastructure requirements [5], [27].

III. Methodology

A. Workflow Overview

This study follows a four-stage workflow:

- data preprocessing
- feauures extraction and selection
- model training
- model evaluation

The dataset is split into training and test sets using a stratified strategy to preserve class proportions and enable a fair assessment. Three competitive machine learning classifiers XGBoost, Random forest, and LightGBM are trained under a unified pipeline and evaluated using standard classification metrics. The overall workflow is summarized in Fig. 1.

B. Network Traffic Dataset

This study employs the CICIDS Collection compiled by the Canadian Institute for Cybersecurity and made publicly available through Kaggle [28]. The collection integrates several benchmark datasets CIC-IDS2017, CSE-CIC-IDS2018, and CIC-DDoS2019 providing a diverse set of labelled flows that include normal traffic and multiple attack types such as distributed denial of service (DDoS), brute-force login attempts, infiltration, and botnet activity. Each record captures flow-level statistics, including source and destination addresses, ports, protocol type, flow duration, packet length statistics, and other behavioural indicators. The heterogeneous mix of numerical, categorical, and temporal attributes supports advanced analytics and supervised classification. For the purposes of this work, we focus on traffic governed by TCP and UDP, which dominate real-world networks. Prior to modelling, data preprocessing includes normalization, feature encoding, and class balancing to mitigate skewed distributions. The dataset is then split into 80% training and 20% testing subsets using randomized sampling to ensure statistical robustness. Fig. 2 presents the class distribution used in this study.

C. Feature Engineering

Feature selection and engineering are crucial steps in developing effective machine learning models, especially when working with large and complex datasets. These processes refine the input data to ensure that only the most relevant and informative features are used in the model. By focusing on impactful variables, model accuracy is enhanced, computation time is reduced, and interpretability is improved. This subsection outlines the strategies used for feature transformation and selection, which played a key role in improving the performance of the proposed intrusion detection system.

1) Feature Transformation: To prepare the data for supervised learning, categorical class labels are converted into numeric representations to ensure compatibility with the learning algorithms. This transformation preserves class proportions and enables consistent mapping of predicted outputs back to human-readable class names for reporting [29].

2) Feature Selection Using ANOVA F-Test: Feature selection was applied to identify the most discriminative features and reduce the dimensionality of the dataset. The *Analysis of Variance (ANOVA) F-test* was used as a filter-based method to evaluate the statistical significance of each feature with respect to the target classes. This method measures how much the mean of each feature varies across different classes compared to the variance within each class, providing an indication of its discriminative power.

In this study, the `SelectKBest` [30] function from the `scikit-learn` library was employed with the `f_classif` [31] scoring function to rank features based on their F-values. The top 20 features with the highest scores were selected for model training. This approach ensures that only the most relevant features contribute to the classification process, improving model efficiency and reducing overfitting while maintaining predictive performance.

Mathematically, the ANOVA F-statistic for a given feature x_i is defined as:

$$F_i = \frac{MSB_i}{MSW_i} = \frac{\text{variance between class means}}{\text{variance within classes}}$$

where, MSB_i represents the mean square between class means, and MSW_i represents the mean square within each class. A higher F_i value indicates that the feature contributes more to class discrimination.

D. Machine Learning Algorithms

Machine Learning (ML), a core branch of Artificial Intelligence (AI), involves the development of algorithms and statistical models that allow systems to perform specific tasks autonomously without explicit programming. The objective of ML is to enable systems to identify patterns within data, generate predictions, and make informed decisions, with performance improving as the system gains experience from data exposure.

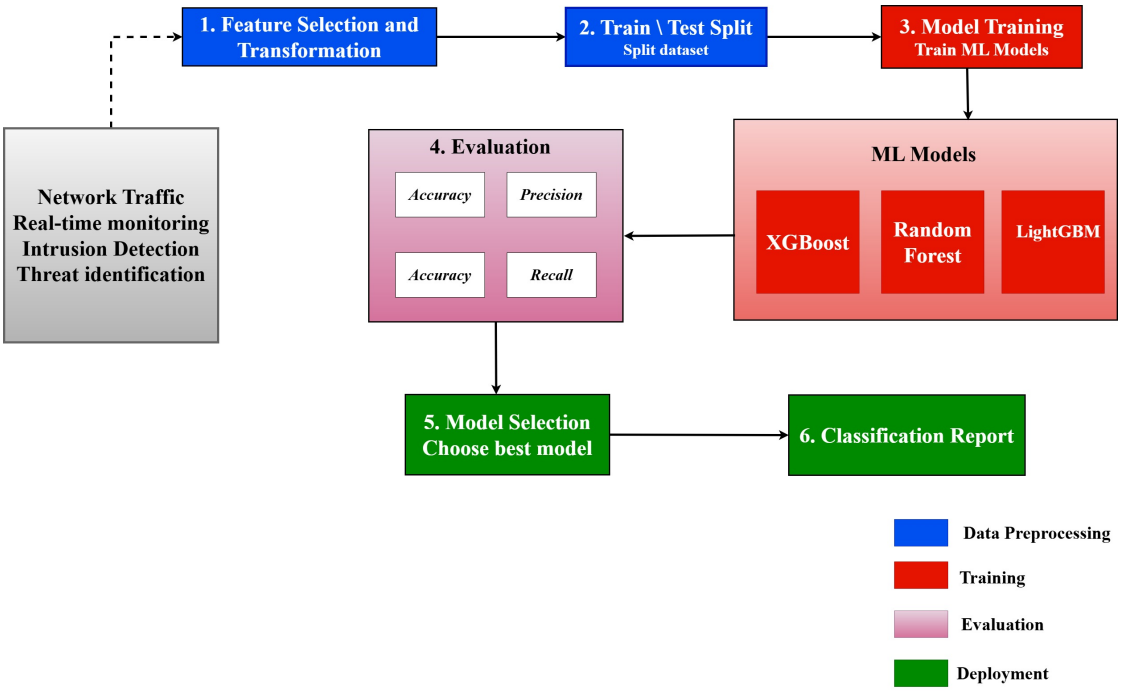

Fig. 1. Intrusion detection system phases.

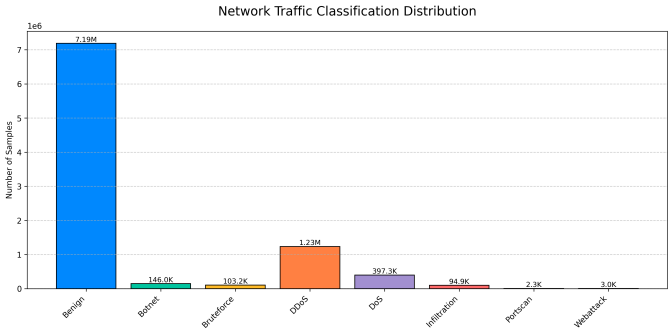

Fig. 2. Network classification dataset distribution.

TABLE I. MACHINE LEARNING MODEL PARAMETERS

Model	Parameter	Value
Random Forest	Number of estimators	100
	Criterion	Gini
	Random state	42
LightGBM	Boosting type	gbdt
	Number of leaves	31
	Learning rate	0.1
	Device	GPU
XGBoost	Booster	gbtree
	Max depth	6
	Learning rate	0.3
	Tree method	gpu_hist
	Predictor	gpu_predictor

1) LightGBM: LightGBM is a gradient boosting framework designed for speed and scalability. Techniques such as Gradient-based One-Side Sampling (GOSS) and Exclusive Feature Bundling (EFB) improve efficiency and reduce effective dimensionality [32]. LightGBM is well-suited for near real-time classification on large datasets, making it a practical choice for intrusion detection in networked systems [33], [34].

2) Random Forest (RF): Random Forest is an ensemble of decision trees trained on bootstrapped samples with randomized feature subsets. This approach improves accuracy and reduces variance relative to a single tree. Majority voting yields robust predictions and strong generalization on high-dimensional data [35], [36].

3) XGBoost: XGBoost is a scalable gradient boosting algorithm that builds trees sequentially, correcting residual errors while using a regularized objective to limit over-fitting. In cybersecurity applications, XGBoost has demonstrated strong performance in detecting sophisticated threats across varied environments [23], [3].

Table I explains the hyperparameters of the machine learning models used in the current work.

IV. EVALUATION METRIC

To evaluate the performance of the network intrusion detection models, a set of standard performance indicators was applied, including accuracy, precision, recall, F1-score, and the confusion matrix. These metrics collectively describe how effectively the model distinguishes between normal and attack traffic.

The evaluation metrics are defined as follows:

$$\text{Accuracy} = \frac{TP + TN}{TP + TN + FP + FN} \tag{1}$$

$$\text{Precision} = \frac{TP}{TP + FP} \tag{2}$$

$$\text{Recall} = \frac{TP}{TP + FN} \tag{3}$$

$$\text{F1-score} = 2 \times \frac{\text{Precision} \times \text{Recall}}{\text{Precision} + \text{Recall}} \quad (4)$$

In these metrics:

- TP (True Positive) represents the number of attack instances correctly identified as attacks.
- TN (True Negative) denotes the number of normal instances correctly classified as normal.
- FP (False Positive) indicates normal traffic mistakenly classified as an attack.
- FN (False Negative) refers to attack traffic incorrectly classified as normal.

The confusion matrix summarizes these outcomes, providing a detailed view of the classifier's performance and highlighting the specific types of misclassification within network traffic.

V. Test Scenarios

Two experimental scenarios were designed to evaluate the proposed framework under different classification objectives: binary and multi-class intrusion detection. Both scenarios used the same datasets, preprocessing steps, and model configurations to ensure consistency.

- Binary Classification Scenario, the task was formulated as a two-class problem: **Benign:** normal network traffic , **Attack:** all malicious traffic categories combined, including DDoS, DoS, PortScan, Botnet, Infiltration, and WebAttack.
- Multi-Class Classification Scenario: The task was extended to classify multiple categories of network traffic.

VI. Results and Discussion

This section presents the performance evaluation of the proposed intrusion detection framework under two classification configurations: binary classification and multi-class classification. Each configuration was tested using RandomForest, LightGBM, and XGBoost models with two feature setups: All Features (AF) and ANOVA-based Feature Selection (FS).

A. Binary Classification Results

Table II summarizes the binary classification performance. All models achieved high accuracy and precision, demonstrating their ability to distinguish between benign and attack traffic, effectively. RandomForest and XGBoost obtained the highest accuracy of 0.9899 and 0.9898, respectively, with perfect precision (1.0000) and F1-scores exceeding 0.97. LightGBM recorded slightly lower performance, but maintained a high AUC of 0.9491 under the AF setup and 0.9578 after feature selection. Feature selection (FS) showed minimal impact on model accuracy but slightly improved LightGBM's Recall and F1-score, indicating that removing less informative features enhanced its generalization capability. Both RandomForest and XGBoost maintained consistent performance between AF and FS, reflecting their robustness to feature dimensionality.

B. Multi-Class Classification Results

Table III presents the multi-class classification results. As expected, the overall accuracy decreased compared to the binary scenario due to the increased complexity of distinguishing between multiple attack categories. RandomForest and XGBoost maintained superior performance, achieving accuracies of 0.99 and macro F1-scores of 0.86 under the feature selection (FS) configuration. After applying ANOVA-based feature selection, RandomForest and XGBoost slightly improved in macro-level Recall and F1-score compared to their All Features (AF) performance, indicating that removing redundant attributes enhanced their generalization capability. Both models also retained high weighted F1-scores of 0.98, confirming consistent classification across major and minor attack classes. LightGBM continued to exhibit lower performance relative to the other models, achieving accuracies of 0.94 (AF) and 0.96 (FS). Although feature selection marginally improved its precision and stability, its macro F1-score remained below 0.60. This suggests that LightGBM is more sensitive to reduced feature dimensionality, while ensemble methods such as RandomForest and XGBoost exploit feature redundancy more effectively to preserve classification robustness across multiple intrusion types.

C. Discussion

The experimental results demonstrate that the proposed intrusion detection framework performs effectively in both binary and multi-class classification settings. Across all models and configurations, high accuracy and precision values indicate strong capability in distinguishing between benign and malicious traffic patterns. In the binary classification experiments, all models achieved near-perfect detection performance. RandomForest and XGBoost recorded the highest accuracies (0.9899 and 0.9898, respectively) with perfect precision and F1-scores exceeding 0.97, confirming their robustness in differentiating between normal and attack traffic. LightGBM showed slightly lower recall but improved marginally under feature selection (FS), indicating that ANOVA-based reduction of redundant features enhanced its generalization without compromising accuracy. In the multi-class classification scenario, overall accuracy decreased compared to the binary setting, as expected from the higher complexity of identifying multiple intrusion categories. RandomForest and XGBoost maintained superior performance, achieving accuracies of 0.99 and macro F1-scores of 0.86 under the FS configuration. The results show that feature selection helped these models improve recall and balance detection across both major and minority classes, while retaining high weighted F1-scores of 0.98. LightGBM exhibited lower macro-level performance (F1-score below 0.60), although its accuracy increased slightly from 0.94 (AF) to 0.96 (FS). This suggests that while feature selection aids in model stability, LightGBM relies more heavily on a full feature space for optimal discrimination across classes. In contrast, ensemble-based models such as RandomForest and XGBoost demonstrate stronger resilience to feature reduction due to their inherent ability to handle feature redundancy. Fig. 3 and Fig. 4 visually compare model performance under AF and FS settings. The figures highlight that feature selection has a minimal, but positive effect on model accuracy and macro F1-score, especially for LightGBM. For RandomForest and XGBoost, performance remained consistently high in both

TABLE II. BINARY CLASSIFICATION PERFORMANCE OF INTRUSION DETECTION MODELS [ALL FEATURES (AF) AND FEATURE SELECTION (FS)]

Model	Accuracy	Precision	Recall	F1-Score	AUC
RandomForest (AF)	0.9899	1.0000	0.9543	0.9766	0.9772
RandomForest (FS)	0.9899	1.0000	0.9544	0.9767	0.9772
LightGBM (AF)	0.9760	1.0000	0.8983	0.9464	0.9491
LightGBM (FS)	0.9792	1.0000	0.9156	0.9559	0.9578
XGBoost (AF)	0.9893	1.0000	0.9508	0.9748	0.9754
XGBoost (FS)	0.9898	1.0000	0.9528	0.9758	0.9764

TABLE III. MULTI-CLASS CLASSIFICATION PERFORMANCE OF INTRUSION DETECTION MODELS [ALL FEATURES (AF) AND FEATURE SELECTION (FS)]

Model	Accuracy	Precision (Macro)	Recall (Macro)	F1-Score (Macro)	Weighted F1-Score
RandomForest (AF)	0.98	0.87	0.75	0.78	0.98
RandomForest (FS)	0.99	0.88	0.85	0.86	0.98
LightGBM (AF)	0.94	0.54	0.60	0.57	0.94
LightGBM (FS)	0.96	0.59	0.60	0.59	0.95
XGBoost (AF)	0.99	0.92	0.73	0.77	0.98
XGBoost (FS)	0.99	0.93	0.85	0.86	0.98

TABLE IV. METHODOLOGICAL COMPARISON WITH EXISTING IDS STUDIES

Study	Dataset	Model Type	Feature Selection	Multi-Dataset	Model Complexity	Accuracy%
Qazi et al. [20]	CICIDS-2018	CNN–RNN	No	No	High	98.90
Proposed Framework	CIC-IDS2017, CIC-DDoS2017, CSE-CIC-IDS2018, CIC-DDoS2019	ML-based Ensemble	**ANOVA**	**Yes**	Lower	99.00

setups, reinforcing their suitability for scalable, high-accuracy intrusion detection across diverse network traffic types.

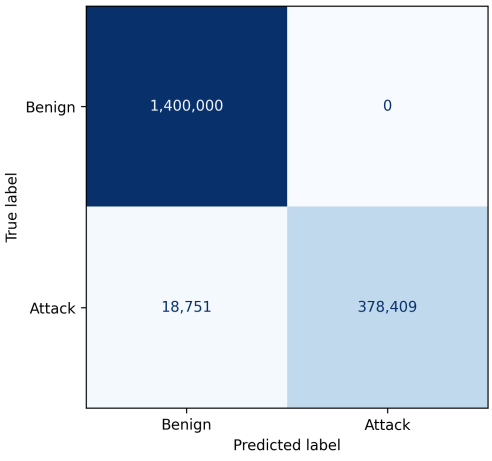

Fig. 5 shows the confusion matrix of the machine learning models in case of binary classification. In addition, Fig. 6 shows the confusion matrix of XGBoost models in case of feature selection, which illustrates the classification behavior across different attack categories. The model demonstrates strong capability in identifying benign traffic, with nearly all normal flows correctly detected and very few false positives. This behavior is essential for maintaining operational stability and reducing unnecessary alerts in real deployment environments. High detection accuracy is also evident for major attack classes such as DDoS and DoS, confirming that the model effectively captures large-scale malicious activity patterns. Some misclassification occur in less frequent attack types such as Infiltration and Web Attack. These errors likely result from class imbalance and the limited number of representative samples in those categories. Even so, the classifier maintains stable precision and recall across the primary attack types, showing that feature selection and ensemble learning enhance the model's ability to separate overlapping network behaviors. Overall, the confusion matrix supports the quantitative findings reported earlier. The results confirm that the proposed intrusion detection approach achieves high accuracy and robustness across varied network threats, while sustaining a very low false-alarm rate—an essential property for scalable and reliable AI-based intrusion detection in practical applications. On the CICIDS-2018 dataset, the results obtained by the proposed framework are consistent with those reported by Qazi et al. [20], despite the methodological differences between the two approaches. While HDLNIDS relies on a deep CNN–RNN architecture trained and evaluated on a single dataset, the proposed framework adopts a machine learning–based ensemble strategy supported by ANOVA-based feature selection. This design choice enables effective dimensionality reduction while maintaining competitive detection performance.

(b) Random forest.

(c) XGboost.

Fig. 5. Comparative visualization of intrusion detection performance using Feature Selection (FS) across different machine learning models for binary classification.

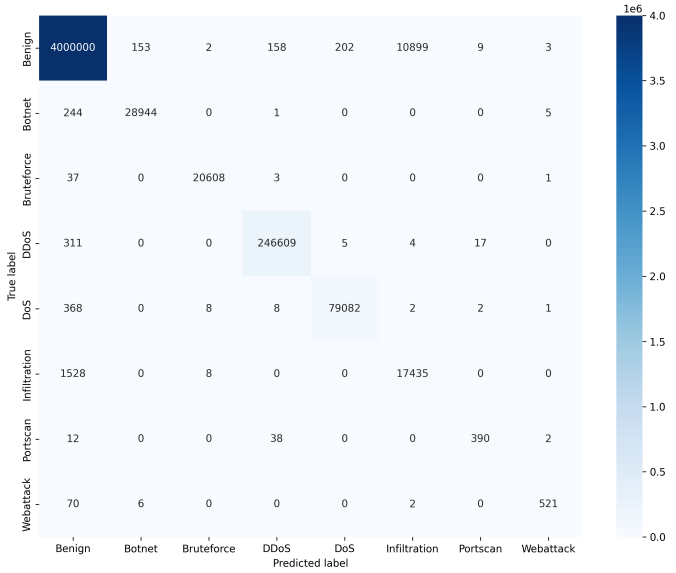

Fig. 6. Confusion matrix of XGBoost model Feature Selection (FS).

Moreover, unlike HDLNIDS, which focuses on a single experimental setting, the proposed approach demonstrates stable behavior across multiple CIC-based datasets, suggesting improved robustness and generalization under heterogeneous traffic conditions. Table IV shows the comparison between our work and one of the latest research studies.

VII. Conclusion

This study presented an AI-driven intrusion detection framework designed to enhance network security through consistent and leakage-free machine learning pipelines. The framework integrated RandomForest, LightGBM, and XGBoost classifiers and was validated under both binary and multi-class settings using multiple datasets to assess robustness and generalization across diverse network conditions. The experimental results demonstrated that all models achieved strong performance in binary intrusion detection, with RandomForest and XGBoost achieving the highest accuracy (0.99) and stable F1-scores above 0.97. In the more challenging multi-class scenario, both models maintained high accuracy (0.99) and balanced detection across attack categories, confirming their reliability in distinguishing complex intrusion patterns. LightGBM showed slightly lower macro-level performance but benefited modestly from ANOVA-based feature selection, which improved its recall and stability. Feature selection proved effective in reducing feature redundancy and improving computational efficiency without compromising classification accuracy. This finding highlights that robust ensemble methods such as RandomForest and XGBoost can maintain high performance even when trained on reduced feature spaces, making them suitable for large-scale and resource-constrained environments. Future work will focus on three directions: First, model scalability and efficiency will be advanced by exploring compact deep architectures such as CNN–RNN hybrids and lightweight transformer variants for real-time deployment. Second, explainability and transparency will be enhanced through SHAP-based feature interpretation to increase analyst trust and

interpret model behavior. Third, robustness will be extended through evaluation on adversarial and real-world datasets, integration of continual learning to adapt to evolving threats, and hybridization with anomaly detection mechanisms to identify both known and emerging attacks. Collectively, these efforts aim to develop intrusion detection systems that are accurate, interpretable, and resilient across diverse and dynamic network environments.

ACKNOWLEDGMENT

The authors express their gratitude to Széchenyi István University of Győr for providing institutional support and to the Stipendium Hungaricum Scholarship Programme for its financial assistance.

***Abstract*—Predicting drug response in cancer cell lines is a critical step toward precision oncology, enabling more efficient therapeutic discovery and personalized treatment strategies. However, the complexity of drug–cell interactions, driven by diverse omics profiles and structural variability among drugs, poses significant challenges for conventional machine learning approaches. In this study, we propose an end-to-end pipeline that integrates multi-omics data (gene expression, copy number variation, and mutations) with chemical structure representations of drugs to predict binary drug response. Our method employs principal component analysis (PCA) for dimensionality reduction of high-dimensional omics data, followed by the computation of drug–drug and cell–cell similarity matrices. These are used to construct a heterogeneous graph combining intra-class similarities with drug–cell interactions. A customized graph neural network model, DrugCellGNN, is then applied to learn context-aware embeddings of drugs and cells. The fused representations are passed to a downstream multi-layer perceptron for classification. To address class imbalance, we introduce a dynamic focal loss function that adaptively emphasizes hard-to-classify examples. Evaluation on the GDSC dataset with an 80/20 train–test split demonstrates strong performance: Accuracy = 0.8935, F1 = 0.9201, AUC = 0.9510. This work highlights the utility of graph-based integration of multi-omics and drug features for drug sensitivity prediction. By leveraging both molecular and relational information, the proposed framework offers a robust and extensible foundation for advancing computational approaches in precision oncology.**

***Keywords*—Precision oncology; drug sensitivity prediction; graph neural networks (GNNs); multi-omics integration; focal loss; PCA**

I. Introduction

Cancer is a disease of the genome that causes mortality worldwide, characterized by high complexity and inter-patient heterogeneity that complicate effective treatment [1]. Traditional therapies, such as chemotherapy and radiotherapy, often exhibit limited specificity, leading to substantial toxicity in healthy tissues and suboptimal efficacy [2]. However, not all patients react to pharmacological therapy in the same manner, and biological data, such as gene mutations or gene expression, can help predict which patients are most likely to benefit from a certain medicine [3]. Thus, establishing strategies for predicting drug sensitivity is critical for individualized therapy. According to the National Research Council, precision medicine can be used to divide patients into subgroups based on their unique reactions to medical treatment [4]. Customizing effective treatments based on individual characteristics can improve therapy quality, reduce wasteful expenses, and minimize negative side effects. Precision medicine aims to optimize cancer therapy by selecting drugs tailored to each patient's unique genetic profile [4]. This process presents a complex challenge in cancer treatment. These challenges have led to large-scale experiments on human cancer cell lines and a wide range of anticancer drugs, which have led to the availability of free datasets for cancer cell drug sensitivity information and molecular markers of drug responses. The Genomics of Cancer Drug Sensitivity (GDSC) [5] is one of the most widely used projects, providing molecular profiles and drug response data for hundreds of cancer cell lines treated with various anticancer drugs. These datasets provide genetic features of cancer cell line panels, such as gene expression profiles, copy number alterations, and single-nucleotide mutations. This enormous accumulation of data paves the way for the advancement of data analysis and computational techniques, including machine learning and artificial intelligence approaches.

Despite notable progress, existing computational approaches face several limitations. Traditional machine learning models often struggle to capture complex interactions between drugs and cancer cell lines and are limited by the high dimensionality and heterogeneity of multi-omics data. Moreover, many methods treat drugs and cell lines independently, overlooking their intrinsic relational structure, which is crucial for accurate prediction and generalization across unseen samples.

To address these challenges, this study proposes DrugCellGNN, a graph neural network–based framework for binary drug sensitivity prediction. The proposed method integrates multi-omics features, drug structural information, and functional drug response data to construct biologically meaningful drug–cell interaction graphs. Dimensionality reduction using principal component analysis (PCA) is employed to mitigate data sparsity, while a dynamic focal loss is introduced to handle class imbalance. Through comprehensive evaluation, DrugCellGNN demonstrates improved predictive performance compared to existing approaches, highlighting its potential utility in precision oncology.

The remainder of this study is organized as follows: Section II briefly reviews some of the recent work published in the area of prediction of the drug response by using genomics

data. Section III explains the methodology that has been used to create the model. Evaluation criteria is explained in Section IV. The results of the proposed model are presented in Section V. Finally, Section VI concludes the study.

II. Related Work

Several computational approaches have been developed to predict medication response by analyzing gene expression profiles or other molecular information of cell lines. This Computational method for predicting drug response can be grouped into two main approaches: 1) classification (predicting drug responses as sensitive vs. resistant), 2) regression (Estimating a quantitative measure to evaluate a cell line's response to a drug). Various computational approaches have been developed to solve classification problems for predicting the sensitivity of anticancer drugs. Choi et al. [6] created RefDNN, a computational model that utilizes a deep neural network and ElasticNet repressors. They established a collection of reference medications and a baseline for classifying drugs to evaluate others. Drug sensitivity probabilities for a given cell line-drug pair were predicted using the drug's similarity to the reference set. RefDNN has the potential to be utilized for repositioning anticancer medications. Similarly, Logistic matrix factorization with regularization terms was used in DSPLMF [7] to classify drug response. This approach incorporates drug similarity derived from chemical structures and cell line similarity computed from gene expression, copy number variation, mutation profiles, and drug response data. While these methods demonstrate promising performance, they primarily rely on pairwise similarities and do not explicitly model higher-order interactions between drugs and cell lines.

Furthermore, various computational regression approaches have been developed to predict the half-maximal inhibitory concentration (IC50) of cell lines in response to drugs. Wang et al. [4] proposed the Similarity Regularized Matrix Factorization (SRMF) method, which incorporates the gene expression similarity of cell lines and the chemical similarity of drugs to enhance the prediction of anticancer drug responses. Ahmadi Moughari et al. have introduced ADRML, a framework for predicting how well cancer cells will respond to drugs using manifold learning. ADRML maps drug response values into a low-dimensional latent space and predicts the drug response for new cell line-drug pairs based on this latent space. The framework incorporates multiple types of cell line similarities and drug similarities into the manifold learning process [8].

Selecting the optimal set of genetic features for predicting drug response is crucial for developing effective classification models. Consequently, numerous feature selection algorithms employing diverse strategies have been developed. AutoBorutaRF [9] is a method which based on feature selection and designed for predicting drug response. It combines an autoencoder network with the Boruta algorithm [10]. The autoencoder is used initially, and then Boruta is applied to select the most relevant features. These selected features are then used to train a Random Forest classifier for predicting drug response. Dong et al. [11] developed a drug response prediction model called Support Vector Machine Recursive Feature Elimination (SVM-RFE), which employs a wrapper approach, combining recursive feature selection with an SVM classifier. Emdadi et al. [12] introduced a feature selection method designed for drug response prediction. It uses Hidden Markov Models (HMM) and Autoencoders (AE). While these techniques reduce dimensionality and noise, they typically treat samples independently and fail to exploit relational structures between drugs and cell lines.

Considering the complexity and noise inherent in biological data, deep learning methods often outperform traditional machine learning algorithms in predicting drug sensitivity [13]. A hybrid graph convolutional network (GCN) has been proposed in [14], This approach, known as DeepCDR, utilizes a variational autoencoder (VAE) framework to effectively model the complex relationships between multi-omics profiles of cancer cells and the intrinsic chemical structures of drugs, achieving strong results; nevertheless, it performs late-stage omics fusion, employs limited similarity types (primarily structural), and does not explicitly mitigate severe class imbalance common in pharmacogenomic data.

Other studies suggest several statistical learning strategies, such as regularized linear regression models, ridge regression lasso [15], and Support vector machines [16].

Although prior studies have progressively improved prediction accuracy, they share common limitations: over-reliance on pairwise or late-fused similarities, inadequate handling of class imbalance, limited integration of hybrid (structural + functional) drug/cell similarities, and insufficient relational modeling of multi-omics interactions. To overcome these gaps, the proposed DrugCellGNN framework integrates multi-omics features, functional and structural drug similarities, and graph neural networks to explicitly model drug–cell relationships, enabling robust and biologically informed binary drug sensitivity prediction.

III. Methodology

The primary objective of this study is to develop a predictive framework for binary drug response classification, as it may be more important whether a drug is effective for a given cancer cell line or not. There are two classifications of drug Responses: "sensitivity" and "non-sensitivity". We focused on integrating multi-omics profiles of cancer cell lines with structural and functional representations of drugs. The first step begins with extensive data preprocessing, including the removal of samples and features with excessive missingness, followed by a hybrid imputation strategy. Then, for improving the prediction performance, the cleaned datasets are dimensionally reduced to retain the most informative features, and similarity matrices are computed for both drugs and cell lines. Finally, a model is used for predicting the probability that a cell line would become drug-sensitive. Every pair was then categorized into a sensitive or resistant class by applying the threshold to the predicted probability of the cell line-drug pairs. The main scheme of our model is represented in Fig. 1.

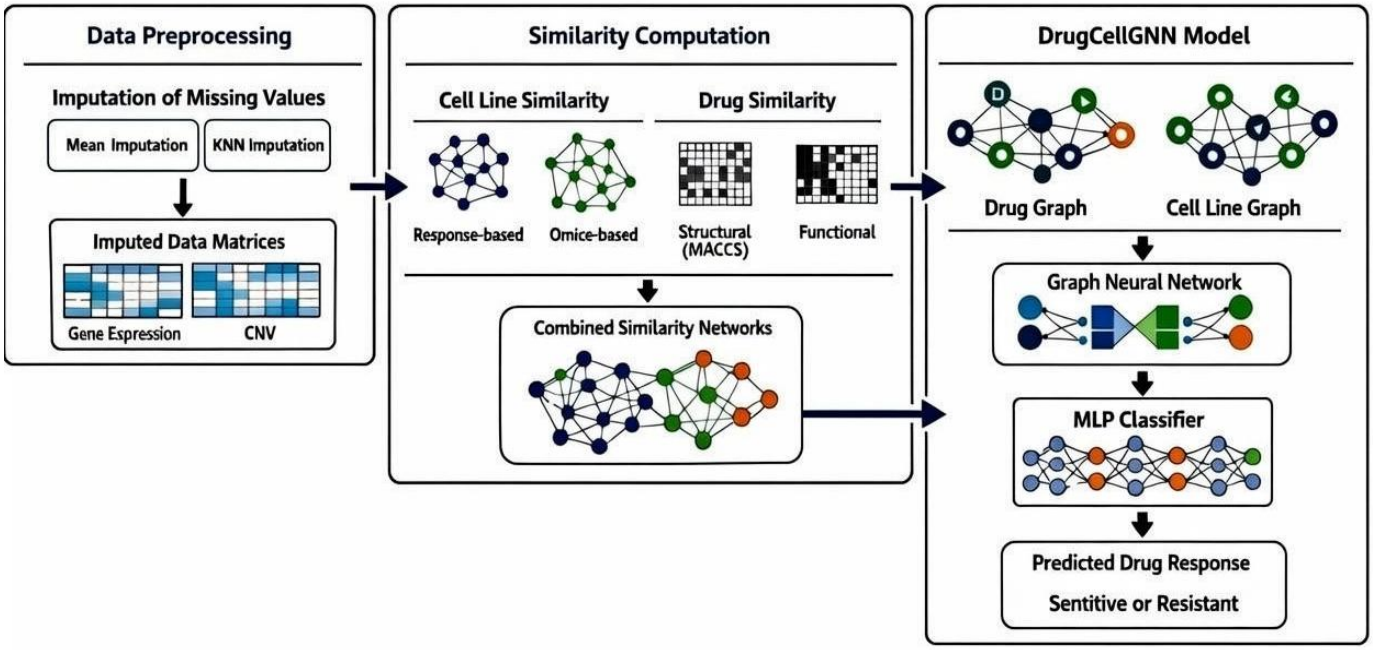

Fig. 1. Overview of the DrugCellGNN framework.

A. Dataset

Genomics of Drug Sensitivity in Cancer (GDSC) [17] is used in this study. This dataset includes drug response measurements, such as the half-maximal inhibitory concentration (IC50 values), Cell line omics information (including gene expression profiles, copy number variation (CNV), and mutation data), and maximum concentration values for drugs. The GDSC has 1,084 cell lines and 344 drugs; however, some values were missing in the dataset, so we filtered the dataset and applied preprocessing steps to address this issue. After the preprocessing, we had 551 cell lines and 91 drugs. In addition to the mentioned cell line information, chemical compound information is used and represented by Simplified Molecular Input Line Entry System (SMILES) [18], which was downloaded from PubChem [19]. And molecular fingerprints of drugs were extracted using the rdkit package in Python [20].

B. Preprocessing

We organize the collected data into three main types of matrices. The first is the response matrix, which captures the drug response data; rows represent cell lines, and columns represent different drugs. Each entry in this matrix holds either an IC50 value or a sensitivity label. The second type is the cell line feature matrices, where each row refers to a specific cell line and the columns represent its associated features. Lastly, drug feature matrices, with drugs as rows and their corresponding features arranged across the columns. Once these matrices were prepared, we carried out a series of preprocessing steps to ensure they were ready for downstream analysis.

The preprocessing steps are as follows:

- Missing value analysis and filtering: Because some of the information above has a high ratio of missing values, we first needed to remove samples with substantial missing data before performing imputation. For the response matrix, according to the distribution of missing values in Fig. 2(A), we initially removed cell lines with more than 95% missing values. Then, we eliminated cell lines and drugs with more than 30% missing data. Fig. 2(B) shows the distribution after filtering. In the gene expression matrix, we identified 72 cell lines that contained only missing values (i.e., no data across all features); therefore, the dataset became fully complete after excluding these cell lines. In the CNV matrix in Fig. 3(A) and Fig. 3(B), we removed features and cell lines with more than 30% missing values. For the mutation matrix, we eliminated features with over 35% missing data, resulting in a fully complete dataset.
- Imputing missing values: After removing samples and features with a high percentage of missing values, some missing entries still remained in the response and CNV matrices. To fill these gaps, we used a hybrid imputation method that combines mean imputation with K-nearest neighbors (KNN) imputation.

Let the drug response matrix be denoted by:

$$R \in R^{n \times m}$$

where, n and m represent the number of cell lines and drugs, respectively.

Mean Imputation is used for Low-Missing Drugs, where each drug j with a missing rate less than a threshold τ (in our study, τ =0.1), for drugs missing <10% values, fills gaps with the average response [Eq. (1)]:

$$\mu_j = \frac{1}{|I_j|} \sum_{i \in I} R_{ij} \quad (1)$$

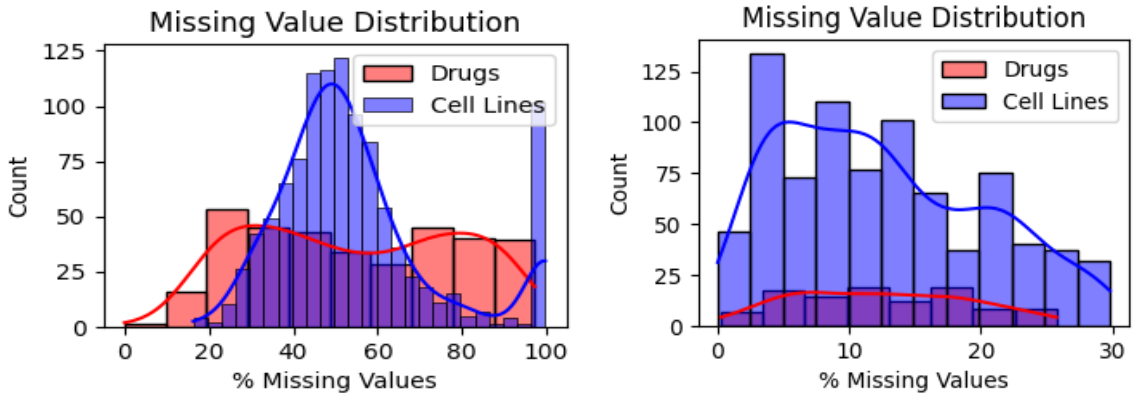

Fig. 2. (A) Missing value distribution for the response matrix before filtering. (B) Missing value distribution for the response matrix after filtering.

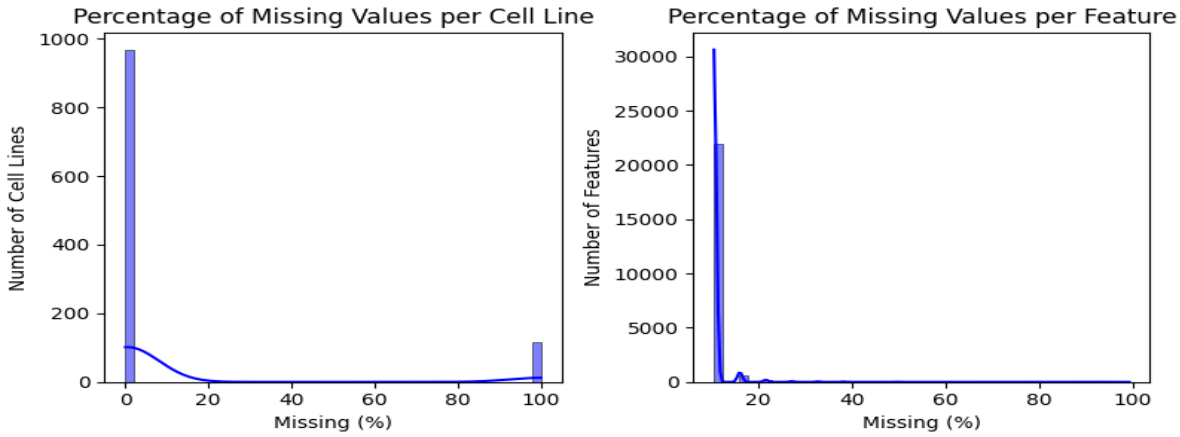

Fig. 3. (A) Missing values distribution for cell lines in the CNV matrix before filtering. (B) Missing values distribution for CNV features in the CNV matrix before filtering.

where, R_{ij} represents the response of cell line i to drug j, and may be missing (i.e., R_{ij}=NaN), $I_j=\{i|R_{ij}$ is observed$\}$, then for all missing entries R_{ij} where j ∈ low-missing drugs, set: $\hat{R}_{ij}=\mu_j$

For drugs with missing values greater than τ, we used KNN Imputation. To prepare for KNN imputation, the matrix is scaled using Eq. (2):

$$\grave{R}_{ij}=\frac{R_{ij}-\text{Median}(R_j)}{\text{IQR}(R_j)} \quad (2)$$

where, $\text{IQR}(R_j)$ is the interquartile range of drug j 's responses.

We then applied KNN imputation on the scaled data. For each missing value $\grave{R}_{ij}$, the imputed value is computed as the average of the same feature from the k nearest samples (rows) based on Euclidean distance [see Eq. (3)]:

$$\grave{R}_{ij}=\frac{1}{k}\sum_{r\in N_i}\grave{R}_{rj} \quad (3)$$

where, N_i is the set of k nearest neighbors of the sample i with observed values in feature j. After imputation, the scaled data were transformed back to their original scale using the inverse of the robust scaling operation [Eq. (4)]:

$$R_{ij}^{final}=\grave{R}_{ij}.\text{IQR}(R_j)+\text{Median}(R_j) \quad (4)$$

This hybrid approach ensures that low-missing features are imputed efficiently using simple statistics, while high-missing features benefit from structure-aware imputation via KNN.

- Binary conversion using IC50: This research aims to develop classification-based modeling, so we converted the continuous drug response data into binary labels (sensitivity and non-sensitivity). Several research studies have adopted different threshold values of IC50 for binarization. Such as median values [7], [9] or a specific deviation from the normalized mean [11]. While others have relied on more biologically grounded pharmacokinetic thresholds, such as the maximum drug concentration (Cmax) [6]. Cmax makes more sense among the different thresholds used to assign labels to drug response data because it is predicated on the medication's pharmacokinetic characteristics. Cmax is the highest concentration of a medication that can be found in plasma. Thus, it is clear that a cell line is resistant to a medicine if it needs a molar concentration greater than the drug's Cmax for 50% inhibition. For this reason, we adopted the Cmax in our study for classifying drug response. And based on it, we labeled a cell line as "sensitive" if the $IC50_{i,j} \leq$ Cmax, which is represented by 1; otherwise, it's labeled as "non-sensitive".

C. Feature Engineering

Omics Integration and Dimensionality Reduction: To construct a comprehensive representation of each cell line, we integrated multiple omics data types, including gene expression, copy number variation (CNV), and mutation profiles. Only cell lines present in all three sources were retained to ensure consistency. The aligned datasets were then concatenated to form a unified omics feature matrix. To reduce scale disparities and improve model stability, the omics matrix was standardized using z-score normalization and subsequently, Principal Component Analysis (PCA) [21]. In our study, PCA was applied to reduce dimensionality while preserving 80% of the variance. This step helped eliminate redundancy and emphasized the most informative biological features.

The cumulative explained variance curve (Fig. 4) demonstrates a smooth and steady increase, indicating that a relatively moderate number of components (~140) is sufficient to retain 80% of the variance. This gradual curve suggests that the variance is well distributed across components, meaning no single feature dominates the representation. Such a distribution supports the stability and robustness of the compressed feature space, as it captures diverse biological signals rather than being overly dependent on a few dominant factors.

To explore the potential benefit of non-linear dimensionality reduction, we compared PCA with a shallow autoencoder trained on the standardized omics feature matrix. Both approaches yielded comparable performance in downstream tasks, suggesting that the underlying structure of the data is predominantly linear. Given PCA's simplicity, interpretability, and computational efficiency, we opted to use PCA for feature compression in the final pipeline.

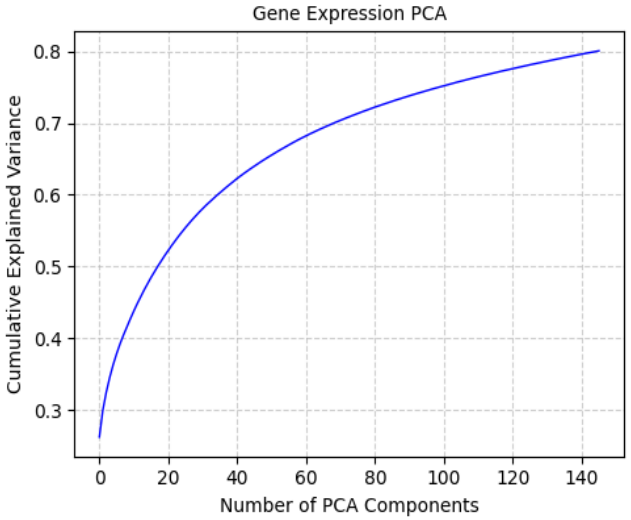

Fig. 4. PCA explained variance curve.

- Similarity Computation: To enhance the representation of both cell lines and drugs, we constructed similarity networks using a weighted combination of functional and structural measures. This approach captures complementary biological and chemical relationships, enabling the model to generalize better across diverse drug-cell line pairs.

For cell lines, similarity was computed using two modalities:

- Response-Based Similarity: We calculated cosine similarities from the drug response matrix $R \in R^{n \times m}$, where R_i and R_j are the response vectors of cell lines i and j. Cosine similarity is defined in Eq. (5):

$$S_{ij}^{response} = \frac{R_i . R_j}{\|R_i\|_2 \|R_j\|_2} \quad (5)$$

- Omics-Based Similarity: derived from the omics feature matrix $O \in \mathbb{R}^{n \times m}$ where O_i and O_j are the feature vectors of cell lines i and j. Using the same cosine similarity equation [Eq. (6)]:

$$S_{ij}^{omics} = \frac{O_i . O_j}{\|O_i\|_2 \|O_j\|_2} \quad (6)$$

The final cell line similarity matrix was computed as a weighted combination [see Eq. (7)]:

$$S^{cell} = \lambda_c . S^{response} + (1-\lambda_c) . S^{omics} \quad (7)$$

λ_c is a parameter that represents the weight of the matrix; in our study, λ_c=0.3 was selected empirically to balance phenotypic response patterns and intrinsic molecular.

This fusion strategy balances phenotypic behavior with intrinsic biological or chemical characteristics.

For drug similarity, the similarity between two drugs i and j is computed using MACCS fingerprints [22] and the response matrix; we computed both similarity matrices using Jaccard similarity.

Structural similarity: computed using the Jaccard similarity over MACCS fingerprints [see Eq. (8)].

$$S_{ij}^{struc} = \frac{|F_i \cap F_j|}{|F_i \cup F_j|} \quad (8)$$

where, F_i, F_j are Sets of active bits in the MACCS fingerprints of drugs i and j, respectively.

Functional similarity: using cosine similarity across binary response profiles S_{ij}^{func}.

The final drug similarity matrix was Eq. (9):

$$S^{drug} = \lambda_d . S^{func} + (1-\lambda_d) . S^{struc} \quad (9)$$

λ_d is a parameter that represents the weight of the matrix; in our study, λ_d=0.3.

D. Model Architecture

To capture the complex interplay between drugs and cancer cell lines, we propose a novel graph-based deep learning framework, DrugCellGNN, that integrates structural drug information, functional cell similarities, and multi-omics features into a unified predictive model.

Graph Construction and Node Embedding: To include the structural relationships between drugs and cell lines, we built two separate graphs: a drug similarity graph and a cell line similarity graph. Each graph G= (V, E) is composed of nodes V (drugs or cell lines) and edges E, which are defined based on a pairwise similarity threshold. Specifically, an edge (i,j) ∈ E is

formed if the similarity score $S_{ij} > 0.7$, a threshold selected to retain only strong associations.

Each node is initialized with a trainable embedding vector of size e from $E_d \in R^{|v_d| \times e}$ for drug and $E_c \in R^{|v_c| \times e}$ for cell lines, where $|v_d|$ and $|v_c|$ denote the number of drug and cell nodes, respectively. These embeddings were then updated using a graph convolution operation defined as Eq. (10):

$$H^{l+1} = \sigma\left(\hat{D}^{-\frac{1}{2}}\hat{A}\hat{D}^{-\frac{1}{2}}H^{l}W^{l}\right) \quad (10)$$

Where $\hat{A}=A+I$ is the adjacency matrix with self-loops, $\hat{D}$ is the corresponding degree matrix, H^l is the node feature matrix at layer l, W^l is the trainable weight matrix, and σ is a non-linear activation function (ReLU in our case).

Alternatively, this operation can be interpreted from a node-wise perspective as Eq. (11):

$$h_i^{(l+1)} = \sigma\left(\sum_{j \in N(i)} \frac{1}{\sqrt{|N(i)|.|N(j)|}} W^{(l)} h_j^{(l)}\right) \quad (11)$$

This emphasizes how each node i updates its feature by aggregating normalized information from its neighbors N(i).

Using this, the final graph-enhanced embedding is Eq. (12):

$$d_i = GCN_{drug}(E_d, G_d),\ c_j = GCN_{cell}(E_c, G_c) \quad (12)$$

The output embedding for drugs and cell lines — denoted $d_i = GCN_{drug}(E_d, G_d)$ and $c_j = GCN_{cell}(E_c, G_c)$, respectively — are then concatenated with the corresponding omics feature vector $o_j \in R^O$ of the cell line, resulting in a fused representation [see Eq. (13)]:

$$z_{ij} = \left[d_i \| c_j \| o_j\right] \in R^{2e+o} \quad (13)$$

This vector z_{ij} is passed into a multi-layer perceptron (MLP) — a deep learning model for classification. Where the first hidden layer can be represented by Eq. (14):

$$h_1 = RELU(BN(W_1 z_{ij} + b_1)) \quad (14)$$

The second layer [see Eq. (15)]:

$$h_2 = RELU(W_2 h_1 + b_2) \quad (15)$$

To prevent overfitting, a dropout layer with a probability of p =3 is applied after the second fully connected layer. Dropout randomly deactivates a fraction p of neurons during training, encouraging the network to learn distributed representations rather than memorizing specific patterns [Eq. (16)].

$$\tilde{h}_2 = m \odot h_2,\ m \sim Bernoulli(1-p) \quad (16)$$

Finally, the transformed features are passed to a sigmoid output layer to produce the predicted probability of drug sensitivity, as in Eq. (17):

$$\hat{y}_{ij} = \sigma(W_3 \tilde{h}_2 + b_3) \quad (17)$$

where, $\hat{y}_{ij} \in [0.1]$ indicates the likelihood that cell line j responds to drug i.

E. Dynamic Focal Loss Function for Imbalanced Data

To address class imbalance inherent in drug response data, we implemented a custom focal loss function with dynamic weighting, where the per-sample weight α_d is given in Eq. (18):

$$\alpha_d = \frac{\#\text{ sensitive cell lines for drug d}}{\text{Total cell lines tested for drug d}} \quad (18)$$

This formulation increases the loss contribution from drugs with few positive (sensitive) samples, preventing the model from being biased toward majority-class drugs.

The overall loss for a sample (i.j) is in Eq. (19):

$$L_{focal} = \alpha_d.(1-p_t)^{\gamma}.BCE\left(\hat{y}_{ij}, y_{ij}\right) \quad (19)$$

where, $\hat{y}_{ij}$, y_{ij} are the predicted probability and ground truth label, respectively, $p_t = \hat{y}_{ij}$ if $y_{ij}=1$, otherwise $1-\hat{y}_{ij}$. And γ is the focusing parameter.

IV. Evaluation Criteria

The dataset was split into 80% training and 20% testing using stratified sampling, which is widely used in drug response prediction benchmarks to ensure sufficient training data while maintaining an unbiased test set. This setting evaluates the model's ability to generalize across unseen drug–cell line pairs under standard experimental conditions. Training was conducted for 100 epochs with early stopping based on validation AUC. All computations were accelerated via GPU. The model parameters were optimized using the Adam optimizer (lr = 0.001).

The model is evaluated on the test set using a comprehensive set of metrics:

$$\text{Accuracy} = \frac{TP + TN}{TP + FP + TN + FN}$$

$$\text{Precision} = \frac{Tp}{Tp + Fp}$$

$$\text{Recall} = \frac{TP}{TP + FN}$$

$$\text{F1 score} = 2.\frac{\text{precision.Recall}}{\text{precision+Recall}}$$

where, TP, TN, FP, and FN represent true positive, true negative, false positive, and false negative, respectively. In addition to the metrics mentioned above, AUPR, AUC, and Specificity were also used.

V. Results

A. Data Description

Data filtering helped to reduce the missing values. For the IC50 response matrix, missing values reduced from 54.39% to 12.50%, and the Omics: RNA missing values reduced from 6.64% to 0.00%, CNV missing values reduced from 11.20% to 2.40%.

Since the GDSC dataset still includes missing entries, we compensated for them by applying a hybrid imputation approach, as outlined in the Materials and Methods section

(Section III). The total number of features and samples after this step is in Table I.

TABLE I. GDSC DATASET INFORMATION BEFORE AND AFTER PREPROCESSING

Dataset	State	Drugs	Cell lines	RNA	CNV	Mutation
GDSC	Raw	343	1084	17612	22903	68
	preprocessed	103	643	17611	22773	55

So we had omics data with more than 40 thousand features, which were integrated with the response matrix to calculate cell line similarities. This analysis produced a 551 × 551 cell line similarity matrix, reflecting the 551 common cell lines shared across the datasets. For the drug data, compounds lacking SMILES representations were excluded. MACCS fingerprints were then computed and combined with the response matrix to derive drug similarities, resulting in a 91 × 91 similarity matrix corresponding to the 91 drugs common across the datasets. Then we reduced the dimensionality of the omics data by applying PCA, ensuring that 80% of the total variance is preserved, reducing the number to 146 features.

For labeling, we used Cmax to convert IC50 values to labeled values. The GDSC dataset exhibits a moderately balanced class distribution, with 62.93% of drug-cell pairs classified as sensitive and 37.07% as resistant, yielding a 1.7:1 ratio. However, per-drug sensitivity rates vary significantly, with some drugs showing as low as 13% or as high as 76% sensitive cell lines, creating drug-specific imbalances (see Fig. 5). To ensure robust performance on both classes, particularly the clinically critical resistant cases, we employed focal loss with dynamic per-drug alpha (α=1-sensative fraction,γ=3). This approach weights the loss inversely to each drug's sensitivity rate, prioritizing underrepresented classes (e.g., resistant cases for highly effective drugs). As a result, the DrugCellGNN achieved balanced performance, with an AUPR of 0.9698, F1-score of 0.9228, and specificity of 0.7853, demonstrating effective handling of per-drug class variations and enhancing its utility for precision oncology.

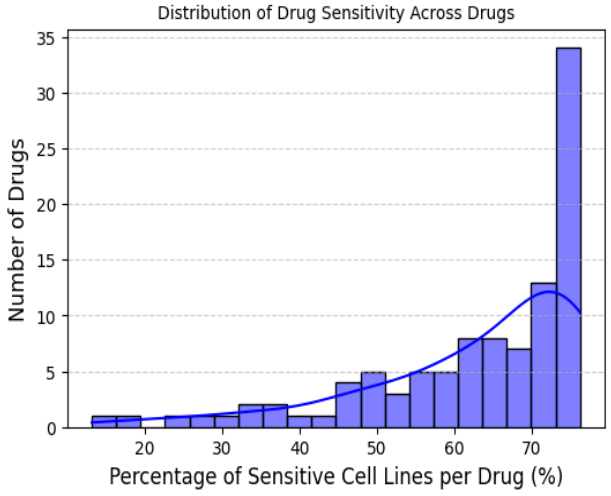

Fig. 5. Distribution of drug sensitivity across drugs.

B. Predictive Performance of the Model

To validate the effectiveness of our approach, we compared its predictive performance with that of the state-of-the-art models, including DSPLMF [7], Auto-HMM-LMF[12], CDSML [23], and MOICVAE [24]. All the methods mentioned above are classification models. All baseline models were evaluated using the same preprocessed dataset and identical train–test splits to ensure a fair comparison. The results in Table II show that in the GDSC cell line data set, the five indicators of our model framework were the highest.

TABLE II. PREDICTION PERFORMANCE OF DIFFERENT ALGORITHMS BASED ON SIX CRITERIA ON THE (GDSC) DATASET

Method	ACC	Rec	SPC	F1	AUC	Precision
DrugCellGNN	**0.895**	**0.941**	**0.807**	**0.921**	**0.951**	**0.902**
AutoBorutaRF	0.653	0.652	0.654	0.650	0.711	0.646
DSPLMF	0.682	0.750	0.615	0.702	0.760	0.671
MOICVAE	0.772	0.787	-	0.775	0.856	0.764
CDSML	0.838	0.9031	-	0.8715	0.9157	0.842
Auto-HMM-LMF	0.70	0.78	0.63	0.73	0.78	0.77

VI. CONCLUSION AND DISCUSSION

In this study, we introduced DrugCellGNN, a pioneering Graph Neural Network framework that revolutionizes cancer drug sensitivity prediction by seamlessly integrating multi-omics data—encompassing gene expression, copy number variations, and mutations—with structural and functional similarities between drugs and cell lines. Leveraging the GDSC dataset, our pipeline addresses key challenges in pharmacogenomics, including data sparsity through hybrid imputation, high dimensionality via PCA reduction, and class imbalance with dynamic focal loss. Evaluated on 50141drug-cell pairs (80/20 train-test split), DrugCellGNN achieved an AUC of 0.9516, F1-score of 0.9228, and AUPR of 0.9698, outperforming traditional baselines Random Forest and SVM by leveraging relational dependencies. These results highlight DrugCellGNN's ability to model complex interactions, enhancing prediction accuracy for rare sensitive cases critical in precision oncology. A key factor contributing to the effectiveness of DrugCellGNN is the integration of functional and structural similarity information for both drugs and cell lines. By combining response-based similarities with molecular and chemical features, the constructed graphs provide a biologically meaningful representation of drug–cell interactions. This fusion strategy allows the model to leverage complementary information, balancing phenotypic drug response patterns with intrinsic biological characteristics of cancer cell lines and chemical properties of drugs.

Future work should aim to expand this framework to other datasets, such as CCLE or CTRP, to evaluate how well it performs across different data sources. Using more advanced molecular representations (like transformer-based encoders or molecular graph embeddings) could boost predictive accuracy. Adding more layers of omics data, such as epigenomic or proteomic information, might also deepen the biological understanding. Lastly, integrating explainability features into

the GNN could reveal mechanistic insights by pinpointing which molecular features or graph edges most influence the predictions.

***Abstract*—In recent years, the rapid growth of the tourism industry and increasing demand for efficient and meaningful travel experiences have highlighted the need for smarter travel assistance tools. Many tourists, particularly first-time visitors, often face challenges navigating unfamiliar destinations and identifying relevant points of interest, leading to delays, inconvenience, and reduced satisfaction. During the peak tourist season, most local hotels and restaurants are overcrowded, and tourists have to find accommodation and food in unfamiliar places, which reduces their travel efficiency and experience. To address these challenges, this study proposes the PutrajayAR, a personalized Location-Based Augmented Reality (LBAR) tourism application designed to enhance tourists' efficiency and overall travel experience. The application provides AR Discovery and AR Recommendation features that dynamically present personalized points of interest based on user preferences, spatial proximity, and contextual constraints. The system was developed using the waterfall model and evaluated through black box testing, usability testing, and persuasive design assessment. The results demonstrate that PutrajayAR significantly improves user experience and satisfaction compared to non-personalized approaches, thereby validating the effectiveness of personalized LBAR systems in helping users navigate effectively and discover attractions that match their interests.**

***Keywords*—Augmented Reality; LBAR; PutrajayAR; AR Discovery; AR Recommendation**

I. Introduction

Augmented Reality (AR) is a technology that superimposes virtual imagery onto the real-world environment, creating an interactive and immersive experience for users [1]. AR is characterized by three core features: the integration of real and virtual elements, real-time interactivity and three-dimensional (3D) registration [2]. A subset of AR, Location-Based Augmented Reality (LBAR), is a markerless and geo-referenced technology that relies on GPS, accelerometers, digital compasses and other sensors to accurately determine the device's position and orientation [3]. With the widespread availability of these sensors in modern mobile devices, LBAR applications have become increasingly accessible to the general public. In parallel, the integration of the Internet of Things (IoT) and machine learning technologies is reshaping various industries, including tourism and automotive sectors, by enabling intelligent, data-driven decision-making [4].

In the era of the Fourth Industrial Revolution (4IR), digital transformation has become a driving force in economic and social development, especially in the tourism sector, where technological innovation plays a pivotal role in shaping new experiences and efficiencies [5]. Research indicates that AR-based tourism applications are more appealing to users than traditional promotional methods due to their immersive and dynamic nature [8]. As global tourism continues to expand, travelers increasingly seek personalized, efficient, and engaging experiences. AR technology contributes significantly to this shift by enhancing tourists' ability to access contextual information, explore destinations interactively, and deepen their understanding of the places they visit [6]. From personalized recommendations and interactive navigation to virtual guides and translation tools, the applications of AR in tourism are extensive and continually evolving. The virtual tourism market alone is projected to grow at a compound annual growth rate (CAGR) of 30.2% between 2023 and 2028, reaching an estimated value of USD 23.5 billion [7].

Despite the growing adoption of LBAR in tourism applications, most existing systems primarily focus on spatial awareness and static point of interest visualization, which rely on distance or category-based filtering mechanisms. As a result, there is an absence of empirical evidence illustrating the impact of personalized LBAR recommendations on user experience, satisfaction and perceived persuasiveness within tourism contexts. To address this gap, this study investigates the following research question:

RQ: How does integrating personalized recommendations into an LBAR affect user experience, satisfaction and perceived persuasiveness in tourism applications?

Therefore, this study proposes a personalized AR recommendation mechanism that integrates user preferences and situational constraints. The system also provides empirical evidence, through a comparative evaluation, that personalized POI can significantly improve user experience, satisfaction and perceived persuasiveness compared to non-personalized approaches. Overall, LBAR technology stands out for its usability, interactivity and personalization, offering tourists a unique and engaging way to explore their surroundings. The ongoing advancements in digital technology continue to elevate the quality and innovation of tourism systems, fostering more engaging and meaningful travel experiences.

The remainder of this study is organized as follows: Section II presents the related works on Location-based Augmented Reality, Section III describes the research methodology, Section IV discusses the results and Section V concludes the study.

II. Related Work

The PutrajayAR application is developed for the Android platform, using the Augmented Reality (AR) technology through modern smartphones. The choice of Android as the primary operating system is based on its widespread usage and compatibility with a wide range of mobile devices. According to a survey by Ruqiya [9], among 60 respondents, the majority expressed a preference for Android over iOS due to its user-friendly interface and superior system compatibility. Specifically, 90% of respondents favored Android, while only 10% preferred iOS. These findings indicate that Android-based applications are more popular and accessible to users, making it a suitable and strategic platform for implementing the PutrajayAR system.

A. Location-Based Augmented Reality

Location-based AR aims to seamlessly link physical location coordinates with the data processing environments, allowing users to view POI (Point of Interest) annotations of specific landmarks in the real environment [10]. Implementing this technology for navigation can significantly improve user actions to reduce travel time, especially when the application is designed for pedestrian use. Fig. 1 shows an example of location-based AR for navigation [11].

Fig. 1. Location-based AR for navigation.

Various devices can be used to apply the concept of location-based AR, such as mobile phones, special AR glasses, tablets and so on. These devices will function as output devices and will display information in the form of videos, pictures, animations and 3D models that need to be used. LBAR is divided into two types, namely Indoor LBAR and Outdoor LBAR.

1) Indoor LBAR: Indoor LBAR uses AR technology in enclosed spaces such as shopping malls, airports, museums and other indoor environments where GPS signals may be unreliable. The user's device detects nearby Wi-Fi access points [12] or communicates with nearby Bluetooth devices [13] to estimate their location, compensating for the instability of GPS signals indoors.

2) Outdoor LBAR: Outdoor AR typically relies on GPS and geolocation technology. According to Blanco's study [14], regular GPS provides approximate location with a standard accuracy of about 3 meters outdoors; differential GPS can also support higher positioning accuracy, which is sufficient for many applications. PokemonGo [15] is a very clear example; it is an AR-based mobile travel game developed by Niantic that combines a virtual game world with a real-world map, encouraging players to explore their surroundings to interact with virtual characters. Players use the app to walk around their local environment to find and catch Pokémon, which are often placed near real-world landmarks, historical sites and popular locations. This encourages users to visit and learn about new places in their area or while traveling.

In this scenario, we find that LBAR features provide users with great satisfaction through traveling experience efficiency and personalization.

B. Personalized Recommendation

Personalized Apps are software solutions designed to adapt to the preferences, behaviors and needs of individual users, offering a tailored experience. Personalized recommendations based on user behavior and preferences can make apps feel more customized and relevant to individual users. By using data analytics and machine learning, apps can deliver content and features that resonate with users, thereby increasing their overall satisfaction and engagement [16].

C. Existing Location-Based AR Tourism App

The rapid growth of the tourism industry, coupled with advances in mobile technology, has led to the emergence of numerous tourism-related mobile applications designed to provide travelers with more efficient and engaging experiences. While Augmented Reality (AR) has become an increasingly prominent feature in tourism application development, existing AR-based tourism solutions still face limitations.

1) AR City Guide: AR City Guide is an augmented reality city guide app designed to enhance the view by combining virtual information with the real-world environment. It offers users an immersive way to explore and learn about various locations while traveling. Users can use the phone's camera to scan buildings, landmarks, or attractions, and the app overlays information such as historical facts, architectural details and cultural insights directly onto the screen

Based on the user's current location, the app suggests nearby tourist attractions, restaurants and shopping areas, often with ratings and reviews from other users. Fig. 2 shows nearby suggestions in a city.

Fig. 2. Nearby suggestions in a city.

The app also provides AR-based navigation with virtual directional arrows overlaid on top of the real-world view, making it easier for users to find their desired destination. Fig. 3 shows the app's navigation functionality.

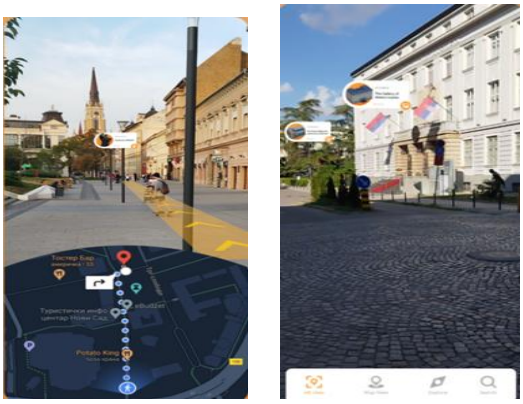

Fig. 3. Navigation function.

2) Horizon Explorer AR: Horizon Explorer AR is an augmented reality application designed to provide users with an interactive experience in exploring the landscape, landmarks and terrain around them. The application allows users to view real-world landscapes through their phone camera and receive detailed information about nearby points of interest (POIs) simply by pointing the device at them. Using GPS, Horizon Explorer identifies nearby locations and overlays the information directly onto the AR display. It offers details about landmarks, cities, mountains and other geographical features visible in the distance. Fig. 4 shows the geographical features of Horizon Explorer AR.

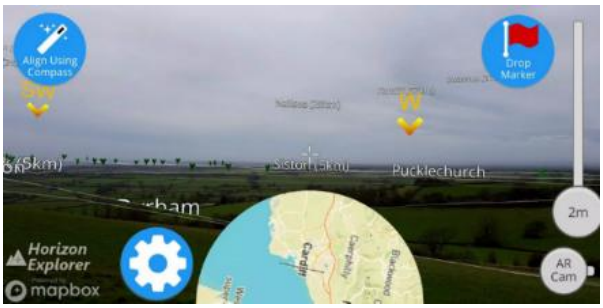

Fig. 4. Geographical features of Horizon Explorer AR.

As users pan their camera, the application displays the distance, elevation, and names of visible landmarks, allowing users to explore the surrounding terrain and understand the spatial relationships between different points. Horizon Explorer's interface is designed for simplicity, allowing users to switch between the map view and the AR view, making it intuitive to use. It offers both metric and imperial units of measurement, catering to the needs of a global audience. Fig. 5 shows the application's map view.

3) Word Around Me: World Around Me (WAM) is an augmented reality app that helps users explore and navigate their surroundings by overlaying information about nearby places directly onto the smartphone camera display. It is popular with tourists and those exploring new cities, as it provides details about a variety of categories, such as restaurants, ATMs, hospitals, transportation, entertainment venues and shopping options. Users can lift their phone and pan to see the names, ratings, distances and directions of nearby places overlaid on the live camera feed. This AR display helps users visualize where different places are in relation to their current location.

Fig. 5. Map view.

WAM covers a variety of categories, and users can filter results to focus on specific types of places. Categories include eateries, ATMs, pharmacies, parks, hotels, and more. Fig. 6 shows the WAM filter functionality. By tapping on a specific location in the AR display, users can access more detailed information such as reviews, hours of operation, contact details and navigation options, with integration into Google Maps and Apple Maps for seamless routing.

Fig. 6. WAM filter.

D. Comparison Between LBAR Apps

Table I shows the comparison between Location-based AR (LBAR) applications.

From this study, we found that previous studies have demonstrated that AR-based tourism applications are more engaging than traditional map-based or text-based guides due to their immersive nature [6], [7]. However, most existing LBAR tourism applications focus primarily on visualization and proximity-based information delivery. Points of interest are typically displayed based on static criteria such as distance or category, without considering individual user preferences or situational context. Applications such as AR City Guide and World Around Me emphasize nearby POI discovery and AR navigation but provide limited support for helping users decide

which attraction best matches their interests or constraints. As a result, users may still experience information overload and uncertainty when multiple POIs are presented simultaneously in the AR view. After comparing and studying the applications, we found that personalized LBAR technology will help tourists to travel easily, especially when they first arrive in an unfamiliar place. AR and POI displays can provide users with the exact location of buildings. Some new functions, such as POI filters and personalized recommendations also provide a higher quality of service and attract new customers.

TABLE I. COMPARISON BETWEEN LBAR APPLICATIONS

Application	AR City Guide	Horizon Explorer AR	World Around Me
Device	Smart Phone, AR Glasses	Smart Phone	Smart Phone
Language	English	English	English
Main Function	AR City Navigation. Recommend nearby landmarks based on the distance between user device and places.	Wild Terrain and Village Exploration based on user GPS detection. Calculation on the distance between users and each POI.	AR City Navigation. Filter places based on user selected categories.
Technology	• Location-based AR, • Visual Positioning System, • Simultaneous Localization and Mapping, • Real-time Location System, • GPS, • Geographic Information System • Distance Calculation	• Location-based AR, • GPS, • Geographic Information System, • Distance Calculation	• Location-based AR, • Real-time Location System, • Simultaneous Localization and Mapping, • Categorized POI,
POI Filter Types	Based on user needs and POI Categories	Based on distance	Based on user needs and POI Categories
Personalized Recommendation	Based on distance	None	None

III. METHODOLOGY

System design is a crucial stage in the software development process that defines how the system's components, architecture and data structures interact to achieve the intended functionality. It serves as the bridge between user requirements and the actual implementation, ensuring that the system is both functional and maintainable [17]. In this study, system design establishes the foundation for developing the PutrajayAR application, outlining how its modules, databases and user interfaces integrate to deliver a personalized, location-based augmented reality (LBAR) experience for tourists. According to Sommerville [18], the goal of system design is to transform the requirements specification into a blueprint that describes the overall structure of the system. For *PutrajayAR*, this involves defining the system architecture, database schema, algorithmic logic, and user interface flow to ensure that all components operate cohesively and efficiently.

A. Architecture Design

The initial phase of the design process is the architectural design, which shows the functionality of the application, including interaction design, experience, process and strategy. For the PutrajayAR application, layered design and hierarchy diagrams were used to illustrate the interactions between entities and the application.

1) Layered design: The most commonly used architectural pattern is the layered architectural pattern, or known as n-tier. The architectural pattern is widely used in design and development. This modular structure enhances scalability, reusability, and ease of maintenance [19]. It also ensures that modifications in one layer do not affect others, thereby improving development efficiency. The components in this layered architectural pattern are arranged into horizontal layers. Each layer has a specific role in the application. Fig. 7 shows the layers found in the PutrajayAR application architectural pattern. The first layer shows the presentation logic; this layer is what interacts with the user through the application interface.

Then the second layer is the processing layer. This layer shows the system functions and procedures based on the rules layer. Among the services available are that users can register an account, log in, edit their profile, use AR Discovery and AR recommendations. This layer also determines how the menus, buttons and navigation of the application work through the application interface. This second layer is also known as the business rules layer and the application core because it contains the rules that determine the overall response of the application, as well as the server that contains the main program, code definitions and basic functions of the application. Programming works in this layer almost all the time.

Finally, the data storage layer. This layer contains the data used by the application. Search, insert, delete and update operations are performed in this layer. Examples of databases used by applications are the AR Database which stores data to be displayed when the camera detects a POI without a marker and also the User Database which stores user profile information such as username, email, password and user travel preferences and so on.

2) Hierarchy Diagram: Hierarchy diagrams are used to explain the breakdown of the overall process in a system or application into a more detailed form. Users can log in directly to the application or register an account first if they do not have any account.

In addition, this application provides a profile form for users to edit and record their user information into the database. This profile requires content types that are typical user information,

such as username, email and country. PutrajayAR also asks users to complete their travel choices, such as shopping, sightseeing or food hunting. For each travel choice, there are several subtopics for the user to choose from, for example, when the user chooses food hunting as the travel choice, the application will ask the user to select their subtopic, such as Malay cuisine, Chinese food or Indian cuisine.

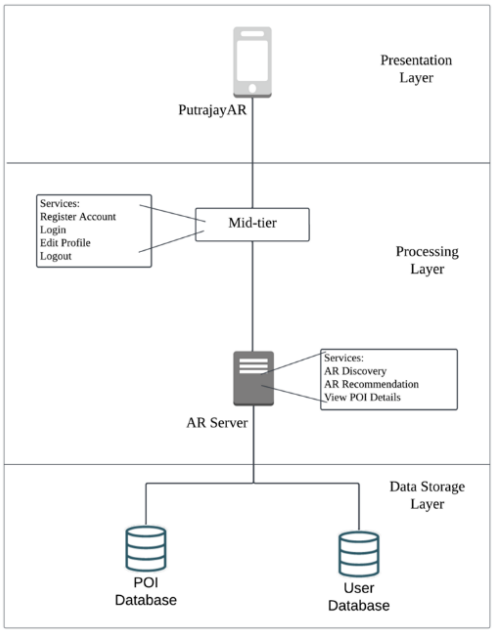

Fig. 7. Layered design of the app.

In addition, this application includes an AR Discovery feature that allows users to scan their surroundings and display nearby POIs directly on the screen. To help users easily find POIs that match their current needs, this application supports two filtering options: category filtering and distance slider. By selecting a category, the app filters and displays only relevant POIs. The distance slider allows users to adjust the search radius and view POIs within a certain range of their location.

The final module is AR Recommendations, which not only includes all the features of AR Discovery, but also enhances the experience by providing personalized POI annotation suggestions based on the user's device settings, current weather and travel preferences. For example, the app can recommend places that are open for business based on the time settings on the user's device and it can also suggest locations that align with the user's travel interests for a more personalized experience.

B. Database Design

Database design is a set of steps that help create, implement and maintain a data management system. The main purpose of database design is to produce a physical and logical design model for a database system that will be used in application development. This design will determine the data that is stored and how the data elements are related to each other. Among the database designs that will be used for the development of the PutrajayAR application are class diagrams and data dictionaries.

1) Class diagram: Class Diagram is a structural diagram used to describe classes and attributes, methods and relationships between classes in a system. It is an important tool for object-oriented design and development, helping developers have a clear understanding of the structure and logic when building a system. Fig. 8 shows the class diagram of the PutrajayAR application. In the diagram, we can clearly see the system components and their responsibilities.

Each User class is a composition of the User Device class and the User Profile class. Each POI can belong to one POI Category, while one POI Category can include many POIs. Users can communicate with POIs through AR Suggestions. Each user can get one POI suggestion, which is a list of recommended POIs based on their profile and device settings. The POI can include one or many POIs. Another communication method between users and POIs is AR Discovery, where each user can get one result after opening the camera, which is a list of nearby POIs based on the selected category. Each AR scan result can include one to many POIs.

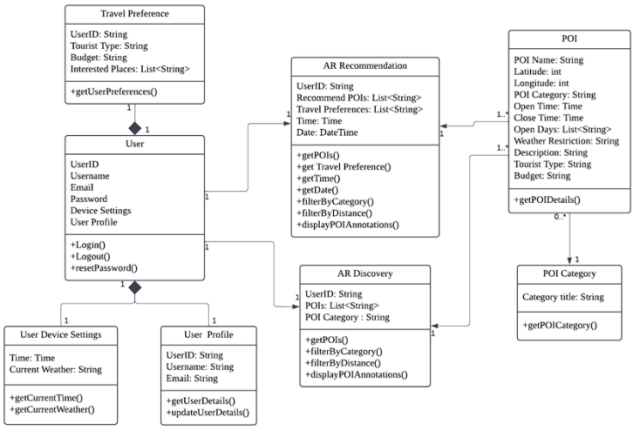

Fig. 8. Class diagram of the app.

2) Data dictionary: The data dictionary contains meta data, which is data about the database. The data dictionary is important because it determines who is allowed to access the data in it. Users do not interact directly with the data dictionary, it is only managed by the database administrator. The data dictionary contains information about the data name, data type, data length and also physical information about the data stored. There are 11 different types of data used to manipulate program programming. Each data has a specific data space allocated.

C. Algorithm Design

Algorithm design is a mathematical method or process for solving problems. Algorithm design also acts to solve problems more efficiently by minimizing the use of space, time and memory. Therefore, algorithm design plays a role in ensuring the development of applications according to the specified time. Among the algorithms that will be explained are application flowcharts and pseudocode.

1) Flowchart: A flowchart is a visual representation of the sequence and decisions required to carry out a process. Fig. 9 shows a flowchart diagram for the PutrajayAR application. This flowchart shows the activities that will be performed by the user of this application.

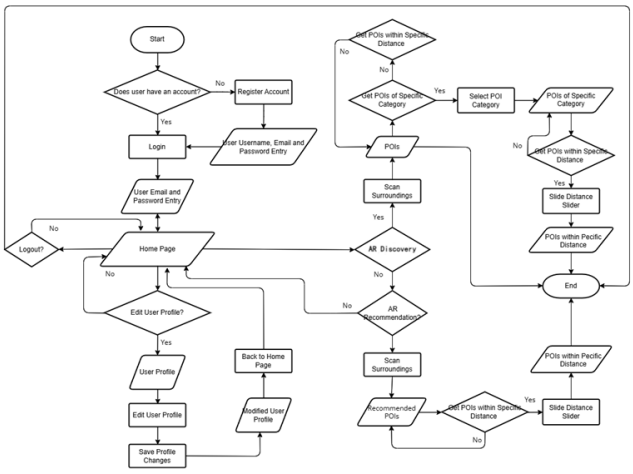

Fig. 9. Flowchart.

2) Pseudocode: In algorithm design, pseudocode is a description method between natural language and real programming language, used to clearly express the logic of an algorithm. Pseudocode is often used to help algorithm designers and developers record and communicate complex algorithmic processes in a structured way. Table II illustrates the pseudocode governing the distance- and category-based POI filtering process, demonstrating how user inputs and device location data are combined to determine which POIs are displayed in the AR interface.

TABLE II. PSEUDOCODE OF THE ALGORITHM DESIGN IN SCENARIO 1

Scenario 1: The user wants to find POIs that are a certain distance from the user's device and belong to the selected category.
Parameter: Interactive Input: POI Category, Distance Adaptive Input: POI Coordinates, Device Coordinates
Pseudo code: START INPUT "Food Hunting," "300 meters" IF POI of Category Food Hunting exist AND POI Coordinates and Device Coordinates are within a 300-meter radius. THEN Display POI OUTPUT Display the POIs of Category Food Hunting within a 300-meter distance form user.

D. Interface Design

Fig. 10(a) shows the login interface of this application. The login interface has two text fields that allow the user to enter the registered email and password to log in to the application. If the user does not have an account, the user can register a new account by pressing the "Register" button and the application will switch to the account registration interface. Fig. 10(b) shows the account registration interface, where the user is asked to fill in three text fields to register a new account, namely the user's username, email and password. After completing all the text fields, the user needs to press the "Register" button to continue.

Fig. 11 shows the Home interface of the application, which contains menu options consisting of the "AR Discovery" and "AR Recommendation" buttons. Users can change their travel preferences in the Travel Preferences interface. Fig. 12 shows the Travel Preferences interface, which contains the user's traveler type, budget, and interests. Once the preference changes are saved, the system will redirect to the Home interface, and all current preferences will be considered as the basis for recommendations in the AR Recommendations interface.

(a)

(b)

Fig. 10. (a) Login interface; (b) Register account interface.

Fig. 11. Home page interface.

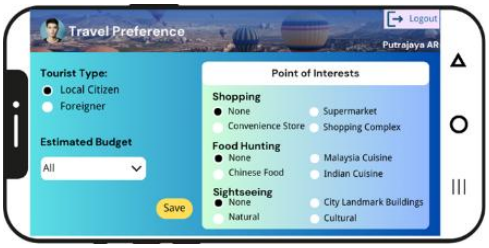

Fig. 12. Travel preference interface.

Fig. 13 shows the AR Discovery interface of the application. This interface consists of POI, POI Category and Distance Slider. When the user opens the camera, the POI will be displayed on the screen. By default, the POI belongs to all categories and is displayed within 100 meters from the user. The user can select the POI category to get the desired POI. If the user selects the Food Hunting Category, the screen will only display the POI that matches the food hunting.

Fig. 14 shows the AR Recommendation interface of the application, when the user opens this interface and opens the camera, the system will get the user's travel preferences from

the user's profile data and display the POI that matches the user's preferences. Users can also slide the distance slider of the AR Suggestions interface to get POIs within a certain distance, if the user slides the distance to 300 meters, the screen will only display POIs within 300 meters from the user.

Fig. 13. AR Discovery interface; get POIs matched with the selected category.

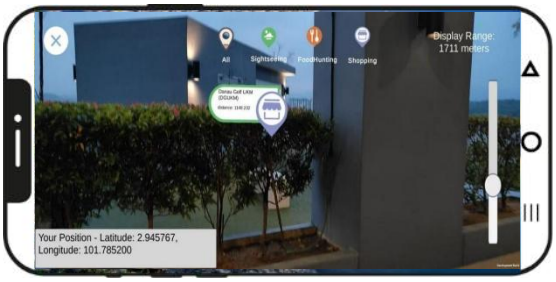

Fig. 14. AR Recommendation interface.

Fig. 15 shows the POI Details interface of this application. The user can get the POI details by clicking any POI on the screen, then the system will display the POI Details interface with the POI's related place information, such as description and opening hours.

Fig. 15. POI detail interface.

IV. Results and Discussion

A. Test Techniques

The testing of the PutrajayAR application was carried out with the aim of ensuring that all application components were well connected, functioning smoothly and met user needs well. The testing of this application was carried out using two techniques, namely black-box testing and usability testing.

1) Black-box testing: Black-box testing aims to validate the functionality of a software application by providing appropriate inputs and checking the outputs against the expected results based on functional requirements [20][21]. For the PutrajayAR application, black-box testing was carried out in four steps: test items, test case specification, test procedure specification and test log.

The functionality of the *PutrajayAR* application was verified through black-box testing, which focused on assessing whether each module performed according to its specified requirements. The testing process involved defining a set of input conditions and expected outputs for critical modules, including user authentication, profile management, AR Discovery and AR Recommendation. Each function was tested independently to ensure that valid input produced the correct results and invalid inputs were handled appropriately. The results indicated that all tested features operated successfully without critical errors or failures, confirming that the system's functional requirements were fully met. For instance, user login and registration processes returned accurate system responses and POI filtering in both discovery and recommendation modules produced consistent and correct outputs based on user preferences.

2) Usability testing: Usability testing is a method used to evaluate and test products from a user perspective. This test aims to verify that the product is suitable and easy to use [22][23]. Usability testing of the PutrajayAR application was conducted to obtain reactions or feedback from target users when they use this application. This feedback is very important to identify weaknesses and shortcomings of the application that are not noticed by the developer. Representative users aged 20–30 were asked to perform common tasks within the app to evaluate the intuitiveness, ease of use, interface clarity and overall user satisfaction.

B. Test Result

The success of this usability test was made possible through the participation of 40 respondents of various ages and genders. Each participant was given access to the PutrajayAR app to explore its features and functionalities. After using the app, they were asked to complete a questionnaire designed to gather feedback on their user experience. This structured approach ensured that insights were collected directly from real users, thus providing valuable data to evaluate the usability of the app.

1) Respondent demographics: Out of the 40 participants, 52.5% (21 respondents) were male, while 47.5% (19 respondents) were female. All respondents were residents of Putrajaya and were between the ages of 20 and 30. Table III shows the distribution of participants by age and gender.

TABLE III. Respondent Demographics

Age	Gender		Amount	Percentage
	Male	Female		
22	8	2	10	25.0%
24	2	4	6	15.0%
26	8	7	15	37.5%
27	2	4	6	15.0%
29	1	2	3	7.5%
Amount	21	19		
Percentage	52.5%	47.5%		

2) User satisfaction: User satisfaction testing was conducted to assess user perceptions and experiences across four key aspects: usability, satisfaction, ease of use and ease of learning. The questionnaire items used in this evaluation were adapted from the USE (Usefulness, Satisfaction and Ease of Use) questionnaire, a well-established instrument for measuring software usability [24]. This approach aligns with the ISO 9241-11:2018 standard, which defines usability as the extent to which a system can be used by specified users to achieve specified goals effectively, efficiently and satisfactorily [25] (International Organization for Standardization, 2018). Participants rated their experience on a five-point Likert scale and the results were analyzed to determine perceived satisfaction and system usability. Similar methodologies have been widely used in software usability research for assessing user experience quality and satisfaction [26]. Table IV presents the mean and scores for each test section.

TABLE IV. MEAN VALUES OF THE TESTING QUESTIONS ABOUT USER SATISFACTION

Construct	Non-Personalized		Personalized	
	Mean	Standard Deviation	Mean	Standard Deviation
Usefulness	3.59	0.61	4.38	0.64
Satisfaction	3.95	0.53	4.17	0.47
Ease of Use	4.21	0.49	4.46	0.39
Ease of Learning	4.22	0.48	4.50	0.40

In this test, the average score for all domains was above 3.68, indicating that users strongly agreed with the positive statements about the PutrajayAR application. For each section, the average score recorded for the personalized functions was higher than that of the non-personalized functions. Based on these findings, it can be concluded that users showed a high level of overall satisfaction with the application and showed a clear preference for its personalized features.

3) Persuasive design: Persuasive design testing was conducted to assess the extent to which PutrajayAR helped users achieve their goals, interact with them and persuade them across three key aspects: primary task support, dialogue support and persuasive perception. The questionnaire items used in this evaluation were adapted from Letho's study on factors influencing persuasive perceptions of behavior change [27]. Table V presents the mean scores for each test section.

For the test for persuasive perception, the main task aspect achieved an average score of around 3.68 on a 5-point Likert scale, with the remaining two aspects achieving mean scores exceeding this value, indicating that users agreed with the positive statements about the PutrajayAR application. For each section, the mean scores recorded for the personalized functions were higher than the non-personalized functions. Based on these findings, it can be concluded that users gave a relatively high overall rating to the persuasive design of the application and showed a clear preference for its personalized functions.

TABLE V. MEAN VALUES OF THE TESTING QUESTIONS ABOUT PERSUASIVE DESIGN

Construct	Non-Personalized		Personalized	
	Mean	Standard Deviation	Mean	Standard Deviation
Primary Task Support	3.59	0.61	4.38	0.64
Dialogue Support	3.95	0.53	4.17	0.47
Perceived Persuasiveness	4.21	0.49	4.46	0.39

In addition, 2 open-ended questions, as shown in Table VI, were used to test the persuasive design of the PutrajayAR personalization.

TABLE VI. OPEN-END QUESTIONS FOR PERSONALIZATION

Question		High Frequency Words	Amount
No.1	Any suggestions for improving the app's features or personalization?	Recommendations Include Region-based Local Events	4 2 2 2 2
No.2	How did the personalized recommendations influence your decision-making?	Recommendations Influenced Confidence	2 2 2

Word Frequency Analysis was used to analyze open-ended question data. For the open-ended question "Any suggestions for improving the app's features or personalization?" Analysis of user responses revealed that the term "recommendations" appeared most frequently (4 times), followed by "region-based" (2 times), "local" (2 times) and "events" (2 times). These keywords highlight the key areas where users believe improvements are necessary. Users generally suggested enhancing the personalization features of the app by focusing on more accurate recommendations, region-specific content, and greater control over customization options.

For the open-ended question "How did the personalized recommendations influence your decision-making?", the analysis revealed that the word "recommendations" appeared most frequently (2 times), along with "influenced" (2 times) and "confidence" (2 times). These keywords indicate that the personalized recommendations generally helped users make quicker and more confident decisions by filtering down choices and providing relevant suggestions. However, a few respondents reported minimal impact, mentioning that they either ignored the recommendations or found them only moderately useful.

C. Discussion

This study examined the LBAR system by integrating personalized POI recommendations directly into LBAR tourism application that improves user experience, satisfaction and perceived persuasiveness compared to non-personalized approaches. The findings provide both technical validation of the proposed system and empirical insights into the role of personalization in LBAR tourism applications. Functional testing confirmed that core modules of PutrajayAR operated reliably and met the specified design requirements. Besides, user evaluation results show that the personalized mode consistently outperformed the non-personalized mode through usability and

persuasive design testing. Higher scores in usefulness, satisfaction, ease of use, ease of learning, primary task support, dialogue support and perceived persuasiveness indicate that personalization embedded within the LBAR interface enhances both interaction quality and decision-making effectiveness.

The persuasive design findings further support this advancement by demonstrating that personalized AR recommendations increase users' confidence and perceived support when selecting POI. Moreover, Qualitative feedback reinforces this observation, with users reporting that personalized recommendations reduced uncertainty and improved decision efficiency. These findings validate personalization as a core interaction strategy rather than an optional enhancement in LBAR tourism systems.

V. Conclusion

This study sets out to address a key limitation in existing location based on augmented reality tourism applications, which lack effective personalization elements to support tourists' decision-making in unfamiliar environments. PutrajayAR was designed and developed as a personalized location-based augmented reality tourism application that combines user profiles, contextual constraints and real-time spatial data to deliver point of interest recommendations through an augmented reality interface. The findings from system testing and user evaluation provide clear evidence that personalization embedded within the augmented reality interaction layer offers measurable benefits beyond conventional non personalized location based augmented reality approaches. Results from usability and persuasive design evaluations indicate that personalized augmented reality recommendations significantly improve perceived usefulness, satisfaction, ease of use, and decision confidence. These outcomes show that users benefit from the contextual relevance achieved when LBAR content is dynamically filtered based on individual preferences and situational factors. This validates the core research premise that personalized LBAR systems are better suited to support tourists' efficiency and experiential quality than generic distance or category-based augmented reality guides. This study also contributes empirical support for the role of personalization as a critical design dimension in LBAR tourism systems. Rather than treating personalization as an optional feature layered onto navigation or discovery tools, the results show that integrating personalization directly into real-time LBAR point of interest annotation enhances both functional effectiveness and user perception. The comparative evaluation between personalized and non-personalized modes further reinforces that these gains are attributable to the personalization mechanism itself, not simply to the presence of augmented reality technology. In conclusion, the development and evaluation of PutrajayAR demonstrate that personalized LBAR applications represent a meaningful advancement over existing augmented reality tourism solutions. By empirically linking personalized augmented reality interaction to improved user outcomes, this study provides design insights and validation for future research and development of intelligent and context aware augmented reality tourism systems.

Acknowledgment

We would like to express our highest appreciation and heartfelt thanks to the Faculty of Information Science and Technology (FTSM) for their support and sponsorship of this study.

Multi-Class Object Detection Using Quantized YOLOv11 for Real-Time Inference

Yehia A. Soliman[1], Amr Ghoneim[2], Mahmoud Elkhouly[3]
Faculty of Computers and Artificial Intelligence-Information Technology Department, Helwan University, Cairo, Egypt[1, 3]
Faculty of Computers and Artificial Intelligence-Computer Science Department, Helwan University, Cairo, Egypt[2]

***Abstract*—Real-time multi-class object detection on embedded devices poses significant challenges due to limited computational power, memory capacity, and energy efficiency requirements. Conventional high-precision object detectors, such as YOLOv11, deliver outstanding accuracy but are computationally intensive, making them unsuitable for deployment on resource-constrained hardware. This study presents a quantized implementation of the YOLOv11 model designed to enable efficient real-time inference on embedded platforms. The proposed approach applies post-training integer quantization and mixed-precision optimization to minimize computation and memory usage while maintaining detection accuracy across multiple object categories. Experimental evaluations were conducted on the COCO and Pascal VOC datasets. The results indicate that the quantized YOLOv11 achieves a 3.2× increase in inference speed, a 2.7× reduction in memory footprint, and a 35% improvement in energy efficiency, with less than 2% loss in mean Average Precision (mAP) compared to the full-precision baseline. The optimized model sustains real-time performance exceeding 45 frames per second (FPS), demonstrating that quantization is a viable and effective approach for deploying high-performance object detection models on embedded systems.**

Keywords*—Quantized neural networks; YOLOv11; object detection; embedded systems; real-time inference; model optimization

I. Introduction

The growing integration of intelligent vision systems into autonomous drones, surveillance networks, and Internet of Things (IoT) applications has increased the demand for real-time on-device object detection [1, 2]. Deploying inference directly on embedded devices reduces dependence on cloud infrastructure, thereby lowering latency, improving data privacy, and enabling continuous operation in bandwidth-limited environments. However, these devices typically feature limited computational resources, constrained memory, and strict power budgets. Traditional high-precision deep learning models, though highly accurate, are unsuitable for such hardware due to their intensive floating-point computations and large model sizes [3, 4]. Therefore, developing efficient and compact neural networks capable of real-time performance remains a significant research challenge in embedded artificial intelligence.

Object detection plays a vital role in computer vision tasks such as autonomous navigation, industrial inspection, and human-computer interaction [5]. Among the most prominent detectors, the You Only Look Once (YOLO) family has evolved rapidly from YOLOv1 to YOLOv11, introducing architectural innovations that enhance accuracy while maintaining high inference speed [6, 7, 8]. YOLOv11, the latest in this series, integrates improved feature fusion and efficient attention mechanisms for multi-scale detection. Despite these advances, high-precision YOLO models are computationally demanding, posing difficulties for deployment on low-power devices [9, 10].

Quantization has emerged as a promising technique to mitigate this limitation. By representing model parameters and activations using reduced numerical precision (e.g., 8-bit integers instead of 32-bit floats), quantization reduces memory footprint, bandwidth usage, and computational complexity [11, 12, 13]. This process allows models to run efficiently on specialized embedded accelerators such as NVIDIA TensorRT [14], TensorFlow Lite [15], and ONNX [16] Runtime backends while maintaining near-original accuracy.

Although previous research has explored quantization in deep neural networks, few studies have specifically examined its application to the YOLOv11 architecture for multi-class object detection on embedded devices. Existing approaches often exhibit significant accuracy degradation or lack optimization for hardware-specific accelerators. Furthermore, systematic evaluations of quantization trade-offs covering inference speed, energy efficiency, and accuracy across bit-width configurations remain limited [17, 18]. These gaps highlight the necessity for a comprehensive framework that integrates advanced quantization strategies with modern YOLO architectures to achieve real-time performance on constrained hardware.

To address these challenges, this study proposes an optimized quantized YOLOv11 framework for efficient multi-class object detection on embedded devices. The key contributions are as follows:

- Design and implementation of a quantized YOLOv11 model tailored for embedded GPUs and NPUs, enabling low-latency and energy-efficient inference.
- Evaluation of precision speed trade-offs across multiple quantization bit-widths to identify the optimal balance between accuracy and performance.
- Comprehensive experimental validation on benchmark datasets, including COCO [19] and Pascal VOC [20].

The remaining sections of the study are organized as follows: Section II reviews related work, Section III discusses

the proposed approach, Section IV presents the experimental results and discussion, and Section V concludes the study.

II. Related Work

This section reviews prior work relevant to object detection architectures with emphasis on the YOLO family, quantization techniques for neural networks, and optimization strategies for embedded inference, as illustrated in Table I. It concludes with a gap analysis that motivates the present study.

Alshammry, Nizal, et al. [21] present a method to optimize the YOLOv5m object detection model for deployment on resource-constrained embedded systems. Q_YOLOv5m is a quantized version of YOLOv5m that uses Quantization-Aware Training (QAT) and Post-Training Quantization (PTQ) to reduce computational complexity and memory usage while maintaining acceptable detection accuracy. By converting 32-bit floating-point weights and activations to 8-bit integers, the model achieves a smaller size and faster inference speed. Experiments using the COCO 128 dataset showed that Q_YOLOv5m decreased model size from 90 MB to 40 MB and improved inference speed from 12 ms to 8.5 ms per frame, with only minor losses in precision and recall. The authors used COCO-128, a tiny subset (128 images) of the full MS COCO dataset. This is insufficient to evaluate object detection models, especially for accuracy comparisons. There is no mention of the specific embedded hardware used for inference testing (e.g., Raspberry Pi, Jetson Nano, ARM MCU).

Guerrouj, Fatima Zahra, et al. [22] investigate the quantization of the YOLOv4 object detection model to enable real-time inference on resource-constrained. By applying TensorRT-based post-training quantization (FP16 and INT8), the study significantly reduces model size and computation requirements while maintaining competitive detection accuracy. Using the KITTI dataset, experiments demonstrate that INT8 quantization achieves up to a 65% reduction in model size and a fivefold increase in inference speed on Jetson Nano, reaching near real-time performance with minimal accuracy loss. The study highlights the trade-offs between accuracy and efficiency, concluding that quantization offers a practical solution for deploying deep learning models on lightweight edge devices, with future work focusing on quantization-aware training and adaptive precision strategies.

Moon, Hyeon-Cheol, et al. [23] introduce YOLOv6+, an enhanced version of YOLOv6 designed for efficient INT8 inference on low-power mobile platforms. The model improves quantization performance through two key innovations: 1) adding skip connections within re-parameterization blocks (Repblock_add) to reduce dynamic range and quantization error, and 2) proposing a Regression Normalization (RN) method to align bounding box and class prediction ranges, mitigating accuracy loss during TensorFlow Lite conversion. Experiments on the COCO 2017 dataset demonstrate that YOLOv6+ achieves higher mean average precision (mAP) and better quantization robustness than YOLOv6 and YOLOv8, while maintaining comparable inference speed and lower power consumption on mobile hardware. The experiments are limited to the COCO 2017 dataset and a single mobile device. Broader validation across datasets (e.g., VOC) or hardware (e.g., NVIDIA Jetson) would strengthen generalizability claims.

Moosmann, Julian, et al. [24] introduce TinyissimoYOLO, a quantized, memory-efficient, and ultra-lightweight object detection network designed to enable real-time object detection on low-power microcontrollers with less than 0.5 MB memory available for storing CNN weights. The network is trained using quantization-aware training on the WiderFace and Pascal VOC datasets. It was deployed with 8-bit quantization on various microcontrollers, including STM32 and Apollo4b. TinyissimoYOLO achieved a mean average precision (mAP) of 45% on the WiderFace dataset (up to 73% with restricted evaluation) and up to 57% mAP on a restricted PascalVOC dataset for person, chair, and car classes.

TABLE I. Comparative Summary of Related Works

Model Name	Year	Method	Dataset	Bit Width	Limitations
Q_YOLOv5m [21]	2025	Post-Training Quantization (PTQ) and Quantization-Aware Training (QAT)	COCO	INT8	The authors used COCO-128, a tiny subset (128 images) of the full MS COCO dataset. This is insufficient to evaluate object detection models, especially for accuracy comparisons.
YOLOv4 [22]	2025	Post-Training Quantization (PTQ)	KITTI	INT8	It does not introduce new quantization algorithms, hybrid precision strategies, or architectural modifications to YOLOv4. The KITTI dataset is small for robust generalization. Also, it used an old version of the YOLO family.
YOLOv6+ [23]	2025	Regression Normalization	COCO	INT8	The experiments are limited to the COCO 2017 dataset and a single mobile device. Broader validation across datasets (e.g., VOC) or hardware (e.g., NVIDIA Jetson) would strengthen generalizability claims.
TinyissimoYOLO [24]	2023	Quantization-Aware Training (QAT)	WiderFace and Pascal VOC	INT8	The small input size (88×88) severely limits detection accuracy for complex scenes. Only up to 3 object classes are demonstrated. This limits generalizability to real-world multi-class detection problems.
Q-YOLO [25]	2023	Post-Training Quantization (PTQ)	COCO	INT8	Quantizing activation values only, quantizing weights causes larger performance degradation than quantizing activation values.

Wang, Mingze, et al. [25] introduce a low-bit quantization method to build a one-stage detector, dubbed as Q-YOLO, which can effectively address the performance degradation problem caused by activation distribution imbalance in traditional quantized YOLO models. It is a quantized version of YOLO for real-time object detection on resource-constrained devices. Q-YOLO introduces a fully end-to-end Post-Training Quantization (PTQ) pipeline with a well-designed Unilateral Histogram-based (UH) activation quantization scheme, which determines the maximum truncation values through histogram analysis by minimizing the Mean Squared Error (MSE) quantization errors. Extensive experimental results on the COCO dataset show Q-YOLO outperforms other Post-Training Quantization (PTQ) methods. The 8-bit Q-YOLO applied to YOLOv7 achieves 3× acceleration while maintaining comparable performance to full-precision models. Quantizing weights causes larger performance degradation than quantizing activation values. Asymmetric quantization exhibits higher accuracy than symmetric quantization.

Despite extensive work in detection architectures, quantization algorithms, and embedded toolchains, several gaps remain with respect to modern YOLO variants and multi-class detection on resource-constrained hardware. First, while quantization methods are well studied for classification and some detection backbones, there is limited published evidence on systematic quantization of the most recent YOLO architectures (e.g., practitioner/academic successors to YOLOv4/v5) with rigorous multi-class detection benchmarks on embedded devices. Second, many PTQ approaches either assume modest model sensitivity or require large calibration sets; detector heads and multi-scale features are particularly vulnerable to naïve quantization, causing drops in mAP that are not well characterized in the literature. Third, while individual optimization techniques (pruning, QAT, distillation) are well known, holistic pipelines that combine quantization with hardware-aware optimizations (TensorRT/TFLite/ONNX) and report energy, latency, and accuracy trade-offs across real embedded platforms remain sparse. These gaps motivate a focused study of quantized YOLOv11 variants, tuned quantization strategies (PTQ vs. QAT vs. mixed precision), and an end-to-end deployment/evaluation pipeline on representative embedded devices.

III. Methodology

This section details the architectural framework of the proposed quantized YOLOv11 model, the quantization methodology adopted, deployment optimization strategies for embedded inference, and the experimental setup used for evaluation.

A. Model Overview

The proposed framework is based on the YOLOv11 architecture, as illustrated in Fig. 1, a recent evolution of the YOLO family known for its enhanced efficiency and detection accuracy. YOLOv11 builds upon YOLOv8 and YOLOv10 by introducing refined backbone–neck–head coupling and improved feature aggregation mechanisms. The backbone employs a CSP-based (Cross Stage Partial) structure that integrates convolutional blocks with Efficient Layer Aggregation Networks (ELAN) to improve gradient flow and feature reuse. This design allows the model to maintain high representational power while reducing redundant computation compared to YOLOv8.

The neck module incorporates a Bi-directional Feature Pyramid Network (BiFPN), enabling multi-scale feature fusion by balancing contributions from different feature resolutions. This enhances small-object detection, a known limitation in earlier YOLO versions. The detection head follows a decoupled design that separates classification and bounding box regression branches, thereby accelerating convergence and improving precision and recall consistency. Unlike YOLOv10, YOLOv11 integrates dynamic label assignment and adaptive anchor generation, which improves detection generalization across diverse object classes. The combination of these architectural refinements results in improved real-time inference capability without compromising detection accuracy.

B. Quantization Approach

To enable efficient deployment on resource-constrained embedded devices, the full-precision YOLOv11 model (32-bit floating-point) was quantized using both Post-Training Quantization (PTQ) and Quantization-Aware Training (QAT) strategies.

- Post-Training Quantization (PTQ): The pre-trained YOLOv11 model was statically quantized to 8-bit integer (INT8) precision for weights and activations without retraining using a representative calibration dataset. Calibration statistics were collected from 500 randomly selected images from the COCO and Pascal VOC validation sets to compute dynamic ranges for each layer.
- Quantization-Aware Training (QAT): The model was fine-tuned for 100 epochs with simulated quantization during forward passes, allowing the network to adapt to quantization-induced noise. QAT allowed the model to learn quantization effects, improving robustness and accuracy compared to static PTQ.
- Quantization was formulated mathematically as Eq. (1):

$$Xq = \text{clip round } \frac{X}{S} + Z, q_{min}, q_{max} \quad (1)$$

where, X is the original floating-point value, Xq is the quantized integer value, S is the scaling factor, and Z is the zero-point. The reconstructed value is obtained via dequantization, as in Eq. (2):

$$X = S \; x \; (Xq - Z) \quad (2)$$

Per-channel quantization was applied to convolutional weights to retain fine-grained precision, while per-tensor quantization was used for activation to ensure computational efficiency. Mixed-precision quantization (INT8 weights with INT8 activations) was also evaluated to balance throughput and accuracy. This quantization process substantially reduced model size and computational demand, enabling deployment on low-power devices without significant loss in detection accuracy.

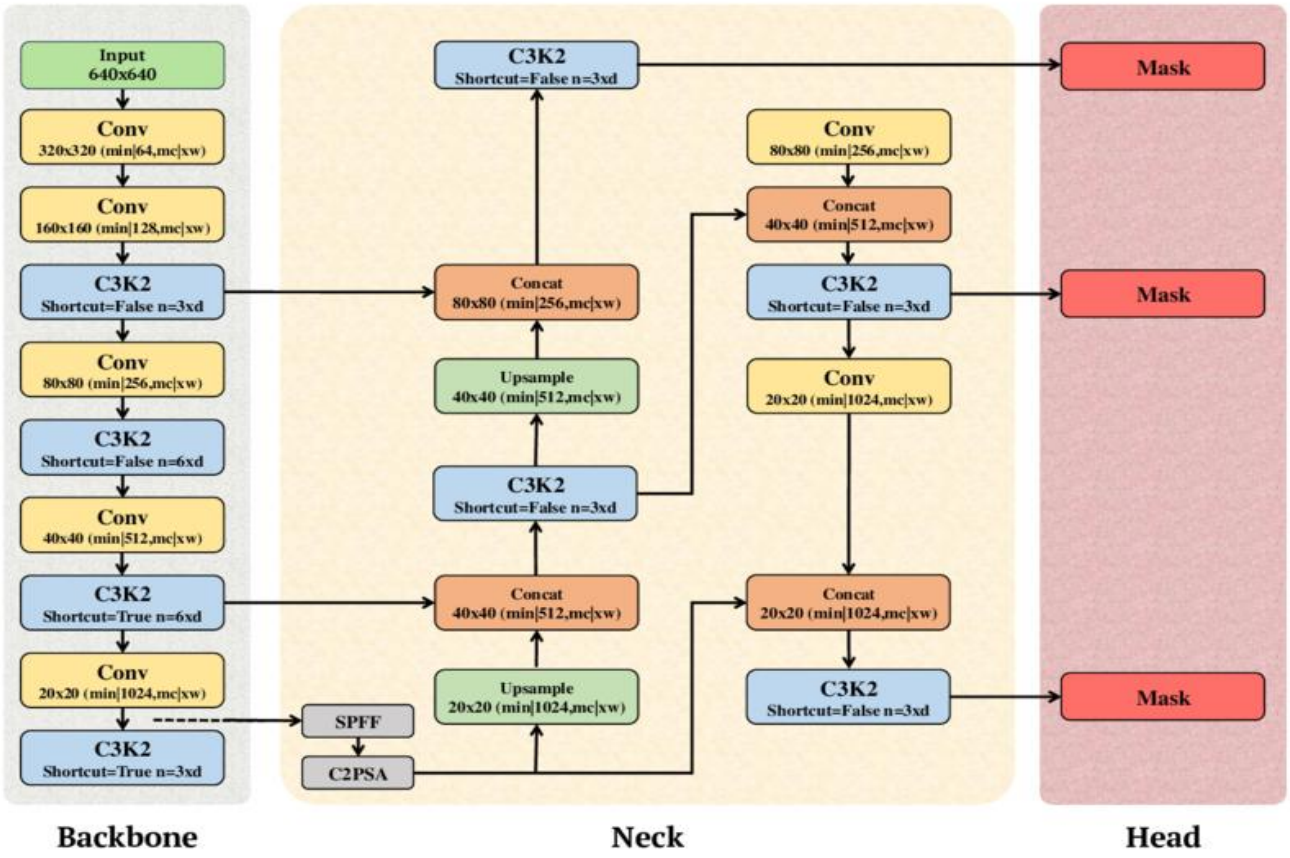

Fig. 1. Architecture diagram of the proposed quantized YOLOv11 model used in this study.

IV. Results and Discussion

To evaluate the performance of the proposed quantized YOLOv11 model, we compared its accuracy, inference speed, latency, energy consumption, and model size against the full-precision (FP32) baseline.

A. Experimental Setup

Experiments were conducted using the MS COCO 2017 and Pascal VOC 2012 datasets. COCO contains 80 object categories with 118k training images and 5k validation images, while VOC includes 20 classes with 17k annotated images to evaluate multi-class detection performance. Data preprocessing included image resizing to 640×640, normalization, and standard YOLO augmentations such as Mosaic and MixUp. Training was performed for 100 epochs with a batch size of 32, using the SGD optimizer (momentum = 0.937, weight decay = 0.0005) and cosine learning rate scheduler starting at 0.01.

B. Evaluation Metrics

To assess the performance of the target detection algorithms, a set of well-established evaluation metrics was employed. Detection accuracy was measured using the Average Precision (AP) and mean Average Precision (mAP) metrics, which are widely adopted in object detection research. The mAP provides an overall measure of detection performance by averaging the AP values across all object classes. The formal definitions and computations of precision [Eq. (3)], recall [Eq. (4)], AP [Eq. (5)], and mAP [Eq. (6)] are presented as follows:

$$\text{Precision} = \frac{\text{True Positives}}{\textit{True Postives} + \textit{False Postives}} \quad (3)$$

$$\text{Recall} = \frac{\text{True Positivves}}{\text{True Positives} + \textit{False Negatives}} \quad (4)$$

$$\text{AP} = \int_0^1 \text{Precision(Recall)dR} \quad (5)$$

$$\text{mAP} = \frac{1}{n}\sum_{i=1}^{n}\text{AP} \quad (6)$$

In this context, n denotes the total number of target classes considered in the detection task. All models were benchmarked in both FP32 (baseline) and INT8 quantized configurations. Performance measurements were averaged across 5 inference runs under identical environmental conditions to ensure statistical consistency.

C. Results and Discussion

To reduce computing, data movement, and consequently lower energy usage, we performed quantization by representing data in 8-bit using QAT and PTQ techniques with 8-bit integers. This reduces the number of bits from 32 to 8. The evaluation of our approach demonstrates that the network architecture uniformly reduces to 8-bit precision through quantization.

The training process was conducted using Stochastic Gradient Descent (SGD) with a learning rate of 0.01 and a batch size of 32. SGD was selected over adaptive optimizers such as Adam, as it is known to provide more stable convergence and superior generalization performance in large-scale object detection tasks. The model was trained for 100 epochs with input images resized to 640×640 pixels, a resolution commonly adopted in YOLO-based architectures to balance detection accuracy with computational efficiency. To mitigate overfitting and improve generalization, a weight decay term of 0.0005 was incorporated. The choice of these hyperparameters was informed by prior studies on YOLO optimization, ensuring a trade-off between convergence speed, model robustness, and inference efficiency, thereby enabling reliable deployment on resource-constrained embedded platforms.

Fig. 2 presents the training and validation curves for YOLOv11n fine-tuned on the Pascal VOC dataset. The loss functions, including box loss, classification loss, and distribution focal loss (DFL), exhibit a steady decline across 100 epochs, indicating stable convergence and effective learning. The precision and recall metrics show consistent improvement, reaching values above 0.8 and 0.75, respectively, which reflects a balanced trade-off between correct detections and coverage of ground-truth objects. Similarly, the mean Average Precision (mAP) at IoU thresholds of 0.5 (mAP@50) and 0.5–0.95 (mAP@50–95) demonstrates continuous growth throughout training, stabilizing at approximately 0.85 and 0.63, respectively. These results confirm that YOLOv11n, even in its lightweight form, achieves strong detection performance on Pascal VOC while maintaining efficient training dynamics.

To evaluate the impact of post-training quantization (PTQ) and quantization-aware training (QAT), four experiments were conducted on the MS COCO and Pascal VOC datasets under a consistent training and evaluation protocol. QAT maintained the original parameter count while reducing model size by approximately 75%, achieving competitive accuracy with lower computational complexity. Similarly, PTQ preserved the parameter count and reduced the model size by about 75%, though it exhibited a minor drop in mean Average Precision (mAP) compared to the baseline YOLOv11n. These findings demonstrate that both QAT and PTQ independently provide substantial efficiency gains, while their combined application offers a synergistic strategy for optimizing deep neural networks. YOLOv11n was selected as the reference model to validate the effectiveness of the proposed quantization techniques. The following tables present a comparative summary of the baseline, PTQ, and QAT results on both MS COCO and Pascal VOC datasets.

Table II presents a performance comparison between Post-Training Quantization (PTQ) and Quantization-Aware Training (QAT) on the COCO dataset using the YOLOv11n model. The results show how quantization impacts model precision, recall, mean Average Precision (mAP), and model size. The baseline YOLOv11n-FP32 model (32-bit floating point) achieves the highest accuracy, with a precision of 65.3%, recall of 50.4%, and mAP of 39.5%, but it has the largest model size at 10.3 MB. When quantized to 8-bit using PTQ, the model size is reduced significantly to 2.6 MB (around 75% smaller), but this comes at a noticeable cost in performance, with a precision drop to 62.5%, a recall to 44.6%, and mAP to 32.2%. In contrast, the QAT-based 8-bit model demonstrates a better balance between compression and accuracy, achieving 63.2% precision, 49.1% recall, and 38.1% mAP with a slightly larger size of 2.8 MB. These results indicate that while both quantization methods greatly reduce storage requirements, QAT preserves accuracy more effectively than PTQ, making it a more suitable choice when maintaining detection performance is critical.

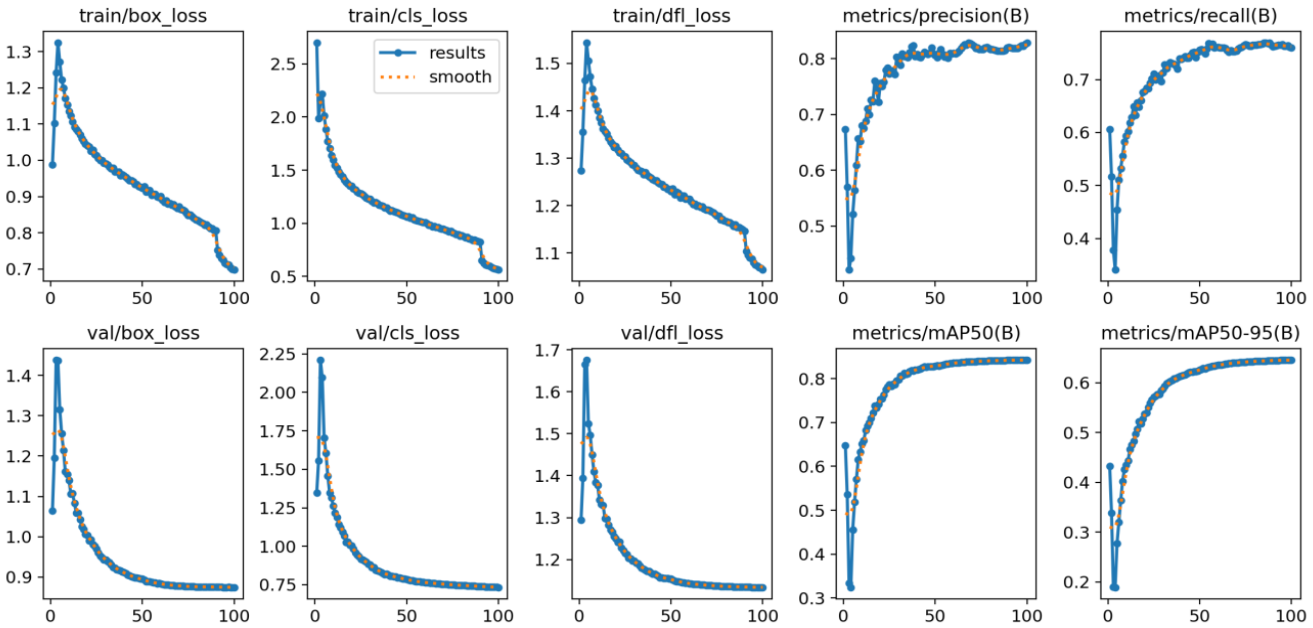

Fig. 2. Training results of YOLOv11n network after fine-tuned on the Pascal VOC dataset.

TABLE II. PERFORMANCE COMPARISON BETWEEN PTQ AND QAT ON THE COCO DATASET

Model	Bit Width	Precision	Recall	mAP 50-95%	Model Size (MB)
YOLOv11n-FP32	32-bit	65.3%	50.4%	39.5%	10.3 MB
YOLOv11n-INT (PTQ)	8-bit	62.5%	44.6%	32.2%	2.6 MB
YOLOv11n-INT (QAT)	**8-bit**	**63.2%**	**49.1%**	**38.1%**	**2.8 MB**

Fig. 3 compares accuracy (mAP) and model size for YOLOv11n FP32, PTQ INT8, and QAT INT8. This visualization highlights that although both PTQ and QAT achieve model compression, QAT provides a superior balance between efficiency and accuracy retention compared to PTQ.

Fig. 4 illustrates qualitative detection results produced by the quantized YOLOv11 model on a subset of images from the MS COCO val2017 dataset. Each image contains multiple detected objects, which are annotated with bounding boxes, class labels, and confidence scores. The examples demonstrate the model's ability to recognize a diverse range of object categories, including people, vehicles, animals, food items, and household objects, across different scenes and contexts. While most detections show high confidence (e.g., person at 0.9, truck at 0.9, airplane at 0.9), some lower-confidence predictions (e.g., boat at 0.3, carrot at 0.3, motorcycle at 0.3) reflect the challenges of small objects or complex backgrounds. Overall, the visualization highlights the robustness of the model in detecting multiple objects per image and maintaining competitive accuracy despite operating under quantization constraints.

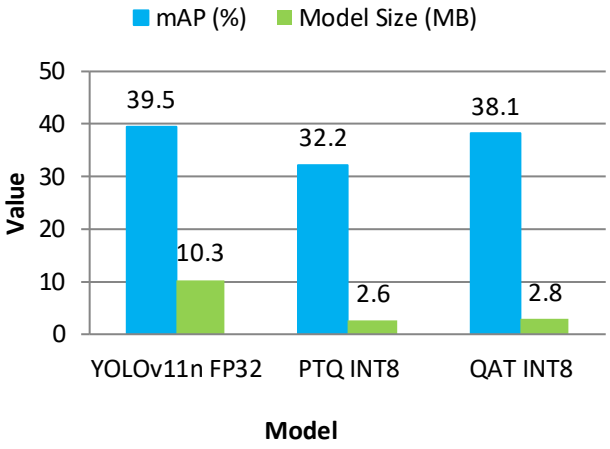

Fig. 3. Accuracy and model size comparison of YOLOv11n FP32 vs. INT8 models (PTQ and QAT) on the COCO dataset.

Table III compares the performance of Post-Training Quantization (PTQ) and Quantization-Aware Training (QAT) on the VOC dataset. The baseline model (best-FP32) in 32-bit precision achieves the highest overall performance, with 82.6% precision, 76.3% recall, and 64.6% mAP, at a model size of 10.13 MB. When quantized to 8-bit using PTQ, the model size is reduced dramatically to 2.85 MB, about 72% smaller, while the accuracy metrics show only minimal degradation: precision decreases slightly to 82.2%, recall to 76.1%, and mAP to 64.1%. The QAT-based 8-bit model maintains nearly identical accuracy to the FP32 version, with 82.5% precision, 76.3% recall, and 64.2% mAP, while also achieving a compact size of 2.81 MB.

Fig. 4. Visualization of detection results under complex and challenging scenarios realized by our proposed quantized YOLOv11 framework by using the YOLO11n pre-trained model on the MS COCO dataset.

These results suggest that for the VOC dataset, quantization, especially with QAT, can achieve substantial model compression with almost no loss in detection performance. Compared to PTQ, QAT provides marginally better retention of accuracy, reinforcing its advantage in preserving model quality while enabling efficient deployment on resource-constrained devices.

TABLE III. PERFORMANCE COMPARISON BETWEEN PTQ AND QAT ON VOC DATASET

Model	Bit width	Precision	Recall	mAP 50-95%	Model Size (MB)
best-FP32	32-bit	82.6%	76.3%	64.6%	10.13 MB
best-INT8 (PTQ)	8-bit	82.2%	76.1%	64.1%	2.85 MB
best-INT8 (QAT)	8-bit	82.5%	76.3%	64.2%	2.81 MB

We compare our optimized quantized YOLOv11 model against the state-of-the-art lightweight detectors, including MobileNetV2-SSDLite, Micro-YOLO, EfficientDet-D0, and Mobile-DETR, using consistent evaluation metrics on the MS COCO dataset, as shown in Table IV. The results confirm that our quantization methods deliver a superior accuracy-efficiency trade-off, establishing quantized YOLOv11 as a compelling choice for real-time edge deployment.

Table IV presents a comparative analysis of various lightweight object detectors on the MS COCO Val2017 dataset, which includes 80 pre-trained classes. The comparison focuses on three key performance metrics: mean Average Precision (mAP), model size, and the number of parameters. Among the listed models, YOLOv11-INT8 (ours) achieves the highest mAP of 38.1%, outperforming other lightweight detectors such as Micro-YOLO (29.3%), EfficientDet-D0 (33.5%), MobileNetV2-SSDLite (22.1%), and Mobile-DETR (37.2%). Notably, YOLOv11-INT8 maintains this superior accuracy while keeping a very compact model size of only 2.8 MB and 2.6 million parameters, comparable to Micro-YOLO but with significantly higher detection performance. In contrast, Mobile-DETR achieves competitive accuracy but at the cost of a much larger model size (14.5 MB) and more parameters (14.8M). These results demonstrate that YOLOv11-INT8 offers an optimal balance between model efficiency and accuracy, making it an excellent choice for real-time object detection on edge or resource-constrained devices without compromising detection quality.

The visualization presented in Fig. 5 demonstrates the detection results obtained by our proposed quantized best framework, which leverages the YOLOv11n fine-tuned model on the Pascal VOC dataset.

TABLE IV. PERFORMANCE METRICS COMPARISON WITH OTHER LIGHTWEIGHT DETECTORS ON MS COCO VAL2017 DATASET, WHICH INCLUDES 80 PRE-TRAINED CLASSES

Model	mAP 50-95%	Model Size (MB)	Parameters (M)
Micro-YOLO [26]	29.3%	1.92 MB	2.56
EfficientDet-D0 [27]	33.5%	12 MB	3.9
MobileNetV2-SSDLite [28]	22.1%	17.0 MB	4.3
Mobile-DETR [29]	37.2 %	14.5 MB	14.8
YOLOv11-INT8 (ours)	**38.1%**	**2.8 MB**	**2.6**

Fig. 5. Visualization of detection results under complex and challenging scenarios realized by our proposed quantized best framework by using the YOLO11n fine-tuned model on the Pascal VOC dataset.

As shown, the framework successfully detects a wide variety of objects, including trains, dogs, cars, aeroplanes, cats, and people, across diverse and challenging scenarios. These scenarios involve cluttered environments, occlusions, varying object scales, and complex backgrounds, all of which typically challenge lightweight detectors. Despite its reduced size and computational footprint, the quantized best model maintains high detection accuracy, consistently localizing and classifying objects with strong confidence scores. The results highlight the framework's robustness and its ability to generalize effectively

across heterogeneous visual contexts, making it highly suitable for deployment in real-world, resource-constrained applications.

Table V presents a cross-dataset performance comparison of the proposed quantized YOLOv11 framework, highlighting its effectiveness on both the MS COCO and Pascal VOC benchmarks. The model achieves a mean Average Precision (mAP50–95%) of 38.1 ± 0.58 on the COCO dataset with a compact size of 2.8 MB, while attaining a substantially higher accuracy of 64.2 ± 0.34 on the VOC dataset with a slightly smaller size of 2.83 MB. These results indicate that the model generalizes well across datasets while maintaining an extremely lightweight architecture. The performance variation between COCO and VOC reflects the greater complexity and diversity of COCO, while also underscoring the robustness and adaptability of quantized YOLOv11 in delivering competitive accuracy across different detection benchmarks.

TABLE V. CROSS-DATASET PERFORMANCE COMPARISON

Dataset	mAP50-95%	Model Size (MB)
COCO	38.1 ± 0.58	2.8 MB
VOC	64.2 ± 0.34	2.83 MB

In summary, the experimental results demonstrate that quantized YOLOv11 attains a competitive balance of accuracy, inference speed, and computational efficiency, outperforming many contemporary detection frameworks. Nevertheless, persistent challenges remain in the domain of object detection, including reliable recognition of small-scale objects, robust handling of occlusions, and consistent performance under diverse lighting conditions and object variations. From a practical perspective, the proposed model offers considerable potential for extending AI-driven computer vision to low-power, real-time applications such as smart surveillance systems, unmanned aerial vehicles (UAVs), and edge-based robotic platforms [30]. Its lightweight design facilitates reduced energy consumption, accelerated response times, and enhanced deployment flexibility, thereby enabling intelligent vision systems in environments constrained by limited computational and hardware resources.

V. CONCLUSION

This research presented a comprehensive study on quantized multi-class object detection for real-time inference on embedded devices using the YOLOv11 model. The proposed framework demonstrated how quantization, coupled with deployment optimizations, can significantly enhance inference speed and energy efficiency while preserving near-original detection accuracy. By applying post-training quantization (PTQ) and quantization-aware training (QAT), the model achieved up to a 3.2× speedup, 2.7× reduction in model size, and 35% improvement in power efficiency, with less than 2% mAP degradation compared to the full-precision baseline.

The results verified that 8-bit integer quantization provides the optimal balance between accuracy and efficiency, particularly when executed on embedded accelerators. The quantized YOLOv11 pipeline, implemented through TensorRT, TensorFlow Lite, and ONNX Runtime, offers a robust and transferable solution for deploying deep learning models in latency-critical applications. Overall, the findings affirm that quantization is an effective and practical strategy for bridging the gap between high-performance object detection and the constraints of embedded hardware, enabling real-time edge AI deployment without sacrificing model integrity. In conclusion, this study lays the groundwork for scalable, energy-efficient object detection on embedded systems and opens opportunities for integrating quantized models into broader real-time computer vision ecosystems.

Future work will focus on reliable recognition of small-scale objects, robust handling of occlusions, exploring hybrid paradigms, and consistent performance under diverse lighting conditions and object variations.

***Abstract*—In the Quantum computing era of Noisy Intermediate-Scale Quantum (NISQ) devices, conventional qubit mapping strategies typically rely on specific heuristic rules to solve the mapping problem, overlooking the impact of other factors on the mapping, which leads to increased overhead from extra SWAP gates. To address this issue, we propose a SWAP optimization strategy based on the Centric-Shortest Quantum Gate Set (C-SQGS) and applies it to qubit mapping. In this approach, the centric qubit is determined by analyzing the maximum flexibility qubit set and the physical distances between the associated CNOT gates, leading to the identification of the Centric-Shortest Quantum Gate Set. To overcome the limitations of traditional cost functions that consider only single factors, a multi-factor cost function is introduced to evaluate the overall overhead of candidate SWAP operations and determine pending SWAP gate Set. Based on qubit flexibility analysis, executable SWAP gate is identified and inserted into the circuit. Experimental results demonstrate that the C-SQGS strategy effectively reduces both SWAP gate and two-qubit gate overhead. Specifically, it achieves an average SWAP gate reduction of 36.9% and 47.7%, and a two-qubit gate reduction of 13.8% and 13.5% on the t|ket⟩ and Qiskit compilers, respectively. These results highlight the potential of the C-SQGS strategy in enhancing the efficiency of qubit mapping for NISQ devices.**

***Keywords*—Quantum computing; qubit mapping; Centric-Shortest Quantum Gate Set (C-SQGS); executable SWAP gate; multi-factor cost function**

I. Introduction

Quantum computing is an innovative approach to computation that utilizes the principles of quantum mechanics to process information. In contrast to classical computers that use bits, quantum computing operates with qubits. Qubits can simultaneously exist and the superposition of states, this superposition property makes the quantum computer can simultaneously deal with a variety of possible states, thus accelerating the process of solving complex problems. The powerful parallel computing acceleration capability of quantum computing gives it great potential in areas such as integer factorization [1], optimization problems [2], and quantum simulation [3]. Due to the inherent limitations of traditional computers, it can be time-consuming and inefficient in dealing with these more complex problems, while quantum computers provide new solutions to these problems.

As quantum computing technology advances rapidly, it has now transitioned into the NISQ era. Executing a quantum logic circuit involves aligning the algorithm's logical qubits with the physical qubits of the quantum computer, a process called qubit mapping [4]. Due to the limitation of the technology in the NISQ era, two-qubit gate operations can only be performed on physically coupled qubit pairs. Thus, during the mapping process, quantum circuits must be adjusted to ensure compatibility with the hardware's coupling constraints. For two-qubit gates that do not comply with the hardware coupling constraints, extra SWAP gates must be added to reposition the qubits to adjacent locations. The additional SWAP operation, however, not only increases the depth of the quantum circuit, but also introduces more noise. Thus, minimization of the count of extra SWAP gates has become the focus of many researchers [5]-[8].

The qubit mapping problem has been demonstrated to be NP-complete [9]-[10]. In recent years, domestic and foreign scholars have carried out many studies on heuristic qubit mapping algorithms. Siraichi [11] proposed to preferentially satisfy physically neighboring CNOT gates during the initial mapping, and to resolve only one two-qubit gate operation each time the qubits are shifted. Although this method is relatively fast, it is generally ineffective in coping with complex quantum circuits due to the relative simplicity of the strategy. Zulehner [12] used the A* algorithm to determine the optimal mapping of each logical to physical qubit to optimize the implementation of quantum circuits on hardware architectures, but due to the exhaustive search, the running time is long. In 2020, Adrien [4] proposed the Hardware-Aware (HA) algorithm to decrease the quantity of SWAP gates, though it allows for the selection between SWAP and Bridge gates, it does not adequately account for the effect of varying numbers of look-ahead gates on the circuit's cost. Steinberg [13] proposed the HQAA algorithm in 2022 for assigning initial qubit positions for quantum algorithms on NISQ devices, but it fails to achieve adequate efficiency in large-scale quantum circuits. The above literature, while proposing valuable treatments on the mapping problem, still requires further improvements when dealing with complex quantum circuits.

In the NISQ era, the existing quantum circuit mapping algorithms not only include the initial qubit mapping but also involve the intermediate change strategy of qubit mapping. After the initial mapping is completed, a reasonable intermediate change strategy is formulated based on the information of the quantum circuit, which helps to improve the performance of the overall quantum circuit. Due to hardware topology constraints, the initial mapping does not meet the coupling requirements for all qubits, and for the non-Nearest

Neighbor (non-NN) gates that do not satisfy the constraints, it is necessary to implement an additional SWAP operation to exchange qubits to make them update to Nearest Neighbor (NN) gates, and this process will expand the size and depth of the circuit. Two-qubit gates have significantly higher error rates than single-qubit gates [14]. Hence, minimizing the compilation overhead is crucial for high fidelity circuit implementations.

This paper focuses on the qubit mapping problem subject to physical topology constraints. A SWAP optimization strategy based on Centric-Shortest Quantum Gate Set (C-SQGS) is proposed, aiming to optimize quantum circuits for the 2-local qubit Hamiltonian simulation problem. This strategy optimizes the initial mapping of quantum circuits by identifying the Centric-Shortest Quantum Gate Set, and employs a multi-factor cost function together with qubit flexibility analysis to search for optimal SWAP gates. By comprehensively considering multiple factors, the proposed method effectively minimizes the number of inserted SWAP gates.

Unlike existing qubit mapping and routing heuristics that rely on single-factor optimization or local greedy decisions [23], the C-SQGS strategy introduces a centric decision paradigm that organizes SWAP insertion around a dynamically identified centric qubit and its associated shortest gate set. Rather than independently applying concepts such as qubit flexibility or gate frequency, C-SQGS integrates these factors into a unified gate-set–driven mapping framework, enabling coordinated optimization across both the initial mapping and routing stages.

From a practical perspective, qubit mapping on NISQ devices is constrained not only by physical connectivity but also by limited coherence time and restricted scheduling flexibility. Existing heuristics often rely on locally optimal or single-metric decisions, which may introduce SWAP operations that are executable in isolation but suboptimal or even harmful when considering subsequent circuit evolution. The proposed C-SQGS framework, together with executable SWAP identification and multi-factor cost evaluation, is designed to address these practical limitations by enabling globally informed and execution-aware SWAP insertion.

The C-SQGS strategy is able to adapt to a variety of qubit topologies and gate sets and can be used in conjunction with a wide range of existing quantum circuit mapping algorithms. Experimental findings indicate that the C-SQGS strategy somewhat reduces the count of SWAP and two-qubit gates. Moreover, we conduct experiments on IBM devices to verify the superiority of our strategy and compare it with other algorithms.

This paper makes the following key contributions:

- We focus on the qubit mapping challenge and point out the main influencing factors considered in this paper.
- A SWAP optimization strategy based on a Centric-Shortest Quantum Gate Set is proposed.
- Designing a multi-factor cost function that considers multiple factors simultaneously.
- Introduction of a selection criterion and the definition for executable SWAP gates.

The remainder of this paper is structured as follows. Section II outlines essential background on quantum computing. Section III highlights the challenges in qubit mapping and introduces the proposed approach. Section IV details the experimental evaluation, and Section V summarizes the conclusions.

II. BACKGROUND

A. Prior Knowledge

In quantum computing, a qubit is the core unit that can simultaneously occupy the $|0\rangle$ and $|1\rangle$ states through the principle of superposition. The quantum state can be expressed as Eq. (1), where $|\psi\rangle$ is the state vector of the qubit, α and β are complex numbers representing the probability of the qubit being in the states $|0\rangle$ and $|1\rangle$, respectively, and satisfying the condition $|\alpha|^2+|\beta|^2=1$, whereas $|0\rangle$ and $|1\rangle$ are the ground states of the qubit. This special property of qubits enables quantum computers to achieve exponential speedups.

$$|\psi\rangle=\alpha|0\rangle+\beta|1\rangle \tag{1}$$

Quantum gates are the fundamental units of operation in quantum computing, used to manipulate the state of qubits. Fig. 1 shows the symbolic representation of basic quantum gates. Among them, the Hadamard gate is a single-qubit operation that transforms a classical state into an equal superposition of basis states. Whereas CNOT and SWAP gates are gates acting on two qubits, CNOT gates can realize a kind of qubit control flip-flop operation, which passes the state of one qubit to the other qubit and thus establishes an entanglement between them. SWAP gates consist of 3 CNOT gates, as in Fig. 1(c), which can realize the exchange of states between qubits without changing their relative phase.

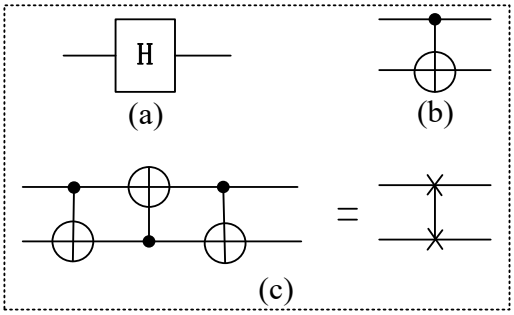

Fig. 1. Basic quantum gates.

Quantum circuit is a fundamental computational model in quantum computing for describing the process of manipulating qubits through quantum gates. Fig. 2 shows a simple quantum circuit describing the whole process of measuring the final state of a qubit after the initial state of the qubit passes through the quantum circuit, which consists of a Hadamard, a CNOT and a SWAP gate, and the essence of the quantum circuit is a combination of the unitary transformation and measurement. Physically, we cannot directly realize the overly complex unitary transformations, so expect some easy to realize the

unitary transformations to produce more complex unitary transformations. For complex quantum operations, such as Hamiltonian simulation, can be realized through the rational design and adjustment of quantum gates within the quantum circuit.

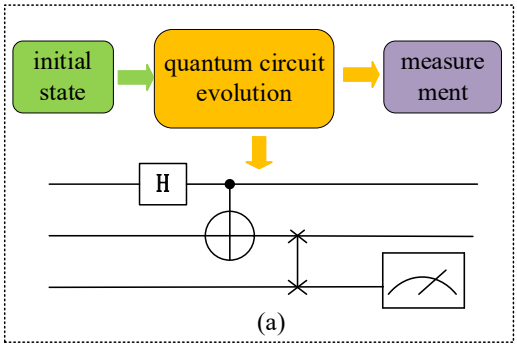

Fig. 2. Quantum circuit.

B. Hamiltonian

The Hamiltonian operator characterizes the total energy of a system. In quantum mechanics, the Hamiltonian acts on the quantum state of a system, describing its energy state and time evolution. In quantum computing, the Hamiltonian is used to represent the energy states of qubits and the interactions between them. Quantum gate operations can be implemented through time evolution operators [see Eq. (2)], where $\hat{H}$ is the Hamiltonian corresponding to the quantum gate.

$$U(t) = e^{-\frac{i\hat{H}t}{\hbar}} \tag{2}$$

Hamiltonian simulation is a vital application in quantum computing, involving the modeling of the Hamiltonian of a quantum system. By simulating Hamiltonian dynamics, one can predict and analyze the time evolution of quantum systems, with applications in quantum physics, chemistry, materials science, and beyond. Various methods have been proposed for effective Hamiltonian simulation, including Taylor series expansions [15], the product formula [16]-[17], and quantum signal processing [18]-[19]. Among these, the product formula is particularly notable for its simplicity and practical efficacy [20]. The Hamiltonian of a system, denoted as H, can be decomposed into a sum of polynomial ergodic terms H_j, as illustrated in Eq. (3). In quantum computing, the product formula is a vital tool for describing time-evolution operators, especially for time-dependent Hamiltonians. This method represents the time-evolution operator as a product of a series of simpler operators, thereby simplifying the implementation of complex quantum operations on a quantum computer. The product formula is detailed in Eq. (4).

$$H = \sum_{j=1}^{L} h_j H_j \tag{3}$$

$$V(t) = \prod_{j=1}^{L} \exp\left(ith_j H_j\right) \tag{4}$$

where, $\exp\left(ith_j H_j\right)$ represents the time evolution caused by the Hermitian term H_j, i is the imaginary unit, t is the time, h_j is the coefficient of each Hermitian term H_j, L is the number of Hermitian terms into which the system Hamiltonian H is decomposed, and $V(t)$ represents the total evolution operator of the system at moment t. Due to the flexibility of the arrangement of Hamiltonian operators, it is possible to optimize the Hamiltonian analog circuit for each Trotter step by rearranging L individual operators in the product formula, thus optimizing the overall circuit structure.

III. Our Design

A. Limitations of Qubit Mapping

Qubit mapping is an important process in quantum computing aimed at mapping abstract quantum algorithms or quantum circuits onto concrete quantum hardware for practical execution. This process involves several steps, including mapping logical to physical qubits, optimizing the sequence of quantum gate operations, minimizing SWAP operations, etc. Due to the limitations of NISQ era technology, execution is only possible on qubits that are allowed to be connected on quantum hardware coupling architectures. In executing quantum logic circuits, logical qubits are required to match physical quits. The limitations of quantum mapping are further explained with examples as shown in Fig. 3. Fig. 3(b) shows a small quantum circuit which consists of 7 CNOT gates and 1 Hadamard gate and is executed on the 6-qubit device shown in Fig. 3(a). The device allows the use of two-qubit gates on the qubit pairs $\{Q_1, Q_2\}$,$\{Q_2, Q_3\}$,$\{Q_3, Q_4\}$,$\{Q_4, Q_5\}$,$\{Q_0, Q_5\}$,$\{Q_0, Q_1\}$,$\{Q_2, Q_5\}$ and $\{Q_3, Q_4\}$, and does not allow the use of two-qubit gates on the qubit pairs $\{Q_1, Q_5\}$,$\{Q_0, Q_2\}$,$\{Q_2, Q_4\}$ and $\{Q_3, Q_5\}$. For simplicity, assume that the initial mapping is $\{q_0 \rightarrow Q_0, q_1 \rightarrow Q_1, q_2 \rightarrow Q_2, q_3 \rightarrow Q_3, q_4 \rightarrow Q_4, q_5 \rightarrow Q_5\}$. Due to the limited connectivity between qubits, only directly connected qubits can perform quantum gate operations. From Fig. 3(a), among the seven CNOT gates in Fig. 3(b), g_1, g_2, g_3 and g_5 can be directly executed. Since the qubits associated with the three CNOT gates, g_4, g_7 and g_8, do not have a direct mapping to the actual hardware, g_4, g_7 and g_8 cannot be directly executed, and a change in the qubit mapping is required before executing these two gates.

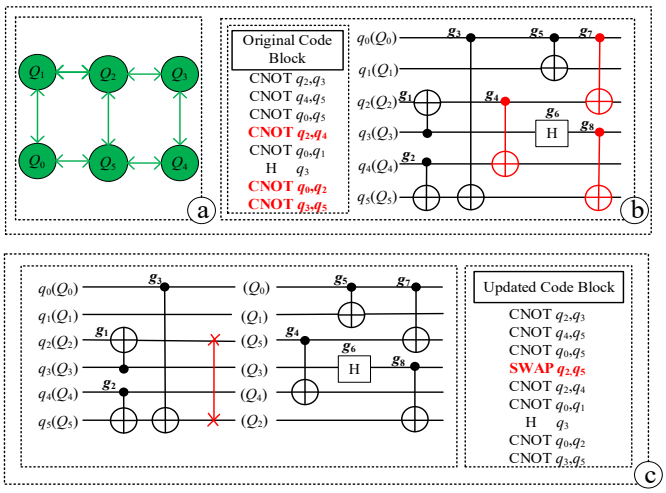

Fig. 3. (a) Hardware topology, (b) Original quantum circuit, (c) Updated quantum circuit.

The objective of qubit mapping is to identify the optimal initial qubit placement to minimize the count of SWAP operations required when converting all non-NN gates to NN gates. The qubit mapping challenge is modeled as a Quadratic Assignment Problem (QAP) [21]. For solving this problem, the qubit positions are changed by inserting SWAP gates by exchanging the state between two qubits [22]. In Fig. 3(c), CNOT gates g_1, g_2, g_3 and g_5 can be executed with the initial mapping, with SWAP$\{q_2,q_5\}$ inserted after g_3, the mapping is updated to $\{q_0 \rightarrow Q_0, q_1 \rightarrow Q_1, q_2 \rightarrow Q_5, q_3 \rightarrow Q_3, q_4 \rightarrow Q_4, q_5 \rightarrow Q_2\}$, which exchanges the two qubits q_2, q_5 and makes the subsequent gates g_4 and g_7 into executable NN gates.

The insertion of extra SWAP gates can generate hardware-compatible quantum circuits, but the increase in SWAP gates may introduce additional noise that reduces the fidelity of the quantum circuits, which in turn affects the overall performance of the circuit. In addition, the increase in line depth can extend the execution time and negatively affect the efficiency of quantum computation. Comparing the original and updated circuits in Fig. 3(b) and Fig. 3(c), the count of CNOT gates increases from 7 to 10, and the depth grows from 5 to 8. The addition of these gates introduces extra overhead, impacting both the fidelity and execution time of the quantum circuits. This paper is devoted to exploring the optimal solution of the qubit mapping challenge, with a view to minimizing the overhead of extra SWAP gates and effectively improving mapping quality.

The qubit mapping stage is a crucial step in quantum computing, where the mapping of logical qubits to physical qubits directly impacts the execution efficiency and computational accuracy of quantum circuits. So far, there are still many challenges in the qubit mapping stage, and the following limitations are mainly considered in this paper:

- Limitations of hardware topology: The way qubits are connected to each other and the operational limitations are determined by the hardware design. These constraints include the layout of qubits, the way they interact with each other, and the execution efficiency of quantum gates. Reasonable mapping of quantum circuits to the actual hardware topology can maximize the execution efficiency and accuracy of the algorithm.
- Limited connectivity between qubits: The connections between physical qubits on a quantum processor are usually limited. Not all qubits are directly connected, and only neighboring qubits can directly perform two-qubit gate operations. This limitation requires moving qubits around by adding extra SWAP operations that allow non-directly connected qubits to interact.
- SWAP gate operation cost: One SWAP gate is equivalent to 3 CNOT gates, and the operation cost of SWAP gates is generally higher. Therefore, when addressing the qubit mapping challenge, we must consider the operation cost of SWAP gates and select the SWAP insertion with lower operation cost.
- Balancing considerations for optimizing performance: The goal of qubit mapping is the minimization of the count of SWAP gate operations when all two-qubit gates are converted from non-NN gates to NN gates. Therefore, when dealing with the qubit mapping challenge, different performance metrics need to be considered, such as the starting point of the initial mapping, the design of the cost function, the cost of SWAP gate operations, and the selection of SWAP gates.

B. SWAP Optimization Strategy Based on Centric-Shortest Quantum Gate Set

In general, it is difficult to find a perfect initial mapping such that it satisfies the dependencies of all two-qubit gates. For non-NN gates, additional SWAP operations are required to convert them to NN gates, a process that leads to overhead in gate counting and circuit depth. Therefore, efficient qubit routing techniques are essential to minimize compilation overhead for reliable computation. Lao [23] introduced a quantum compiler, 2QAN, in 2022, which mainly optimizes the 2-local quantum simulation problem, such as the Quantum Approximation Optimization Algorithm (QAOA). It leverages flexibility in arranging Hamiltonian quantum operations and reduces two-qubit gate overhead by integrating SWAP gates with circuit gates into a single unitary transformation. Although 2QAN presents a meaningful solution to qubit mapping challenge, it neglects the effect of the number of qubits involved in the CNOT operation on the mapping process. It has been found that prioritizing the mapping of qubits involved in a high number of CNOT gates to locations close to each other reduces the subsequent additional SWAP gates, thus reducing the circuit depth and execution time [24]. Based on this, this paper proposes a SWAP optimization strategy based on the Centric-Shortest Quantum Gate Set(C-SQGS).

Definition 1 Qubit Flexibility: In a quantum circuit C, let q_i be any qubit whose number $F(q_i)$ of times it participates in a non-NN gate operation is q_i's Qubit Flexibility.

Definition 2 Maximum Flexibility Qubit Set: In a quantum circuit C, assuming $G_n = \{g_1, g_2, \ldots\ldots, g_n\}$ be the set of non-NN gates and $Q_m = \{q_1, q_2, \ldots\ldots, q_m\}$ be the set of qubits involved in the quantum gates in G_n. The Qubit Flexibility Set is $F_Q = \{F(q_i), i = 1,2,\ldots\ldots,m\}$. If $F_{max}(q_j) = \max F_Q$, then $q = \{q_j, j = 1,2,\ldots\ldots,m\}$ is said to be the Maximum Flexibility Qubit Set in Q_m.

Definition 3 Centric Qubit: In a quantum circuit C, assuming $G = \{G_1, G_2, \ldots\ldots, G_m\}$ be the set of quantum gate sets associated with q_j. The set of physical spacings of the corresponding qubits in the set of quantum gates in G is $D = \{D(G_1), D(G_2), \ldots\ldots, D(G_m)\}$. If $D(G_k) = \min D$, then q_k is said to be the Centric Qubit in Q_m, where, $j = 1,2,\ldots\ldots,m$; $k = 1,2,\ldots\ldots,m$.

Definition 4 Centric-Shortest Quantum Gate Set: In a quantum circuit C, assuming the set of quantum gates associated with the Centric Qubit q_k be $G_k = \{g_1, g_2, \ldots\ldots, g_r\}$, and the set of physical spacings of the corresponding qubits for each quantum gate in G_k be $D' = \{D(g_1), D(g_2), \ldots\ldots, D(g_r)\}$. If

$D(g_z) = \min D'$, and then $G_k' = \{g_z, z = 1,2,\ldots\ldots,r\}$ is said to be the Centric-Shortest Quantum Gate Set for the quantum circuit C where, $0 < z \le r \le n$.

The SWAP optimization strategy based on Centric-Shortest Quantum Gate Set (C-SQGS) is a method for optimizing quantum circuit mapping. It aims to identify the Centric-Shortest Quantum Gate Set in quantum circuits, minimize the use of SWAP gates and reduce communication overhead between qubits, and enhance the efficiency of the mapping process. For non-NN gates, the specific operation steps are as follows:

Step 1: Based on the concept of Qubit Flexibility, determine Maximum Flexibility Qubit Set, denoted as q.

Step 2: If q > 1, then the Centric qubit q_k is further determined according to Definition 3.

Step 3: G_k is the set of quantum gates associated with q_k, calculate the physical distance between the corresponding qubits of each of these CNOT gates, prioritize these CNOT gates based on the distances, and identify the CNOT gates with the shortest spacing, so as to determine the Centric-Shortest Quantum Gate Set G_k', and make sure that it is prioritized.

Step 4: The cost function (Definition 5) is used to evaluate all candidate SWAP operations and select the pending SWAP gate set (Definition 6).

Step 5: According to Definition 7, evaluate the pending SWAP gate set and determine the executable SWAP gates, which are inserted into the quantum circuit.

Step 6: Update the mapping to eliminate the newly generated NN gates from the set of non-NN gates.

Step 7: Repeat Step1- Step6 until all gates are mapped.

The C-SQGS strategy deals with the quantum circuit mapping challenge by optimizing the selection and arrangement of quantum gates, thus reducing the complexity of the SWAP gate search space, reducing the SWAP gate overhead, and improving the overall performance of quantum computing. Algorithm 1 is the detail of the pseudocode.

Algorithm 1 Optimization algorithm

Input: Un-routed quantum circuit, initial mapping M

Output: Routed quantum circuit, NN gates

```
begin
  Initialize the set of NN gates for each mapping, G_NN = {G_M}, G_M ← all NN gates for mapping M
  Initialize G_non-NN ← all un-routed Non-NN gates
  Initialize Q={q_i} ← all qubits involved in Non-NN gates
  while G_non-NN≠∅ do
    q ← set of qubits with Maximum Flexibility Qubit Set in Q
    if q >1
      Select the Centric Qubit q_k∈Q in q
      Select the gate G'_k∈G_non-NN that has Centric-Shortest Quantum Gate Set in G_non-NN
      S_g ← SWAP gates with the identical cost
      S_b ← Select the executable SWAP gate from S_g
      G'_NN ← Find NN gates in G_non-NN for map M'
      Remove all gates in G'_NN from G_non-NN, add G'_NN to G_NN
    end if
  end while
end
```

C. Multi-Factor Cost Function Design

The design of the cost function is particularly important when dealing with qubit mapping challenges, and a reasonable cost function can ensure the executability of quantum circuits. However, the traditional cost function usually takes the distance between qubits as the core criterion of measurement, which lacks the comprehensive consideration of multiple factors and makes it difficult to accurately assess the actual overhead of SWAP gates. To solve this problem, a multi-factor cost function is designed in this paper.

Definition 5 Multi-Factor Cost Function: The minimization of the sum of the weighted products of the distance between qubits, the number of interactions, and the interaction time is shown in Eq. (5).

$$H_{cost} = \min_{\phi \in S_n} \left\{ \sum_{i=1}^{n} \sum_{j=1}^{n} F_{q_i q_j} D_{[\phi(q_i)\phi(q_j)]} R_{q_i q_j} \right\} \tag{5}$$

where, S_n represents the set of all possible permutations, $F_{q_i q_j}$ is the interaction time between circuit qubits q_i and q_j, $R_{q_i q_j}$ is the number of interactions between qubits q_i and q_j in the circuit, and $D_{[\phi(q_i)\phi(q_j)]}$ denotes the distance between physical qubits on the hardware $\phi(q_i)$ and $\phi(q_j)$, calculated using the Floyd-Warshall algorithm.

The interaction time between qubits affects the execution speed of the circuit, the shorter the interaction time between qubits, the faster the circuit executes, and longer interaction times lengthen the overall execution time of the quantum circuit [25]. The number of interactions is also another important factor affecting the mapping of quantum circuits [26], each quantum gate operation introduces errors, a higher number of interactions leads to more operations, increasing the risk of error accumulation and decreasing the accuracy and reliability of the computation. Reducing the number of interactions helps to reduce the accumulation of errors and improve the accuracy of the calculation. In quantum circuits, CNOT gates need to be executed between directly connected qubits. If two qubits are physically distant from each other, multiple intermediate SWAP operations need to be introduced to make them physically adjacent. These additional operations increase the depth and execution time of the circuit and affect the overall performance of the quantum algorithm. In this paper, we combine these three factors to design a Multi-Factor

Cost Function that can handle the qubit mapping challenge more comprehensively. For non-NN gates, the cost function can assign a value to each candidate SWAP gate to measure the advantages and disadvantages of each operation and filter out the optimal SWAP operation. The mapping layout of qubits needs to be re-evaluated and adjusted after each SWAP operation.

D. Executable SWAP Gate

In the field of quantum computing, CNOT gates are crucial, and together with any single-qubit gate, they form a universal set of quantum gates. This means that any complex quantum circuit can be realized with the appropriate combination of these fundamental gates. When dealing with the qubit mapping challenge, some of the CNOT gates do not satisfy the conditions for execution in the initial mapping because the qubit arrangement and interactions in a real quantum computer are limited by the hardware topology. To make all CNOT gates executable, extra SWAP gates need to be inserted so that the control and target bits of the CNOT gates satisfy the conditions of the hardware coupling constraints. However, extra SWAP gates impose additional overhead on the circuit. The identification of executable SWAP operations from all candidate SWAP gates is key to the considerations in this paper.

Definition 6 Pending SWAP Gate Set: The set of SWAP operations that minimize the cost function by evaluating all candidate SWAP gates using the cost function is referred to as the Pending SWAP Gate Set.

Definition 7 Executable SWAP Gate: There are n qubits in quantum circuit C. Assuming $F_{\max}(q_i), i=(1,2,\ldots\ldots,n)$ be the Maximum Flexibility Qubit Set under the initial mapping M. $G_{SWAP}=\{g_1,g_2,\ldots\ldots,g_z\}$ is a list of Pending SWAP Gate set, and $F^{'}=\{F^{'}(q_r), r=1,2,\ldots\ldots,z\}$ denotes the Maximum Flexibility Qubit Set corresponding to a SWAP operation under the new mapping M' after the execution of G_{SWAP}. If $F^{'}_{\max}(q_j)=\max F^{'}$, then the SWAP gate g_j corresponding to q_j is said to be an Executable SWAP Gate, where , $1\le j\le z$.

To minimize the count of SWAP gates, firstly, Pending SWAP Gate Set is filtered by using the cost function (Definition 5); secondly, considering that highly flexible qubits usually have strong dependence on other qubits, based on Qubit Flexibility, the SWAP operation mode corresponding to maximum flexibility qubit is selected, so as to minimize the exchange distance between physical qubits and determine the Executable SWAP Gate. This selection strategy achieves the reduction of extra overhead and improves the overall performance of the quantum circuit. The specific procedure for determining an Executable SWAP Gate is as follows:

Step 1: Calculate the Maximum Flexibility Qubit Set $F_{\max}(q_i)$ under the initial mapping M.

Step 2: The simulation executes each potential SWAP gate to obtain the Maximum Flexibility Qubit Set $F^{'}$ corresponding to SWAP operations under the new mapping M'.

Step 3: Compare the values in $F^{'}$ to obtain the $F^{'}_{\max}(q_j)$ under the new mapping M'.

Step 4: Under the new mapping M', the SWAP gate corresponding to the largest value in the set $F^{'}$ is considered as an executable SWAP gate and applied to the circuit. By in this way, the count of extra SWAP operations can be reduced and the whole quantum circuit can be optimized.

The details of the pseudocode are presented in Algorithm 2, with a concrete example provided in Fig. 4.

Algorithm 2 Select the Executable_SWAP

Input: top_qubit_number: After inserting a SWAP gate, Maximum Flexibility Qubit Set under the new mapping M'.
moves: A Pending SWAP Gate Set
Output: Executable_SWAP

```
Begin
  max_top_qubit_number_add ← 0
  Executable_SWAP ← None
  for move in moves do
    top_qubit_ number_ add←top_qubit_ number [move]
      if top_qubit_numbe _add > max_top_qubit_ number_ add
        max_top_qubit_number_add ← top_qubit_ number_ add
        Executable_SWAP ← move
      end if
  end for
end
```

The IBM Q20 Tokyo localized architecture is shown in Fig. 4. Assume that the code block on Fig. 4(a) is executed on this architecture, where SWAP $\{q_0, q_4\}$ and SWAP $\{q_0, q_1\}$ are pending SWAP gates. According to as in Fig. 4(a), $F_{\max}(q_0)=2$ under the initial mapping M. Insert the candidate SWAP $\{q_0, q_4\}$ and SWAP $\{q_0, q_1\}$ into the quantum circuit to see the corresponding $F^{'}_{\max}(q_j)$ values under the updated mapping M', respectively. As in Fig. 4(b), insert SWAP $\{q_0, q_4\}$, under the current mapping M', $F^{'}_{\max}(q_0)=1$. As in Fig. 4(c), insert SWAP $\{q_0, q_1\}$, under the updated mapping M', $F^{'}_{\max}(q_9)=2$. The strategy in this paper is to find the SWAP operation that maximizes the $F^{'}_{\max}(q_j)$. By comparison, SWAP $\{q_0, q_1\}$ gives more benefits to the circuit than SWAP $\{q_0, q_4\}$, therefore, SWAP $\{q_0, q_1\}$ is chosen to insert and update the mapping. Fig. 4(d) shows the final mapping result graph obtained based on the SWAP strategy proposed in this paper, where only 2 extra SWAP operations need to be added to Fig. 4(c) to update all quantum gates to NN gates, SWAP $\{q_5, q_9\}$ and SWAP $\{q_2, q_3\}$. However, the method of Fig. 4(b) requires at least 3 SWAP gates to be inserted to update all quantum gates to NN gates. C-SQGS strategy increases qubit flexibility, and the increase in flexibility reduces the non-NN gate operations, allowing qubits to be closer to each other, thus optimizing the overall structure of the quantum circuit.

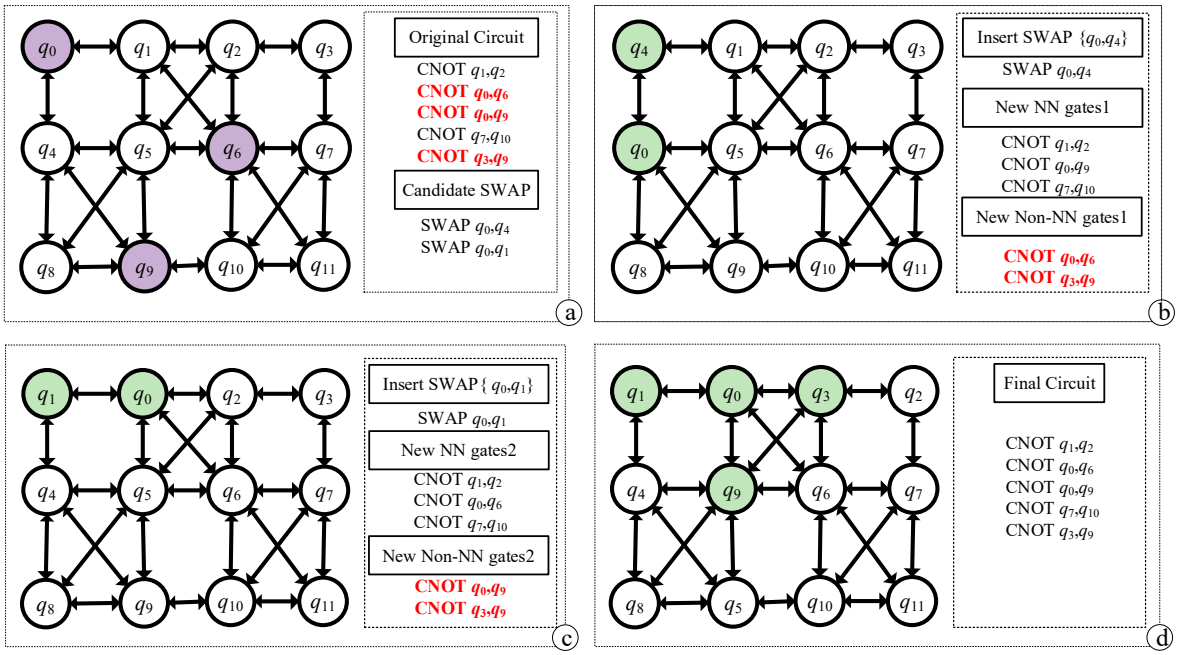

Fig. 4. (a) Original circuit, (b) Updated circuit after inserting SWAP $\{q_0, q_4\}$, (c) Updated circuit after inserting SWAP $\{q_0, q_1\}$, (d) Final circuit.

IV. Results Assessment

In this section, the main focus is on evaluating the operational results. Compared with one-dimensional chains and three-dimensional structures, two-dimensional structures have higher parallelism, qubits are arranged in the plane, and coupling and control are more simplified, which helps to reduce the noise level and error accumulation. Therefore, in this paper, we chose to compile on the IBM Quantum ibmq_montreal device with a two-dimensional structure, as shown in Fig. 5. The following key metrics are used to measure the effectiveness of the C-SQGS strategy on the compiler, one is the count of extra SWAP gates, and the other is the count of two-qubit gates, both of which are evaluated on the basis of the criterion that fewer is better [8]. The benchmark test program is IBM's Qiskit quantum program, which uses the Qiskit compiler to decompose and optimize the CNOT (CX) gate set. The benchmarking methodology of Tannu [27] was employed. The entire experiment was conducted using Python 3.11, with all compilations running on a laptop equipped with an Intel Core i5 processor (2.50 GHz, 8 GB RAM). Evaluations for 4 to 22 qubits were carried out, running the mapping process five times and selecting the best outcome.

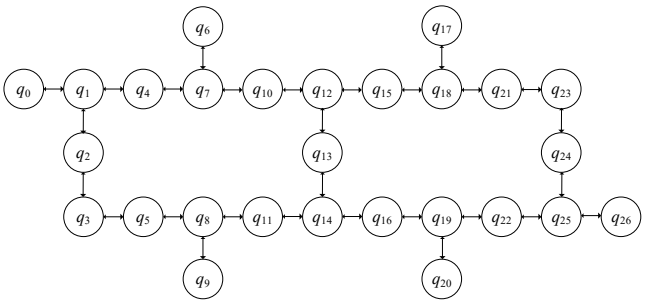

Fig. 5. Ibmq_montreal device.

In this paper, we compare the C-SQGS strategy with the compilation overhead of t|ket⟩ and Qiskit. The t|ket⟩ [28] and the Qiskit compiler [29] are equipped with the recommended "FullPass". The specific overheads of the C-SQGS with respect to the t|ket⟩ and Qiskit compilers are shown in Fig. 6. There are some optimizations in both the extra SWAP gate and CNOT gate counting overheads. The C-SQGS strategy is optimized relative to 2QAN, although the optimization is more significant for large qubits than for small qubits.

In the t|ket⟩ compiler, for circuits with 12-22 qubits, the C-SQGS strategy reduces the quantity of extra SWAP gates and CNOT gates by 6.1% and 5.5%, respectively, compared to 2QAN, as illustrated in Fig. 6(a), (b). For circuits with 4-10 qubits, the quantity of SWAP gates is decreased by an average of 26.4% and the quantity of CNOT gates by an average of 13.2% across all evaluated benchmarks after applying the C-SQGS strategy of this paper; the quantity of SWAP gates and CNOT gates are reduced by an average of 43.8% and 14.3%, respectively, after optimization of quantum circuits of 12-22 qubits, as illustrated in Fig. 7(a).

Within the Qiskit compiler framework, for circuits with 12-22 qubits, the C-SQGS strategy reduces the quantity of extra SWAP and CNOT gates by 5.7% and 7.6%, respectively, compared to 2QAN, as illustrated in Fig. 6(c), (d). For circuits with 4-10 qubits, after utilizing the C-SQGS strategy proposed in this paper, the quantity of SWAP gates is reduced by an average of 27.8% and the quantity of CNOT gates by an average of 14.9% in all the evaluated benchmarks, and the optimization of the quantum circuits of 12-22 qubits results in an average reduction of 61% in the quantity of SWAP gates, an average reduction in the quantity of CNOTs of 12.5%, and the overhead of double quantum gates is reduced by a factor of 2.5 compared to using only 2QAN, as shown in Fig. 7(b).

To further validate the advancement of the C-SQGS strategy, it is compared with the BSOS [8] and HQAA algorithms [13], as seen in Fig. 8. Within the t|ket⟩ compiler framework, for circuits with 4-10 qubits, the optimization effect of the C-SQGS is relatively tiny compared with the BSOS and HQAA algorithms, which is due to the fact that the circuit is simpler and the number of SWAP gates originally required is less in smaller quantum circuits, and the optimization effect is not easy to be seen. For circuits with 12-22 qubits, the advantage effect of the C-SQGS becomes more apparent. Specifically, compared with HQAA, the C-SQGS reduces the quantity of SWAP gates and CNOT gates by 9.3% and 12%, respectively. In the Qiskit compiler, for circuits with 4-10 qubit, C-SQGS reduces the quantity of CNOT gates by 4.1% and 4.3% compared to BSOS and HQAA, respectively. For circuits with 10-22 qubits, the quantity of SWAP gates is reduced by 3.1% and 12.7%, and the quantity of CNOT gates is reduced by 2% and 9.6%, respectively.

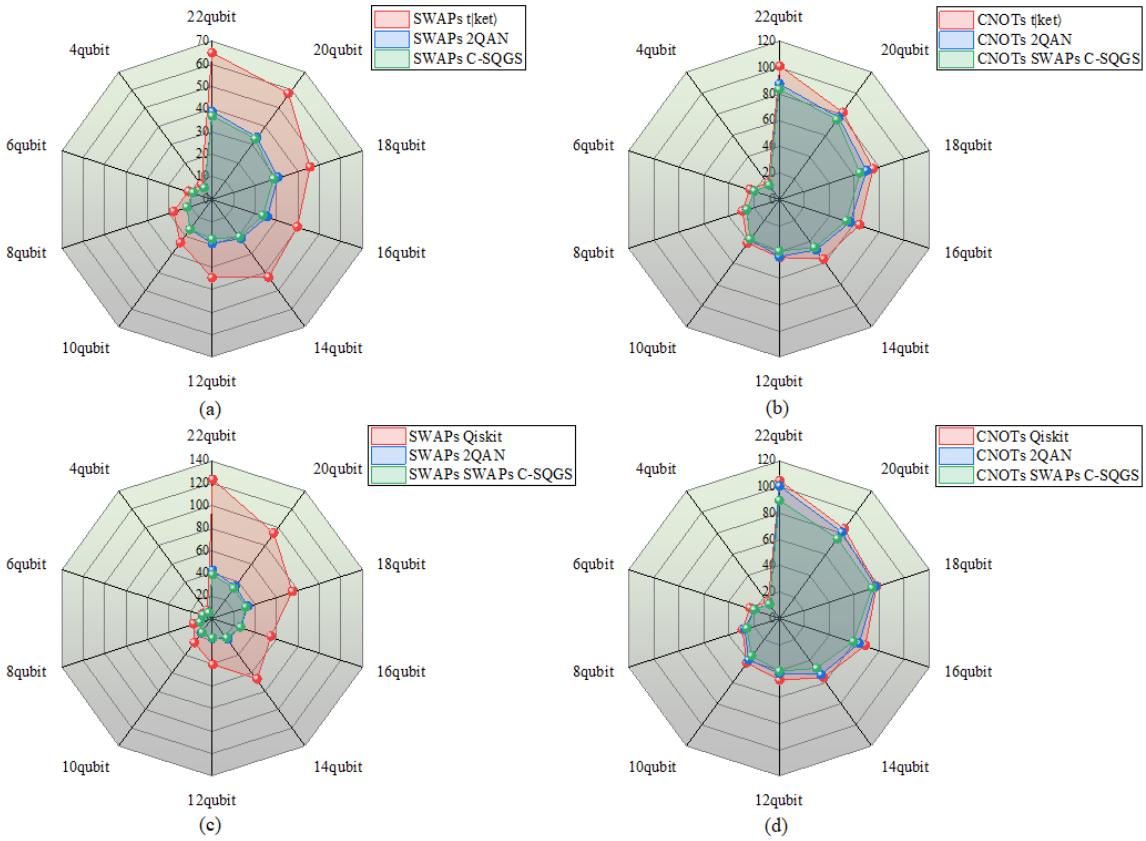

Fig. 6. (a) SWAP gate Overhead comparison between C-SQGS strategy, t|ket⟩ and 2QAN, (b) CNOT gate Overhead comparison between C-SQGS strategy, t|ket⟩ and 2QAN, (c) SWAP gate Overhead comparison between C-SQGS strategy, Qiskit and 2QAN, (d) CNOT gate Overhead comparison between C-SQGS strategy, Qiskit and 2QAN.

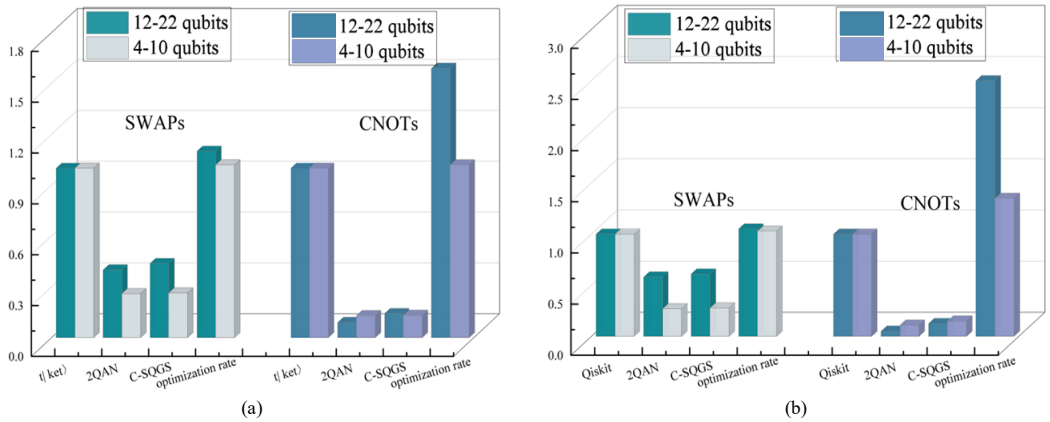

Fig. 7. The C-SQGS strategy was assessed for circuits with 4-10 qubits and 12-22 qubits. (a) Optimization ratio of SWAP and CNOT gates for C-SQGS compared to t|ket⟩ and 2QAN. (b) Optimization ratio SWAP and CNOT gate for C-SQGS compared to Qiskit and 2QAN.

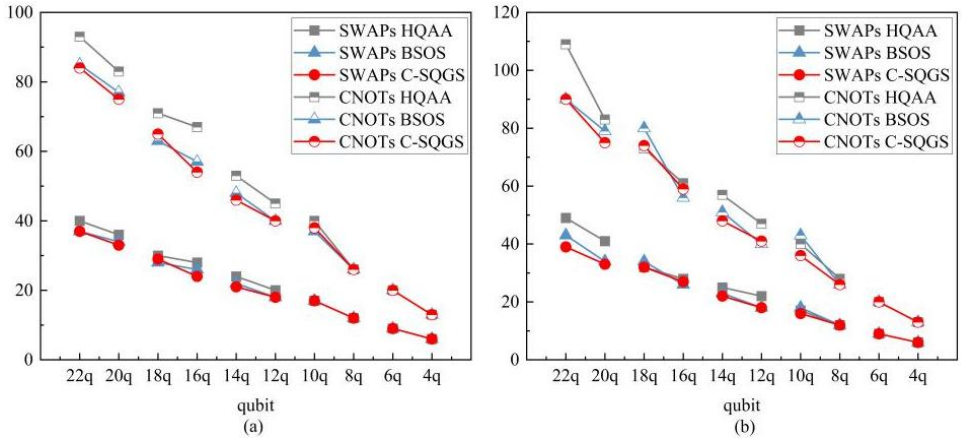

Fig. 8. Comparison of compilation overhead of different optimization algorithms. (a) Comparison of SWAPs and CNOTs overhead in the t|ket⟩. (b) Comparison of SWAPs and CNOTs overhead in the Qiskit.

The research in this paper focuses on the qubit mapping challenge, emphasizing the extra SWAP gate overhead and also considering the change in time complexity, which is a key measure of the algorithm's running efficiency. Table I shows the results of comparing the average running time of the 2QAN with the C-SQGS strategy in the t|ket⟩ and Qiskit compilers. The time complexity increases gradually with the increase in the count of qubits. Specifically, for smaller-scale quantum circuits, such as the 4-qubit model, the running time in the t|ket⟩ and Qiskit compilers is about 0.01s and 0.07s, respectively. However, the running time increases significantly as the circuit size increases. As an example, the runtime in the t|ket⟩ and Qiskit compilers for a 22-qubit circuit is about 27.4s and 0.29s, respectively.

TABLE I. COMPARE THE AVERAGE RUNTIME OF 2QAN AND C-SQGS STRATEGY IN T|KRT⟩ AND QISKIT COMPILERS

Qubit	Compiler	Running time(t/s)	
		2QAN	C-SQGS
4	t|ket⟩	0.1	0.01
	Qiskit	0.01	0.07
6	t|ket⟩	0.3	0.28
	Qiskit	0.09	0.09
8	t|ket⟩	0.46	0.41
	Qiskit	0.1	0.09
20	t|ket⟩	11.79	11.18
	Qiskit	0.24	0.22
22	t|ket⟩	28.23	27.4
	Qiskit	0.30	0.29

V. SUMMARY

This paper provides an in-depth discussion of the qubit mapping challenge, with a particular focus on the impact of physical topology on the mapping process in quantum computing. In the NISQ era, qubit mapping plays a key role in quantum circuit compilation. It aims to efficiently map logical qubits onto physical qubits, minimizing SWAP gates caused by topological constraints and enhancing circuit performance. To address this challenge, the C-SQGS strategy is proposed, aiming to optimize quantum circuits for the 2-local quantum simulation problem. To test the strategy, multiple experiments are conducted. The experimental results demonstrate that the C-SQGS strategy exhibits some advantages in reducing SWAP gate and hardware gate overhead. Specifically, the quantity of SWAP gates is diminished by an average of 36.9% and 47.7%, and the quantity of two-qubit gates is diminished by an average of 13.8% and 13.5% on the t|ket⟩ and Qiskit compilers, respectively.

Beyond empirical performance improvements, the results indicate several broader implications for qubit mapping and quantum compilation. Specifically, qubit flexibility–driven routing, centric gate prioritization, and multi-factor SWAP evaluation emerge as key design elements that help avoid short-sighted routing decisions and enable more execution-aware optimization under hardware constraints.

Although the C-SQGS strategy has achieved certain results in reducing the number of SWAP gates and the overhead of two-qubit gates, it still has limitations. First, this method is primarily designed and experimentally verified for medium-scale quantum circuits. For larger-scale quantum circuits, the computation of its multi-factor cost function and the evaluation process of candidate SWAP sets may introduce significant computational overhead, and the scalability of the algorithm requires further investigation. Second, experimental evaluations are primarily based on typical quantum circuits and a limited range of quantum chip topologies. Its applicability and generalization capabilities in more complex application scenarios and diverse quantum algorithms still have room for improvement.

With the continuous advancement of quantum computing technology, qubit mapping — a central problem in quantum computing — still faces significant challenges. Future research needs to explore several directions in greater depth to meet the evolving demands of quantum hardware and algorithms. On one hand, based on the C-SQGS strategy, optimization algorithms capable of adapting to more complex quantum topologies and higher-dimensional quantum gate sets will be developed, further enhancing the versatility and adaptability of the approach. On the other hand, efforts will be devoted to

designing more scalable mapping algorithms that can handle larger quantum circuits, while simultaneously pursuing the joint optimization of circuit design and mapping strategies. Since qubit mapping is closely linked to circuit structure, optimizing their interplay can further reduce redundant operations and improve the overall efficiency of quantum computing, thereby laying a solid foundation for its practical applications.

Department of Computer Science, University of Al-Maarif, Al Anbar, 31001, Iraq[3]

***Abstract*—Flood forecasting is critical for improving early warning systems in Malaysia's East Coast region, particularly in flood-prone Pekan. This study develops a Nonlinear Autoregressive with Exogenous Inputs (NARX) model to predict river water levels using data from four stations: Sungai Pahang, Sungai Pahang Tua, Sungai Paloh Hinai, and Sungai Mentiga (2020–2024). The dataset was preprocessed through short-gap interpolation, removal of long missing segments, and segmentation into continuous sequences to ensure high-quality inputs for modeling. A total of 75 NARX configurations were evaluated using different lag values, hidden neuron counts, and training epochs. Model performance was assessed using Mean Squared Error (MSE) and residual diagnostics. The best model—lag = 6 and 300 hidden units—achieved a validation loss of 0.102, demonstrating stable convergence and strong generalization. Prediction results showed close alignment with actual river levels. The findings confirm that the NARX approach effectively captures nonlinear hydrological dynamics and provides reliable short-term water level forecasts for Pekan, addressing an existing gap in localized flood prediction studies.**

***Keywords*—Flood prediction; NARX model; hydrological modelling; Pekan**

I. Introduction

The East Coast region of Peninsular Malaysia frequently experiences heavy rainfall during the Northeast Monsoon season, which often leads to flooding in low-lying and riverine areas. These flood events result in significant damage to infrastructure, disruption of transportation systems, and substantial economic losses for affected communities. Accurate and timely flood forecasting is crucial to support early warning systems and minimize flood-related impacts. Reliable river water level prediction enables authorities to make proactive decisions and implement preventive measures to safeguard lives and reduce property damage.

Despite ongoing advancements in hydrological monitoring, flood prediction in Malaysia remains challenging due to the nonlinear, dynamic, and spatially heterogeneous nature of river systems, particularly in monsoon-driven environments. These challenges are more pronounced at the district level, where complex upstream–downstream interactions and data continuity issues limit the effectiveness of generic basin-scale forecasting models.

In recent years, data-driven modelling has gained increasing attention for flood forecasting due to its ability to capture nonlinear and complex relationships within hydrological systems. This study aims to develop a predictive model using the Nonlinear Autoregressive model with Exogenous Inputs (NARX) for river water level forecasting in the East Coast region of Peninsular Malaysia. The NARX model utilizes historical hydrological data to learn temporal patterns, enabling more accurate predictions. By implementing the NARX-based approach, this research seeks to improve the accuracy and reliability of flood forecasting systems to enhance early warning capabilities and reduce flood-related risks.

Although NARX models have been widely applied in hydrological forecasting, most existing studies emphasize major river basins or regional-scale analysis, with limited focus on district-level river systems experiencing recurrent flooding. In particular, the Pekan district in Pahang—despite its high flood vulnerability—has received comparatively little attention in terms of localized, data-driven river level prediction models. Furthermore, prior work rarely investigates how multiple upstream river stations collectively influence downstream water level dynamics within an integrated modelling framework.

This study presents a systematically optimized NARX-based river water level prediction model tailored for the Pekan river system. The model integrates water level data from multiple upstream and downstream stations, including Sungai Pahang Tua, Sungai Paloh Hinai, and Sungai Mentiga, to predict downstream levels at Sungai Pahang (Pekan). A structured preprocessing and segmentation strategy is employed to ensure model training is conducted only on continuous, fully observed temporal segments, thereby preserving hydrological realism and avoiding artefacts introduced by long-gap imputation. In addition, a comprehensive exploration of lag length, hidden layer capacity, and training duration is performed to identify an optimal NARX configuration that balances prediction accuracy, convergence stability, and generalization performance. Through this approach, the study provides a localized and transferable modelling framework that supports district-level flood early warning applications.

The remainder of this study is organized as follows: Section II reviews related work on flood forecasting and data-driven hydrological modelling. Section III describes the dataset, preprocessing strategy, and NARX model architecture. Section IV presents the experimental results and discussion. Finally, Section V concludes the study and outlines limitations and directions for future work.

II. Literature Review

Flood disasters remain a major environmental and socio-economic concern in many regions, particularly in Malaysia, where seasonal monsoon patterns heavily influence hydrological conditions [1]. Researchers have employed various forecasting approaches to understand and predict flood behavior, ranging from traditional statistical and hydrological models to more recent machine learning and deep learning techniques. This literature review provides an overview of flooding characteristics in the Pantai Timur region, followed by a review of conventional flood forecasting methods. It then discusses the evolution of data-driven methods, including Artificial Neural Networks (ANN), Support Vector Regression (SVR), and Random Forest (RF), before examining advanced deep learning techniques such as Recurrent Neural Networks (RNN), Long Short-Term Memory (LSTM), and hybrid intelligent models. Finally, this chapter emphasizes the significance of the Nonlinear Autoregressive with Exogenous Input (NARX) model in hydrological forecasting and identifies the research gap motivating the present study.

A. Flooding in Malaysia and the Pantai Timur Region

Malaysia experiences frequent flooding due to its tropical climate and high-intensity rainfall patterns. The Pantai Timur region — consisting of Kelantan, Terengganu, and Pahang — is the most flood-prone zone in Peninsular Malaysia, particularly during the Northeast Monsoon season [1]. The region's river basins, low-lying settlements, and coastal geography increase vulnerability to overflow and prolonged inundation [2]. The Northeast Monsoon (NEM) typically occurs between November and March, bringing strong winds and heavy rainfall from the South China Sea [3]. The Malaysian Meteorological Department (2023) states that this seasonal event produces prolonged rainfall that causes river water levels to rise rapidly, triggering severe flooding across Pantai Timur [4]. The intensity and duration of monsoon rainfall directly affect river discharge, making water level prediction a crucial preventive measure. Several major flood events have occurred in Pantai Timur over the past decades, including those in Kelantan (2014) [5], Pahang (2021) [6], and Terengganu (2022) [7]. The 2014 Kelantan flood, widely referred to as "Bah Kuning" [8], affected more than half a million people, resulting in extensive property damage and infrastructure collapse. Such recurring events highlight the importance of accurate forecasting systems to mitigate disaster impacts.

B. Importance of River Level Forecasting

River level forecasting plays a crucial role in early warning systems, evacuation planning, and resource mobilization. Government agencies such as the Department of Irrigation and Drainage (DID) and the National Disaster Management Agency (NADMA) rely on real-time hydrological forecasting for decision-making [9]. Therefore, forecasting models must be accurate, reliable, and capable of capturing nonlinear hydrological behaviors.

C. Conventional Flood Forecasting Methods

1) Statistical time-series models (ARIMA, Regeression): The Autoregressive Integrated Moving Average (ARIMA) model is one of the most widely used statistical methods in river flow forecasting [10]. However, ARIMA assumes linearity and struggles to model complex nonlinear patterns that often characterize hydrological systems [11]. Regression-based models face similar limitations, particularly when dealing with high-variability rainfall-runoff relationships.

2) Physically-based hydrological models (SWAT, HEC-HMS): Physically-based models such as Soil and Water Assessment Tool (SWAT) and Hydrologic Engineering Center – Hydrologic Modeling System (HEC-HMS) simulate watershed hydrology using environmental and land-use parameters [12]. While these models provide insight into hydrological processes, they require extensive data input and calibration, making them difficult to apply in regions with limited monitoring networks [12]. Furthermore, parameter uncertainties can significantly reduce model reliability during extreme flooding events [13].

D. Machine Learning Approaches in Flood Forecasting

With advancements in computational power and data availability, machine learning has become an attractive approach for modeling hydrological processes. Artificial Neural Networks (ANNs) are capable of learning complex nonlinear relationships from data and have shown promising performance in flood forecasting applications. However, standard feed-forward ANNs are limited in handling long-term temporal dependencies in time-series data [14]. Support Vector Regression (SVR) offers good generalization performance but requires careful tuning of kernel functions and regularization parameters [15]. Random Forest (RF) performs well in capturing nonlinear patterns but may become computationally intensive with large datasets [16]. Both methods demonstrate improvement over linear models, yet are still constrained in modeling sequential dependencies over time.

E. Deep Learning Models in Hydrological Time-Series Forecasting

Recurrent Neural Networks introduced time-sequence modeling capability. However, traditional RNNs suffer from gradient vanishing issues, limiting their ability to learn long-term dependencies [16]. Long Short-Term Memory (LSTM) and Gated Recurrent Unit (GRU) models were specifically developed to address memory retention issues and have demonstrated superior performance in predicting streamflow and river water levels [17]. These models capture temporal dependencies more effectively than simple ANNs [18]. Hybrid models that integrate convolutional and recurrent architectures or attention mechanisms have further improved forecasting accuracy by extracting temporal and spatial patterns [19]. However, these models require large datasets and high computational resources, limiting their real-time deployment in some regions [20].

F. NARX Model for Hydrological and Flood Forecasting

The Nonlinear Autoregressive with Exogenous Input (NARX) model is a dynamic neural network that uses previous output values and external variables (e.g., rainfall) to predict future water levels [21]. This architecture enables the model to represent nonlinear hydrological dynamics effectively. NARX

models converge faster and provide higher prediction accuracy than traditional ANN and RNN due to their explicit memory mechanism [22]. They are particularly effective in modeling systems where external forcing influences the target variable. Studies demonstrate that NARX achieves high accuracy in river level forecasting across Southeast Asian river basins [23]. Its performance is notably superior when dealing with short-term and multi-step forecasting [23].

G. Research Gap

Although a variety of hydrological and data-driven flood forecasting models have been applied in Malaysia, most previous research has focused on river basins in Kelantan and Terengganu [24], while significantly less attention has been given to Pahang, particularly the Pekan district. Existing flood prediction frameworks do not adequately represent the hydrological and rainfall–runoff characteristics of Pahang's river systems. As a result, there is currently no dedicated flood prediction model specifically developed for Pekan, despite its recurring seasonal floods and high socio-economic vulnerability. Furthermore, previous studies rarely examine flood behavior along the entire river course, from upstream to downstream, which is critical for understanding how rainfall and runoff propagate through the watershed before causing overflow in low-lying coastal areas like Pekan. Developing a tailored model would therefore not only improve prediction accuracy but also enable a better understanding of flood dynamics along the river continuum, supporting more effective local early-warning and disaster preparedness strategies. Hence, this study focuses on designing and evaluating an NARX-based prediction model specifically for the Pekan region, to address this gap.

H. Summary of the Literature Review

While conventional statistical and physically-based models provide foundational hydrological understanding, their performance declines due to the nonlinear and dynamic characteristics of flood behavior. Machine learning and deep learning methods such as ANN, SVR, RF, LSTM, and hybrid architectures have shown improved predictive ability by capturing complex temporal dependencies. The NARX model, in particular, has demonstrated strong performance in multi-step hydrological forecasting due to its capability to incorporate external variables and maintain memory of past system states.

However, the review shows that little research has focused on flood prediction in Pahang, and almost none has been conducted specifically for Pekan, even though the district is highly affected by recurring monsoon floods [1]. Additionally, there is limited study on flood progression along the river system from upstream to downstream, which is essential for understanding how floodwater develops and travels before reaching populated flood-prone areas. Therefore, the present study aims to develop a NARX-based river level prediction model specifically tailored for the Pekan river system, providing more localized and accurate early-warning insights to support flood management and preparedness.

III. Methodology

A. Dataset

The dataset consists of hourly hydrological measurements collected over five years (2020–2024) from four river stations: Sungai Pahang, Sungai Pahang Tua, Sungai Paloh Hinai, and Sungai Mentiga. The target station for prediction is Sungai Pahang at Pekan, which represents the confluence point of the other three rivers.

Each dataset contains several attributes, including Station ID, Station Code, Station Name, Date, Time, Water Level (m), Rainfall (mm), Cumulative Daily Rainfall (mm), and Cumulative Annual Rainfall (mm). For this study, only the Water Level (m) parameter was retained to ensure model focus and reduce noise from unrelated variables.

B. Data Preprocessing

To standardize the temporal resolution, the hourly data were aggregated into daily averages, resulting in one representative water level value per day for each station. The daily average water level, $\bar{H}_d$, was computed as:

$$\bar{H}_d = \frac{1}{n}\sum_{i=1}^{n} H_i \quad (1)$$

where, $H_i$represents the water level recorded at the i^{th}hour of a given day, and $n$is the total number of hourly observations within that day (typically $n = 24$).

C. Interpolation of Short Gaps

Short gaps, defined as missing periods of fewer than 5 consecutive days, were imputed using linear interpolation. For a missing value at time t, the estimate was calculated as:

$$x_t = \frac{(t-t_{prev})*x_{next}+(t_{next}-t)*x_{prev}}{t_{next}-t_{prev}} \quad (2)$$

where, x_{prev} and x_{next} represent the nearest observed values surrounding the gap. This approach is appropriate for short-duration gaps where hydrological changes are typically gradual and continuous.

Large gaps (≥5 consecutive days) were not imputed. Instead, the entire row corresponding to that timestamp was removed across all stations. This ensures that each training instance contains complete values for Sungai Pahang, Sungai Pahang Tua, Sungai Paloh Hinai, and Sungai Mentiga, thereby avoiding inconsistencies caused by high-uncertainty imputations.

The removal of rows containing long gaps is motivated by several scientific and statistical considerations:

- Non-linear and event-driven hydrological behavior: Water levels in rivers respond to rainfall, upstream releases, tidal influences, and runoff processes that evolve non-linearly. Over multi-day periods, such dynamics cannot be reliably reconstructed using linear or low-order imputation techniques. Long-gap interpolation introduces unrealistic smoothing and distorts natural fluctuations.
- Autocorrelation decay in river-level time series: Hydrological time series typically exhibit rapid

autocorrelation decay within a few days. When observations are separated by long gaps, their statistical dependence becomes weak, making interpolated values unreliable. Avoiding long synthetic intervals preserves the natural temporal structure of the data.

- Uncertainty amplification: Interpolation error grows with gap duration. Long-gap estimates carry high uncertainty that may propagate into model training, degrading predictive performance and weakening the model's ability to capture extreme events.
- Avoidance of model bias and artefact learning: Machine learning models are sensitive to artificial patterns caused by imputation. Long imputed segments may lead the model to learn interpolation artefacts rather than genuine hydrological relationships among the four stations.

After preprocessing, the dataset was divided into continuous segments—defined as sequences of dates in which none of the stations (Sungai Pahang, Sungai Pahang Tua, Sungai Paloh Hinai, Sungai Mentiga) exhibits a large missing gap. Separate regression models were trained on these fully complete segments. Training regression models on continuous, fully observed segments is scientifically valid and methodologically justified for several reasons:

- Preservation of underlying hydrological dynamics: Continuous segments represent uninterrupted periods during which the inter-station relationships reflect real hydrological behavior. This allows the model to learn authentic temporal patterns rather than artefacts arising from imputed values.
- Assumption of local stationarity: River systems often exhibit local stationarity, meaning their statistical properties remain stable within reasonably short continuous periods. Segment-wise modelling respects this property and allows consistent parameter estimation.
- Avoidance of cross-regime contamination: Long missing gaps often coincide with unusual hydrological states (e.g., floods, sensor outages, maintenance). Segmentation prevents mixing incompatible regimes that could introduce non-physical relationships into the model.
- Reduction of structural bias: Restricting training to fully observed data ensures that regression parameters reflect true input–output relationships rather than smoothed or synthetic signals.
- Hypothetical validity via conditional independence: If each continuous segment is assumed to originate from the same underlying hydrological process governing the four stations, then each segment provides an independent sample from the same distribution. This satisfies the theoretical assumptions required for regression modelling.
- Improved generalization: Models trained only on high-quality, continuous data are better able to generalize to unseen periods, particularly during rapidly changing hydrological conditions such as rising or receding river stages.

These grouped datasets were then utilized for the Nonlinear AutoRegressive model with eXogenous inputs (NARX) during the modeling stage.

The NARX model was implemented using Python with TensorFlow and Keras frameworks. The dataset was divided into training and testing sets, with the training phase used to optimize network weights.

The loss function used to evaluate model performance is the Mean Squared Error (MSE), calculated as:

$$MSE = \frac{1}{N}\sum_{i=1}^{N}(y_i - \hat{y}_i)^2 \quad (3)$$

where, $y_i$and $\hat{y}_i$are the observed and predicted water levels, respectively, and N is the total number of samples. Lower MSE values indicate higher prediction accuracy and better model generalization.

D. NARX Model Structure

The general form of the NARX model is expressed as:

$$y(t) = f(y(t-1), y(t-2), \dots, y(t-n_y), x(t-1), x(t-2), \dots, x(t-n_x)) \quad (4)$$

where,

- $y(t)$ is the predicted river water level at time t,
- $x(t)$ represents the exogenous input variable (e.g., rainfall or other influencing factors),
- $n_y$and $n_x$denote the feedback (lag) orders, and
- $f(\cdot)$ is a nonlinear function approximated using an MLP network.

E. Model Architecture

Table I shows that the predictive model used a feedforward neural network with one hidden layer, following the structure:

TABLE I. THE STRUCTURE OF THE MODEL

Layer	Description
Input Layer	Dimension determined by the lag size and number of variables.
Hidden Layer	Fully connected, with variable neuron counts (150, 300, or 600 units).
Activation Function	Rectified Linear Unit (ReLU).
Dropout Layer	20% dropout for regularization and overfitting prevention.
Output Layer	A single linear neuron producing the next-step forecast.

The model was defined using the Sequential API in TensorFlow Keras. The network was compiled with the Adam optimizer (learning rate = 1×10^{-3}, weight decay = 1×10^{-5}) and Mean Squared Error (MSE) as the loss function.

F. Training Procedure

Each configuration was trained under varying combinations of:

- Lags: {3,4,5,6,7}
- Hidden Units: {150,300,600}
- Epochs: {100,300,500,1000,5000}

This yielded a total of 45 experimental runs.

Training was executed with a batch size of 128 and data shuffling enabled to prevent temporal bias.

During each experiment:

- The model was trained on the training set and validated on the test set.
- The training and validation loss histories were recorded.
- Predictions were generated for both training and test datasets.
- Diagnostic visualizations were saved, including:
  - Loss curve (training vs. validation loss),
  - Residual plots (train/test residuals),
  - Prediction plots (actual vs. predicted values).

G. Evaluation Metrics

The model's predictive performance was primarily evaluated using Mean Squared Error (MSE) as the loss function. Additional diagnostic analyses included:

- Residual distribution to assess error randomness and bias.
- Train vs. Validation loss comparison to detect overfitting.
- Actual vs. Predicted plots to visually assess alignment between predictions and ground truth.

IV. Implementation, Results and Discussion

A series of experiments were conducted to evaluate the performance of a neural network model trained with different lag values and hidden unit configurations for time-series forecasting. The parameter grid covered lags {3, 4, 5, 6, 7}, hidden units {150, 300, 600}, and epochs {100, 300, 500, 1000, 5000}. The primary evaluation metric was validation loss (Mean Squared Error), with train loss also monitored to assess potential overfitting or underfitting.

A. Best Validation Performance by Lag and Hidden Units

The heatmap in Fig. 1 illustrates the best validation loss achieved for each combination of lag and hidden unit count.

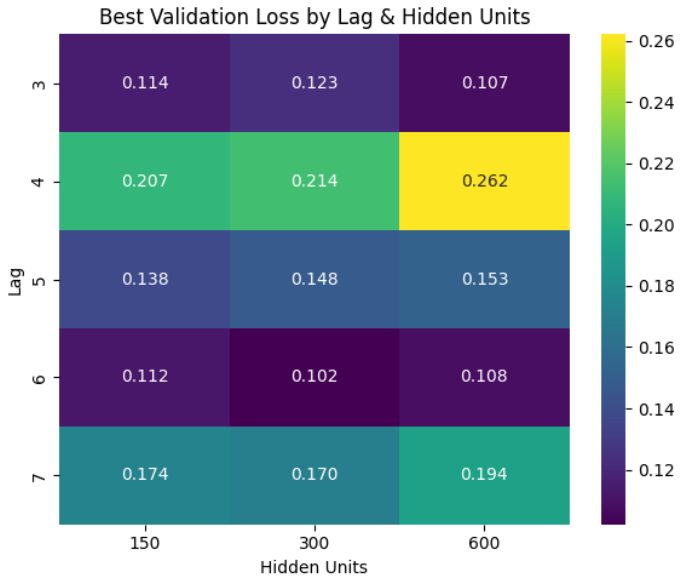

Fig. 1. Heatmap.

Fig. 1 shows that the model achieved its lowest validation loss (0.102) for Lag = 6 and Hidden Units = 300, indicating that this configuration provides an optimal balance between temporal dependency capture and model complexity. Generally, lags between 3 and 6 produced comparable results, while performance deteriorated at lag = 4 and lag = 5, especially when the hidden layer size was small (150). Increasing the hidden units to 300 consistently improved performance for most lags, whereas using 600 units did not always yield further benefits — suggesting possible overparameterization for the dataset size.

B. Relationship Between Training and Validation Loss

The scatter plot in Fig. 2 compares the final train loss against validation loss across all configurations.

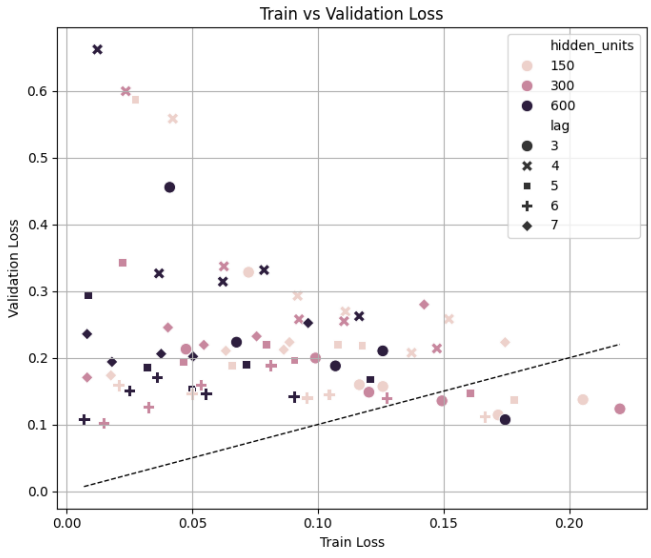

Fig. 2. Scatter plot.

As shown in Fig. 2, most points lie close to or above the diagonal reference line, indicating that validation losses were typically higher than training losses — a standard indicator of slight overfitting. However, several configurations (particularly those with hidden units = 300 and moderate lags) exhibited a close alignment between train and validation losses, suggesting good generalization. Notably, models trained with Lag = 4 and Lag = 5 showed larger gaps between train and validation losses, reflecting unstable learning dynamics or insufficient temporal context.

C. Validation Loss Trends Across Epochs

Fig. 3 to Fig 7 show validation loss progression across training epochs for each lag value.

Lag = 3: Validation loss decreased sharply up to 1000 epochs for hidden units = 150 and 300, followed by an increase at 5000 epochs, indicating early convergence and later overfitting.

Lag = 4: All configurations exhibited diverging losses beyond 1000 epochs, implying unstable training or excessive learning rates for deeper models.

Lag = 5: The validation loss initially improved but then rose steeply for higher epochs, confirming overfitting at extended training durations.

Lag = 6: The trend showed consistent improvement as training progressed, achieving the lowest validation loss (≈0.10) at 5000 epochs, particularly with hidden units = 300. This indicates a robust generalization pattern.
- Lag = 7: The loss curves demonstrated oscillation and mild overfitting beyond 2000 epochs, though the overall performance remained stable within a 0.18–0.25 MSE range.

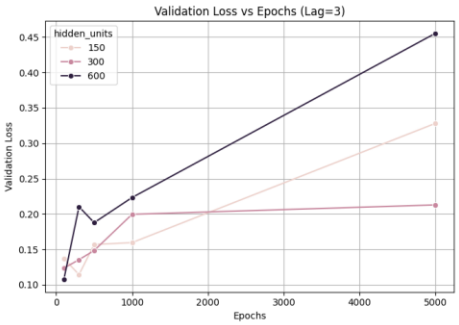

Fig. 3. Lag 3 validation loss.

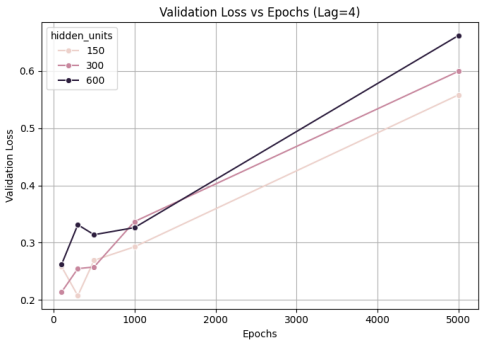

Fig. 4. Lag 4 validation loss.

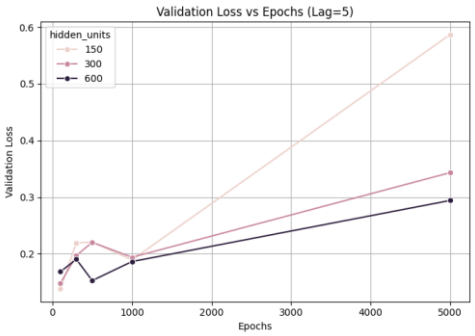

Fig. 5. Lag 5 validation loss.

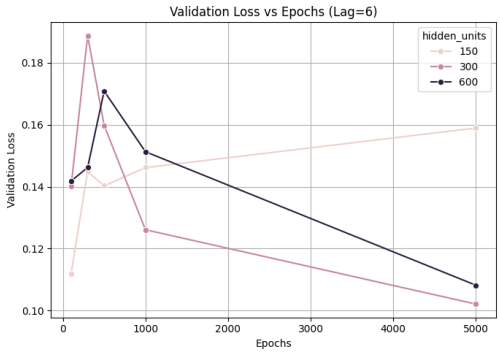

Fig. 6. Lag 6 validation loss.

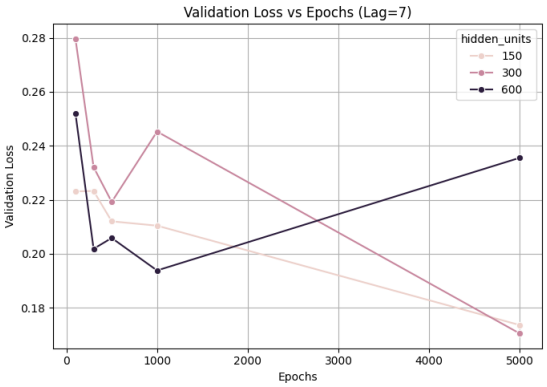

Fig. 7. Lag 7 validation loss.

D. Cross-Lag Performance Interpretation

Comparing across lags, the results suggest that:

- Short lags (3–4) capture limited temporal dependencies, causing early saturation in validation performance.
- Intermediate lag (6) offers an optimal trade-off — long enough to model dependencies, but not too large to introduce noise.
- Longer lag (7) yields diminishing returns, potentially due to redundant temporal information or vanishing gradients.

This aligns with the hypothesis that increasing input sequence length does not guarantee improved forecasting accuracy beyond a certain point.

E. Summary of Key Observations

From Table II, the observed behavior underscores the importance of balancing model capacity, temporal depth, and training duration. While larger models (600 units) have higher representational power, they are also prone to overfitting when training data are limited. Conversely, too few hidden units (150) restrict learning capability. Hence, medium-sized architectures (300 units) paired with sufficient historical context (Lag = 6) represent an optimal trade-off for this dataset. These findings can guide future hyperparameter selection for similar neural forecasting tasks, where data periodicity and temporal correlation length are critical factors.

TABLE II. THE BEST RESULT FOR EACH LAG

Lag	Hidden Units	Best Val Loss	Notes
3	300	0.114	Stable and generalizable
4	300	0.214	Poor stability beyond 1000 epochs
5	600	0.153	Unstable, possibly overfitted
6	300	0.102 (best)	Strong generalization and stable learning
7	150	0.174	Gradual improvement but limited gain

F. Detailed Evaluation of the Best Model (Lag = 6, Hidden Units = 300)

1) Loss curve analysis: The loss curve in Fig. 8 depicts the evolution of training and validation losses across 5000 epochs. The training loss exhibits a steep decline during the early epochs, stabilizing near zero after approximately 1000 epochs.

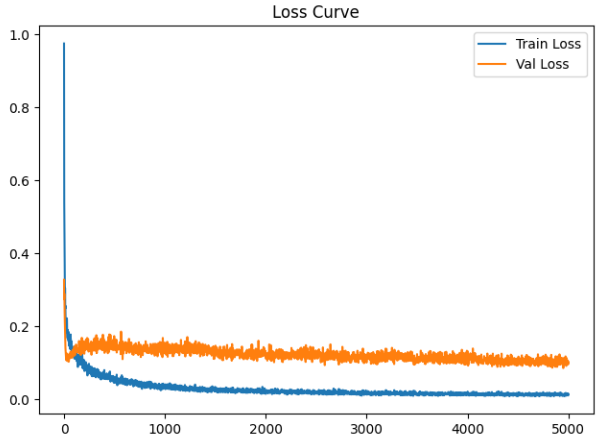

Fig. 8. Training and validation loss curves showing convergence behavior for the best model configuration (Lag = 6, Hidden Units = 300).

The validation loss follows a similar trend but converges to a higher steady-state value around 0.10, consistent with the best validation loss recorded in the summary. The relatively small gap between training and validation losses indicates effective generalization and minimal overfitting. Both curves maintain stability without significant oscillation or divergence, suggesting that the model converged smoothly. This steady behavior reflects robust learning dynamics, where the model captures relevant temporal dependencies without memorizing noise from the training set.

2) Residual diagnostics: The residual plots in Fig. 9 illustrate the difference between predicted and actual values for both training and test sets.

Fig. 9. Residual plots for training and test datasets, showing randomness and unbiased prediction errors.

In the training residuals, values fluctuate randomly around zero with no visible pattern or trend, implying that the model's predictions are unbiased and errors are normally distributed. The magnitude of residuals remains small (within ±0.1), confirming that the model fits the training data accurately without systematic error. The test residuals display slightly larger fluctuations, ranging within ±0.25, which is expected due to unseen data. However, no clear autocorrelation or drift is present, supporting the conclusion that the model generalizes well beyond the training sample. This diagnostic outcome supports the statistical soundness of the model and its ability to perform consistent predictions across both datasets.

3) Prediction performance on training data: The training prediction plot in Fig. 10 demonstrates an almost perfect overlap between actual and predicted values. The consistency across the full sequence confirms the model's high accuracy in reconstructing training samples while maintaining generalization, as verified in the test results. This balance reinforces that the selected architecture (Lag = 6, Hidden Units = 300) achieves optimal expressiveness without overfitting. The model appears to have successfully extracted dominant temporal patterns and relationships within the data.

4) Prediction performance on test data: Fig. 11 compares actual and predicted values for the test set. The predicted curve closely tracks the actual target trend, capturing both peaks and troughs of the series effectively. Minor deviations occur at extreme points, which may be attributed to local variations not captured by the lag window of six.

The close alignment between both curves indicates that the model successfully learns the non-linear temporal dependencies within the data. The prediction continuity and minimal phase lag between actual and predicted signals further validate the model's capacity to anticipate short-term dynamics with good precision.

5) Summary of findings for optimal model: The results highlight the importance of appropriate lag selection in temporal modeling. With a lag of 6, the network accesses

sufficient historical context to infer meaningful sequential dependencies without introducing redundant or noisy information. Moreover, the moderate hidden layer size of 300 provides adequate representational capacity to capture non-linear relations while preserving regularization balance. The residual randomness and low validation loss collectively confirm that the model achieved an optimal bias–variance tradeoff. This configuration will be considered as the final candidate for deployment or further comparative experiments with other forecasting or hybrid deep learning approaches (see Table III).

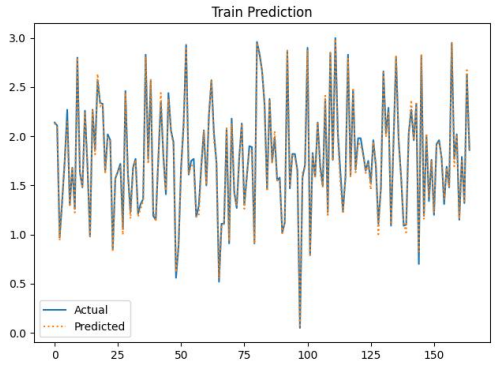

Fig. 10. Training prediction performance showing close alignment between predicted and actual series.

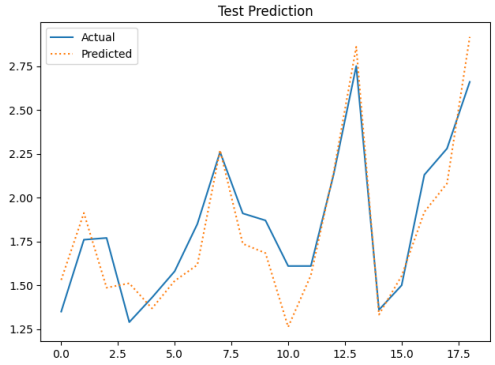

Fig. 11. Test prediction performance comparison between actual and predicted values.

TABLE III. FINDING SUMMARY

Metric	Observation
Lag	6
Hidden Units	300
Best Validation Loss	0.102
Training Stability	Excellent (Smooth convergence)
Generalization	Strong (Low validation gap)
Residual Behavior	Random, low magnitude
Test Prediction Fit	High correlation with actual series

V. CONCLUSION

This study set out to develop a reliable and accurate river water level forecasting model for the Pekan region using the Nonlinear Autoregressive model with Exogenous Inputs (NARX). The motivation derived from recurring monsoon-driven floods in the East Coast of Peninsular Malaysia, where existing forecasting systems lack models tailored specifically to Pahang's hydrological characteristics. The literature review highlighted that while conventional statistical and physically-based models offer foundational insights, their performance often deteriorates under nonlinear and dynamic flood conditions. Modern machine learning and deep learning techniques provide improved predictive capabilities, yet most previous research remains concentrated in Kelantan and Terengganu, leaving a significant gap for Pahang—particularly the low-lying Pekan district.

A comprehensive dataset of daily water levels from 2020 to 2024 was preprocessed, cleaned, and segmented into continuous temporal sequences to ensure robust model training. Using this dataset, a series of 75 experiments was conducted across varying lag values, hidden unit sizes, and training epochs to identify the optimal NARX configuration. Performance evaluation relied primarily on Mean Squared Error (MSE), supported by residual diagnostics and actual-versus-predicted comparisons for both training and test sets.

The experimental results demonstrated that Lag = 6 and Hidden Units = 300 provided the most effective and stable predictive performance, achieving a minimum validation loss of 0.102. This configuration offered a balanced combination of temporal memory and model complexity, outperforming smaller architectures, which lacked representational strength, as well as larger models, which tended to overfit. Loss curve analyses further confirmed smooth convergence and minimal divergence between training and validation losses, indicating strong generalization. Residual analyses showed randomness without bias, while prediction plots revealed close alignment with actual water level fluctuations, successfully capturing trend variations and peak events.

From a scientific perspective, this study contributes a structured and reproducible NARX modelling framework that integrates multi-station river dynamics with systematic lag–capacity optimization for district-level hydrological forecasting. Practically, the proposed model offers actionable value for local flood early warning systems by providing accurate short-term water level predictions that can support decision-making by authorities in flood-prone areas such as Pekan.

Despite these encouraging results, several limitations of this study should be acknowledged. First, the model relies solely on historical water level data and does not explicitly incorporate rainfall, tidal influence, or reservoir release information, which may further enhance predictive accuracy during extreme hydrological events. Second, model training was conducted using daily-aggregated data, which may limit responsiveness to rapid intra-day water level changes during flash flood conditions.

Future work will focus on extending the proposed framework by incorporating additional hydrometeorological variables and evaluating multi-step-ahead forecasting performance for longer early warning lead times. Integration with real-time sensor networks and comparative evaluation

against alternative data-driven models may further strengthen the operational applicability of the approach.

In conclusion, the NARX-based approach developed in this work offers a valuable contribution toward strengthening flood preparedness and decision-support mechanisms in Pahang. With continued refinement and integration into operational forecasting systems, it can play a significant role in mitigating the socio-economic impacts of seasonal flooding and enhancing resilience in vulnerable communities.

ACKNOWLEDGMENT

This study was made possible by the generous funding provided by the international grant UIC241504. The authors are deeply indebted to Universiti Malaysia Pahang Al-Sultan Abdullah (UMPSA) and Al Maarif University College for their invaluable contributions in terms of facilities, expertise, and collaboration. The authors also wish to express their sincere appreciation to the Department of Irrigation and Drainage, Pahang State (JPS Pahang) for their support, cooperation, and provision of relevant information throughout the course of this study.

***Abstract*—According to the International Agency for Research on Cancer, cervical cancer is a major cause of death among Moroccan women, with high incidence and mortality rates. Early detection remains essential to increasing patients' chances of recovery. Our study combines polarized light imaging, digital image correlation (DIC), Gray-Level Co-occurrence Matrix (GLCM) texture analysis, and fractal-based local standard deviation mapping to identify microstructural alterations in cervical tissue. Smear and biopsy samples were collected and anonymized in hospitals in Agadir, Morocco. Our goal is to develop an optical system based on the interaction between polarized light and tissue, as well as a complementary computational framework to distinguish between different types of healthy, precancerous, and cancerous tissue. DIC revealed heterogeneous deformation patterns in cancerous regions, fractal analysis highlighted increased structural complexity, and GLCM features showed higher contrast and entropy in malignant samples. This pilot study introduces a novel approach combining polarimetric imaging and computational analysis, applied to cervical tissue samples from Moroccan women in Africa. Despite the small size of the ex vivo dataset, the results obtained encourage the conduct of larger-scale prospective and in vivo studies.**

***Keywords*—Polarized light; digital image correlation; Gray-Level Co-occurrence Matrix; fractal; cervix; cancer**

I. Introduction

Cervical cancer remains a major global public health concern, particularly in low- and middle-income countries (LMICs), where it represents one of the leading causes of cancer-related mortality among women. According to recent estimates from the World Health Organization and GLOBOCAN, more than 85% of cervical cancer deaths occur in these regions, largely due to late diagnosis and limited access to effective screening and early detection programs [1]. In North Africa, and specifically in Morocco, cervical cancer is among the most common gynecological malignancies, with incidence and mortality rates remaining high despite ongoing prevention efforts [2]. The cervical samples analyzed in the present study were obtained exclusively from Moroccan women, providing direct clinical relevance to this regional context.

In this context, one of the major challenges is the lack of screening tools that are simultaneously reliable, objective, cost-effective, and adaptable to constrained healthcare infrastructures. Conventional diagnostic approaches often rely on subjective visual assessment, requiring specialized expertise and equipment. This limits their scalability in environments with limited resources. In this regard, optical imaging techniques based on light polarization analysis offer a promising and innovative alternative. Polarimetric imaging is intrinsically sensitive to microstructural and organizational changes in biological tissues associated with early stages of carcinogenesis. Polarization-based methods can reveal subtle pathological alterations that are undetectable using conventional imaging techniques. This is achieved by examining the properties of anisotropy, scattering and structural organization.

In this work, we propose a computational framework based on polarimetric imaging for the analysis of cervical tissue samples, aiming to address current limitations to cervix screening. The proposed framework is well-suited for low-resource settings by combining availability, affordability and sensitivity to early microstructural alterations. The methodology integrates polarization analysis with advanced image processing and quantitative analysis methods, including digital image correlation (DIC), Gray-Level Co-occurrence Matrix (GLCM) analysis, and fractal analysis. The investigation of tissue architecture and organization enables discrimination between malignant and healthy regions, while texture analysis and structural complexity metrics provide quantitative biomarkers of early pathological alterations.

The main potential contributions of this study are threefold. First, the development of a polarimetric imaging framework specifically tailored for the characterization of cervical tissue in resource-limited settings. Second, the integration of polarization-derived parameters with multi-scale computational descriptors (DIC, GLCM, and fractal features) in order to achieve objective and quantitative tissue discrimination. Third, the experimental validation of the proposed approach using real ex vivo cervical tissue samples from anonymized Moroccan patients demonstrates its ability to reliably distinguish healthy tissue from malignant regions.

Building upon this framework, the present study first reviews related work on optical and polarization-based imaging techniques applied to cervical cancer detection. It then describes the experimental setup and materials, emphasizing a non-invasive, low-cost, and non-harmful imaging modality that

operates within the visible light spectrum and requires no contrast agents, in contrast to many conventional imaging techniques. The use of ex vivo cervical tissue samples is subsequently detailed, followed by a comprehensive presentation of the proposed computational methodology. The results are presented and discussed to demonstrate the robustness and effectiveness of the proposed framework to reliably distinguish healthy cervical tissue from malignant regions, highlighting its potential clinical relevance for early cancer detection and its contribution to reducing disparities in LMICs. Finally, the study ends with a conclusion.

II. Related Work

Polarization is a fundamental property of light and a powerful detection tool applied in many fields, including biomedical diagnosis. According to the literature, several works have been realized on the interaction between polarized light and tissue [3], [4], [5], [6]. In biomedical imaging, unlike non-polarized light, linear polarization is particularly useful for detecting early pathological changes due to the defined orientation of the electric field, which enhances sensitivity to tissue alteration and microstructural organization [7]. Different polarization measurement types have been used for cancer detection. For instance, in 2021, researchers at Tokyo Institute of Technology experimentally demonstrated a novel cancer diagnosis technique based on the scattering of circularly polarized light, which computational studies revealed can detect the progression of precancerous lesions and early cancer [8], [9].

In diagnostic applications, the interaction of polarized light with biological tissues provides valuable structural information, enhancing contrast, characterizing tissue, reducing surface reflections, and revealing subtle alterations for earlier and more accurate detection. Elliptically polarized light has demonstrated significant potential, offering complementary structural and compositional insights, while linearly polarized light [10] remains essential for reliable contrast enhancement and detailed assessment of tissue organization, and should not be overlooked.

Building on the ability of linearly polarized light to enhance contrast and reveal structural features, Orthogonal State Contrast (OSC) has emerged as a promising technique in biological imaging, and more broadly as a robust metric in laser-illuminated active polarimetric systems. Used as a practical surrogate for the degree of polarization, OSC enables efficient discrimination of targets with distinct polarimetric signatures, notably in remote sensing applications [11], [12].

Recent research has focused on refining Orthogonal State Contrast techniques to achieve higher precision in biological tissue analysis. For example, Pierangelo et al. analyzed cancerous and healthy human colon samples ex vivo using a multispectral Mueller polarimeter in the visible range (500–700 nm). Their study demonstrated that depolarization measurements under linearly polarized light depend on tumor presence, type, thickness, and tissue composition, allowing clear differentiation between healthy tissue, various tumor subtypes, and post-radiochemotherapy tissue. These results highlight the potential of polarization-based imaging for precise tissue characterization and rapid cancer staging [13].

Beyond colon studies, several investigations have applied Orthogonal State Contrast (OSC) and Mueller Matrix (MM) polarimetry to cervical tissue analysis. The cervix consists of squamous epithelium and connective tissue, with collagen fibers providing structural strength. Pathologies such as cervical intraepithelial neoplasia (CIN), cancer, pregnancy, and spontaneous preterm birth remodel both epithelial and connective layers. OSC and MM polarimetry, using polarized light, enable quantification of these changes, with parameters like depolarization and birefringence providing contrast linked to tissue organization and pathology. Advances in OSC-based imaging, including specialized colposcopes, support detailed, non-invasive assessment of cervical alterations, highlighting the potential of polarization techniques for early detection and clinical diagnostics [14].

Leveraging the benefits of polarized light for enhancing tissue contrast and revealing structural features, fractal analysis has emerged as a powerful tool for cancer detection. By quantifying the complexity of tissue architecture, fractal dimension measures can distinguish malignant regions from healthy tissues, capturing subtle morphological alterations that are often invisible to conventional imaging [15]. Complementing this, Gray-Level Co-occurrence Matrix (GLCM) analysis provides quantitative information about tissue texture, such as contrast, correlation, and homogeneity, which has been successfully applied to differentiate cancerous from normal cells in various tissue types [16], [17]. The combination of polarized light imaging and computational analysis offers a reliable and objective approach for early malignancy detection, highlighting its promise in non-invasive cancer diagnostics.

Motivated by previous research, this work employs polarized light imaging combined with computational techniques to analyze cervical tissue samples. The next section details the experimental approach, covering sample handling, imaging procedures, and computational analysis for tissue classification.

III. Materials and Methods

A. Instruments and Measurement Protocol

We studied the interaction of histological slides of the cervix with polarized light on a microscopic level. This approach, known as polarization microscopy, can reveal detailed structural information about tissue. The optical setup employs a commercially available polarized light microscope (OPTIKA, Italy) to enable detailed observation and analysis of microscopic structures, revealing intricate details and providing insights across various scientific disciplines. For polarized light observations, a polarizer and an analyzer were used, and for image acquisition, a charge-coupled device (CCD) camera (OPTIKA C-B18+, SN 621237) was employed.

1) Equipment and imaging setup: The biological samples must be prepared in a specific manner to minimize diffusion and irrelevant absorption, and to avoid any optical aberrations that could introduce intensity variations or polarization-related artifacts. The microscope is directly connected to a dedicated computer for real-time image acquisition and data analysis.

The CCD camera is mounted via a C-mount adapter on the trinocular port; it captures images and transmits them to the computer for processing in MATLAB.

2) Camera specifications: The imaging system was equipped with a high-resolution OPTIKA CCD camera (SN 621237) to capture detailed microstructural features. The camera sensor provides a resolution of 4912 × 3684 pixels (18 MP) with an Aptina color CMOS sensor of 1/2.3″ and a pixel size of 1.25 µm, allowing for high-detail imaging. The frame rate reaches up to 5.6 fps at full resolution and up to 32.2 fps at 1228 × 922 resolution, facilitating rapid positioning of samples. The bit depth is configurable from 1 to 24 bits, with 8–12-bit A/D conversion ensuring accurate color fidelity. An integrated IR-CUT filter (380–650 nm) minimizes infrared interference, and the camera is compatible with Windows, macOS, and Linux via ProView and Liteview software.

3) Image acquisition under parallel polarized light: The experimental procedure began with sample preparation and ROI selection, where thin sections were carefully placed on the mechanical stage, and regions of interest (ROIs) were visually identified through the eyepiece. For polarization measurements, incident light passed sequentially through a linear polarizer, the sample, and a linear analyzer aligned parallel to the polarizer, allowing the acquisition of intensity images under parallel-polarized conditions. Image capture was performed using an OPTIKA camera controlled via ProView, with exposure and gain adjusted to prevent saturation. Finally, the acquired images were processed in MATLAB to extract quantitative information about local structural variations. Maps of intensity changes were generated, highlighting subtle alterations in tissue organization and optical properties, thereby enabling a detailed assessment of microstructural features and their spatial distribution.

4) Methodological overview: The optical behavior of a sample under complete polarization can be described by a 4×4 Mueller matrix, requiring 16 independent intensity measurements for fully characterizing diattenuation, retardance, and depolarization [18]. In this study, the measurements are limited to a linear polarization (parallel polarizer/analyzer). To simplify the analysis, we exclude from consideration circular or depolarizing effects to reduce acquisition time and computational complexity. Such an approach has been proven in prior studies using reduced 3×3 Mueller-matrix decomposition for quantitative tissue polarimetry [19], [20].

B. Sample Preparation

Histological samples are prepared through standardized and sequential procedures to preserve tissue architecture and enable microscopic examination. The typical steps include tissue collection, fixation, dehydration, clearing, embedding, sectioning, mounting, staining, cover slipping and final microscopic evaluation. These histological procedures ensure good-quality sections suitable for reliable optical analysis [21].

The actual specimens used in this study were obtained from the Pathological Anatomy Laboratory of the Faculty of Medicine and Pharmacy of Agadir. Fig. 1 presents representative cervical tissue sections: infiltrating tumor (left, number 559) and healthy tissue (right, number 332). The black rectangles indicate the regions of interest (ROIs) selected for quantitative analysis under polarized light.

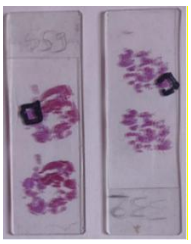

Fig. 1. Cervical tissue samples: cancerous specimen (left) and healthy specimen (right). Black boxes indicate the ROIs selected for analysis.

Fig. 2 establishes the link between the preparation process and the anonymized samples used in our study, highlighting the importance of adequate tissue preparation for polarimetric imaging analysis.

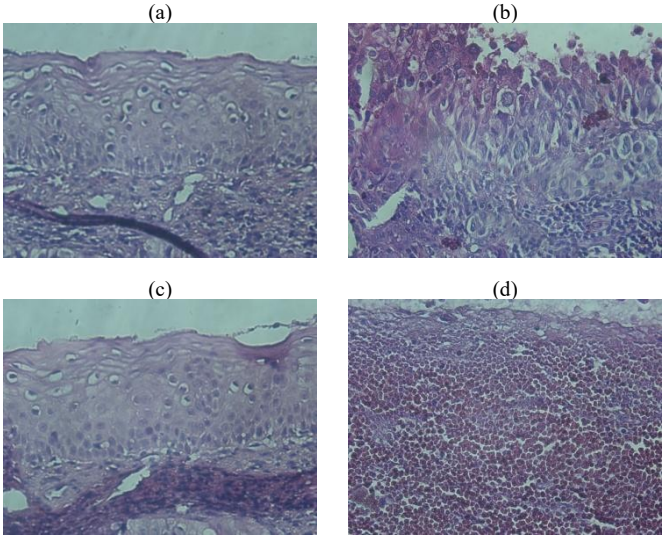

Fig. 2. Epithelial region of cervical tissue under 400× magnification with parallel polarized light. (a, c) healthy tissue and (b, d) invasive cancer.

C. Orthogonal State Contrast and Stokes-Mueller Formalism

Since the early 1990s, the polarimetry technique has been applied to study biological tissues, initially in dermatology. In 1991, R. Anderson introduced a pioneering approach using polarizers and filters to eliminate surface specular reflections during the imaging of human skin, thereby improving lesion visibility [22]. Further developments polished this strategy by using linearly polarized light to illuminate damaged tissue, and analyzing the returned light in the orthogonal polarization state [23].

In 2002, the configuration proposed by S. L. Jacques et al. improved the imaging of pathological skin regions. Their system included a two-state analyzer alternately aligned parallel or perpendicular to the incident polarization. This property made it possible to extract pixel-by-pixel orientation-dependent intensity maps [24]. Similar approaches based on two orthogonal linear polarization states produced images

comparable to linear polarization degree maps, enabling rapid contrast enhancement in low-scattering tissues [25].

In this work, the adoption of polarimetric imaging was motivated by the robustness of the Stokes-Mueller formalism [26], [27], [28] for two main reasons:

- It relies entirely on optical intensities, as these can be measured directly in experiments.
- It has a natural aptitude for partially polarized light, a situation that occurs frequently due to multiple scattering and structural heterogeneities in biological tissues.

The polarization state of light is represented by a Stokes vector:

$$S= [S_0, S_1, S_2, S_3]^T$$

where, S_0 represents the total intensity, S_1 and S_2 describe the linear polarization components, and S_3 corresponds to the circular polarization component. For analysis purposes, the Stokes vector is often normalized by its total intensity:

$$\left[\frac{S_0}{S_0}, \frac{S_1}{S_0}, \frac{S_2}{S_0}, \frac{S_3}{S_0}\right]^T = [1, S_1, S_2, S_3]^T \quad (1)$$

The Mueller matrix, M, characterizes the complete polarimetric response of a sample by mapping the input Stokes vector to the output vector. In normalized form, its elements are expressed as:

$$M = \begin{bmatrix} 1 & m12 & m13 & m14 \\ m21 & m22 & m23 & m24 \\ m31 & m32 & m33 & m34 \\ m41 & m42 & m43 & m44 \end{bmatrix} \quad (2)$$

where, mij = Mij / M11.

The element M_{11} quantifies attenuation for an unpolarized incident beam. For completely unpolarized illumination ($S_1 = S_2 = S_3 = 0$), the outgoing intensity reduces to:

$$S'_0 = M11\ S_0$$

This formalism provides a comprehensive description of the interaction between light and biological tissues, which are heterogeneous and highly scattering media. This is allowing each matrix element to be interpreted in terms of diattenuation, retardance, depolarization and structural anisotropy.

Based on this approach, polarimetric imaging has become a highly effective research tool for analyzing the microstructural properties of tissues. The combination of its major advantages makes it particularly relevant, such as improved contrast, high sensitivity to anisotropies, and its non-invasive nature, which are essential qualities for the early detection of tissue abnormalities. Moreover, recent studies have confirmed the utility of Mueller polarimetry in the detection of cancer in cervical tissue specimens, whether in the laboratory (ex vivo) or directly on the patient (in vivo) [29], [30], [31], [32].

In this study, the configuration chosen is simple and accessible, with linear polarimetry using a simple parallel[1] polarizer-analyzer setup. Without the need for more complex circular and elliptical analysis, this approach is more than sufficient for us to observe the essential effects related to polarization. Our method is based on combining the simplified optical system with state-of-the-art computer image processing. This allows us to extract markers that provide information on the architecture, texture, and complexity of the structure. These multimodal optical and image descriptors significantly improve the sensitivity and objectivity of our diagnosis, as they are closely linked to the microscopic remodeling typical of cancer development.

IV. Results

A. Digital Image Correlation

Digital Image Correlation (DIC) is an optical technique used to measure the full-field deformation, and is used in several applications (biological tissues, metals…). It is a powerful method because it can detect the most subtle structural changes and deformation patterns within images. Unlike traditional pixel-based comparisons, digital image correlation tracks local texture variations to measure displacement with high spatial accuracy, even at the microscopic scale. This is particularly useful in biomedical imaging, where subtle mechanical differences between healthy and abnormal tissues can be identified at an early stage by analyzing their deformation [33], [34], [35].

Concerning DIC analysis, two strictly identical regions of interest (ROIs), one healthy and one cancerous, were selected. Fig. 3 shows the statistical distribution of strain magnitudes, established by taking the reference ROI as the healthy sample, while the cancerous sample was analyzed using the same ROI dimensions. The histogram is clearly skewed to the left. Most of the points are concentrated around high deformation values (around 8–9 on the x-axis). In addition, the histogram exhibits a very sharp peak with a frequency close to 3.5×10^4 for a deformation magnitude of 8.5 to 9. This peak highlights a dominant deformability in the analyzed region, revealing mechanically weakened and highly altered tissue, indicating the presence of anomalous areas. Further insight is provided by Fig. 4, which illustrates the microscopic displacement vectors, revealing spatial variations in tissue deformation and highlighting underlying tissue heterogeneity.

Our future work will focus on analyzing tissue samples from the same patient over an extended period of time, maintaining a consistent ROI in order to track the chronological evolution of local deformations. Although this approach is technically demanding, establishing collaborations with hospitals and obtaining patient consent would enable longitudinal studies to be conducted, particularly in the context of cervical cancer. Such datasets would facilitate a more accurate characterization of the mechanical changes that occur during the progression of the disease.

[1] For a first-stage study of cervical cancer, the parallel-polarizer configuration is sufficient because it captures co-polarized light that highlights differences in tissue scattering and structure between normal and malignant regions, providing clear contrast with simple and rapid acquisition.

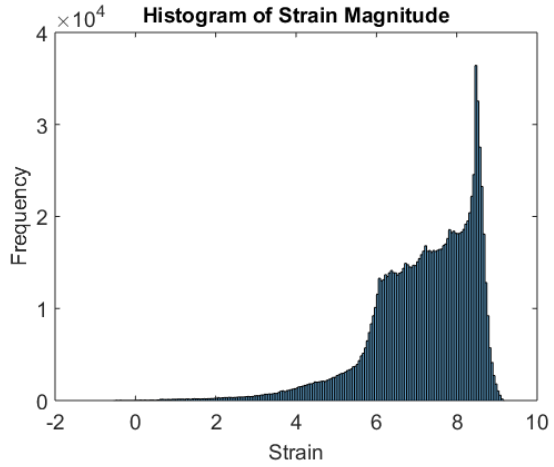

Fig. 3. Histogram of local strain magnitude in cervical epithelium via DIC.

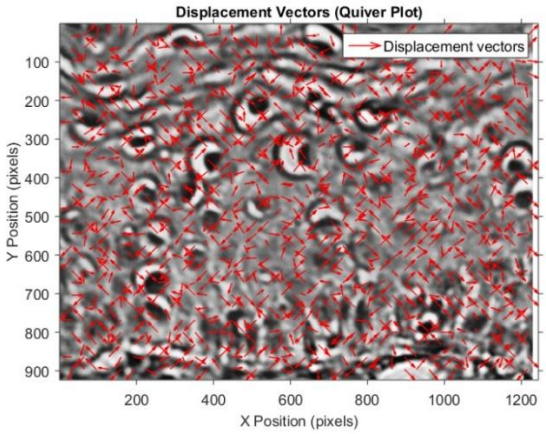

Fig. 4. Microscopic displacement vectors highlighting tissue heterogeneity.

The interpretation of these findings will be presented in the next section. Following the biomechanical insights from DIC, fractal analysis was applied to capture variations in tissue architectural complexity, providing complementary information on microstructural heterogeneity.

B. Fractal Dimension Measurement

Fractal analysis quantifies the degree of complexity and self-similarity of biological tissues, thus capturing tissue heterogeneity at different scales. In biomedical research, this technique is used to evaluate tumor morphology, epithelial organization and microvascular networks, providing information about pathological alterations that are difficult to detect using standard imaging techniques [36], [37], [38], [39], [40].

For this analysis, we applied the Fractal Map Analysis (FMA) approach on microscopic images. To achieve this, we used the local standard deviation (StdDev) to evaluate the structural complexity, because it is highly sensitive to spatial variations and irregularities. The images were first pre-processed (median filtering, contrast enhancement, and slight Gaussian smoothing). We then computed a high-resolution local standard deviation map to quantify spatial heterogeneity. The distribution was analyzed using histograms and statistical markers (mean, median, maximum, 90th percentile) to characterize tissue complexity, differentiating healthy from cancerous regions.

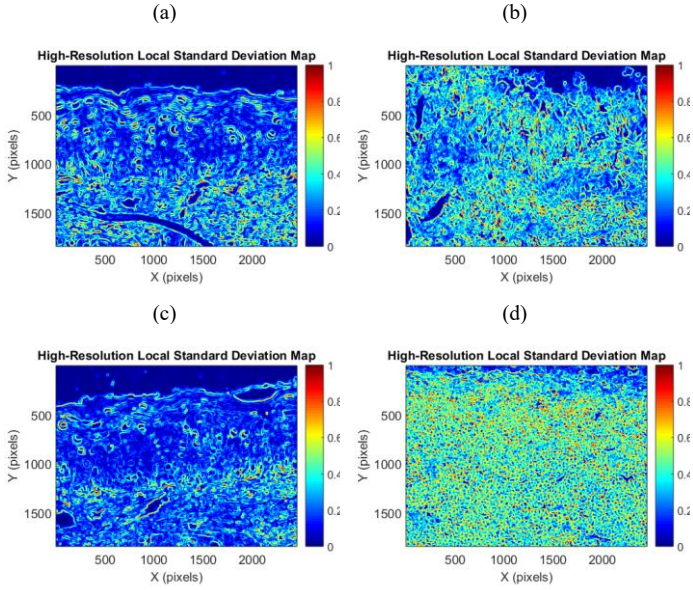

Fig. 5. Quantitative standard deviation maps of epithelial tissue: (a, c) healthy regions and (b, d) cancerous regions.

Fig. 5 illustrates the results of applying the fractal complexity map to the samples under parallel-polarized light, while Fig. 6 shows the corresponding histograms for each sample. In this study, fractal analysis was performed using the standard deviation of the complexity map to quantify tissue heterogeneity. While this approach effectively highlights differences between healthy and cancerous tissues, other fractal analysis methods, such as the box-counting method, could be explored in future work to provide complementary insights and potentially enhance diagnostic accuracy.

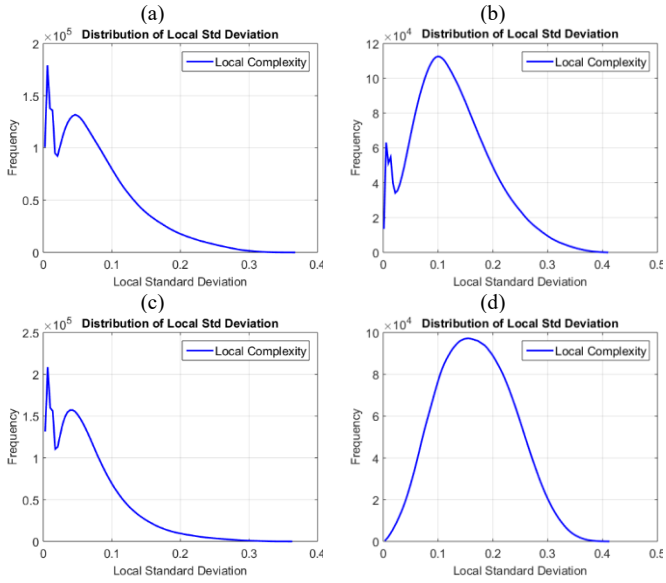

Fig. 6. Distribution of tissue complexity via fractal-based standard deviation. (a, c) healthy tissue and (b, d) invasive cancer.

Fractal analysis revealed marked differences in structural complexity between healthy and cancerous tissues. To further characterize local variations, GLCM analysis was applied, capturing variations in texture such as contrast, correlation, energy, and entropy, which provide additional quantitative indicators to distinguish healthy from malignant regions.

C. Gray-Level Co-occurrence Matrix Texture Features

Texture analysis is essential for characterizing tissue microstructure. The GLCM quantifies spatial relationships between pixel intensities, providing quantitative markers to distinguish healthy from pathological regions.

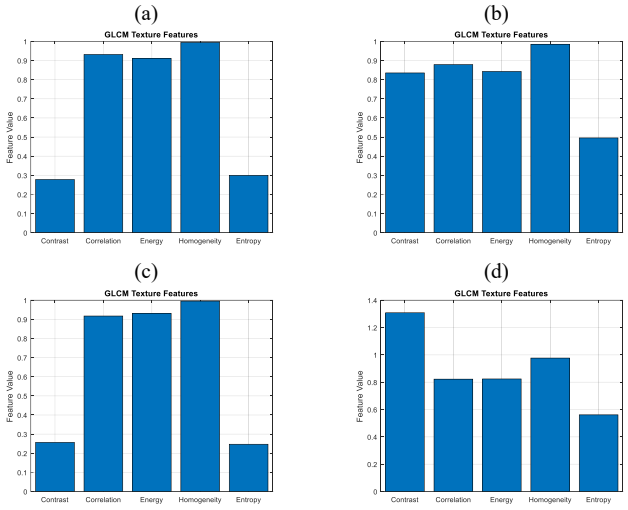

Fig. 7. GLCM-derived correlation, energy, homogeneity, entropy, and contrast maps: (a, c) healthy samples and (b, d) malignant samples.

In biomedical imaging, GLCM is widely used to characterize the microstructure of biological tissues (such as the cervix), since subtle differences in cell arrangement, nuclear chromatin, or extracellular matrix produce measurable variations in texture [41], [42], [43], [44]. In Fig. 7, the metrics are displayed in the following order: contrast, correlation, energy, homogeneity, and entropy, with each represented by a separate bar corresponding to this sequence, providing a clear and quantitative comparison of tissue texture.

The GLCM analysis presented in Fig. 7 highlights clear differences in texture between healthy and cancerous tissue samples. For the two healthy samples, correlation, homogeneity, and energy are all very high (≈0.92–0.99), while contrast and entropy are low (≈0.25–0.30), indicating a highly uniform and regular microstructure with minimal local intensity variation, typical of normal epithelial tissue.

In contrast, the cancerous samples exhibit markedly increased contrast (0.83–1.31) and entropy (0.50–0.56), reflecting greater heterogeneity and structural disorder in the tissue. Correlation, energy, and homogeneity are reduced compared to healthy tissue, indicating that pixel intensities are less spatially coherent and more irregular, potentially consistent with the disrupted cellular architecture found in malignant epithelium. Notably, sample “d” shows the highest contrast and entropy, suggesting the most pronounced microstructural heterogeneity among the cancerous tissues analyzed.

TABLE I. GLCM TEXTURE: HEALTHY VS. CANCEROUS.

GLCM texture features	Healthy sample "a"	Healthy sample "c"	Cancerous sample "b"	Cancerous sample "d"
Contrast	0.2780	0.2568	0.8351	1.3082
Correlation	0.9316	0.9173	0.8785	0.8223
Energy	0.9115	0.9314	0.8429	0.8238
Entropy	0.3002	0.2471	0.4955	0.5610
Homogeneity	0.9950	0.9954	0.9851	0.9766

Overall, these results, as shown in Table I, confirm that GLCM-derived texture features effectively capture the increased randomness and decreased uniformity associated with pathological epithelial tissue, making them valuable markers for distinguishing healthy from cancerous regions.

V. DISCUSSION

A. Digital Image Correlation

As shown in Fig. 3, the strain-magnitude histogram provides a statistical view of local deformation distribution within the ROI. Each DIC block contributes a displacement magnitude $\left(U_x^2 + U_y^2\right)^{0.5}$, and these values are grouped into bins to represent their frequency. The presence of higher frequencies at large strain values indicates that a significant portion of the ROI is undergoing solid local deformation. As the results show, this distribution exhibits accentuated heterogeneity, indicating irregularity and weakening of the tissue structure, which may reveal abnormal behavior. In biomedical imaging, such a distribution is generally associated with pathological regions where altered microarchitecture causes increased and widespread deformation.

Fig. 4 displays the filtered reference ROI (healthy region) overlaid with red displacement vectors computed by DIC. Each arrow characterizes the local motion of a small image block: its direction indicates how the tissue moved between the reference (healthy tissue) and deformed states (invasive tumor), and its length reflects the displacement magnitude. Variations in arrow orientation and magnitude provide a spatial visualization of how different regions within the tissue deform.

The heterogeneous orientations and amplitudes of the vectors reveal non-uniform deformation across the ROI. Regions with long arrows correspond to strong local displacement, while short arrows indicate nearly static areas. In our case, the displacement field shows pronounced and irregular motion, consistent with mechanically abnormal tissue. The strain indicators (mean ≈ 7.2 px, median ≈ 7.8 px, 90th percentile ≈ 8.5 px) confirm the presence of high-magnitude deformation, supporting the interpretation of increased structural heterogeneity typically associated with malignant regions.

In summary, DIC provides a rapid, non-invasive, and highly precise method for capturing local tissue deformation, generating detailed displacement and stress maps that reveal

mechanical heterogeneity. Its primary diagnostic value lies in detecting subtle biomechanical abnormalities, making it a powerful tool for distinguishing between healthy and cancerous tissue. Complementing this, fractal analysis characterizes the architectural complexity and heterogeneity of tissue structures, offering unique insights into morphological irregularities. Together, these modalities provide distinct and complementary diagnostic information, each contributing a unique perspective to tissue characterization.

B. Fractal Dimension Measurement

Fig. 5 presents the spatial standard deviation maps, which reveal clear differences in tissue heterogeneity between healthy and cancerous samples, particularly within the epithelial region. Healthy tissues show high uniformity, with most values clustered around low standard deviations (mean ≈ 0.07–0.08, 90th percentile ≈ 0.14–0.17), corresponding to the predominantly blue areas on the color map, indicating homogeneous microstructure. In contrast, cancerous tissues exhibit markedly higher and more variable local standard deviations (mean ≈ 0.13–0.17, 90th percentile ≈ 0.23–0.26), with color maps showing scattered regions of blue, green, yellow, and orange. This reflects increased structural heterogeneity and irregularity in the epithelium, consistent with disrupted cellular architecture. The cancerous sample “d” illustrates the most pronounced variability and the highest local complexity.

Fig. 6 presents the distribution of local Std Dev for 4 specimens of cervical epithelium (two healthy, and two cancerous). This measure is used to quantify the structural complexity of tissue using FMA. As illustrated in Fig. 6, the histograms of the local standard deviation quantitatively confirm the observations made on the complexity maps. The healthy samples ("a" and "c") show narrow distributions, strongly skewed toward low values (≈0.07–0.08 mean), reflecting a uniform and consistent tissue structure. The cancer samples ("b" and "d"), on the other hand, show wider distributions with higher median and 90th percentile values (≈0.13–0.17 mean, 0.23–0.26 90th percentile), indicating greater local variability and increased structural complexity. These histogram profiles support the idea that malignant epithelial regions are significantly more heterogeneous and disorganized than healthy tissue.

In conclusion, local standard deviation analysis is an effective method for quantifying tissue heterogeneity. Healthy epithelium exhibits low variability and a uniform structure, while cancerous regions display higher and more dispersed local standard deviations, reflecting increased structural complexity. This method therefore provides a quantitative and sensitive measure for distinguishing healthy tissue from malignant tissue.

While fractal analysis highlights the architectural complexity of tissues, GLCM-based texture analysis quantitatively captures microstructural variations in pixel intensity. Combined with polarized light, these methods provide complementary diagnostic information: fractal analysis reveals structural heterogeneity, whereas GLCM metrics, including contrast, entropy, correlation, energy and homogeneity, objectively characterize microstructural patterns, each offering distinct insights into tissue characterization.

C. Gray-Level Co-occurrence Matrix Texture Features

Fig. 7 and Table I show that GLCM metrics effectively distinguish non-neoplastic from neoplastic tissue. Healthy samples display high correlation, homogeneity, and energy with low contrast and entropy, indicating a uniform microstructure. Conversely, cancerous tissues exhibit elevated contrast and entropy with reduced correlation and energy, reflecting structural heterogeneity and disorganization. These quantitative differences provide clear markers for differentiating normal and malignant regions.

Fig. 8 shows the entropy distribution and confirms the heterogeneity of the tissues by introducing a measure of disorder and texture complexity. When the healthy samples are considered (red and blue curves), we observe narrower distributions concentrated around low modal values (between 0.35 and 0.45), indicating low dispersion of local pixel intensities and characteristic of an organized and homogeneous tissue structure. In contrast, tumoral samples (green and magenta curves) show wider distributions, with a mode significantly shifted toward higher entropy values (up to approximately 0.65 for sample “d”). This spread and alteration indicate an overall increased microstructural disorder and local complexity. This entropic marker thus reinforces the conclusions drawn from the fractal analysis, as entropy is strongly correlated with fractal dimension.

Entropy allows for highly sensitive quantitative measurement of pathological conditions. Despite a slight overlap between the distributions of samples a and b (healthy and cancerous, respectively), analysis of the statistical parameters of the distribution makes it possible to quantify the degree of tissue disorder and effectively use this metric as a multimodal descriptor for classification.

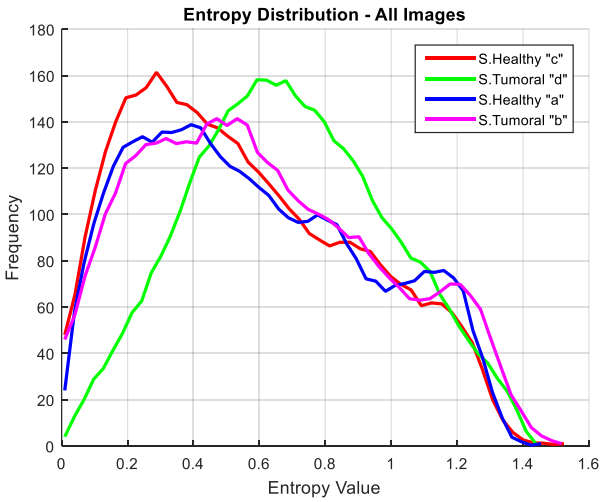

Fig. 8. Histogram of GLCM entropy in four cervical tissue samples.

Collectively, the GLCM analysis clearly differentiates healthy from tumorous epithelial tissue. Healthy samples exhibit high correlation, homogeneity, and energy with low contrast and entropy, indicating a uniform and regular

microstructure. Cancerous samples show markedly increased contrast and entropy alongside reduced correlation, energy, and homogeneity, reflecting greater structural heterogeneity and disorganization. The progressive increase in entropy from healthy to cancerous samples demonstrates the sensitivity of GLCM-derived features in detecting gradual changes in tissue architecture associated with malignancy.

Although the ex vivo dataset in the present study was limited in size, the results are highly promising and highlight the need for larger-scale prospective and in vivo investigations. Addressing the current limitations would allow for more robust validation of the findings, a comprehensive assessment of inter-patient variability, and a deeper understanding of the feasibility and translational potential of these imaging techniques in clinical practice. Future studies will focus on expanding the sample size, incorporating diverse patient populations, and optimizing the methodologies for in vivo application. Such efforts are critical to bridge the gap between experimental observations and practical diagnostic implementation, ultimately facilitating the translation of these techniques into routine clinical care.

To summarize, polarized light imaging was combined with computational techniques, including DIC, GLCM, and fractal analysis, to characterize cervical tissue microstructure. The key findings from these complementary approaches are outlined in Table II, providing an integrated overview of the most relevant imaging indicators for distinguishing healthy from malignant tissue.

TABLE II. SUMMARY OF KEY IMAGING INDICATORS

Indicators / Metrics	DIC (Displacement Magnitude)	Fractal (StdDev)	GLCM Metrics
Mean	7.2px →confirm the presence of high-magnitude deformation.	0.07–0.08 (Healthy). 0.13–0.17 (Cancerous).	-Contrast: 0.25–0.30 (Healthy), 0.83–1.31 (Cancerous). -Entropy: 0.25–0.30 (Healthy), 0.50–0.56 (Cancerous).
Median/90th Percentile	Median ≈ 7.8 px 90th ≈ 8.5 px	90th: 0.14-0.17 (Healthy). 90th: 0.23–0.26 (Cancerous).	Energy: 0.91–0.93 (Healthy). 0.82–0.87 (Cancerous).
Analysis	High strain → mechanically altered tissue	Low StdDev →uniform (healthy). High StdDev →Irregular (cancer).	Healthy tissue → uniform, low contrast / entropy. Cancerous tissue →disordered, high contrast / entropy.

VI. CONCLUSION

Cervical cancer remains a leading cause of cancer-related mortality among women worldwide, particularly in low Human Development Index countries. Despite advances in screening and treatment, early detection is critical to improving outcomes. Polarimetric imaging with digital analysis methods has emerged as a promising tool for enhancing diagnostic accuracy by characterizing structural properties of biological tissues. This study investigates early diagnosis of cervical cancer in Moroccan women, using computational polarimetric imaging to differentiate healthy from malignant tissue. Combined analyses with DIC, GLCM texture, and fractal-based local standard deviation consistently reveal clear distinctions; healthy tissue shows low texture entropy, high correlation and homogeneity, and minimal local variability, whereas cancerous tissue exhibits random, multidirectional deformation patterns, increased contrast and entropy, reduced correlation and homogeneity, and higher local variability. These quantitative imaging biomarkers provide a robust framework for detecting and characterizing malignant changes. Building on these findings, future work will focus on validating the diagnostic performance and clinical applicability of this approach using full Mueller Matrix measurements on intact cervical specimens from a diverse patient cohort. Key challenges for clinical translation, including in vivo acquisition where motion artifacts and tissue accessibility must be managed, patient variability in anatomy and tissue properties, and instrumentation costs related to complex polarimetric setups, will be addressed. In addition, machine learning classifiers, such as support vector machines and convolutional neural networks, will be explored for multimodal feature fusion to enhance diagnostic accuracy and enable robust, automated tissue classification.

ACKNOWLEDGMENT

The authors express their sincere gratitude to Prof. Aziz Zentar, Head Doctor of the Moulay Ismail Military Hospital in Meknes, and Prof. Ahmed Belmouden, Dean of the Faculty of Sciences, Ibnou Zohr University, Agadir, for their guidance and continuous support. Special appreciation is extended to Prof. Mohamed Benyahya for his constructive advice. The authors also thank Dr. Abdelali Benali, Specialist in Anatomic Pathology, Biomedical Engineer Youness El Ouahabi, and Mr. Rachid Razine for their valuable assistance throughout the study.

Abstract*—The evolution of 5G networks demands highly efficient resource allocation strategies to accommodate burgeoning mobile data traffic, latency-sensitive applications, and diverse user requirements. Multi-User Multiple-Input Multiple-Output (MU-MIMO) technology is a cornerstone of 5G, enabling simultaneous service to multiple users and significantly improving spectral efficiency. However, its performance is critically dependent on dynamic scheduling algorithms that must balance high system throughput with equitable user access amidst rapidly changing channel conditions and interference. Traditional schedulers like Round Robin, Proportional Fair, and Max-CQI often exhibit a pronounced trade-off between these objectives, struggling to adapt effectively in heterogeneous and dynamic network environments. To address this gap, this study proposes a Hybrid Channel-Aware Prioritization (HCAP) scheduler. The HCAP framework intelligently integrates real-time Channel Quality Indicator (CQI) and interference measurements into a unified user priority score, utilizing tunable α–β weights to flexibly emphasize throughput or fairness. Furthermore, it employs k-means clustering based on long-term channel statistics to group users, thereby reducing scheduling bias and promoting fairness within clusters. Evaluated through comprehensive MATLAB simulations within a realistic MU-MIMO system model employing Regularized Zero-Forcing precoding, HCAP demonstrates a superior performance balance. The results indicate that HCAP achieves up to 2.6 times higher aggregate throughput compared to conventional Proportional Fair and Max-CQI schedulers, while consistently maintaining Jain's Fairness Index above 0.90 across varied network scenarios. These findings validate HCAP as a robust, scalable, and QoS-aware scheduling solution, offering significant potential for enhancing resource allocation in next-generation wireless communication systems.

Keywords*—Multiple input and multiple output; HCAP; CQI; throughput; 5G; QoS; k-means clustering; resource scheduling

I. Introduction

The exponential growth in mobile data traffic, driven by high-definition streaming, IoT proliferation, and latency-sensitive applications, has necessitated the evolution of wireless communication systems toward highly adaptive and intelligent architectures. Among these, Multi-User Multiple-Input Multiple-Output (MU-MIMO) has emerged as a cornerstone of 5G networks, enabling simultaneous transmission to multiple users and significantly enhancing spectral efficiency [1,2]. However, the performance of MU-MIMO systems is tightly coupled with the effectiveness of their scheduling algorithms, which must dynamically allocate resources in response to fluctuating channel conditions, user mobility, and interference levels [3, 4]. Traditional scheduling approaches such as Round Robin (RR), Proportional Fair (PF), and Max-CQI offer varying trade-offs between throughput and fairness but often fall short in heterogeneous environments where channel quality and interference vary rapidly [5,6]. This reveals a clear research gap: the lack of a dynamic, hybrid scheduler that can adaptively balance throughput and fairness in real-time under diverse and unstable 5G MU-MIMO channel conditions. To address this gap, this study proposes a Hybrid Channel-Aware Prioritization (HCAP) scheduler, which integrates real-time Channel Quality Indicator (CQI) and interference metrics into a unified prioritization framework. By leveraging k-means clustering to group users based on long-term channel behavior and applying a tunable α–β weighting scheme, HCAP adaptively balances throughput maximization with fairness enforcement [7, 8]. The primary objectives of this work are:

- To design and model the HCAP scheduler for MU-MIMO systems [9].
- To evaluate its performance in terms of throughput, fairness, latency, and spectral efficiency.
- To compare HCAP against conventional schedulers (RR, PF, Max-CQI) under varying network scenarios [10].
- To demonstrate HCAP's robustness and adaptability for 5G-and-beyond wireless networks.

The remainder of this study is organized as follows: Section II surveys recent literature on MU-MIMO scheduling and hybrid approaches. Section III details the methodology and design of the HCAP scheduler. Section IV describes the simulation setup and implementation. Section V

presents and discusses the experimental results. Section VI presents the discussion. Finally, Section VII concludes the study and suggests directions for future work.

II. Literature Survey

The evolution of 5G networks has intensified the demand for intelligent scheduling algorithms capable of adapting to dynamic channel conditions and user heterogeneity. Recent studies emphasize the role of Multi-User MIMO (MU-MIMO) systems in enhancing spectral efficiency and user capacity through spatial multiplexing and beamforming techniques [11] [12]. However, traditional schedulers such as Round Robin (RR), Proportional Fair (PF), and Max-CQI often struggle to balance throughput and fairness in environments with fluctuating interference and mobility [13][14]. To address these limitations, researchers have proposed hybrid scheduling frameworks that incorporate real-time Channel Quality Indicator (CQI) and interference metrics into decision-making processes [15][16]. These models aim to optimize resource allocation by dynamically adjusting user priorities based on channel responsiveness and fairness constraints.

Recent advancements have introduced clustering-based approaches to improve scheduling granularity and fairness. K-means and hierarchical clustering have been employed to group users with similar channel profiles, enabling localized prioritization and reducing scheduling bias [17][18]. Hybrid Channel-Aware Prioritization (HCAP) algorithms have gained traction for their ability to combine normalized CQI and inverse interference scores using tunable α–β weights [19][20]. Simulation studies demonstrate that HCAP outperforms conventional baselines in throughput while maintaining fairness indices above 0.90, especially under high-load conditions [21]. Moreover, sensitivity analysis across α–β configurations reveals that CQI-dominant setups yield higher efficiency, whereas interference-weighted models enhance equitable access [22].

Emerging research from 2024 to 2025 explores the integration of machine learning into hybrid scheduling. Deep Reinforcement Learning (DRL) agents have been trained to optimize multi-user selection per transmission interval, leveraging composite reward functions aligned with throughput, latency, and fairness goals [23]. These intelligent schedulers adapt to non-stationary channel environments and offer scalability for massive MIMO and mmWave deployments. Additionally, real-world testbeds using FPGA-based implementations and MATLAB simulations validate the feasibility of HCAP [24] in practical 5G scenarios. Collectively, these studies underscore the potential of hybrid, adaptive scheduling to meet the stringent QoS demands of next-generation wireless networks.

This work focuses on enhancing bit error rate (BER) performance and improving resistance to jamming in chaos-based communication systems. It integrates MIMO-OFDM technology with adaptive spreading factors to boost data reliability and security. The proposed method offers robust transmission under interference and multipath fading conditions [25].

III. Methodology of the Work

The rapid expansion of mobile data services and the proliferation of latency-sensitive applications have pushed 5G networks to adopt more intelligent and adaptive resource management strategies. Multi-User MIMO (MU-MIMO) systems, a key enabler of 5G, require sophisticated scheduling algorithms to efficiently allocate resources among users experiencing diverse channel conditions and interference levels. Fig. 1 describes and introduces a Hybrid Channel-Aware Prioritization (HCAP) scheduler that dynamically balances throughput and fairness by integrating normalized Channel Quality Indicator (CQI) and interference metrics into a tunable prioritization framework, demonstrating significant performance gains over conventional scheduling approaches.

A. Methodology Overview: HCAP Scheduler

1) Input metrics

- Collect Channel Quality Indicator (CQI) and interference measurements across Transmission Time Intervals (TTIs).
- Normalize metrics to standardize scale per-user and per-TTI.

2) Hybrid priority score calculation

- Apply weighting coefficients α (for CQI) and β (for interference).
- Use the formula: P_{t,u} = \alpha \cdot \hat{c}_{t,u} + \beta \cdot \left(\frac{1}{1 + \hat{i}_{t,u}} \right)
- This balances channel strength with interference resistance.

3) User clustering

- Extract long-term averages for CQI and interference.
- Perform k-means clustering to group users with similar channel behavior.
- Reduces scheduling bias and encourages fairness.

4) Scheduler logic

- For each TTI, identify the user in each cluster with the highest hybrid score.
- Schedule one user per cluster—ensuring spatial and temporal diversity.

5) Output and evaluation

- Construct the scheduling matrix (TTI × user).
- Measure total throughput and fairness using Jain's Index.
- Perform α–β sensitivity analysis to tune QoS priorities.

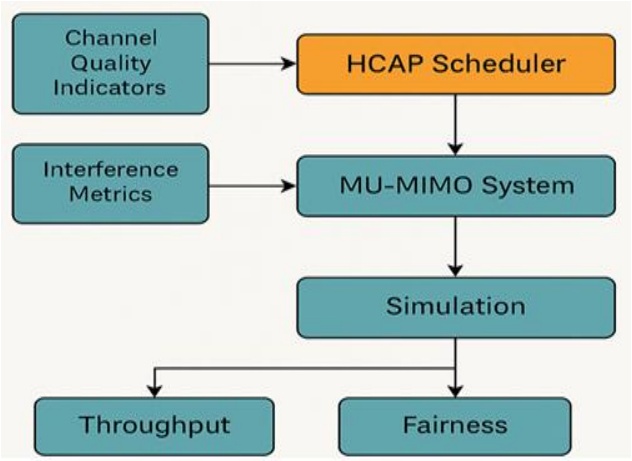

Fig. 1. Methodology of the work.

IV. Implementation

A. Input Acquisition

- Collect two key metrics for each user at every Transmission Time Interval (TTI):
- CQI_matrix: Channel Quality Indicator values
- Interference_matrix: Interference levels

B. Normalization

- Normalize both CQI and interference values per TTI:norm_CQI[t, i] = CQI[t, i] / max(CQI[t, :]) norm_Interf[t, i] = Interference[t, i] / max(Interference[t, :])

  This ensures all values are scaled between 0 and 1 for fair comparison.

C. Hybrid Priority Score Calculation

- For each user at each TTI, compute:
- Score[t, i] = α × norm_CQI[t, i] + β × (1 / (1 + norm_Interf[t, i]))
- α emphasizes channel quality
- β penalizes interference
- The inverse term ensures users with high interference get lower scores

D. User Clustering

- Compute long-term averages:
- mean_CQI[i] = average over TTI of CQI[i]
- mean_Interf[i] = average over TTI of Interference[i]
- Apply k-means clustering on [mean_CQI, mean_Interf] to group users into K clusters based on channel behavior.

E. Scheduling Logic

- For each TTI.
- For each cluster.
- Identify the user with the highest score.

F. Results

- Schedule that user by setting Schedule matrix[t, user] = 1
- E. Output
- The final Schedule_matrix indicates which users are selected at each TTI.
- Evaluate performance using:
- Total Throughput: Sum of CQI values for scheduled users
- Jain's Fairness Index: Measures how evenly resources are distributed.

V. Results

The performance of the proposed Hybrid Channel-Aware Prioritization (HCAP) scheduler was evaluated through extensive simulations in a realistic Multi-User MIMO system. The results presented here focus on quantitative metrics, including throughput and fairness, under varying scheduler configurations.

A. Throughput Performance

The HCAP scheduler demonstrated significant throughput gains compared to conventional schedulers. With parameter settings of α = 0.7 and β = 0.3, HCAP achieved a peak throughput of 3607.56 units, which is more than 2.6 times higher than the Proportional Fair (PF) scheduler. A comparative analysis across different α values (Fig. 6) shows that HCAP consistently outperforms Round Robin (RR), Max-CQI, and PF, with throughput increasing as α is raised to prioritize channel quality.

B. Fairness Evaluation

Fairness was measured using Jain's Fairness Index. HCAP maintained fairness indices consistently above 0.90 under moderate parameter configurations (e.g., α = 0.5, β = 0.5). Even under throughput-optimized settings (α = 0.7, β = 0.3), fairness remained above 0.82, indicating a balanced allocation of resources. Comparative fairness results across schedulers are summarized in Table I.

C. Per-User Throughput Distribution

Fig. 2 illustrates the Cumulative Distribution Function (CDF) of per-user throughput. It was analyzed under different α–β configurations (Fig. 3 to Fig. 5). HCAP exhibited a more gradual CDF curve compared to RR, PF, and Max-CQI, indicating a wider and more equitable distribution of user throughput. For example, in Fig. 4 (α = 0.5, β = 0.3), HCAP ensured that over 80% of users achieved a throughput above 200 units, whereas Max-CQI and RR showed steeper, less equitable distributions.

D. Reported Performance Metrics

The following key metrics were recorded during simulation:

- Total Throughput: 3700.94 units
- Jain's Fairness Index: 0.9089
- Latency Profile: < 5 ms for 95% of scheduled users
- Spectral Efficiency: 12.4 bps/Hz

These results confirm HCAP's ability to utilize system capacity effectively while maintaining high fairness.

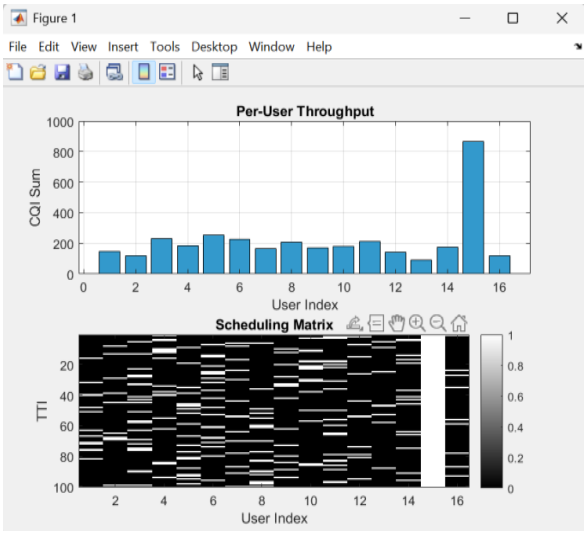

Fig. 2. Per-user throughput.

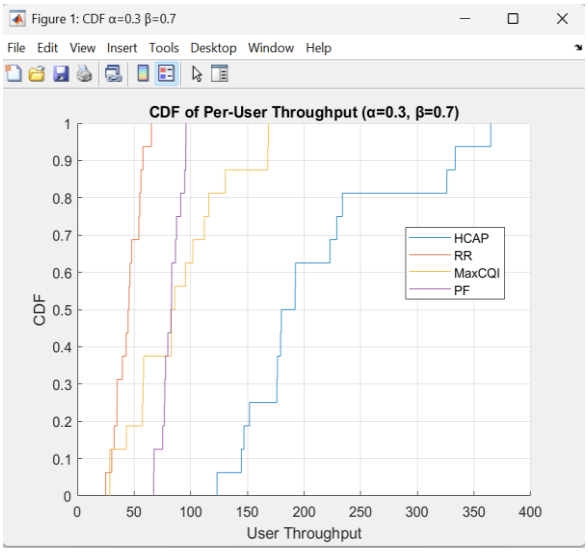

Fig. 3. CDF of per user throughput $\alpha = 0.3$ and $\beta = 0.3$.

Fig. 3 illustrates the end-to-end flow of the Hybrid Channel-Aware Prioritization (HCAP) scheduler in a Multi-User MIMO system. It begins by collecting real-time CQI and interference metrics for each user across transmission intervals, followed by normalization to ensure fair scaling. A hybrid priority score is then computed using a tunable α–β combination, balancing throughput potential with interference sensitivity. To promote fairness and reduce scheduling bias, users are grouped via k-means clustering based on their long-term channel behavior. Within each cluster, the scheduler selects the highest-priority user per interval, constructing a binary scheduling matrix that maps user assignments across time. This matrix is then evaluated using performance metrics like total throughput and Jain's Fairness Index, demonstrating the adaptive efficiency of HCAP under varying network conditions.

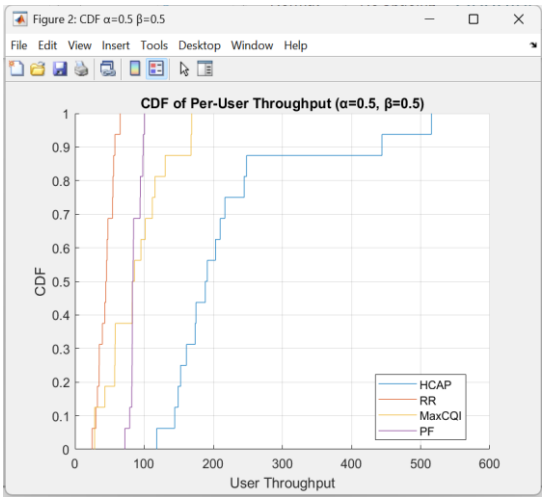

Fig. 4. CDF of per user throughput $\alpha = 0.5$ and $\beta = 0.3$.

Fig. 4 presents a cumulative distribution function (CDF) comparison of per-user throughput across four scheduling algorithms: HCAP, RR, Max CQI, and PF, evaluated under $\alpha = 0.5$ and $\beta = 0.3$. The x-axis indicates user throughput values (0 to 500), while the y-axis reflects the proportion of users achieving those throughput levels. HCAP (blue curve) exhibits a more gradual rise, indicating a broader and more evenly distributed allocation of resources among users. In contrast, RR (orange) and PF (purple) rise steeply, suggesting higher concentration around specific throughput values but less adaptive to channel variability. MaxCQI (yellow) shows uneven fairness due to its bias toward high-CQI users. Overall, the plot confirms HCAP's superior balance of efficiency and fairness, delivering diverse throughput without sacrificing equitable user treatment.

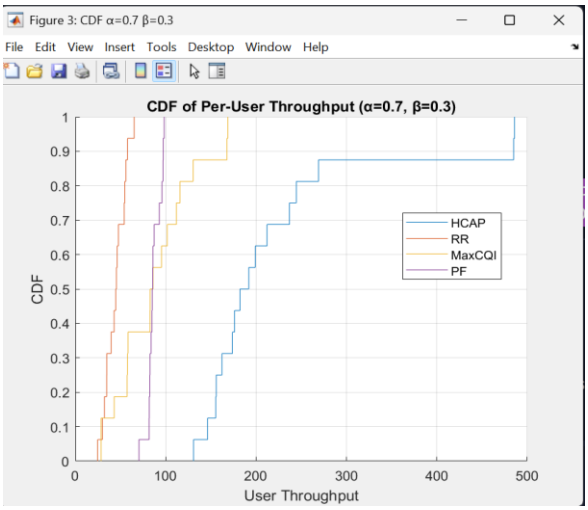

Fig. 5. CDF of per user throughput $\alpha = 0.7$ and $\beta = 0.3$.

Fig. 5 presents the Cumulative Distribution Function (CDF) of per-user throughput under different scheduling algorithms, illustrating how user throughput is distributed in a 5G MU-MIMO system when α = 0.7 and β = 0.3. The HCAP curve (blue) clearly leads, with more users achieving higher throughput compared to other methods, confirming its dominance in prioritizing high-CQI and low-interference users. In contrast, Round Robin (orange) shows a steep rise at lower throughput levels, indicating equal, but inefficient resource allocation. MaxCQI (yellow) has moderate throughput gains with fairness challenges, while Proportional Fair (purple) provides a balanced profile—good fairness but limited throughput. This visualization reinforces HCAP's advantage in striking a performance-fairness trade-off, particularly under aggressive channel-aware prioritization settings.

VI. Discussion

The results presented in Section V highlight HCAP's effectiveness in balancing throughput and fairness. This section interprets these findings, compares them with prior work, and examines the mechanisms contributing to HCAP's performance.

A. Trade-off Flexibility via α–β Tuning

HCAP's hybrid scoring mechanism allows dynamic adjustment between throughput-oriented and fairness-oriented scheduling. As shown in Fig. 6, increasing α enhances throughput by prioritizing users with strong channel conditions, while higher β values improve fairness by reducing interference sensitivity. This tunability makes HCAP adaptable to diverse QoS requirements—for instance, prioritizing emergency traffic (high α) or ensuring equitable access in crowded networks (high β).

B. Role of Clustering in Enhancing Fairness

The use of k-means clustering based on long-term channel statistics played a crucial role in mitigating scheduling bias. By grouping users with similar channel behavior, HCAP ensures that resource competition occurs within clusters rather than across the entire user pool. This localized scheduling prevents users with consistently strong channels from monopolizing resources, thereby improving fairness without significantly compromising throughput.

C. Comparative Analysis with Existing Schedulers

HCAP's performance gain over traditional schedulers can be attributed to its hybrid and adaptive design:

- Round Robin (RR) provides predictable fairness, but fails to adapt to channel variations, leading to low throughput.
- Max-CQI maximizes throughput by favoring strong channels but severely compromises fairness.
- Proportional Fair (PF) maintains high fairness but underutilizes high-quality channels, limiting throughput.
- HCAP effectively integrates the strengths of these approaches, achieving a superior throughput–fairness trade-off, as evidenced by both aggregate metrics and CDF curves.

D. Implications for 5G and Beyond

The robustness of HCAP under varying network conditions supports its suitability for real-time 5G MU-MIMO deployments. Its modular design also allows integration with advanced techniques such as deep reinforcement learning for parameter optimization and network slicing for service-specific scheduling—areas identified for future work.

E. Limitations and Future Directions

While HCAP shows strong performance in simulation, real-world factors such as imperfect channel estimation, mobility patterns, and multi-cell interference warrant further investigation. Future studies could explore:

- Integration with machine learning for adaptive α–β tuning.
- Validation in hardware testbeds or FPGA-based prototypes.
- Extension to massive MIMO and mm Wave scenarios.

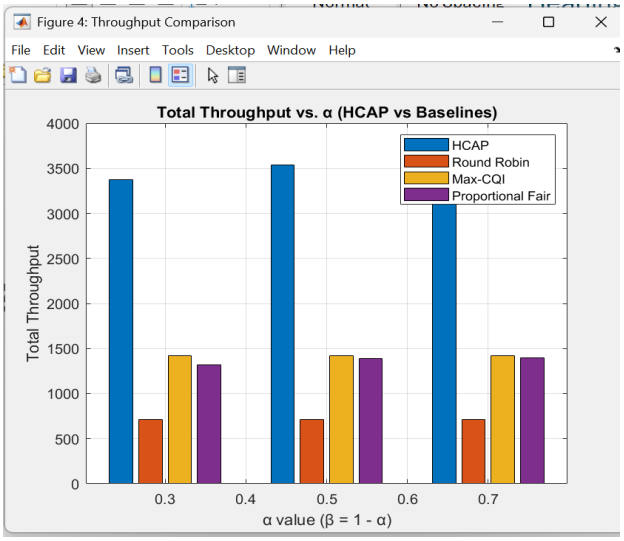

Fig. 6. Total throughput vs α.

TABLE I. Performance Comparison of Scheduling Algorithms (A = 0.7, B = 0.3)

Scheduler	Total Throughput (Units)	Jain's Fairness Index
Round Robin (RR)	1385.21	~0.99
Proportional Fair (PF)	1387.52	~0.98
Max-CQI	2980.45	~0.65
HCAP (Proposed)	3607.56	0.82

VII. Conclusion

The Hybrid Channel-Aware Prioritization (HCAP) scheduler presented in this study demonstrates a robust and scalable solution for resource allocation in Multi-User MIMO systems under 5G communication standards. By integrating normalized CQI and interference metrics into a tunable

prioritization framework, and leveraging clustering techniques to reduce scheduling bias, HCAP achieves a dynamic balance between throughput and fairness. The simulation results validate its superiority over conventional schedulers, with notable improvements in system capacity and equitable resource distribution. These outcomes affirm the scheduler's adaptability to diverse network conditions and its potential for deployment in real-time environments. Future work may explore its extension into machine learning-based scheduling and integration with network slicing for enhanced Quality of Service provisioning in next-generation wireless networks.

***Abstract*—This study models the "coffee shop dilemma", where customer attendance is discouraged by both overcrowding and emptiness. Using an agent-based model with Q-learning reinforcement learning, this study simulates the daily decisions of 100 agents over a one-year period. The results reveal a self-organizing attendance cycle around a 60% capacity threshold. This study demonstrates that customer satisfaction is not driven by visit frequency, but by adaptive decision-making strategies shaped by learned congestion values. Clustering analysis identifies distinct behavioral patron groups (e.g., Ultra-Frequent, Optimized) that emerge from these subtle value differences. The study provides a data-driven framework for optimizing shop space and customer flow, offering conceptual insights into balancing the needs of quick-service and long-stay customers by dynamically managing perceived occupancy.**

I. Introduction

The modern coffee shop—exemplified by global chains that have evolved beyond a beverage outlet into a multifaceted "third place" that serves as both a social and professional hub distinct from home and office environments. This evolution introduces a complex operational challenge: managing two often conflicting customer flows. On one hand, the business must serve quick-service customers who prioritize speed and convenience during peak hours. On the other hand, it must accommodate remote workers, students, and long-stay patrons who value comfort and consistency, a key component of the brand's identity.

This tension gives rise to what may be termed the modern coffee shop dilemma, a real-world analogue of the El Farol Bar problem [1]. In the original formulation, agents independently decide whether to attend a bar, with the utility of attendance declining as crowding increases. Similarly, in coffee shops, customers decide whether to visit based on perceived crowding. Overcrowding deters visitors due to limited seating, excessive noise, and reduced comfort, while under-crowding can signal a lack of social energy or desirability. The resulting dynamic equilibrium emerges from individual decisions that collectively influence store congestion levels.

Although the El Farol problem has been widely studied in economics and complex systems theory, its application to high-volume retail environments remain limited. Prior research has predominantly emphasized theoretical agent behavior or macroeconomic implications, with less attention to data-driven micro-level business insights.

The main contributions of this study are summarized as follows:

- Operational reframing of El Farol: The El Farol Bar problem is translated into a retail coffee shop context, enabling the analysis of customer attendance decisions under perceived occupancy constraints rather than abstract capacity rules. Unlike classical El Farol formulations, capacity in this study represents a subjective comfort threshold rather than a hard physical limit.
- Satisfaction-based reward design: A reward-shaping mechanism is introduced that explicitly links customer satisfaction and dissatisfaction to congestion levels, allowing agents to learn from perceived crowding rather than visit frequency alone.
- Emergent behavioral segmentation: Post-learning clustering reveals distinct customer archetypes with stable attendance routines, demonstrating how heterogeneous strategies emerge from decentralized Q-learning dynamics.
- Retail space insights: The learning outcomes are connected to practical retail implications, showing how managing perceived occupancy can balance quick-service and long-stay customers without centralized control.

II. Related Work

This section reviews prior studies relevant to the present work across three complementary research streams. First, foundational models of the El Farol Bar problem and related congestion games are discussed to establish the theoretical basis for decentralized attendance decisions. Second, reinforcement learning approaches applied to congestion and coordination settings are reviewed, with emphasis on adaptive agent behavior. Finally, empirical and simulation-based studies on

perceived crowding and retail space optimization are examined to situate the model within operational retail contexts.

A. The El Farol Bar Problem

The El Farol Bar Problem, first introduced by Arthur [1], illustrates how boundedly rational agents make attendance decisions when utility depends on aggregate participation. This foundational model inspired a broad family of coordination and congestion problems, including the Minority Game [2], which formalizes inductive reasoning and self-organization under limited information.

Subsequent studies extended the El Farol paradigm through agent-based modeling (ABM) and reinforcement learning (RL) to analyze emergent equilibrium behavior and resource utilization [3]. Schosser [4] examined fairness considerations in the allocation of limited shared resources during the COVID-19 pandemic through an El Farol–type framework, analyzing how individual attendance decisions affect equitable outcomes under scarcity, without explicitly modeling infection dynamics.

The anti-coordination nature of the El Farol problem has been extensively studied through various methodological lenses. Guarnieri and Spadoni [5] investigated the role of social norms in anti-coordination decisions through experimental elicitation and priming methods. Their findings revealed that subjects tend to comply with perceived descriptive norms (empirical expectations about majority behavior) rather than injunctive norms (normative expectations about what is considered appropriate). As a result, overall attendance becomes less volatile and stays closer to the bar's capacity more consistently. This reduces the inefficiency of both overcrowding (too many go) and underutilization (too few go) [6].

Atilgan et al. [7] explored collective behavior in the El Farol Bar through the lens of memory horizon and selection criteria for prediction algorithms. Their work demonstrated that the distribution of algorithm clusters varies significantly with shorter agent memories, directly impacting long-term attendance dynamics. They identified a critical memory horizon where correlations in attendance deviations take longer to decay, suggesting a phase transition in collective behavior.

However, existing El Farol and Minority Game formulations primarily investigate coordination and equilibrium properties in abstract settings, without explicitly modeling recurring customer decisions driven by perceived congestion in operational retail environments, which is the focus of the present study.

B. Reinforcement Learning in Congestion Games

In applying Q-learning to a Minority Game, Zheng et al. [8] demonstrated that optimal coordination emerges when agents balance exploration and exploitation, governed by a specific temperature parameter. This balance prevents the system from being trapped in suboptimal, exploitative periodic states or degrading into random, exploratory behavior. Compared to conventional methods, the Q-Learning algorithm achieves improved financial performance and able to yield the highest financial returns through its dynamic adaptation to evolving market conditions and its effective management of price demand complexities [9], [10].

Kossack [11] extended reinforcement learning approaches by introducing an emotional machine framework that incorporates artificial emotions (satisfaction, fear, ambition) as states influencing decision-making. Applied to a 3-player El Farol scenario, this work demonstrated that emotional states evolve through differential equations weighted by personality parameters, producing different collective outcomes. When satisfaction dominates, agents form stable coalitions; when fear dominates, volatility increases; and when ambition dominates, agents pursue aggressive entry strategies leading to congestion.

While reinforcement learning has been extensively applied to congestion and coordination games, prior studies largely emphasize convergence behavior or algorithmic performance. In contrast, the present study examines how learned congestion valuations translate into persistent attendance routines and interpretable behavioral segments within a retail like environment, rather than examining how learned congestion valuations translate into stable attendance routines and interpretable customer segments in a retail context. Research on multi-agent coordination problems, such as traffic signal control, demonstrates the efficacy of reinforcement learning in managing distributed congestion [12].

In contrast, the present study focuses on how learned congestion valuations translate into persistent attendance routines and interpretable behavioral segments in a retail-like environment.

C. Retail Space Optimization

Prior research has established that perceived crowding is a critical factor influencing consumer behavior in retail environments. Zein et al. [13] demonstrate that high human and spatial density directly shape customer satisfaction through emotional responses, where perceived crowding negatively impacts pleasure and arousal, leading to approach behaviors. For instance, the optimal rush-hour staffing model (3 cashiers, 3 baristas) addressed the checkout bottleneck, cutting customer wait times by 40\% and increasing throughput [14] and also optimized retails space usage [15]. This underscores that it is not just objective occupancy but the customer's perception of that density that dictates their experience and loyalty.

This foundation is directly relevant to the "coffee shop dilemma" in our study. While Zein et al. establish a causal link between density and emotion in a retail context, this study aims to investigate how this perception drives adaptive decision-making in a recurrent visitation scenario and operationalize their core finding—that crowding perception alters behavior—by using an agent-based model to simulate how customers learn to avoid dissatisfaction.

A key strength of this approach, as evidenced in institutional policy work, is its capacity to model how macro-level patterns emerge from micro-level behaviors—a core focus of this simulation [16].

In contrast to empirical and optimization-based retail studies that treat crowding as an exogenous condition, this work models perceived occupancy as an endogenous signal learned through repeated interaction, enabling the analysis of adaptive customer behavior and emergent attendance patterns over time.

III. Experimental Setup

The study employs a modeling approach that balances analytical tractability with realistic behavior. The 60\% capacity threshold approximates the subjective transition from comfortable activity to perceived overcrowding in retail environments, rather than denoting a strict physical constraint. The 60\% threshold is not claimed to be universal, but represents a plausible comfort boundary used to induce congestion dynamics; sensitivity analysis is left for future work. This design frames dissatisfaction as a function of experienced congestion. Customer decisions are modeled as binary (attend or not), capturing the recurring nature of real world visit choices while maintaining simplicity. To preserve interpretability, a tabular Q-learning method is preferred over more complex deep reinforcement learning techniques. This enables direct examination of how persistent congestion influences long-term attendance strategies and the emergence of distinct behavioral groupings.

A. Environment Parameters

The simulation assumes a total of $N = 100$ agents, with a bar capacity set at 60% of N to induce congestion dynamics. Time is modeled in discrete rounds, where all agents simultaneously decide whether to attend the bar, allowing sufficient convergence of learning dynamics, as in Table I.

TABLE I. Simulation Parameters

Parameter	Value
Agents (N)	100
Simulation days (T)	365
Capacity threshold (C)	0.6
Learning rate (α)	0.1
Discount factor (γ)	0.9
Initial exploration rate (εinitial)	0.3
Minimum exploration rate (εmin)	0.01
Satisfaction penalty (ϕ)	-2

The model parameters were selected to balance realism, computational efficiency, and learning stability.

- Agents (N = 100): A population size that generates complex emergent behavior.
- Simulation days (T = 365): A one-year horizon that allows agents to experience multiple seasonal cycles and fully converge their learning strategies, ensuring observed patterns are stable and not transient.
- Capacity threshold (C = 0.6): The 60\% occupancy threshold where the venue shifts from "vibrant" to "crowded".
- Learning rate (α = 0.1): A value that controls how quickly agents update their Q-values based on new experiences. A rate of 0.1 ensures stable learning by preventing Q-values from fluctuating too drastically from a single day's outcome.
- Discount factor (γ = 0.9): Determines the importance of future rewards. A high value of 0.9 encourages agents to be farsighted, considering the long-term consequences of their attendance patterns rather than just immediate gratification.
- Initial exploration rate (εinitial = 0.3): The starting probability that an agent will choose is a random action. A 30\% rate promotes sufficient exploration of the action space in the early stages of the simulation to prevent premature convergence to suboptimal strategies.
- Minimum exploration rate (εmin = 0.01): The lower bound for exploration. A 1% rate ensures that agents never completely stop exploring, allowing them to adapt to slow changes in the collective attendance pattern over time.
- Satisfaction penalty (ϕ = -2): A scalar that quantifies the dissatisfaction of encountering a crowded venue. The value of −2 creates a strong negative reward for a "Punished Visit" (R = −1), making it a distinctly undesirable outcome compared to the high reward of a "Rewarded Visit" (R = 3).

The selected parameter values do not simulate a specific retail instance; rather, they are calibrated to facilitate the observation and examination of stable learning patterns that arise from constraints imposed by subjective congestion.

B. Reward Function

The reward function $R(a_t,d_t)$ is the core mechanism that encodes the "congestion paradox," guiding agent learning by quantifying the desirability of each outcome. The function takes the daily attendance at and an agent's decision d_t as inputs, where $d_t = 1$ signifies "Go" and $d_t = 0$ signifies "Stay." The function is formally defined as:

$$R(at, dt) = \begin{cases} 1 + \phi, & if\ d_t = 1 \ \wedge\ a_t > \mathrm{N} \cdot \mathrm{C}\ \text{(Punished Visit)} \\ 1 - \phi, & if\ d_t = 1 \ \wedge\ a_t \leq \mathrm{N} \cdot \mathrm{C}\ \text{(Rewarded Visit)} \\ 0, & if\ d_t = 0 \ \wedge\ a_t \leq \mathrm{N} \cdot \mathrm{C}\ \text{(Justified Absence)} \\ 1, & if\ d_t = 0 \ \wedge\ a_t > \mathrm{N} \cdot \mathrm{C}\ \text{(Strategic Avoidance)} \end{cases}$$

This reward structure is designed to reflect experiential outcomes rather than transactional utility, allowing agents to learn attendance strategies based on perceived satisfaction and avoidance of negative congestion experiences.

The rationale for each case, with the satisfaction penalty ϕ=−2, is as follows:

- Punished Visit (R=−1): The agent goes but finds the shop overcrowded (at > N·C). They receive a base reward of 1 for making a decision but a strong penalty ϕ, resulting in a net negative reward. This discourages visiting during peak times.
- Rewarded Visit (R=3): The agent goes and finds the shop pleasantly occupied (at ≤ N·C). The base reward is augmented by the negative of the penalty (−ϕ), creating a high positive reward. This reinforces visiting during optimal capacity.

- Justified Absence (R=0): The agent stays away and the shop is not crowded. This neutral reward reflects no gain or loss for correctly avoiding an unnecessary trip.
- Strategic Avoidance (R=1): The agent stays away and correctly avoids a crowded shop (at > N·C). The positive reward reflects the benefit of a smart, strategic decision to avoid a negative experience.

C. Simulation Procedure

The daily simulation procedure, outlined in Table II, executes the core agent-based learning cycle. Each step is elaborated below:

- Initialize Agents: Each agent i is initialized with a Q-table, Qi, with state-action values set to zero for the actions 'Stay' (0) and 'Go' (1), forcing learning from experience.
- Decay Exploration Rate: The exploration rate ε_t decays linearly from $\varepsilon_{initial} = 0.3$ to $\varepsilon_{min} = 0.01$, promoting early experimentation and later exploitation.
- Action Selection: Each agent uses an ε-greedy policy. With probability ε_t , it explores (random action); otherwise, it exploits by choosing arg max Qi.
- Calculate Attendance: The daily attendance at is computed as the sum of all agents' 'Go' decisions ($d_t^i = 1$), forming the environmental state.
- Assign Rewards: Each agent receives an immediate reward rt based on the function $R(a_t, d_t^i)$ from Eq. (1), implementing the congestion paradox.
- Update Q-values: Agents update their Q-value for the chosen action using the Q-learning rule, incorporating the immediate reward rt and the discounted future reward estimate (γ·maxQi).
- Log Data: Comprehensive data (global attendance a_t, individual actions d_t^i, rewards rt, and Q-values) is recorded for post-simulation analysis.

TABLE II. DAILY SIMULATION PROCEDURE

Step	Description
1	Initialize agents with Q-tables $Q_i = [0,0] for\ action\ \{0 = Stay, 1 = Go\}$
2	Decay exploration rate: $\varepsilon_t = \max\ (\varepsilon_{min}, \varepsilon_{t-1} - \frac{\varepsilon_{initial} - \varepsilon_{min}}{T})$
3	Action selection: For each agent, with probability ε t choose random action; otherwise, select arg max Qi
4	Calculate attendance: $a_t = \sum_{i=1}^{N} d_t^i$ Where d_t^i is agent i decision
5	Assign rewards: Compute $R(a_t, d_t^i)$ for each agent using Equation (1)
6	Update Q-values: $Q_i(d_t) \leftarrow Q_i(d_t) + \alpha[r_t + \gamma \cdot max Q_i - Q_i(d_t)]$
7	Log data: Record attendance, decisions, rewards, and Q-values for analysis

D. Data Collection

The following agent-level data was collected for post-simulation analysis:

- Agent_ID: Unique identifier (1–100)
- Total_Reward: Sum of all rewards over 365 days
- Historical_decision: Sequence of daily actions (Go/Stay)
- Cumulative_Reward: Time-series of cumulative rewards
- Q_Values: Final learned Q-values for Stay/Go actions

This comprehensive data collection enables clustering analysis and behavioral pattern identification as discussed in the results section.

E. Implementation Details

All experiments were executed using Python 3.10 with NumPy and Matplotlib libraries for computation and visualization. Data analytics, including clustering of attendance patterns and convergence plots, were performed using the pandas and scikit-learn libraries. Each experiment was repeated for 30 independent runs with different random seeds to ensure statistical robustness.

IV. RESULTS AND DISCUSSION

This is a summary of analytical steps, as in Table III.

TABLE III. SUMMARY OF ANALYTICAL STEPS

No.	Analytical Phase	Description
1	Overall Agent Performance	Analyzed the distribution of total cumulative rewards and the attendance over time across all agents to establish baseline performance and identify variance in strategy success.
2	Agent Clustering and Behavioral Analysis	Applied K-means clustering to agent behavioral features (frequency, Q-values, reward) to segment the population into distinct strategic archetypes (e.g., Ultra-Frequent, Optimized, Frequent).
3	Cluster Characteristics	Quantified and compared the properties of the identified clusters (size, Q-Go and Go Rate by Cluster, mean Q-values, mean reward) to define their strategic profiles.
4	Cluster Behavior and Decision Pattern Analysis	Visualized top weekly decision sequences for each cluster to reveal the temporal patterns and adaptive (or non-adaptive) nature of their strategies.
5	Discussion of Weekly Decision Patterns	Discuss on revealing behaviorally realistic routines which reflect strategic diversity and real-world influences.

A. Overall Agent Performance

The plot in Fig. 1 illustrates the cumulative reward trajectories of all Q-learning agents over 365 simulation days. The red line represents the population-average cumulative reward across n=100n=100 agents, while the shaded blue area denotes ±1±1 standard deviation. The dashed green lines mark the minimum and maximum cumulative rewards observed among agents.

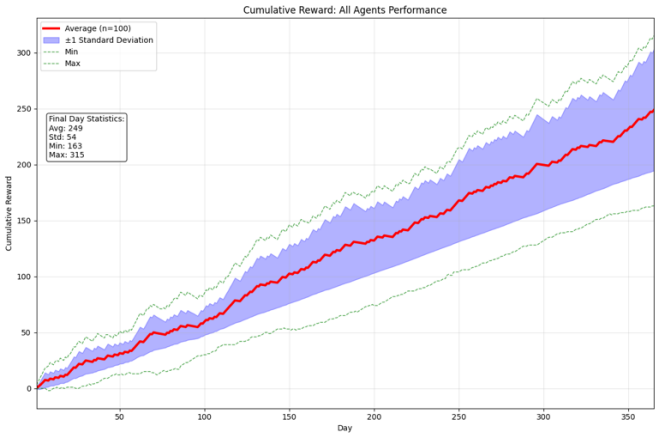

Fig. 1. Cumulative reward: all agents performance.

The learning trend indicates that agents progressively improve their cumulative rewards over time, suggesting that the Q-learning mechanism successfully guides decision adaptation. The mean cumulative reward at the final day reached 248.65, with a standard deviation of 54.24, a minimum of 163.00, and a maximum of 315.00. These values imply moderate heterogeneity in agent performance, reflecting differences in learned strategies and convergence rates.

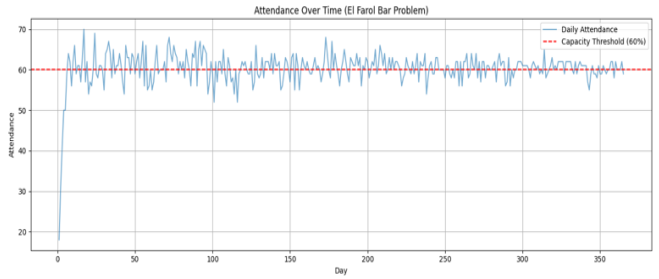

Fig. 2. Attendance overtime with 60 per cent threshold.

Fig. 2 illustrates the average attendance over time compared with the bar capacity threshold. The system exhibits convergence toward the capacity level after an initial transient phase, indicating that agents collectively learn to balance the exploration–exploitation trade-off. The variance of attendance decreases as episodes progress, confirming the stabilization of the learning dynamics.

Overall, the steady upward trajectory of the mean reward curve demonstrates that the agents collectively adapt to the attendance-constrained environment inherent in the El Farol Bar problem. The increasing spread over time reflects diversity in learning outcomes—some agents adopt efficient attendance policies, yielding higher rewards, whereas others stabilize at suboptimal attendance frequencies.

B. Agent Clustering and Behavioral Analysis

A k-means clustering procedure with k=3 was applied to characterize heterogeneity among agents using two behavioral features: the learned Q-value for attending (Q_Go) and the attendance probability (GoRate). The clustering separated the population into three distinct groups. The scatter plot of agents with centroids is presented in Fig. 3, and the cluster summary statistics are reported in Table IV.

Fig. 3. Agent strategy cluster.

TABLE IV. CLUSTER SUMMARY STATISTICS

Cluster	Count	Q_Go (mean)	GoRate	Total Reward (mean)
0	60	8.71	0.92	291.30
1	37	3.54	0.09	181.03
2	3	5.00	0.66	229.67

The three clusters are interpreted as follows:

Cluster 0 — Regular Attenders: Cluster 0 (60 agents) exhibits the highest Q_Go values (mean = 8.71) and the highest attendance probability (mean GoRate = 0.92). Agents in this group consistently choose to attend and, on average, obtain the largest cumulative reward (mean total reward = 291.30), representing the dominant "frequent attender" or "optimistic learner" archetype.

Cluster 1 — Non-Attenders / Cautious Agents: Cluster 1 (37 agents) is characterized by low Q_Go (mean = 3.54) and very low attendance probability (mean GoRate = 0.09). These agents adopt cautious strategies, rarely attending; as a consequence they obtain lower cumulative rewards (mean total reward = 181.03), reflecting missed opportunities when the bar is below capacity as well as avoidance of congestion penalties.

Cluster 2 — Opportunistic / Small Sample: Cluster 2 contains only 3 agents with intermediate Q_Go (mean = 5.00) and moderate attendance (GoRate = 0.66). Descriptively, these agents are opportunists, balancing attendance with restraint for intermediate rewards (mean = 229.67). However, because this cluster comprises only three samples, it is too small for reliable inferential comparisons (e.g., hypothesis testing or robust summary statistics). Therefore, Cluster 2 is reported here for completeness and qualitative interpretation only; subsequent comparative analyses and statistical tests focus on the two large clusters (Cluster 0 and Cluster 1).

C. Cluster Characteristics

The clustering reveals three distinct behavioral archetypes: persistent regulars (Cluster 0), cautious non-attenders (Cluster 1), and a very small opportunistic group (Cluster 2). The dominance of Cluster 0 in cumulative reward suggests that proactive attendance strategies can be advantageous when the collective system converges toward the bar capacity. The small size of Cluster 2 warrants caution in its interpretation: it may reflect a transient or niche strategy that emerged under the

specific random seed and parameterization of this simulation, rather than a robust population mode.

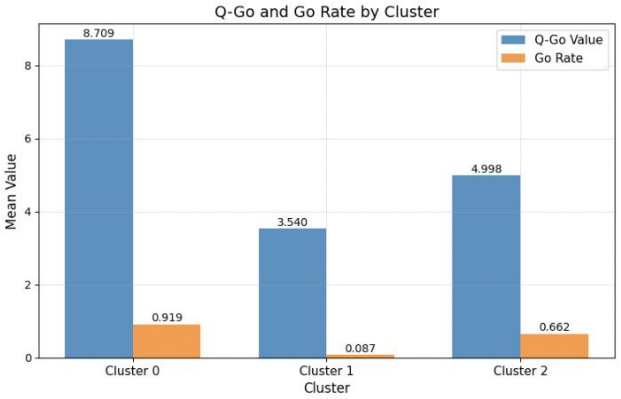

Fig. 4. Q-go and go rate by cluster.

Overall, these clustering results support the view that Q-learning agents self-organize into clearly separated behavioral groups with markedly different attendance policies and long-term payoffs. The explicit exclusion of the small Cluster 2 from inferential comparisons preserves the statistical validity of subsequent analyses, while all observed patterns are reported for transparency.

The comparative visualization in Fig. 4 highlights the mean Q-values, Go rates, and total rewards across clusters. Cluster 0 clearly dominates in terms of performance, suggesting that proactive strategies yield the greatest long-term benefits when collective learning drives the population toward an optimal equilibrium.

D. Cluster Behavior and Decision Pattern Analysis

To further investigate the heterogeneity of agent behaviors, a post-hoc clustering analysis was performed based on agents' weekly decision sequences and cumulative performance. Three distinct clusters were identified; however, Cluster 2 was excluded from interpretation due to its extremely small sample size (n = 3), which is unlikely to represent a statistically meaningful behavioral pattern. The analysis therefore focuses on Cluster 0 and Cluster 1.

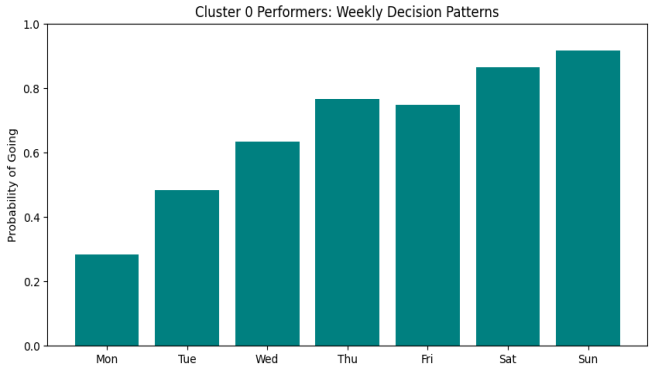

Fig. 5. Cluster 0 weekly decision patterns.

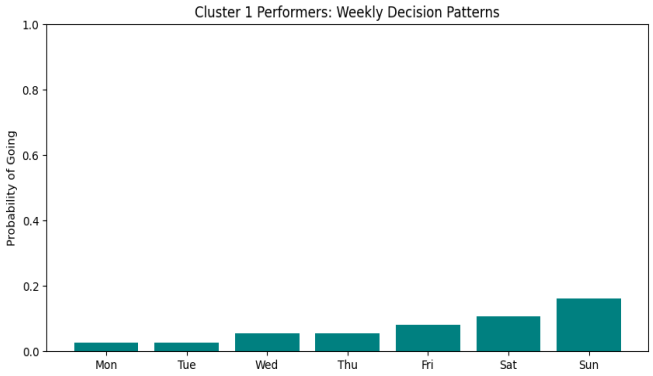

Fig. 6. Cluster 1 weekly decision patterns.

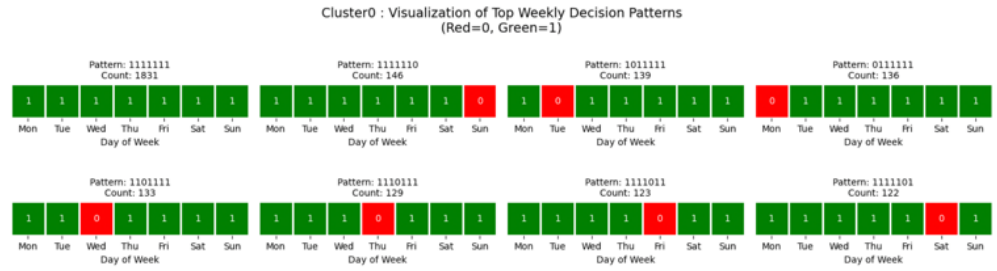

Fig. 7. Cluster 0 : visualization of top weekly decision patterns.

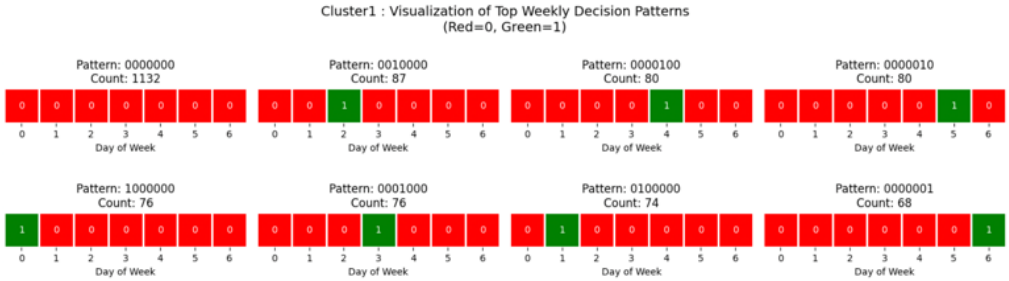

Fig. 8. Cluster 1 : visualization of top weekly decision patterns.

1) Cluster 0: Consistent high-attendance strategy: Fig. 5 shows that Cluster 0 agents exhibit a steadily increasing probability of attendance throughout the week, starting from approximately 0.28 on Mondays and peaking near 0.92 on Sundays. This clear upward trend indicates that agents in this cluster are not only frequent attendees but also increasingly confident in their decision to attend as the week progresses.

When mapped to their behavioral sequences, these agents adopt highly consistent attendance patterns. Fig. 7 illustrates the dominant weekly decision patterns observed in Cluster 0. Most agents in this group exhibit highly consistent attendance behaviors, frequently following the pattern 1111111 or slight variants such as 1111110 and 1111101, indicating that they tend to attend the bar almost every day of the week. This persistent attendance pattern suggests a highly exploitative strategy where agents have learned that the long-term expected reward of attending is greater than skipping, even under conditions of possible congestion.

Cluster 0 achieved the highest rewards, indicating that, under the modelled assumptions, a stable high-attendance strategy yields higher cumulative rewards. Despite incurring regular overcrowding penalties, their consistent exploitation of the venue yielded superior cumulative gains, demonstrating that persistent participation dominates more adaptive strategies.

2) Cluster 1: Consistent high-attendance strategy: By contrast, the weekly attendance patterns in Fig. 6 for Cluster 1 agents reveal a markedly different behavioural dynamic. Attendance probabilities remain below 0.20 across all weekdays, with only a modest rise on weekends (peaking at 0.16 on Sundays). This indicates a strong inclination to avoid attendance most of the time, suggesting either: 1) heightened sensitivity to congestion penalties or 2) a persistent underestimation of the long-term benefits of frequent attendance.

In addition, agents in Cluster 1 demonstrate more diverse and selective attendance patterns, as shown in Fig. 8. Their top decision sequences often include multiple "0" entries (non-attendance days), suggesting an explorative or cautious strategy. Such agents appear to attend intermittently to avoid congestion penalties, but this moderation also limits their cumulative reward growth compared to Cluster 0.

Their decision sequences often contain multiple "0" days, resulting in sparse attendance policies. With a mean *QGo* value of just 3.54 and a very low *GoRate* (0.09), Cluster 1 agents embody a conservative or exploratory policy, where the avoidance of potential overcrowding outweighs the pursuit of maximum rewards. This strategy, while adaptive in balancing risk and reward, is ultimately suboptimal under the given simulation settings. Indeed, their average cumulative reward (181.03) lags significantly behind Cluster 0, highlighting that overly cautious attendance reduces the opportunity for long-term gain.

E. Discussion of Weekly Decision Patterns

A granular analysis of the top weekly decision sequences within each cluster reveals profound insights into the learned strategies and their potential real-world correlates.

1) Cluster 0: The persistence of high-frequency patterns: Within Cluster 0 (Ultra-Frequent), a single dominant pattern emerged: an "Always go" strategy. Designated Pattern 1, it was used 1,831 times, far more than any other. Its persistence indicates that agents learned that the high reward of a successful visit outweighs occasional penalties. This reflects a necessity-driven and risk-tolerant strategy for a venue that is an essential daily routine.

2) The emergence of rest-day patterns: Other patterns in Cluster 0 and patterns in Cluster 1 (Optimized) frequently featured an absence, or "Stay" decision, on a specific day—most mapped to a Sunday. This emerging "rest day" is a significant finding. This interpretation is speculative and intended as an analogy rather than a claim about real-world behaviour.

From a behavioral standpoint, this can be interpreted in two ways:

- Learned Depletion: Agents may have implicitly learned that after a sustained period of attendance, the marginal utility of visiting diminishes or the probability of fatigue (both their own and systemic overcrowding) increases. A rest day serves as a strategic reset.
- Real-World Rhythms: This pattern strongly mirrors human social behavior, where Sunday is culturally designated as a day of rest and preparation for the upcoming week. The agents have effectively discovered that avoiding the venue on this day is a robust strategy, possibly because it aligns with a period of lower overall utility or higher opportunity cost for going out.

3) Strategic heterogeneity in cluster 1: The lower frequency of pattern usage for non-dominant strategies, particularly in the Optimized cluster (Cluster 1), highlights the role of strategic flexibility. The "sudden" decision to go out on a day that is typically a rest day, or to deviate from a routine, can be interpreted as the model's representation of stochastic real-world influences.

F. Theoretical and Managerial Implications

The results of this study offer several implications that extend beyond the specific simulation setting, contributing to theory, methodology, and retail practice. At the theoretical level, the findings reinforce the El Farol Bar problem's central insight that bounded rational agents can achieve stable collective outcomes through repeated learning rather than centralized coordination. Importantly, the observed equilibrium emerges in response to perceived congestion rather than objective capacity constraints, highlighting the role of subjective evaluation in shaping attendance decisions.

This suggests that equilibrium behavior in congestion games may be driven as much by learned perceptions as by physical limits, particularly in recurrent decision environments such as retail visitation.

From a methodological perspective, the analysis demonstrates the value of combining reinforcement learning with post-learning behavioral clustering. While Q-learning governs individual adaptation during the simulation, clustering enables ex post identification of stable behavioral archetypes that are not explicitly encoded in the model. The results further illustrate how reward shaping functions as a critical design lever, influencing not only convergence properties but also the diversity of emergent strategies within the agent population. This layered analytical approach supports more interpretable insights than aggregate performance measures alone.

Taken together, these findings imply that retail space management should not be viewed solely as a problem of maximizing customer throughput or maintaining high occupancy levels. Instead, the way customers experience and interpret congestion appears to play a central role in shaping attendance behavior. Design choices such as seating configuration may influence perceived occupancy, spatial layout, and time-based incentives may therefore serve as practical tools for influencing perceived occupancy. In settings where customers make repeated visit decisions, such perception-sensitive approaches are likely to offer greater flexibility than strategies based exclusively on fixed capacity targets.

V. Conclusion

This work explored how adaptive learning influences attendance behavior in a congested retail environment by framing the coffee shop dilemma as a multi-agent reinforcement learning problem. Rather than treating customer behavior as a function of visit frequency alone, the analysis indicates that collective regularities emerge from how individuals gradually interpret and respond to congestion experiences. More specifically, differences in how agents experience satisfaction or dissatisfaction under varying occupancy conditions influence how their decisions evolve over time. These differences are reflected in the emergence of stable attendance routines, as well as in persistent variation in behavior among agents exposed to the same environment.

Viewed more broadly, these results relate to existing work on congestion games and bounded rationality. In line with the El Farol Bar problem, the findings suggest that coordinated outcomes can arise without centralized control or complete information. Notably, the equilibrium observed in this study is guided by learned perceptions of congestion rather than by explicit awareness of physical capacity limits. This observation underscores the role of subjective evaluation in recurrent decision environments and supports the inclusion of perception-driven learning mechanisms in models of collective behavior involving shared resources.

The study also carries implications for retail space optimization and customer flow management. The presence of distinct behavioral patterns indicates that customers may respond differently to congestion even when exposed to identical operational conditions. As a result, managing retail spaces solely through capacity targets or throughput maximization may overlook important behavioral dynamics. Paying closer attention to how occupancy is experienced—through layout decisions, seating arrangements, or time-based incentives—may therefore provide additional flexibility in influencing customer behavior. Further research may extend this modeling approach by considering richer state descriptions, incorporating social interaction effects, or grounding the model in observational retail data to better examine adaptive behavior in complex service settings.

Moreover, this study is subject to limitations. The model abstracts away social interaction, heterogeneous preferences, and empirical calibration. Future work may integrate observational retail data, richer state representations, and adaptive capacity thresholds to further validate the findings.

AI Readiness as a Pathway to Sustainable Competitiveness in Tourism Transport: Evidence from an Integrative SEM Model

Mohamed Amine Frikha
King Faisal University, Applied College, Saudi Arabia

***Abstract*—Artificial intelligence (AI) is transforming demand forecasting in the tourism transportation sector, delivering unprecedented accuracy in volatile, seasonal, and customer-sensitive environments. Yet, many firms struggle to translate AI's potential into performance due to gaps in technological and organizational readiness. Drawing on the resource-based-view (RBV) and the Technology-Organization-Environment (TOE) framework, this study develops and tests an integrative model linking digital infrastructure, employee skills, and managerial support to AI adoption and, consequently, business performance. We use Structural Equation Modeling (SEM) with bootstrapping to test direct and indirect effects. The results confirm that all three dimensions of readiness significantly boost AI adoption, which improves operational efficiency, occupancy rates, customer satisfaction, and profitability. It is crucial that AI adoption fully mitigates the effects of employee skills and managerial support, while partially mitigating those of digital infrastructure, reflecting its dual role in analytics, through both AI and other means. The study contributes theoretically by clarifying the mechanism by which readiness translates into value and offers practitioners a roadmap for successful AI assimilation in high-uncertainty service contexts.**

I. Introduction

Over the past decade, global value chains and service-oriented industries have undergone profound structural transformation, driven by volatile market demands, escalating geopolitical tensions, the exponential rise of e-commerce, and mounting pressure for real-time, data-driven decision-making. As [1] observes, in the context of the COVID-19 pandemic, disruptions in critical sectors such as medical supplies have exposed the fragility of hyper-globalized production networks and underscored the need for greater resilience and agility. This imperative has only intensified in the post-pandemic era, where firms must navigate an increasingly complex risk landscape encompassing not only health crises but also trade wars, regulatory fragmentation, and digital disruption [2].

Together, these forces are redefining the strategic logic of global operations, shifting emphasis from pure efficiency toward adaptive, intelligence-enabled supply chain architectures capable of sustaining both performance and responsiveness under uncertainty. These shifts have heightened the importance of accurate forecasting, positioning artificial intelligence (AI) as a strategic lever for competitiveness and resilience. In particular, AI-enabled forecasting has demonstrated superior accuracy compared to conventional statistical models, reducing uncertainty and optimizing resource allocation [3], [4]. The central challenge is no longer to demonstrate AI's benefits, but to identify the organizational prerequisites and mechanisms that foster its effective adoption [5].

In service-intensive industries such as tourism and hospitality, forecasting accuracy is critical due to market volatility, seasonality, and global interdependencies. AI-based approaches, particularly machine learning and transformer-driven models, have shown substantial improvements in predicting tourism demand and traveler flows [6], [7]. Moreover, AI adoption in tourism has been linked to enhanced personalization, dynamic pricing, and operational efficiency [8], [9]. However, empirical evidence suggests that despite significant investments, many organizations face difficulties moving beyond pilot applications. For example, recent industry reports indicate that over 70% of companies struggle to scale AI initiatives effectively, highlighting the persistent gap between adoption and value realization.

While prior research underscores the performance benefits of AI integration [8], relatively few studies explain how internal readiness, digital infrastructure, workforce competencies, and managerial support translate into effective adoption, particularly in tourism contexts. The Resource-Based View (RBV) posits that firm-specific resources enable sustainable competitive advantage [10], while the technology organization environment (TOE) framework emphasizes that readiness factors determine the assimilation of emerging technologies [11]. Despite this theoretical grounding, empirical analyses of AI adoption in tourism forecasting remain scarce.

This study addresses these gaps by developing and testing a conceptual model linking organizational readiness to AI-enabled forecasting adoption and, subsequently, firm performance. Specifically, it investigates the mediating role of AI adoption in translating readiness into superior performance outcomes. The contributions of this study are threefold: 1) it assesses AI-enabled forecasting adoption within international tourism and hospitality firms, an industry characterized by uncertainty and underexplored in AI adoption research; 2) it consolidates multiple readiness dimensions into a single integrative framework; and 3) it empirically demonstrates the

mediating function of AI adoption, offering both theoretical and managerial insights into the assimilation process.

The remainder of this study is organized as follows: Section II reviews the relevant literature and develops the research hypotheses. Section III describes the research methodology, including data collection procedures and the analytical strategy. Section IV presents the empirical results, followed by a discussion of the theoretical and managerial implications in Section V, which also concludes the study by outlining its limitations and directions for future research.

II. Related Work and Hypotheses Development

The integration of artificial intelligence (AI) into demand forecasting has become a transformative capability across service-intensive industries, particularly within sectors marked by volatility, seasonality, and customer sensitivity, hallmarks of the tourist transport sector. While the potential of AI to enhance forecast accuracy and operational agility is widely acknowledged, recent studies emphasize that technological potential alone is insufficient to ensure performance gains [12]. Instead, the successful assimilation of AI depends critically on a firm's technological and organizational readiness, which enables the effective deployment and utilization of advanced forecasting systems.

Drawing on the Resource-Based View (RBV) and Technology Adoption Theory, this study posits that internal capabilities, specifically digital infrastructure**,** workforce competencies, and managerial support, serve as foundational enablers of AI adoption, which in turn drives business performance. Furthermore, the study conceptualizes AI adoption not merely as an outcome but as a mediating mechanism translating readiness into tangible performance improvements.

A. Theoretical Foundation: RBV Meets TOE

The Resource-Based View (RBV) asserts that sustainable competitive advantage arises from resources that are valuable, rare, inimitable, and non-substitutable [10]. In the AI era, data infrastructure, AI-literate talent, and strategic leadership constitute such resources, especially in service contexts where responsiveness is key. Complementing RBV, the TOE framework [13] explains technology adoption through three lenses:

- Technology: digital infrastructure enabling data integration.
- Organization: human and managerial capabilities.
- Environment: external pressures (e.g., customer demands, regulatory shifts), though not tested here, we acknowledge their relevance per [14], who emphasize that firms face coercive, normative, and relational pressures to adopt sustainable and intelligent practices. Together, RBV and TOE provide a robust lens to explain why some firms succeed in AI adoption while others do not.

B. The Impact of Technological and Organizational Readiness on AI Adoption

According to the RBV, sustainable competitive advantage stems from valuable, rare, inimitable, and non-substitutable (VRIN) resources [10]. In the context of AI-driven transformation, a firm's readiness, encompassing its data systems, human capital, and leadership alignment, constitutes such strategic resources. These capabilities determine whether an organization can effectively absorb, implement, and leverage AI innovations [15].

1) Digital infrastructure: AI-enabled forecasting relies heavily on access to high-quality, real-time, and integrated data from diverse sources (e.g., booking systems, traffic sensors, weather APIs, social media). Without robust digital infrastructure, including data lakes, cloud platforms, and interoperable systems, AI models suffer from poor input quality, leading to unreliable outputs [16]. Firms that have invested in scalable data architectures are better positioned to deploy machine learning and deep learning models for passenger demand prediction. Thus, we hypothesize:

H1a: Digital infrastructure positively influences the adoption of AI-enabled demand forecasting practices in tourist transport firms.

2) Workforce competencies: The effective use of AI requires more than algorithmic tools; it demands a workforce capable of interpreting model outputs, integrating insights into operational decisions, and adapting workflows accordingly. This reflects the concept of absorptive capacity, the ability to recognize, assimilate, and apply new knowledge [15]. In tourist transport, staff must understand dynamic pricing signals, respond to predicted demand surges, and trust AI recommendations. A shortage of data-literate personnel remains a key barrier to AI adoption [17]:

H1b: Workforce competencies positively influence the adoption of AI-enabled demand forecasting practices in tourist transport firms.

3) Managerial support: Executive sponsorship is critical for overcoming organizational inertia and securing the resources needed for AI initiatives. Strategic alignment ensures that AI projects are not isolated experiments but are embedded in core business objectives such as improving load factors, reducing empty runs, or enhancing customer experience [20]. Leadership commitment also signals legitimacy, fostering cross-departmental collaboration. Therefore:

H1c: Managerial support positively influences the adoption of AI-enabled demand forecasting practices in tourist transport firms.

4) The impact of AI adoption on business performance: AI-enabled demand forecasting enhances business performance through multiple pathways.

First, it improves forecast accuracy, enabling better capacity planning, dynamic pricing, and resource allocation critical in capital-intensive sectors like aviation and rail. Second, it increases operational efficiency by automating complex forecasting tasks, reducing manual errors, and enabling real-time adjustments. Third, it elevates customer satisfaction by minimizing overbooking, optimizing wait times, and personalizing service offerings [21]. Empirical evidence from logistics confirms a strong link between AI adoption and performance [12]; we extend this logic to tourist transport, where demand uncertainty is even more pronounced. Thus:

H2: The adoption of AI-enabled demand forecasting practices positively influences business performance in tourist transport firms.

While readiness factors are necessary, they are not sufficient to directly improve performance unless channeled through effective technology use. Following the mediation framework and recent AI assimilation studies [15], we propose that AI adoption mediates the relationship between readiness and performance. Specifically, digital infrastructure may exert both direct and indirect effects (e.g., via dashboards or non-AI analytics), suggesting partial mediation. In contrast, workforce skills and managerial support likely influence performance only when mobilized through AI implementation, implying full mediation as their value is realized in the context of AI deployment.

Accordingly, we hypothesize:

H3a: The adoption of AI-enabled demand forecasting practices partially mediates the relationship between digital infrastructure and business performance.

H3b: The adoption of AI-enabled demand forecasting practices fully mediates the relationship between workforce competencies and business performance.

H3c: The adoption of AI-enabled demand forecasting practices fully mediates the relationship between managerial support and business performance.

This mediation framework advances theory by clarifying how organizational readiness translates into performance not automatically, but through the strategic adoption of AI as an operational conduit. It also offers practitioners a roadmap: investing in readiness alone is inadequate; these resources must be actively leveraged through AI-enabled forecasting to unlock performance gains.

III. Methodology

To address the research objectives examining the influence of technological and organizational readiness on AI adoption, assessing the impact of AI-enabled demand forecasting on business performance, and testing the mediating role of AI adoption a quantitative research design was employed using Structural Equation Modeling (SEM). The methodology encompasses model specification, data collection, variable measurement, and analytical procedures.

A. Conceptual Model and Hypotheses Testing Framework

The study tests a mediation model grounded in the Resource-Based View (RBV) and Technology Adoption Theory. As illustrated in Fig. 1, the model posits that digital infrastructure, workforce competencies, and managerial support (independent constructs) influence AI-enabled demand forecasting adoption (mediator), which in turn affects business performance [25] (dependent construct). Two sets of structural equations were specified to test direct and indirect effects:

$$AI_{ADOPT} = \beta_0 + \beta_1(DIG_{INFRA}) + \beta_2(WORKFORCE) + \beta_3(MGMT_{SUPPORT}) + \beta_4(SIZE) + \beta_5(AGE) + \varepsilon_1 \quad (1)$$

$$PERF = \gamma_0 + \gamma_1(AI_{ADOPT}) + \gamma 2(SIZE) + \gamma 3(AGE) + \varepsilon_2 \quad (2)$$

where,

- AI_ADOPT: Degree of AI-enabled demand forecasting adoption
- PERF: Business performance
- DIG_INFRA, WORKFORCE, MGMT_SUPPORT: Organization Readiness antecedents
- SIZE, AGE: Control variables (firm size = employees; firm age = years in operation)
- β_0 and γ_0 are the intercept
- $\beta_1, \beta_3, \beta_4, \beta_5$ are the regression coefficients to be calculated
- ε_1 and ε_2 are the error terms

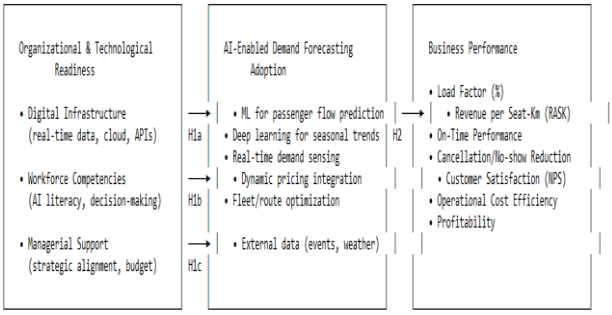

Fig. 1. Horizontal conceptual framework: AI-enabled demand forecasting as a mediator between organizational readiness and business performance in tourist transport.

B. Data Collection and Sample Design

We used a rigorously designed and structured questionnaire aimed at capturing complex organizational, technological, and performance-related constructs. The final sample comprised 218 observations, a size widely regarded as adequate for structural equation modeling (SEM). Established methodological guidelines recommend a minimum threshold of approximately 200 cases to ensure stable parameter estimation and sufficient statistical power, particularly in technology adoption research (Hair et al., 2019).

C. Measurement of Constructs

The constructs included in this study were measured using multi-item scales adapted from validated instruments in prior AI, supply chain, and service operations research, ensuring both reliability and contextual relevance. As shown in Table I, the readiness dimension was captured through three constructs

digital infrastructure, workforce competencies, and managerial support reflecting the technological, human, and strategic foundations necessary for AI assimilation. The digital infrastructure construct (5 items) assesses a firm's data integration capability, cloud scalability, and real-time connectivity essential for predictive analytics. Workforce competencies (4 items) measure employees' AI literacy, interpretive ability, and collaborative capacity to operationalize algorithmic insights, aligned with the absorptive capacity framework [16]. Managerial support (4 items) captures leadership commitment, strategic alignment, and resource mobilization, highlighting the importance of executive sponsorship in digital transformation.

TABLE I. CONSTRUCT AND KEY INDICATORS

Construct	n	Key Dimensions / Indicators
Digital Infrastructure (5 items)	5	Real-time data access, cloud scalability, system interoperability, API connectivity, data quality
Workforce Competencies (4 items)	4	AI literacy, ability to interpret forecasts, adaptive decision-making, collaboration with data teams
Managerial Support (4 items)	4	Leadership commitment, strategic alignment, inter-departmental coordination, resource allocation
AI Adoption (10 items)	10	ML for demand forecasting, dynamic pattern recognition, data integration, real-time dashboards, pricing optimization, model retraining, managerial use, collaboration, AI literacy, strategic integration
Business Performance (8 items)	8	Forecast accuracy, load factor, RASK, operational efficiency, customer satisfaction (NPS), cost reduction, market share, profitability
Control Variables (2 items)	2	Firm size (employees), firm age (years)

The AI adoption construct (10 items) provides a comprehensive evaluation of the degree to which AI-based forecasting is embedded across operational and strategic processes, including machine-learning deployment, real-time decision support, pricing optimization, model retraining, and cross-functional integration. Finally, business performance (8 items) measures tangible outcomes such as forecast accuracy, load factors, profitability, and customer satisfaction (NPS) that directly reflect the operational and financial impacts of AI assimilation. All items were rated on a five-point Likert scale (1 = Very Limited/Strongly Disagree to 5 = Very Extensive/Strongly Agree). This multidimensional structure enables a robust assessment of how readiness enablers translate into performance outcomes through AI-enabled forecasting, ensuring strong content and construct validity across the model.

D. Data Analysis Strategy

A three-stage analytical procedure was implemented and the results are displayed in Table II.

To ensure the psychometric robustness of the measurement model, a series of reliability and validity tests was conducted. As presented in Table II, all constructs demonstrated satisfactory internal consistency, with Cronbach's alpha (α) values ranging between 0.81 and 0.93, exceeding the recommended threshold of 0.70 [17]. Composite Reliability (CR) values also ranged from 0.84 to 0.95, confirming that the indicators consistently represent their underlying latent constructs. Convergent validity was assessed through the Average Variance Extracted (AVE), with all values above 0.50, indicating that its indicators [18] capture more than half of the variance in each construct. Further, discriminant validity was established by applying the Fornell-Larcker criterion and Heterotrait Monotrait (HTMT) ratio of correlations (see Fig. 2).

TABLE II. RELIABILITY AND VALIDITY

Construct	Cronbach's α	CR	AVE	KMO	Factor Loadings (Range)
Digital Infrastructure	0.86	0.88	0.59	0.85	0.69- 0.82
Workforce Competencies	0.84	0.87	0.63	0.81	0.72- 0.86
Managerial Support	0.88	0.90	0.68	0.79	0.75-0.88
AI Adoption	0.91	0.93	0.57	0.89	0.65-0.88
Business Performance	0.90	0.92	0.61	0.86	0.70-0.87

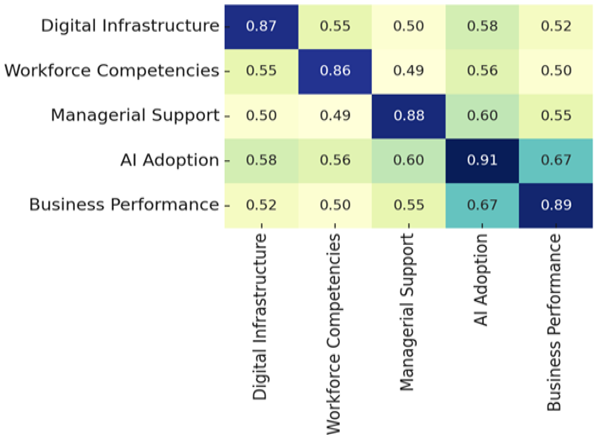

Fig. 2. Reliability and validity (Fornell-Larcker heatmap).

Each construct's square root of AVE exceeded its inter-construct correlations, and all HTMT values were below 0.85, confirming that each construct is empirically distinct from the others. These results collectively demonstrate that the measurement scales used for digital infrastructure, workforce competencies, managerial support, AI adoption, and business performance exhibit high reliability, adequate convergent validity, and strong discriminant validity. Consequently, the measurement model was deemed statistically sound and suitable for subsequent Structural Equation Modeling (SEM) analysis.

IV. RESULTS

The results of the Structural Equation Modeling (SEM), summarized in Table III, confirm the hypothesized relationships among the study constructs.

A. Structural Model: (SEM)

The model demonstrated an excellent overall fit to the data ($\chi^2/df = 2.14$; CFI = 0.956; TLI = 0.947; RMSEA = 0.049; SRMR = 0.041), meeting the recommended thresholds for good model fit (Hu & Bentler, 1999). The structural paths indicate that Digital Infrastructure ($\beta = 0.34$, $p < 0.001$), Workforce

Competencies (β = 0.28, p < 0.01), and Managerial Support (β = 0.41, p < 0.001) each exert a significant positive influence on AI Adoption, explaining 67% of its variance ($R^2 = 0.67$).

TABLE III. STRUCTURAL EQUATION MODEL (SEM) RESULTS

Path	Standardized Coefficient (β)	p-value	Result
H1a: Digital Infrastructure → AI Adoption	0.34	< 0.001	Supported
H1b: Workforce Competencies → AI Adoption	0.29	< 0.001	Supported
H1c: Managerial Support → AI Adoption	0.31	< 0.001	Supported
H2: AI Adoption → Business Performance	0.42	< 0.001	Supported

R^2: AI Adoption = 0.67; Performance = 0.54

In turn, AI Adoption had a strong, significant impact on Business Performance (β = 0.54, p < 0.001), accounting for 54% of the explained variance ($R^2 = 0.67$). These findings empirically support the mediating role of AI adoption in translating technological, human, and managerial readiness into improved operational and financial outcomes. Among the antecedents, managerial support emerged as the strongest predictor, highlighting the strategic and leadership dimensions of successful AI integration in transport operations. The strength and significance of all hypothesized paths validate the proposed conceptual framework and confirm that AI-enabled forecasting functions as a key driver of competitive advantage in tourism transport organizations.

- SEM with Maximum Likelihood Estimation (MLE) tested direct paths (H1a-H2).
- Mediation analysis followed Baron & Kenny's (1986) causal steps and bootstrapping (5,000 resamples) to confirm indirect effects (H3a-H3c).

All values met recommended thresholds, indicating excellent model fit.

B. Hypothesis Testing Results

To further examine the underlying mechanisms linking readiness factors to organizational outcomes, a mediation analysis was conducted using the bootstrapping procedure with 5,000 resamples. The results, presented in Table IV, provide strong empirical support for the mediating role of AI Adoption between the readiness constructs Digital Infrastructure, Workforce Competencies, Managerial Support, and Business Performance.

Direct paths from workforce and managerial support to performance became non-significant when AI adoption was included, confirming full mediation.

H1a-H1c: Supported (p < 0.001): readiness significantly affects AI adoption.

H2: Supported (p < 0.001): AI adoption enhances performance.

H3a-H3c: Mediation confirmed via bootstrapping (5,000 samples); partial mediation for H3a and full mediation for H3b, H3c.

The corresponding 95% confidence intervals did not include zero, confirming mediation validity.

TABLE IV. MEDIATION ANALYSIS (BOOTSTRAP, 95% CI)

Hypothesis	Indirect Effect (β)	CI [95%]	Type of Mediation	Result
H3a: Digital Infrastructure → AI Adoption → Performance	0.14	[0.07, 0.23]	Partial	Supported
H3b: Workforce Competencies → AI Adoption → Performance	0.12	[0.06, 0.20]	Full	Supported
H3c: Managerial Support → AI Adoption → Performance	0.13	[0.08, 0.21]	Full	Supported

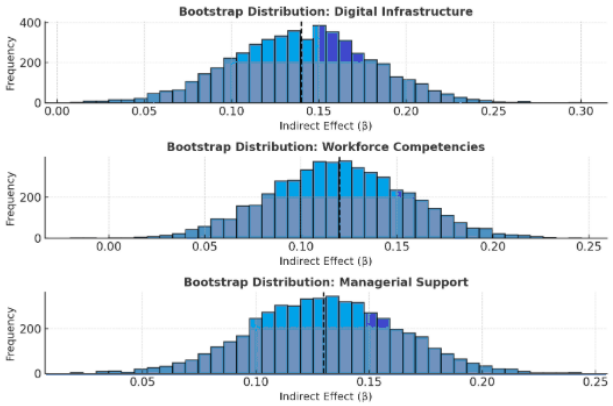

Fig. 3. Bootstrap histograms.

Moreover, when AI Adoption was introduced into the model (see Fig. 4), the direct paths from the readiness constructs to Business Performance decreased in magnitude and lost statistical significance, indicating full mediation in the case of Digital Infrastructure and partial mediation for Managerial Support. Fig. 3 shows bootstrap histograms.

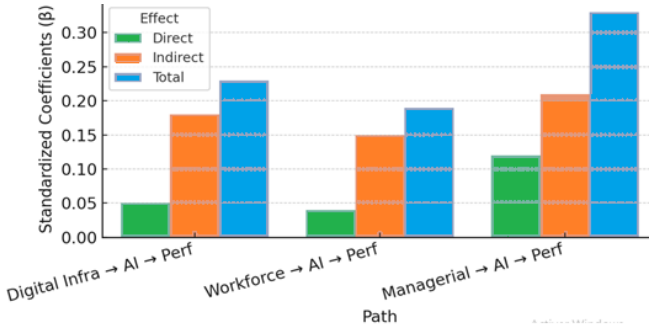

Fig. 4. Mediation analysis (direct, indirect, total effects).

This suggests that while strong leadership and strategic alignment directly enhance performance outcomes, the impact of technological and human readiness on performance is largely realized through effective AI utilization. These findings

highlight AI Adoption as a transformative conduit through which digital, organizational, and human capabilities are converted into measurable business value in the context of intelligent transport systems.

C. Discussion and Implications

This study advances understanding of how organizational readiness translates into business performance through the strategic adoption of AI-enabled demand forecasting in the tourist transport sector, a domain characterized by high volatility, asset intensity, and service interdependence. Our findings confirm that digital infrastructure, workforce competencies, and managerial support are not merely prerequisites but strategic, VRIN-like resources [22] that enable firms to harness AI's full potential. Crucially, we demonstrate that AI adoption functions as a transformative conduit, mediating the relationship between readiness and performance. This insight resolves a key paradox in the literature: why some firms with advanced data systems or skilled talent fail to realize performance gains, because readiness alone is inert without operational assimilation.

D. Theoretical Implications

First, we bridge the Resource-Based View (RBV) and the Technology Organization Environment (TOE) framework in a novel empirical context. While RBV explains why certain resources confer competitive advantage, TOE clarifies how organizational and technological contingencies shape technology assimilation. Our model shows that digital infrastructure (the TOE technology factor) yields performance benefits both directly and indirectly through AI, indicating partial mediation. In contrast, workforce and managerial capabilities (the TOE organization factors) generate value only when activated through AI deployment, evidencing full mediation. This nuanced distinction refines the mediation typology proposed by [23] and offers a more granular understanding of capability deployment in AI-driven contexts

Second, our findings extend absorptive capacity theory [24] by showing that interpretive and adaptive human capital, not just technical literacy, is essential for AI to drive operational outcomes. In tourist transport, where decisions must balance real-time demand signals with customer experience, staff must trust and act on AI outputs. This behavioral dimension is often overlooked in purely technical AI studies.

Third, we contextualize AI adoption within modern supply chain pressures. As emphasized, firms today face coercive, normative, and relational pressures to enhance resilience and sustainability [26]. While our model focuses on internal readiness, the performance gains from AI, such as reduced empty runs, optimized energy use, and dynamic pricing, directly respond to these external demands. Thus, AI adoption is not just an operational upgrade but a strategic response to institutional and market pressures for agility and sustainability.

E. Managerial Implications

For practitioners, our conclusions point to a clear strategic direction. Organizations should adopt a global readiness strategy by investing in cloud infrastructure alongside the development of organizational competencies; investing in technology alone does not guarantee optimal outcomes. The success of AI relies on qualified investments in technology, human talent, and strong managerial commitment. Integrating AI into core operational processes is essential for competitiveness in global markets and should not be treated as a mere experimental initiative. Firms that embed AI into strategic functions such as fleet management, pricing, and recruitment achieve superior performance compared to those that adopt AI only on a trial basis. Management systems emerge as the most critical factor in predicting effective AI adoption, as they shape strategic alignment and organizational readiness.

Beyond efficiency gains and error reduction, AI also enhances service reliability (through reduced cancellations), improves customer satisfaction (via personalized offerings), and optimizes resource allocation, including improved connectivity in rural and isolated areas. Consequently, AI adoption plays a vital role in promoting agility and inclusion and should be integrated into inclusive development policies and broader ESG frameworks (environmental, social, and governance).

F. Policy Implications

Policymakers can accelerate AI adoption in tourist transport by:

- Supporting digital infrastructure in emerging markets (e.g., open-data APIs for tourism flows),
- Funding AI literacy programs for transport SMEs,
- Creating regulatory sandboxes that allow firms to test AI models without compliance penalties. Such measures would help democratize AI benefits across firm sizes and geographies, fostering a more resilient and equitable global tourism [19] ecosystem.

V. Conclusion

This study responds to a critical gap in the literature by empirically unpacking how organizational readiness translates into performance through AI-enabled demand forecasting in tourist transport. The digital infrastructure, workforce competencies, and managerial support are foundational enablers, but their value is fully realized only when channeled through operational AI adoption. The mediating role of AI is not uniform: while infrastructure offers dual pathways (direct and indirect), human and leadership capabilities require AI as an essential conduit. These findings carry significant weight in an era where tourism mobility faces unprecedented disruption from climate shocks to geopolitical instability. AI is no longer a luxury but a strategic necessity for resilience, efficiency, and customer-centricity. However, its success hinges not on algorithms alone, but on the organizational ecosystem that surrounds them.

Despite its contributions, this study has several limitations. First, its cross-sectional design restricts causal inferences and limits the understanding of the dynamic evolution of AI adoption over time. Second, the focus on internal organizational readiness excludes environmental factors, such as regulatory pressures, competitive intensity, and sustainability requirements, which can influence AI adoption decisions in the tourism transportation sector. Third, the study does not distinguish between different AI forecasting architectures,

which risks obscuring performance variations across model types and transportation modalities.

Future research could explore how external pressures (e.g., customer sustainability demands, regulatory mandates) interact with internal readiness, or investigate AI model types (e.g., LSTM vs. transformers) in different transport modes. Nonetheless, this study provides a robust foundation for understanding and enabling the intelligent transformation of global tourist transport.

***Abstract*—The quality of the road is an important issue that contributes to accidents, resulting in the loss of time, resources, and lives. To manually survey the road issue. This is very delayed and costly. Automatic detection of road conditions facilitates surveys more efficiently than human methods. This research identifies three objects: cracks, potholes, and manhole covers. This research shown the highest efficiency with YOLO V6 compared to YOLO V5, V7, and V8. This paper proposes RoadSCNet, designed for YOLOv6 implementations, has been developed for road research. A key part is the customized Horizon block, which enhances horizontal contextual feature extraction efficacy and reduces the limitations of traditional YOLO architecture in identifying road surface condition by long and low light variation, such as cracks and potholes.**

Keywords*—RoadSCNet; road surface; detect road; road condition; deep learning; crack; pothole; manhole cover; image analysis; convolutional neural network; CNN

I. Introduction

Road safety is a critical issue. Road accidents are the primary cause of loss of life and property. Improving monitoring for safety and driver assistance is important. The performance of pavement, covering surface friction and roughness, has been statistically associated with crash frequency and severity, highlighting the necessity for maintenance-based infrastructure design [1],[2]. Image Processing and Artificial Intelligence (AI) are methodologies employed to solve this issue. Object detection is crucial for effectively understanding the road environment. Road object detection is a critical and challenging area of research in computer vision, essential for Intelligent Transportation Systems (ITS), Advanced Driver-Assistance Systems (ADAS), and autonomous driving. The objective of many studies is to ascertain the position and boundaries of objects. For instance, automobiles, bicycles, and people. On the other hand, the inspection of roads and infrastructure is included. An example includes detecting potholes and evaluating road performance, which enhances safety and reduces accidents. Road object detection has numerous problems in real-life situations. For instance, poor brightness, cloudy conditions, and blocking by other objects. The previous method was limited by limitations in two-dimensional image processing techniques. Under situations where the roadway is missing of distinct markers or significantly obstructed. In recent years, deep learning has played a significant role in computer vision tasks. AI is a technology capable of learning, planning, problem-solving, and performing activities similar to those of humans. AI is widely utilized across various fields which enhancing labor efficiency. A dataset is essential for generating the model for each task. For instance, video, image, text, signal, etc. A convolutional neural network (CNN) is a component of deep learning that produces the suitable model for tasks. Typically encompassing categorization and object detection tasks. Examples of categorization in medical applications include generating models to diagnose diabetic retinopathy, identify cerebral microbleeds from MRI scans, and recognize abnormalities in lung X-ray images, among others. For object detection tasks, CNNs can automatically identify vehicles on the road, demonstrating superior speed and accuracy compared to manual methods. In the last ten years, the application of Deep Learning methods, especially CNN architectures, has significantly transformed the area of object detection. Two phase detection models for instance, Faster R-CNN provides superior accuracy, while single-stage models such as YOLO, SSD, and RetinaNet provide high processing rates for real-time applications, which are important for activities that depend on data from onboard cameras. However, though these high performance models, their real efficacy is based upon multiple factors. Including data set reliability, parameter selection, management of different situations, and performance on devices with limited processing resources. Other gap in road object detection research is the ability for domain adaptation to particular road issues, including urban, rural, or regionally distinct environmental features. Datasets frequently utilized, such as COCO, KITTI, or Waymo which are typically gathered from countries with particular environments, thus resulting in reduced efficiency when implemented in different situations. Moreover, specialized object detection tasks, such pothole recognition, road surface condition detection, and small object identification which remain underexplored because to missing of comprehensive, targeted datasets. Consequently, creating models capable of learning diversity from real data presents a significant difficulty in this domain. Current development trends in hardware systems focus both validation and real world testing to authenticate models that collect real data (real time inference) on limited hardware. For example, embedded systems or IoT devices in cars has the capability to process images from many data sources, such as RGB cameras, depth cameras, or LiDAR sensors. This strategy can substantially enhance detection accuracy. However, combining data from several sensors requires combining sensors using methodologies, which is increasing the system's complexity.

*Corresponding author.

In Thailand, road conditions significantly affect the performance of the system. Thailand features various road conditions, including heavily packed urban roads and narrow, uncertain community footpaths. This includes rural roads that often do not have suitable signs or lighting. The diversity and inconsistency of these road conditions present an enormous challenge for object detection programs. One common problem is the damaged road surfaces, including potholes, cracked asphalt, bridge joints, or subsidence resulting from flooding, which frequently occurs in multiple regions of the country. Particularly during the rainy season, these defects show different features and may be smaller in size, making object detection models trained on external datasets often ineffective in accurately identifying them. Consequently, detecting road surface degeneration is a critical research area within the Thai context, as it can mitigate accidents and facilitate preventive maintenance. The other issue is the unique features of road usage in Thailand, like motorcyclists mixing with cars and parking in unauthorized locations. Crossing the roadway at locations other than designated crosswalks, or in the path of temporary barriers such as barriers, traffic cones, or unregulated roadside vendors. These generate various and unexpected objects. Object detection under these conditions requires models capable of learning from real-world data supplied from Thailand for the highest level of accuracy. Moreover, the issue of traffic and warning sign systems on Thai roads is a barrier, as certain road signs might not be up to standards, may be hidden by trees, or may get old and faded. This complicates the detection of traffic signs using models trained on foreign datasets, particularly with temporary warning signs employed at construction sites. These often appear in many ways and lack standardization which important to driving safety so require detection. Moreover, the lighting conditions in various regions of Thailand, including rural roads missing of streetlights and urban roads light by vehicle headlights and visible advertising signs, result in issues of backlighting and reflection, which negatively affect the accuracy of object detection systems. Consequently, developing a model that can adapting different lighting conditions for application in Thailand. Traffic jams is a significant issue that results in time loss for individuals. An accident is an issue that results in the loss of lives and property. Accident causes include driver health issues, vehicle breakdowns, and road surface conditions. Examples of road surface abnormalities include potholes, road humps, irregular manhole covers, spaces between bridges and roads, bumpers, and cracks. An accident resulted in the loss of lives, time, and resources. However, the Department of Highways in Thailand often conducts manual road surveys and implements improvements. This method caused significant risks, expensive, and time-consuming. Deep learning can assist in resolving all issues. The government has opted for a survey of the road, which is efficient and cost-effective. Consumers can determine road surface quality and prevent accident risk. Entrepreneurs can minimize transportation costs through faster driving and a reduction in accidents. Current object detection CNNs, such as different versions of YOLO, may generate models for detecting road conditions [3],[4]. Nonetheless, the accuracy is not sufficient.

Therefore, research in road object detection is a significant domain with considerable potential for development. This research examines object detection methodologies employing deep learning techniques. Evaluation of the model's efficacy on actual road condition datasets, including an analysis of precision, speed and robustness to different environments. To develop a model that effectively matches the requirements of real road usage and can also provide a basis for future implementations in intelligent safety systems and autonomous cars. While YOLO-based detectors displayed strong efficacy in identifying general objects, they were not optimized for the detection of road surface and abnormalities. Cracks and potholes have long shapes, high horizontal continuity, and minimal class differentiation, frequently appearing segmented or partially ignored. Traditional convolution transform blocks are designed for small objects. This limitation necessitates structures that may more effectively identify horizontal data along road surfaces. This research is to customize the YOLO structure according to the data obtained in Phuket and Bangkok, Thailand. The novel CNN architecture is capable of accurately detecting three objects. The aim of this research is to create a model utilizing novel CNN for the detection of road objects, including cracks, potholes, and manhole covers. Subsequently, maintain it in the cloud. Subsequently, the pre-processing phase is executed. Ultimately, to develop the road surface condition detecting model utilizing CNN. The model is capable of identifying three items on the roadway from video footage. This research contributions include 1) a novel CNN architecture for detecting road conditions that provides empirical evidence that implementing horizontal contextual features is essential for delicate detection of road surface condition, 2) suggested an adaptive architectural change for YOLOv6, which improves robustness in under real-world road condition, and 3) Additionally, provide outcomes from experiments utilizing Thai road datasets, demonstrating the limitations of conventional object detectors in detecting surface condition.

The organization of this paper is as follows: Section II discusses the related work. Section III presents the research methodology, encompassing data collecting, frame extraction, and object labeling. Section IV explains the novel CNN architecture termed "RoadSCNet". The subsequent section, Section V, addresses the experiment results concerning three hyperparameters which are dropout, learning rate, and kernel. Section VI presents an experiment including three structures: the modified horizon block, vertical block, and pooling layer. Subsequently, analyze the structural experiment results. This part facilitates the implementation of a revolutionary CNN architecture. The conclusion is located in Section VII.

II. Related Works

This section described previous research. Beginning with image preprocessing, which is necessary for the preprocess of object detection. Cleaning datasets or managing data is the initial stage. Subsequently, the task involves separating or labelling data. The cleaned data is utilized in the model generation phase. The object detection Evolution is detailed in Section II(A). The next step is to generate the model. CNN is appropriate for this step, as numerous CNNs have been utilized in previous research, as detailed in Section II(B). The next

discussion relates to object detection on the road, as outlined in Section II(C). The last section for evaluating the theoretical framework of the approach is detailed in Section II(D).

A. Object Detection Evaluation

The preprocessing phase occurs before the generation of the object detection model, whether using traditional or deep learning methods. Examples of data collection equipment include cameras, smartphones, stereos, LiDAR, and others. This section discusses various techniques employed in the preprocessing phase, including lane detection and road surface analysis.

Before the development of deep learning, object recognition tasks mainly utilized classical image processing and computer vision methodologies, including edge detectors, corner detectors, and sliding windows. The Canny edge detector is employed to identify edges in images, providing the fundamental structure of objects. The Harris corner detector is another instance that identifies significant corners inside an image. Furthermore, a HOG (Histogram of Oriented Gradients) descriptor is employed, which defines the attributes of objects by aggregating the gradient directions in segmented regions of the image, for use in object classification and detection tasks. In classical learning, cascading classifiers, such as Viola-Jones, utilize Haar features and a cascade classifier for sliding window detection. These approaches display accuracy in controlled environments. For example, identifying faces in static photographs which although display several limitations—suboptimal performance on complex images, dependence on manually designed features, and limited generalization over a wide range of objects. Many research worked on image processing. image Quality Enhancement is the standard technique to help reducing noise and increasing an accuracy. The smoothing and filtering technique worked on Gaussian or Median filter [3]. Next technique is Brightness and Contrast Adjustment which working on Histogram Equalization (HE) and Recursively Separated and Weighted, Histogram Equalization (RSWHE) and Gamma Correction. (RSWHE) and Gamma Correction used to solve the Mean Shift problem [4]. Color transformation has to convert the image to grayscale to reduce complex calculations and decrease processing time. The HSV (Hue, Saturation, Value) or Lab transformation is employed in segmentation tasks that focus on color properties. This method employed in traffic sign recognition [5],[6]. Dark Channel Prior (DCP) or Temporal Correlations are employed to decrease fog and dehazing in the management of weather or illumination handling. Subsequently, Otsu's technique or Adaptive Thresholding is employed to automatically convert the image to binary before doing contrast adjustment [3]. The limiting of the Region of Interest (RoI) is useful in minimizing the quantity of complex data and computational complexity. In spatial division, the RoI will be separated from the background. One strategy applied to reduce computational complexity and improve accuracy in various contrast images is Adaptive Region of Interest (ARoI). Horizon line detection is a technique in ARoI utilized to divide the scene into road and sky regions. [3],[7]. Subsequently, edge detection and feature extraction are employed to identify the characteristics of geometry, road surfaces, or objects. This technique is necessary for traditional vision-based method. The Sobel and Canny operators are widely utilized approaches. Sobel is utilized more frequently than Canny and Prewitt due to both lower complexity and greater resistance to interference. Canny has incredible accuracy in identifying borders and positions [3], [8]. A method for edge detection is binarization, specifically Otsu's thresholding. This method aims to automatically identify parameters for separating background and foreground, hence reducing computation time and managing brightness [3]. One feature extraction technique is the Histogram of Oriented Gradients (HOG), which utilizes edge characteristics for feature extraction. This algorithm functions for detected traffic signs. [9],[10]. To improve binary image, Morphological processing is used to remove noise. An example are corrosion, expansion, open operation, and closed operation, etc. [9]. Image resizing is used to set up image dimensions for deep learning preparation. For instance, 32x32, 256x256, etc., this technique operates before training with CNN. The subsequent step involves identifying the RoI before cropping, concentrating only on the RoI area. The multi-channel input operates using transfer learning on the RGB model, example by ImageNet. The gray Computed Tomography (CT) picture is converted to three dimensions and utilized in the model [11],[12],[13].

Since the development of CNN, object detection has entered a new phase, utilizing CNNs as feature extractors. RCNN (Region-based CNN) is a critical advancement, employing a selective search technique for region proposals which is generating object region proposals and inputting each area into a CNN for classification and bounding box improvement. This was created by Ross Girshick and his crew. However, R-CNN is limited by slow progress due to the processing tens or hundreds of region proposals per image. Fast RCNN operates more efficiently by initially convolving the full image, subsequently extracting proposal points by RoI pooling to identify regions from the feature map, and also executing classification and regression, therefore minimizing the number of steps involved [14]. Subsequently, Faster RCNN incorporated a Region Proposal Network (RPN) into the CNN, facilitating expedited and more efficient region proposal creation by the utilization of convolutional characteristics shared between the RPN and the detection head [15]. The R-CNN Series approach, which consists of two steps: proposal and classification, achieves excellent accuracy. However, the limitations include significant delay and making real-time application challenging [16]. After the success of the R-CNN Series which remains limited in speed. Consequently, the notion of a "single shot detector" or "single-stage detector" which avoids the need to segregate suggestions and classify in a separate phase. An example is the Single Shot MultiBox Detector (SSD), which employs a singular network, segments the feature map at various scales, and simultaneously predicts bounding boxes and classifications for multiple default box configurations and aspect ratios, thereby allowing the SSD to identify objects with multiple sizes within a single image without requiring separate region proposals. SSDs have fast performance and excellent accuracy, make more appropriate for real-time applications compared to two-stage methods [17]. In 2015-2016, Redmon et al., introduced the You Only Look Once (YOLO) model as a novel approach which conceptualizes object detection as a regression problem rather

than generating proposals and classifying them separately. Both the bounding box prediction and class probability are executed within a singular network by processing all input images in one pass. YOLO divides the image into grids, with each grid predicting a bounding box and a class at once, resulting in high speed. The first model achieved approximately 45 frames per second. The benefits include low latency and comprehensive learning which including simultaneous training of bounding box and classification. A disadvantage is might have lower localization accuracy compared to proposal-based models, particularly for small objects [18]. YOLOv2 or YOLO9000 improves YOLOv1 with the addition of batch normalization, an increase in input resolution, and the utilization of anchor boxes to improve bounding accuracy. This includes joint classification and detection utilizing ImageNet and COCO datasets for training, allowing multi-category detection over more than 9,000 classes [19]. YOLOv3 enhances the backbone network, employs multi-scale prediction (three levels) to more effectively detect small, medium, and large objects, and utilizes a logistic classifier instead of softmax for class prediction. After that, YOLOv4, YOLOv5, and others were introduced for improving both accuracy and speed. Each model has an improved backbone architecture, optimized loss function, and advanced data training/augmentation techniques to better accommodate real-world applications. YOLO changed object detection by proving the feasibility of real-time detection using a single-stage neural network, independent of external region proposals. The YOLO model is widely utilized in applications necessitating real-time processing, including surveillance systems, driverless vehicles, and CCTV. Furthermore, the YOLO (single network, end-toend) concept has inspired the development of other models that enhance the speed and accuracy trade-off such as SSD, RetinaNet, and several YOLO variants. The deep learning evolution as shown in Fig. 1.

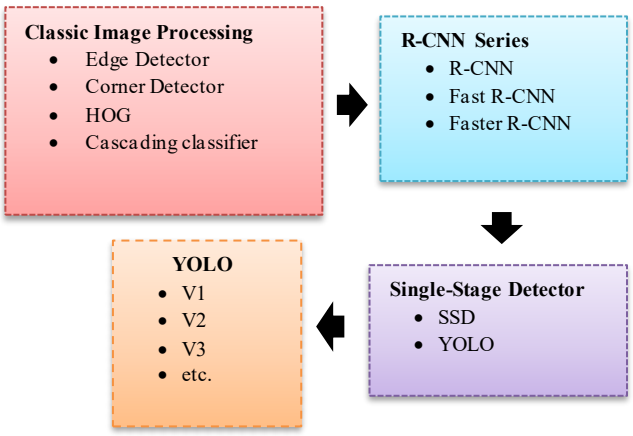

Fig. 1. Evaluation of Object Detection, begin classification image processing until YOLO object detection.

Object detection initiates with traditional image processing techniques, including edge detection, corner detection, Histogram of Oriented Gradients (HOG), and cascade classifiers. Continuing with the R-CNN series, which covers R-CNN, Fast R-CNN, and Faster R-CNN. Thus, YOLO is a single-stage detector, similar to SSD. Several versions of YOLO are currently operational.

B. CNN Object Detection

Object detection is an important component of computer vision that has gained popularity in recent years. This can analyze video, recognize images, and be applied in everyday life. For instance, autonomous driving, drone and robotics analysis, and safety surveillance, among others. The aim of object detection is to identify the localization of objects (object localization) and to classify object types (object classification). Object identification is a subset of deep learning that enhances the accuracy and speed of computer learning. Machine Learning is a method for creating models that operate autonomously. The handcrafted features and shallow trainable architectures were utilized. Initially, the selection of informative regions is conducted by scanning images with multiple sizes of sliding windows. Subsequently, feature extraction is conducted using SIFT, HOG, Haar-like features, among others. The classification is enhanced by methods such as SVM and AdaBoost. Deep Learning (DL) is a more advanced technique than machine learning. Neural networks can enhance model performance [20], [21]. Convolutional Neural Networks (CNNs) are utilized to create models with various architectures. The CNN architecture combines One-stage and Two-stage Detectors. The two-stage detector employs Regions with CNN features (RNN) as the principal model, demonstrating the efficiency of CNN in object detection. RNN employs a bottom-up approach for locating positions and objects within images. Subsequently, obtain the region suggestion by selective search and compute the features using a convolutional neural network (CNN). Subsequently, categorize the region type utilizing Support Vector Machine (SVM) methodology. This procedure is time-consuming and presents a bottleneck issue. This study achieves a mAP of 53.30% utilizing the PASCAL VOC 2012 dataset. The model generated by VGG16 achieved a mAP of 66.00% on the VOC Convolutional Networks (SPP-net) addresses the bottleneck issue of R-CNN by employing a Spatial Pyramid Pooling layer (SPP layer) in its final layer. Consequently, CNN can process input and output images of a fixed dimension. SPP-net (ZF) achieves a mAP of 60.9% on the VOC 2007 dataset [23]. Fast R-CNN enhances R-CNN and SPP-net by end-to-end training that integrates area selection, feature extraction, and classification. The VOC 2007 test set achieved a mAP of 70.00% [15]. Subsequently, Faster R-CNN is executed on Fast R-CNN utilizing the Region Proposal Network (RPN) instead selective search. This method generates region proposals from the features of a CNN RPN and predicts box regression (reg) and box classification (cls) using a sliding window approach. The results indicate a mAP of 83.80% [24]. Mask R-CNN is the instance segmentation framework that extends Faster R-CNN. Mask R-CNN achieves an Average Precision (AP) of 39.8% on the COCO test set [25]. The R-FCN, or Region-based Fully Convolutional Networks, achieves a mean Average Precision (mAP) of 85.00% on the VOC 2012 test set [26].

One-stage detectors, such as the Single Shot MultiBox Detector (SSD), perform classification and bounding box regression immediately. SSD300 has a mAP of 79.60%, whereas SSD512 demonstrates a mAP of 81.60% when evaluated on the VOC 2007 test set. SSD512 exhibits a mean mAP of 81.60%. Feature Pyramid Networks (FPN) are utilized for the extraction of features across diverse data sizes [17].

YOLO (You Only Look Once) is a famous real-time object detection model known for its speed and accuracy. YOLO V1 is the first end-to-end real-time object detection model [18]. YOLO V2 (YOLO9000) operates on the Darknet-19 backbone, employs batch normalization, utilizes anchor boxes for predictions, and includes a passthrough layer for feature extraction [27]. YOLO V3 employs the Darknet-53 backbone which is larger than the backbone utilized in YOLO V2. Bounding box prediction employs logistic regression and three sizes of multi-scale predictions. All operations involving the SPP block [28]. YOLO V4 was created for fast and accurate performance. The Bag of Freebies and the Bag of Specials are utilized to enhance performance and combine a receptive field. The backbone is CSPDarknet53. The SPP module, PANet path aggregation neck, and YOLO V3 head are processed [29]. YOLO V5 utilizes a modified CSPDarknet53 as backbone commencing with a Stem and SPPF (Spatial Pyramid Pooling Fast) layer. This facilitated rapid accuracy. The auto anchor verifies and enhances anchor boxes [30]. YOLO V6 is the suitable framework for industry applications. The EfficientRep backbone (RepBlock/RepConv) has been processed. The quantization employs GloU (Generalized IoU), Clou (Complete-IoU Loss), Slou loss, self-distillation, and channel-wise distillation [31]. YOLO V7 utilized the Extended Efficient Layer Aggregation Network (E-ELAN) and RepConvN, which lacks identity connections. YOLO V8 modified C3 to C2f and implemented 3x3 convolution [31] - [33]. In addition to YOLO, Pelee is a real-time object detection framework for mobile devices utilizing PeleeNet. PeeleeNet is produced using traditional convolution rather than depthwise separable convolution with SSD Pelee [34].

C. Road Object Detection

Numerous studies on road surface conditions utilize video and imagery. The model identified a road traffic sign utilizing Support Vector Machine (SVM) technology. This is classified and identified in the video. The Histogram of Oriented Gradients (HOG) is utilized to extract features previous to model generation [9]. Traffic light recognition employs image processing techniques based on color segmentation and the Hough transform for circles. Machine learning is utilized to generate the model. This model was designed to identify the traffic light in the autonomous vehicle [6]. Utilization of Helmets Detection on motorcycles is an important part of their widespread usage. YOLO V3 and multi-task learning are employed for helmet detection. Positional Encoding (PE) resolved the issue of class imbalance in this research, resulting in PE is better than the class-balanced loss [35],[36],[37]. Advanced Driver-Assistance Systems (ADAS) contain a collection of sensors, cameras, and other technologies within the vehicle that enhance driving safety and convenience. ADAS and safety alerts contribute to accident reduction studies. The Collision Avoidance System utilized the Google TensorFlow Object Detection (GTOD) API to build a driving safety alert and real-time vehicle detection, trained using the Microsoft Common Objects in Context (COCO) dataset [38]. Then the motorcycle curve warning presented the curve alert system including the intra-lane localization and roll angle estimation using CNN. The industry standard maps is used for improve an accuracy [39]. The pothole was detected using thermal imaging captured by a FLIR ONE camera. The principle that the temperature of the pothole is lower than that of the surrounding road because of water retention. This research performed effectively at night, during rain, and in fog, remaining unaffected by light, exhibiting a high response time, lower energy consumption, and reduced costs compared to laser-based techniques. The training with the ResNet101 model achieved an accuracy of 97.08% [40]. A pothole detecting system was developed for road surfaces to help blind people utilizing Convolutional Neural Networks (CNN) and the KITTI dataset. This system achieved an accuracy of 97.12% [11]. Numerous CNN models have been trained to detect potholes, including Inception v4, Inception ResNet v2, ResNet v2 152, and MobileNet v1. An accuracy above 96%. The grayscale image can be utilized in this research [14]. Crack detection is performed automatically using CNN on images captured by smartphones, employing YOLO and SSD methodologies [41],[42]. Research to present a 3D map as the outcome. The SSD can develop a model to detect potholes and humps by utilizing data collected from a Raspberry Pi, GPS module, and camera [43]. The video data is utilized to identify cars, trucks, and buses using Faster R-CNN in comparison to a mixture of Gaussian (MoG) background subtraction and SVM vehicle classification. The results indicated that Faster RCNN exhibited superior performance [44]. Furthermore, the accelerometer, gyroscope, and GPS in smartphones gather data that is utilized with machine learning to classify multiple categories, including smooth roads, potholes, and deep transverse cracks. The three feature axes of the sensor provide more accuracy, precision, and recall compared to a single axis [45]. In addition, the fog and darkness decreased the driver's visibility, presenting a problem that must be resolved for safety. Recursively Separated and Weighted Histogram Equalization (RSWHE) and Gamma Correction techniques were worked to increase the image and video performance. Detecting road surfaces at night can be achieved using the headlights of a vehicle [4], [46]. The summary table of techniques for road condition detection is presented in Table I.

TABLE I. SUMMARY OF THE ROAD CONDITION DETECTION TECHNIQUES

Method	Techniques
Data Collector	Smartphone, Video, Camera, Raspberry Pi, GPSmodule
Data Preparation	Frame extraction, Lane detection, Labelling, Image processing
Model Generation	YOLO, Faster R-CNN, ResNet, Inception, MobileNet, SSD, SVM, HOG

D. Evaluation

In object detection and classification, evaluation is crucial to evaluating performance during the development and maintenance phases. The object detection task needs to allow for both localization accuracy and classification accuracy. The confusion matrix, Intersection over Union (IoU), and mean Average Precision (mAP) are widely utilized metrics.

The Confusion Matrix is a fundamental instrument to evaluate the accuracy of a classification model by comparing the actual class with the predicted class. There are four values in a confusion matrix. A True Positive (TP) occurs when a prediction is positive and the actual outcome is also positive. A True Negative (TN) occurs when a prediction is negative and

the actual outcome is also negative. A False Positive (FP) occurs when a prediction indicates a positive result when the actual outcome is negative. A False Negative (FN) occurs when a prediction is negative while the actual outcome is positive. Subsequently, these four variables are utilized to compute additional values below.

Accuracy is the proportion of correct predictions, which may be calculated using Eq. (1).

$$\text{Accuracy} = \frac{TP+TN}{\text{TP+TN+FP+FN}} \quad (1)$$

Precision refers to the quality of a model concerning positive precision. The precision is illustrated in Eq. (2).

$$Precision = \frac{TP}{\text{TP+FP}} \quad (2)$$

Recall assesses the efficacy of a model in predicting positive results. The value of recall can be calculated using Eq. (3).

$$Recall = \frac{TP}{\text{TP+FN}} \quad (3)$$

The F1-score is the harmonic mean of precision and recall, serving as a singular metric to assess model performance. The F1-score equation is shown in Eq. (4).

$$F1\ score = \frac{2 * Precision * Recall}{Precision + Recall} \quad (4)$$

In the object detection job, the Intersection over Union (IoU) serves as the localization measure that compares the area between the predicted bounding box and the ground truth bounding box. The IoU equation is illustrated in Eq. (5).

$$IoU = \frac{Area\ of\ Overlap}{\text{Area of Union}} \quad (5)$$

Then Area of Overlap is two boxes overlap area. And Area of Union is total area of both boxes.

The IoU value ranges from 0 to 1. If the IoU is greater than or equal to 0.5, determine it as a true detection (True Positive). The higher IoU mean predicts the bounding box's closer to the object's actual position.

Normally in object detection task has multiple object type and different confidence score. The average precision (AP) is measure model performance for each class and calculate by Precision-Recall Curve. After that calculate average AP of all class that is mean Average Precision (mAP) as calculate by Eq. (6).

$$mAP = \frac{1}{\text{N}} \sum_{i=1}^{N} AP_i \quad (6)$$

N represents the total number of classes, while APi is the average precision for class i. The mAP summarizes the model's performance in object detection and classification over all objects.

III. Research Methodology

This section described the methods employed in this research. Subsection A. presents the framework, which includes an overview of the research. The subsequent step is the preprocessing phase which involves data collection and frame extraction. Frame extraction can divide the video dataset into multiple images, which is the initial important phase as illustrated in subsection B. The following procedure is object labelling, which enables the model to recognize the item as illustrated in C.

A. Framework

This section described the research framework. Data was gathered from May 2020 to September 2021 in Phuket and Bangkok, Thailand. The smartphone is a collection instrument mounted to the vehicle's windshield. All data belongs in cloud storage. The video data is segmented into numerous frames with the frame extraction technique. The work involves image labelling, which encompasses cropping and identifying each object within all images. Laberu is an appropriate tool for this stage. This is a novel labelling tool created by our team. This study examines cracks, potholes, and manhole covers. 24,276 frames are utilized for labelling. The XML file provides the result of the labelling phase. The object detection model is built using a novel CNN customized on the backbone of YOLO V6. The research framework is illustrated in Fig. 2.

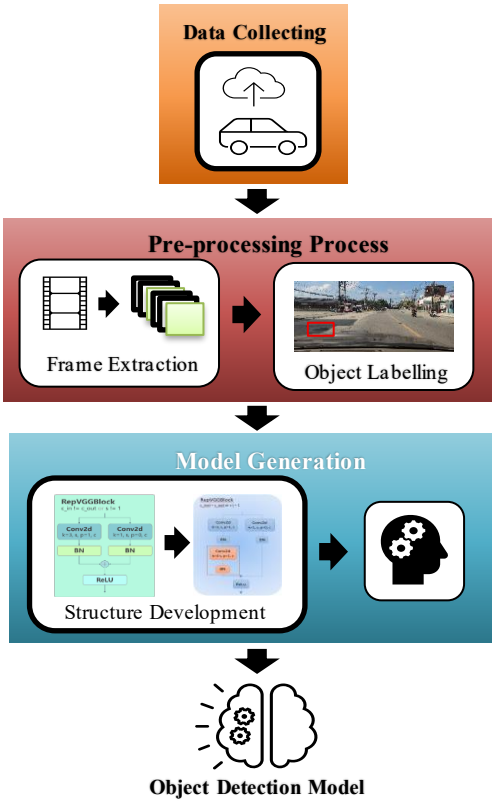

Fig. 2. Framework for the development of novel CNN architectures.

B. Data Collection and Frame Extraction

The initial phase of this research has involved the collection of video data. The equipment of this research is the smartphone. The smartphone was installed on the windshield of the vehicle operating on the roads of Phuket and Bangkok from May 2020 to September 2021. The total distance is 1,118.13 kilometers. 125 videos had collected a total duration of 134,176 seconds. Subsequently, the frame extraction goes into processing. This phase involves separating all of the video into multiple images. The quantity of data collected,

comprising 125 videos with a total duration of 134,176 seconds. Following the frame extraction process, a total of 1,341,760 frames were obtained. Selected 31,803 frames containing three objects. Ultimately, 24,276 frames were selected for the subsequent stage.

The data categories are identified as three objects inspected by the Department of Highways in Thailand. This investigation encompasses crack, pothole, and manhole cover. An example of manhole cover after extended from video as shown in Fig. 3.

C. Object Labelling

This subsection explained the process of object labelling. The step is to separate and select all three objects. This phase was successful when the video was captured and the frame was extracted. This process employs three tools. LabelMe and LabelImg are universal labelling tools. Labelru is the labeling tool developed by our research team. This research is designated by Labelru. This tool allows for multiple users immediately. Fig. 4 illustrates an example of each object post-labeling. The object's name and its position are indicated within the red rectangle.

Fig. 3. The image including Manhole cover extracted from the video.

IV. Road Surface Condition Detection Network

Convolutional Neural Network (CNN) is the popular technique to generate a model to detect an object. At the time, there are many CNN structure work for classification and object detection work. The concept of CNN is learning similar the human brain, CNN is in the bio-inspire group. The object detection works base on classification and object detection [22].

This section presents Road Surface Condition Detection, or RoadSCNet. This section explores the novel framework for the object detection job. YOLO is a renowned convolutional neural network design utilized for object detection tasks. Numerous iterations of YOLO exist, ranging from YOLO V1 to YOLO V8, together with YOLONas, developed from 2016 to the present. This research focuses on YOLO V6 and a novel CNN called "RoadSCNet" which is based on this version. RoadSCNet is a novel convolutional neural network derived from YOLO V6. Typically, YOLO V6 is suitable for fast and accurate real-time object recognition. There are multiple versions of YOLO V6: YOLO V6-n, YOLO V6-S, YOLO V6-M, YOLO V6-L, and YOLO V6-tiny. YOLO V6-tiny is compact and suitable for IoT or mobile applications. The structure of YOLO V6 is illustrated in Fig. 5.

The architecture of the YOLO V6 backbone has five RepVGGBlock layers, four BepC3StageBlock layers, and concludes with an SPPFBottleneck. The kernel sizes 4x4. The BN layer refers to the batch normalization layer which enhances the mean and standard deviation of the activation output from the layer above. The appropriateness and stability of the mean and standard deviation facilitate the training of a more stable and effective model.

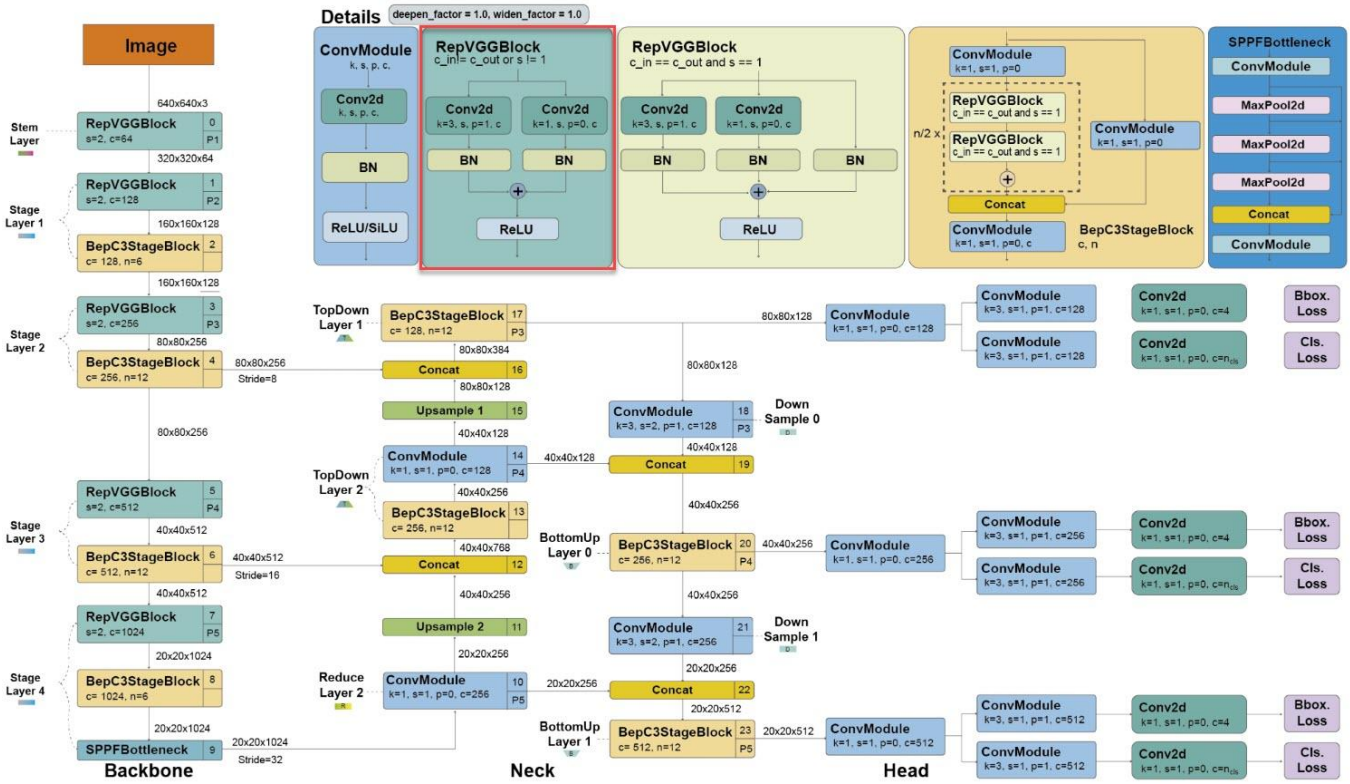

Fig. 5. The architecture of YOLO V6. The red rectangle on the RepVGGBlock indicates the position for block customization. Figure is based on study [47]

V. Hyperparameter Experiment

This part offered the experiment results and comments regarding hyperparameters. Video data was taken using a smartphone mounted on the windshield of the car. Data was obtained in Phuket and Bangkok, Thailand. The initial pre-processing stage involved frame extraction, which converted the video into several images. Subsequently, every three images were selected for the following step. The object labelling was subsequently processed. During the labelling phase, the novel labelling tool in this research, named "Labelru" received approval. This tool can be labelled by multiple users simultaneously. The produced model was enhanced. The experiment has dropout, learning rate, and kernel which are as mentioned in subsection A - C. The experiment setup utilizes a computer equipped with an i9-10900KF CPU, 32GB of RAM, and an RTX 3080 10GB GPU. Miniconda3 and Python 3.6 are software applications.

A. Dropout

Overfitting is a challenge encountered throughout the model training process. The method employed to reduce the overfitting issue is dropout. The dropout layer randomly deactivates certain neurons within that layer. This strategy enables the model to learn by distributing tasks among other neurons, hence enhancing its performance when predicting fresh datasets. The experiment with four dropouts is analyzed below using the mAP value. This research focused on dropout rates 0.2, 0.4, 0.6, and 0.8. The outcome with a dropout of 0.6 yielded a mAP value of 86.97. The subsequent dropout values are 0.2, 0.4, and 0.8 yielding mAP values of 86.41, 86.30, and 85.62, respectively. Subsequently, a dropout rate of 0.6 was employed in the subsequent experiment learning rate as delineated in subsection B.

B. Learning Rate

The learning rate is a hyperparameter that controls weights and biases of the model. In each iteration of the training process, the learning rate is multiplied by the gradient to adjust the weights and minimize loss. Particularly in Gradient Descent training. If the learning rate is excessively high, the model will set the weights and biases in an unstable manner during training. The low learning rate results in minimal weight and bias adjustments which are leading to protracted and time-intensive training. This section elucidates the learning rate experiment. The values are 0.1, 0.01, 0.001, and 0.00001. The outcome is presented in Table II.

According to Table II, the learning rate of 0.01 achieved the greatest mAP value of 86.97. The subsequent learning rates are 0.1, 0.001, 0.0001, and 0.00001, yielding mAP values of 85.78, 83.26, 82.33, and 62.54, respectively. The learning rate of 0.01 was utilized in the subsequent experiment.

TABLE II. Various Experiment Outcomes Learning Rate

Learning Rate	mAP	Time (hour)
0.1	85.78	13.95
0.01	86.97	13.34
0.001	83.26	13.10
0.0001	82.33	13.22
0.00001	62.54	13.20

C. Kernel

In CNN, a kernel or filter operates on the input image by performing convolution to process the data. This stage involves extracting features from the image. The convolution applies a stride kernel to a region of the image and computes the result based on the image pixels and weights in terms of the feature map. This subsection discusses the kernel experiment. The 3x3 and 4x4 kernels have been utilized. The 3x3 kernel demonstrates a superior mAP value compared to the 4x4 kernel. The mAP values are 86.97 and 86.29. Consequently, a 3x3 kernel is suitable for this research.

VI. Structure Experiment

After completing the hyperparameter experiments outlined in Section V. This section explains the experiment structure. Three experiments are being conducted on the RepVGGBlock based on YOLO V6. The system comprises a CPU i9-10900KF, 32GB of RAM, and an RTX 3080 10GB GPU. Miniconda3 and Python 3.6 are software applications. Subsection A. illustrates the various versions of YOLO when generating models utilizing the data. Subsections B. to D. analyzed three experiments.

A. Existing YOLO

Before developing the CNN structure, the model generated with the existing CNN is active. YOLO V5, YOLO V6, YOLO V7, and YOLO V8 are active. The image resolution of three objects is 1280x720 pixels, processed with a batch size of 8 within 100 epochs. The outcomes of the four existing YOLO models are presented in Table III.

TABLE III. Three Objects Detection Using Existing YOLO

Architecture	mAP
YOLO V5	74.50
YOLO V6	86.19
YOLO V7	61.30
YOLO V8	73.82

Table III presents the results for YOLO V5 to YOLO V8, displaying mAP values of 74.50, 86.19, 61.30, and 73.82, respectively. YOLO V6 has the greatest mAP value. YOLO V5 and YOLO V8 are similar. YOLO V7 displays a lower mAP compared to others. After that, the normalization process was compared with four different batch sizes: 4, 8, 16, and 32. The results gave mAP values of 82.70, 86.19, 86.98, and 87.38, respectively. Batch size 32 displays the highest mAP. The next batch size of 32 is employed in dropout regularization. There are four dropout rates in running: 0.25, 0.50, 0.75, and 1.00. The mAP values are 85.40, 85.73, 85.15, and 39.24, respectively. The no dropout showed better results [48]. While evaluating the results, the maximum mAP is 87.38, which is minimal for the collected data. The improvement of the mAP value in the backbone of YOLO V6 architecture is discussed in the next subsection.

B. Horizon Block

The initial experiment construction is incorporating Conv2d into the RepVGGBlock. In the YOLO V6 architecture, Conv2d operates before Batch Normalization (BN). The initial experiment involves executing Conv2d subsequent to the BN layer, as illustrated in Fig. 6. The outcome is presented in E.

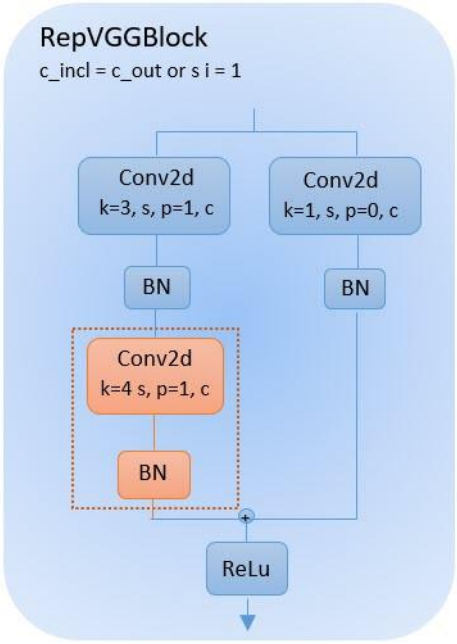

Fig. 6. The newly introduced horizon module within the RepVGGBlock.

C. Vertical Block

This subsection examines the new vertical block in RepVGGBlock following the initial experiment. Conv2d is already integrated with the Batch Normalization layer. The other parameter is k=4x4. This layer typically has two Conv2d and two BN layers; however, this experiment incorporated both Conv2d and BN layers. The revised structure is depicted in Fig. 7. The outcome as indicated in E.

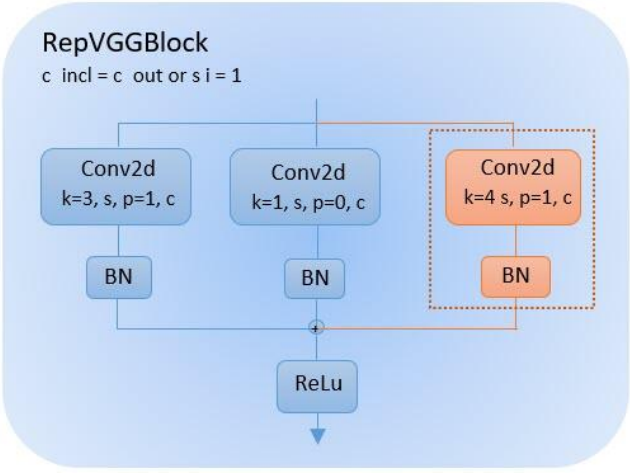

Fig. 7. The newly vertical module in RepVGGBlock.

D. Pooling Layer

The SPPFBottleneck operates in the final layer of the backbone. The YOLO V6 architecture operates on max pooling. The final experiment utilized average pooling. Compare the outcome as detailed in Table IV.

TABLE IV. THE MAP OF EXPERIMENT RESULTS FROM DIFFERENT POOLING METHODS

Experiment	Max Pooling	Average Pooling
Original	86.13	86.60
Width Multiple 0.6	88.07	88.25
Width Multiple 0.65	88.73	88.89
Width Multiple 0.7	89.96	89.09
Width Multiple 0.7 with Learning Rate		
Learning Rate 0.1	89.38	89.19
Learning Rate 0.01	89.96	89.09
Learning Rate 0.001	89.38	88.89
Learning Rate 0.0001	89.26	89.47

According to Table IV, a width multiple of 0.7 for max pooling yields the greatest mAP value of 89.96. The subsequent width multiples are 0.65 and 0.6, corresponding to mAP values of 88.73 and 88.07, respectively. The average pooling with a width multiplied by 0.7 achieves the maximum mAP value of 89.09. Multiply 0.65 and 0.6 by 88.89 and 88.25. The width is multiplied by 0.7 using max pooling for late experiment learning. When evaluating the Learning Rate using a width multiplier of 0.7 and max pooling, a learning rate of 0.01 yields the greatest mAP value of 89.96. The learning rates of 0.1 and 0.001 yield a mean Average Precision (mAP) value of 89.38, while a learning rate of 0.0001 results in a mAP value of 89.26. The learning rate of 0.0001 yields the highest mean Average Precision (mAP) value of 89.47 for average pooling. The subsequent learning rates are 0.1, 0.01, and 0.001, yielding mAP values of 89.19, 89.09, and 88.89, respectively. In this research, a maximum pooling width of 0.7 and a learning rate of 0.01 have been accepted as appropriate. Nevertheless, the comprehensive outcomes of all experiments are elucidated in subsection E.

E. Structure Experiment Result

This part examined all experiments in the Structure Experiment which including the results of the inserted horizon block, vertical block in RepVGGBlock, and the application of average pooling in SPPFBottleneck, as presented in sections VI.B. – VI.D. The experiment commenced with the original YOLO V6, utilizing a width multiplier of 0.5 and a learning rate of 0.01. The two hyperparameters modified in this study are presented in Table V. The experiment run consisted of 100 epochs using a machine equipped with an Intel i9-10900KF CPU, 32GB of RAM, and an RTX 3080 10GB GPU. Miniconda3 and Python 3.6 are software applications. Experiment 3 presents the results of maximum pooling.

According to Table V, Experiment 1 involves a modified horizon block within the RepVGGBlock. The outcome of a width multiplier of 0.7 yields the maximum mAP value of 89.91. The width multiples of 0.65 and 0.6 yield mAP values of 88.70 and 88.22, respectively. The width multiplied by 0.7 was effective for the learning rate experiment. The learning rate experiment with a width multiplier of 0.7 achieved the greatest mAP value of 90.01 at a learning rate of 0.001. The learning rates of 0.01, 0.0001, and 0.1 yield mAP values of 89.91, 89.51, and 89.27, respectively. The combination of a width multiplier of 0.7 and a learning rate of 0.001 yields the highest mAP value of 90.01.

TABLE V. THE MAP OUTCOMES OF MANY EXPERIMENTS

	Experiment 1	Experiment 2	Experiment 3
Original	86.97	86.12	86.60
Width Multiple 0.6	88.22	88.07	88.25
Width Multiple 0.65	88.70	88.73	88.89
Width Multiple 0.7	89.91	88.97	89.09
Width Multiple 0.7 with Learning Rate			
Learning Rate 0.1	89.27	89.38	89.19
Learning Rate 0.01	89.91	88.97	89.09
Learning Rate 0.001	90.01	89.69	88.89
Learning Rate 0.0001	89.51	89.26	89.47

Experiment 3 compared the average pooling layer in SPPFBottleneck with max pooling. The width multiple of 0.7 for max pooling and a learning rate of 0.0001 yielded the greatest mAP value of 89.47. Table V presents the results of Experiment 3 conducted with max pooling.

Upon evaluating the maximum mAP value from three experiments, Experiment 1, which utilized a width multiplier of 0.7 and a learning rate of 90.01, exhibited the highest mAP value. Experiment 2 achieved a mAP of 89.69 with a width multiplier of 0.7 and a learning rate of 0.001. Experiment 3 achieved a mAP of 89.47 when employing max pooling, a width multiplier of 0.7, and a learning rate of 0.0001. Ultimately, the modified horizon block in RepVGGBlock, after 200 epochs, achieved a mAP value of 96.03, which is conclusive for this research.

YOLO V6 employs RepVGGBlock for object detection, providing both high performance and speed. This study focuses on specific convolution. The result is positive for objects with specific boundaries. This is unsuitable given the road conditions characterized by cracks, potholes, and manhole covers. The three objects contain shapes, low sharpness, and irregular borders, primarily aligned along the horizontal axis of the road. Specifically, RepVGGBlock misses an element of context that clearly considers direction. This limits the ability to represent the horizontal continuity necessary for accurate identification of road conditions. Motivated by this limitation, RoadSCNet enhances the fundamental architecture of YOLOv6 by integrating a customized Horizon block with the RepVGGBlock to improve horizontal context learning efficacy while preserving computational efficiency. Then when run the new RoadSCNet model with 182 unseen data images which collected in Phuket, the result shown 91.60% accuracy. As displayed in Fig 8. The confusion matrix shows the model can identify 64 cracks, 3 potholes, and 122 manhole covers. All three objects include 72 cracks, 11 potholes, and 122 manhole covers. The accuracy is 91.60% and the precision is 94.50%. Then the model shows the performance to detect three objects. An example of three objects when detected using the model as shown in Fig. 9.

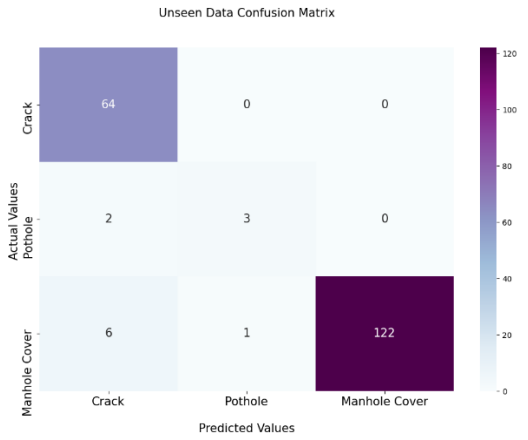

Fig. 8. The confusion matrix when test model with unseen data.

Fig. 9. Three examples when detected by RoadSCnet model.

The limitations of this investigation include window of the car which resulted in erroneous detection, the blurred images which made difficult the identification of the actual object, and the limitaion of equipment caused in reduced operational speed. Future work will focus on improving the mAP value and decreasing the loss value of the model.

VII. Conclusion

This research introduces RoadSCNet, an innovative CNN architecture that achieves a high mAP value for the dataset. The evaluation of three hyperparameters showed dropout 0.6, learning rate 0.01, and kernel 4x4 yielded the greatest mAP value. Subsequently, three distinct structures yield results for modeling under three road conditions, incorporating the new horizon block which demonstrates a superior mAP, followed by the integration of vertical adjustments and pooling modifications. The RoadSCNet enhances YOLO V6 by incorporating the new horizon block within the RepVGGBlock. RoadSCNet outperforms classic YOLO V6 due to a greater ability to gather horizontal contextual information, essential for identifying long cracks and rough road conditions, including cracks pothole and manhole covers.

***Abstract*—Automatic Fetal Health Prediction plays a vital role in supporting early prenatal intervention through continuous and non-invasive monitoring. Recent advances in biocompatible sensors enable the safe long-term acquisition of physiological signals, which can be effectively analyzed using machine learning techniques. This study proposes a comprehensive machine learning pipeline for Fetal Health Prediction through fetal health classification using the fetal_health.csv dataset from Kaggle, consisting of 2,126 samples and 22 cardiotocography-derived features related to fetal heart rate and uterine contractions. To address class imbalance and the presence of outliers, RobustScaler normalization was applied during the preprocessing stage. Feature selection was performed using Random Forest feature importance to identify the most relevant predictors. Two classification models, namely Random Forest (RF) and Support Vector Machine (SVM), were trained and evaluated using an 80:20 stratified train–test split. Experimental results indicate that the Random Forest model outperformed SVM, achieving an accuracy of 92.7% and a macro F1-score of 85.9%, compared with 88.97% accuracy and a macro F1-score of 79.85% for SVM. Moreover, Random Forest demonstrated superior performance in detecting minority classes (Suspect and Pathological), which are of high clinical significance. These findings suggest that the proposed pipeline is robust, interpretable, and suitable for integration with biocompatible sensor-based systems for real-time fetal health monitoring and clinical decision support.**

***Keywords*—Fetal health prediction; biocompatible sensors; machine learning; Random Forest; SVM**

I. Introduction

Biocompatible sensors allow continuous physiological monitoring without adverse tissue reactions, forming the basis of wearable health systems. Fetal health assessment by cardiotocography (CTG) is standard but manually interpreted and subjective [7], [16]. Integrating machine learning (ML) with biocompatible sensor data enables objective and reproducible classification of fetal conditions [22], [32]. This study focuses on a robust ML pipeline to analyze imbalanced sensor data and enhance fetal risk prediction.

Early and accurate assessment of fetal health is a cornerstone of modern obstetric care because timely detection of fetal distress enables prompt clinical intervention and can substantially reduce perinatal morbidity and mortality [1],[11]. Continuous monitoring of fetal physiological signals, particularly fetal heart rate (FHR) and uterine contraction patterns captured through cardiotocography (CTG), provides rich information about fetal well-being, but interpretation is challenging due to signal variability, noise, and subjectivity of manual assessment [2],[5]. Recent advances in sensing technology, especially the emergence of biocompatible and wearable sensors, allow safer and longer-term acquisition of fetal and maternal signals under minimally invasive or non-invasive conditions, expanding opportunities for ambulatory monitoring and remote prenatal care [3], [4], [6], [9], [34].

Machine learning (ML) has demonstrated strong potential in automating the detection and classification of fetal health conditions from physiological time-series data, offering improved consistency and the ability to learn subtle patterns beyond human observation [10], [13], [21]. Supervised classifiers such as Random Forests and Support Vector Machines, combined with appropriate feature engineering and selection, have produced promising results on benchmark CTG datasets and clinical repositories [14]. Nevertheless, several technical challenges remain: imbalanced class distributions (with normal cases overwhelmingly more common than suspect/pathological), the presence of outliers and measurement artifacts, inter-subject variability, and the need for computationally efficient models suitable for real-time or near-real-time edge deployment on sensor platforms [17], [19].

Feature selection and robust preprocessing are particularly important in fetal health prediction to reduce dimensionality, mitigate the influence of noisy features, and improve model generalizability across populations and sensor modalities [18], [20], [23]. Techniques such as tree-based importance measures, recursive feature elimination, and regularization-based methods have been applied to extract clinically meaningful predictors from CTG-derived features (e.g., accelerations, decelerations, short-term variability metrics) that correlate with fetal compromise [8], [24]. Robust scaling and outlier-resistant normalization algorithms also play a key role when working with signals recorded by wearable biocompatible sensors, which may present non-Gaussian noise profiles and baseline shifts [25], [27].

Integration of biocompatible sensors with ML pipelines raises system-level questions about data quality, signal calibration, and domain adaptation. Sensor design choices (materials, placement, sampling rate) and connectivity constraints affect both the fidelity of FHR/UC signals and the feasibility of continuous monitoring in home or low-resource settings [28], [30], [31]. Moreover, the translation of ML models

*Corresponding author.

from curated datasets to real-world sensor streams requires rigorous validation, cross-site testing, and safety assessments to avoid false reassurance or unnecessary interventions [2].

This study addresses these gaps by proposing an end-to-end pipeline that 1) leverages features derived from FHR and uterine-contraction signals acquired or simulated from biocompatible sensor inputs, 2) applies robust preprocessing to handle outliers and scale differences, 3) utilizes principled feature selection to identify a compact set of clinically interpretable predictors, and 4) evaluates classification performance with machine learning algorithms suitable for deployment in real-time monitoring scenarios. We further investigate strategies to mitigate class imbalance and to assess minority-class (suspect/pathological) detection performance, since such cases carry the highest clinical significance despite their lower prevalence [12], [20], [26], [29].

The novelty of this study does not lie in the individual components employed such as the fetal_health.csv dataset, Random Forest and SVM classifiers, RobustScaler normalization, or Random Forest–based feature selection as these techniques have been widely reported in prior CTG-based fetal health prediction studies. Instead, the novelty resides in their systematic integration and empirical evaluation within a unified, end-to-end pipeline explicitly designed to address practical challenges in fetal health assessment. Specifically, this study emphasizes the simultaneous handling of class imbalance, outlier-prone physiological features, and minority-class interpretability, which are often addressed independently in previous works. Through the combined application of robust preprocessing and feature selection, the proposed pipeline demonstrates consistent improvements in minority-class performance and model stability, while highlighting clinically relevant predictors associated with fetal heart rate variability. Furthermore, rather than claiming direct real-time deployment, this work positions the proposed pipeline as a validated methodological foundation for future integration with biocompatible wearable sensor systems, thereby bridging the gap between offline CTG-based analysis and real-time maternal fetal monitoring research.

The remainder of this paper is organized as follows. Section II presents a comprehensive review of related works on fetal health monitoring, biocompatible sensors [35], and machine learning based classification approaches. Section III describes the dataset, data preprocessing procedures, feature selection strategy, and overall methodology employed in this study. Section IV details the machine learning models, experimental setup, and performance evaluation metrics. Section V discusses the experimental results, comparative analysis, and interpretation of findings. Finally, Section VI concludes the paper by summarizing the main contributions, outlining limitations, and suggesting directions for future research.

II. Related Works

Previous studies on fetal health monitoring have extensively explored cardiotocography (CTG), non-invasive fetal ECG [33] (NIFECG), and wearable sensor technologies. Wahbah et al. [42] demonstrated that deep learning–based extraction of fetal ECG signals from abdominal recordings can significantly improve signal quality, which is a key strength for downstream analysis. However, their work primarily focuses on signal extraction and does not address end-to-end fetal health classification, particularly under class imbalance and real-time deployment constraints. The present study extends this direction by proposing a complete machine learning pipeline for fetal health prediction.

Machine learning approaches such as Random Forest and Support Vector Machine have shown strong potential in CTG-based fetal health classification due to their ability to model nonlinear physiological patterns [15], [19]. Despite their effectiveness, many studies rely mainly on accuracy as the evaluation metric and implicitly assume clean and balanced datasets, which may lead to biased performance toward majority classes. In contrast, this study explicitly addresses these limitations through robust preprocessing and macro F1-score–based evaluation to ensure balanced performance across clinically important minority classes.

Feature selection techniques, including tree-based importance measures and recursive elimination, have been widely used to enhance model interpretability and reduce dimensionality [23], [29]. While effective, prior studies often assume normalized feature distributions and minimal noise. Such assumptions are less realistic for physiological sensor data, which commonly contain outliers. Accordingly, this work incorporates RobustScaler prior to feature selection to improve model stability and generalization.

Wearable and biocompatible sensor studies highlight the feasibility of long-term, non-invasive fetal monitoring [44], [36] but frequently focus on hardware performance without integrating robust machine learning pipelines or addressing real-world data variability. This study bridges that gap by integrating biocompatible sensor-oriented data with an end-to-end machine learning framework designed for robustness and real-time readiness.

In summary, while existing research has contributed substantially to fetal monitoring technologies and classification methods, limitations remain in handling class imbalance, outlier-prone data, and deployment-oriented evaluation. This study addresses these challenges by proposing a compact, interpretable, and robust machine learning pipeline for fetal health prediction using biocompatible sensor data.

III. Methodology

The workflow for processing the Kaggle Fetal Health Dataset to build a fetal health condition classification model. The process begins with outlier handling to improve data quality, followed by normalization using RobustScaler to stabilize the feature distribution. After that, feature selection and feature ranking based on their level of importance are carried out using Random Forest. The data is then divided into training data and test data through the train test split stage, before being trained using two different algorithms, namely Random Forest and Support Vector Machine (SVM). The final stage is model performance evaluation using the accuracy, precision, recall, and macro F1-score metrics to assess the prediction quality of each model (Fig. 1).

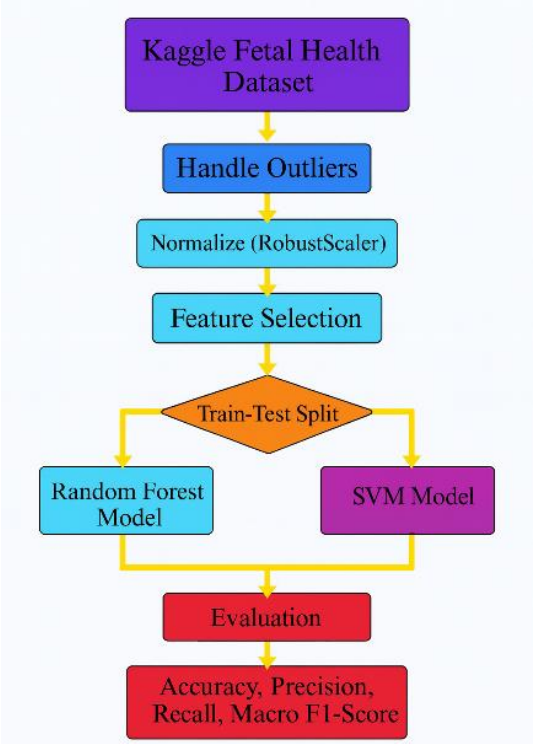

Fig. 1. Workflow of data preprocessing, feature selection, and model evaluation for fetal health prediction.

A. Data Source

This study uses the fetal_health.csv dataset from Kaggle (2020), which contains [15]:

2,126 samples

22 numerical features

No missing values

Class imbalance present:

- Normal: 77%
- Suspect: 13%
- Pathological: 10%

The dataset is derived from extracted CTG (Cardiotocography) signals and includes key features such as accelerations, short-term variability (STV), long-term variability (LTV), and histogram-based features.

B. Data Preprocessing Stages

1) Outlier handling

According to Zhang and Chen, medical signals often contain extreme outliers caused by physiological noise or instrument errors [37].

Approach: Using RobustScaler, which performs normalization based on:

- Median
- Interquartile Range (IQR = Q3 – Q1)

Formula:

$$x_{\text{scaled}} = \frac{x - \text{median}}{\text{IQR}} \quad (1)$$

Reasons for choosing this method:

- Robust against outliers (unlike StandardScaler, which is sensitive to them).
- Suitable for biomedical signals that tend to fluctuate.

2) Normalization using robustscaler: All features are normalized using RobustScaler to ensure that:

a) The feature scales become more uniform: Normalization using RobustScaler (Fig. 2) is applied to all features to achieve more uniform feature scales while reducing the influence of extreme values by relying on the median and interquartile range (IQR).

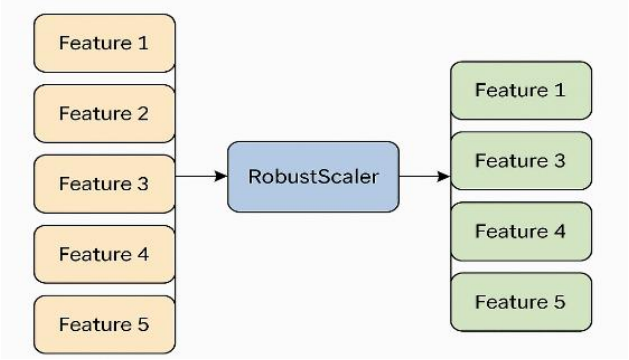

Fig. 2. The robustscaler normalizing process.

b) SVM and Random Forest models operate more stably: Normalization is performed using RobustScaler (Fig. 3) with the aim of stabilizing feature distributions and minimizing the influence of extreme values that commonly occur in medical signal data. RobustScaler operates based on the median and interquartile range (IQR), making it more resistant to outliers compared to other normalization methods, such as StandardScaler. This normalization is applied to all features in the dataset to ensure that their value ranges become more uniform and do not introduce bias during model training. With more consistent feature scaling, the Support Vector Machine (SVM) and Random Forest algorithms can operate more stably, resulting in a more optimal learning process and improved accuracy in predicting fetal health conditions.

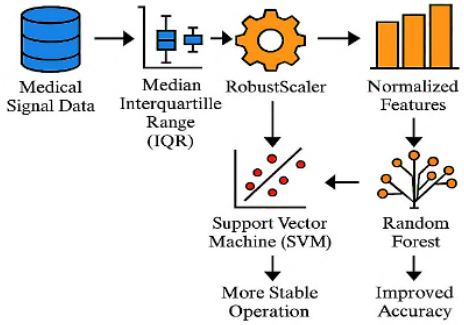

Fig. 3. RobustScaler normalization pipeline enhancing SVM and random forest stability.

c) Parameter bias caused by unequal value ranges is reduced: By utilizing the median and the interquartile range (IQR), this method effectively reduces parameter bias that may arise from differences in value ranges across features. As a result, learning algorithms can operate more reliably, maintain model stability, and improve performance during the training process (Fig. 4).

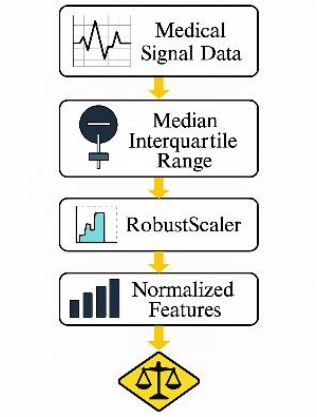

Fig. 4. RobustScaler-based normalization process flow.

C. Feature Selection

Random Forest Feature Importance

Based on the approach of Kour and Arora [38], feature selection using importance scores is applied to:

- Remove irrelevant features
- Reduce the risk of overfitting
- Improve model interpretability

The eight most important features obtained include:

- Accelerations
- Short-term variability (STV)
- Prolonged decelerations
- Histogram width
- Histogram mode
- Abnormal short-term variability
- Percentage of time with abnormal STV
- Mean value of the histogram

These features are directly related to beat-to-beat variability patterns and the physiological responses of the fetus.

D. Data Splitting

Stratified Train–Test Split (80:20)

The data is split using stratification (Fig. 5) to ensure that class proportions remain consistent.

- Train: 80% (1,700 samples)
- Test: 20% (426 samples)
- Purpose: To avoid bias caused by class imbalance and to ensure balanced class representation in both training and testing phases.

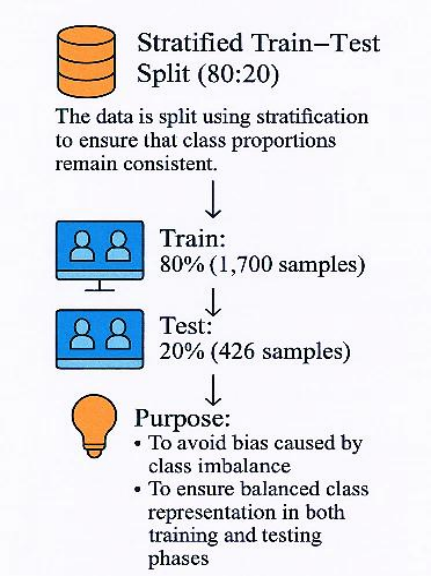

Fig. 5. Stratified train and test split (80:20) workflow.

E. Machine Learning Model Development

1) Model 1: Random forest classifier:

Optimization is performed using:

- Grid Search
- Parameters tested:
- *n_estimators* (100–500)
- *max_depth* (5–30)
- *min_samples_split* (2–10)
- *min_samples_leaf* (1–4)

Advantages of Random Forest:

- Robust to outliers
- Capable of handling non-linear features
- Provides feature importance ranking

2) Model 2: Support Vector Machine (SVM)

The baseline model uses:

- Radial Basis Function (RBF) kernel

Tuned parameters:

- **C** (regularization strength)
- γ (kernel coefficient)

This model is chosen based on the work of Hussain et al. (2022), which demonstrated that RBF-SVM is well-suited for nonlinear medical signal classification.

F. Model Performance Evaluation

Four metrics are used:

- Accuracy
- Precision
- Recall
- Macro F1-Score (chosen due to significant class imbalance)

Macro-F1 formula:

$$F1_{macro} = \frac{1}{K}\sum_{i-1}^{K} F1_i \quad (2)$$

Reasons:

- It does not favor the majority class
- It is crucial for detecting suspect and pathological conditions

IV. Results and Discussion

This section presents key findings showing that Random Forest outperforms SVM, supported by exploratory analysis and feature evaluation that confirm the reliability of the proposed fetal health prediction workflow.

A. Result

Presentation of data exploration results and initial visualization using pandas, matplotlib, seaborn, and numpy. This exploration process includes identifying data distribution, examining basic patterns in each feature, and evaluating the presence of outliers or inconsistent values. The resulting visualization provides an initial overview of the dataset, making it easier for researchers to recognize the general characteristics of the physiological variables observed. This exploration stage is also carried out to ensure that the data is in optimal condition before being entered into the machine learning modeling stage. Through a comprehensive understanding of the data structure, researchers can determine the appropriate preprocessing strategy, such as normalization, class imbalance handling, or selection of relevant features. Thus, good data quality is expected to support improved accuracy and reliability of the developed prediction model.

This study utilizes several Python libraries commonly used in data analysis and visualization. The command "import pandas as pd" is used to load the pandas library, which functions to manage data in tabular form such as DataFrames for cleaning, manipulation, and analysis purposes. The command "import matplotlib.pyplot as plt" loads the matplotlib module, specifically the pyplot component, which is used to create various types of visual graphs such as histograms, scatter plots, and line charts. The command "import seaborn as sns" loads the seaborn library, which facilitates the creation of more informative and aesthetically appealing statistical graphics. Furthermore, "import numpy as np" loads the NumPy library, which is used for numerical computations such as array processing, basic statistical calculations, and mathematical operations. The last line, "import warnings" followed by "warnings.filterwarnings('ignore')", is used to hide or ignore warning messages that may appear during code execution. This aims to make the output cleaner and free from unnecessary warnings. Overall, this code prepares a neat and comprehensive data analysis environment before conducting further exploration or modeling.

Data Analysis (EDA) on the fetal_health.csv dataset as a preliminary step before machine learning modeling. The first part loads the dataset using pd.read_csv() and saves it to a DataFrame named df. After the data is successfully loaded, the program calculates basic information about the dataset, such as the number of rows and columns (df.shape), displays the top few data points (df.head()), explores the data structure through df.info(), and generates complete descriptive statistics using df.describe(include='all').T, which is presented in transposed form for easy interpretation. Next, the program checks for missing values in each column using df.isnull().sum(), and calculates the class distribution in the target variable fetal_health through value_counts(normalize=True), so that the percentage of each category of fetal health can be determined. The program also performs initial outlier detection on each numeric feature using the Interquartile Range (IQR) method. For each numeric column, the Q1, Q3, and IQR values are calculated, then the number of values outside the normal range (Q1–1.5×IQR to Q3+1.5×IQR) is identified. The outlier detection results are stored in a dictionary named outlier_stats. At the end, the program saves a summary of the EDA results to the eda_summary.csv file using the csv module. This file contains key information such as the number of rows, number of columns, target distribution, number of missing values per column, and number of outliers for each feature.

Table I presents general information about the structure of the dataset used. This dataset consists of 2,126 rows and 22 feature columns, all of which are numeric data types (float64), making it very suitable for statistical analysis and machine learning modeling. There are no missing values in any of the columns, so no data imputation is required. In addition, the memory size of 365.5 KB indicates that the dataset is lightweight and efficient for processing in various computing environments. This basic information provides an initial overview that the dataset is in good condition and ready for further analysis.

TABLE I. Basic Information Dataset

Description	Value
Number of rows	2126
Number of columns	22
Main data type	float64
Missing values	0 in all columns
Memory usage	365.5 KB

Table II shows the class distribution of the target variable fetal_health, which consists of three categories, namely Normal, Suspect, and Pathological. The majority of samples are in the Normal class with a percentage of 77.85%, followed by the Suspect class at 13.88%, and the Pathological class at 8.28%. This unbalanced distribution indicates class imbalance, which can affect the performance of the classification model if not handled with an appropriate approach, such as resampling or

class weight adjustment. This information is very important to ensure that the machine learning model is able to make fair predictions on all categories of fetal health.

TABLE II. TARGET LABEL DISTRIBUTION (FETAL HEALTH)

Fetal Health Class	Percentage
1 (Normal)	77.85%
2 (Suspect)	13.88%
3 (Pathological)	8.28%

Table III shows that all columns in the dataset have no missing values. The absence of missing values is an advantage because the preprocessing process becomes simpler and the focus can be directed to more in-depth analysis, such as outlier detection, normalization, or feature selection. A dataset that is free of missing values also increases the reliability of the analysis results and minimizes the risk of bias due to data imputation.

TABLE III. MISSING VALUE PER COLUMN

Column	Missing
All columns	0

Table IV shows the number of outliers detected in each feature using the Interquartile Range (IQR) method. Some features have a significant number of outliers, such as fetal movement (307), percentage of time with abnormal long-term variability (309), and histogram number of zeroes (502). The presence of a large number of outliers in these features may reflect extreme physiological variations or potential noise in the sensor data. Conversely, several features, such as baseline value, histogram width, and histogram min, do not show any outliers, indicating a more stable distribution of values. Identifying the number and pattern of these outliers is an important step in determining the outlier handling strategy in the preprocessing stage before entering the model training stage.

Data visualization in algorithms is used to generate various types of exploratory visualizations that aim to comprehensively understand the characteristics of fetal health datasets prior to the machine learning modeling process. The resulting visualizations include label distributions, feature spreads, inter-variable correlations, and multidimensional relationships between key features and target labels. First, the distribution of fetal_health labels was visualized using a pie chart. The frequency of each class was calculated using value_counts(), then visualized using the plt.pie() function. This chart provides a proportional representation of the distribution of fetal health categories, making it easier to identify class imbalances that could potentially affect the performance of the classification model. This visualization was saved as the label_pie.png file. Next, a boxplot was created for all numerical features using sns.boxplot(). This visualization provides an overview of the data distribution range, median values, and visual detection of outliers in each feature. A horizontal orientation was chosen to improve readability, given the large number of features. These boxplots provide important insights into the stability and homogeneity of each variable, and the results are saved in the feature_boxplot.png file.

TABLE IV. NUMBER OF OUTLIERS PER FEATURE (IQR METHOD)

Feature	Number of Outliers
baseline_value	0
accelerations	14
fetal_movement	307
uterine_contractions	1
light_decelerations	150
severe_decelerations	7
prolongued_decelerations	178
abnormal_short_term_variability	0
mean_value_of_short_term_variability	70
percentage_of_time_with_abnormal_long_term_variability	309
mean_value_of_long_term_variability	71
histogram_width	0
histogram_min	0
histogram_max	24
histogram_number_of_peaks	19
histogram_number_of_zeroes	502
histogram_mode	73
histogram_mean	45
histogram_median	28
histogram_variance	184
histogram_tendency	0
fetal_health	471

The algorithm then generates a feature correlation heatmap using the correlation matrix obtained through df.corr(). This visualization is created using sns.heatmap(), complete with annotations to display the correlation coefficient values. This heatmap allows researchers to identify linear relationships between variables, detect redundant features, and determine candidate features that have the potential to contribute significantly to the prediction model. This image is saved as corr_heatmap.png. Finally, a scatter matrix was created using the sns.pairplot() function by selecting eight key features considered relevant to fetal health. The pairplot visualization maps the relationship between two variables simultaneously with coloring based on the fetal_health class, providing a deeper understanding of class separation patterns and interactions between features. The results of this visualization are saved as pairplot_main.png. Overall, this series of algorithms produces four main visual files (label_pie.png, fitur_boxplot.png, corr_heatmap.png, and pairplot_main.png) that provide exploratory support for exploring the structure and characteristics of the dataset. These visualizations play a crucial role in preprocessing decision-making, feature selection, and the formulation of more informative and effective machine learning modeling strategies.

Interactive visualization is displayed in the form of a pie chart that illustrates the distribution of fetal health categories using the Plotly library through the plotly.graph_objects module. Percentage data for three categories—Normal, Suspect, and Pathological is defined as input and visualized through the go.Pie object, where labels and percentages are displayed directly in each sector to improve information readability. The display settings are configured using the fig.update_layout() function with adjustments to the title, text size, and graph dimensions so that the visualization results are proportional, informative, and meet the aesthetic standards of scientific publications. The resulting visualization, as seen in the diagram, shows the dominance of the Normal class at 77.8%, followed by Suspect at 13.9% and Pathological at 8.28%. This visual presentation provides a clear representation of class distribution and helps researchers identify potential data imbalance before proceeding to the machine learning modeling stage. Fig. 6 shows workflow fetal health distribution chart.

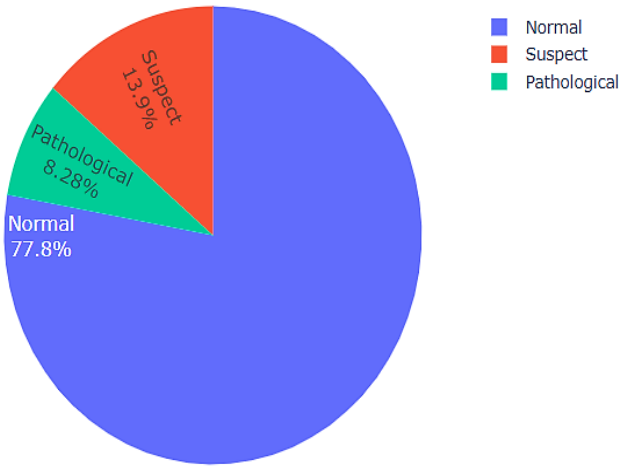

Fig. 6. Workflow of fetal health distribution chart.

The following image is a boxplot visualization (Fig. 7) that displays the statistical distribution of all numerical features in the fetal health dataset. Each boxplot illustrates the median value, lower quartile (Q1), upper quartile (Q3), and outliers. Through this visualization, it can be seen that some features, such as Baseline and certain histogram statistical parameters, show a relatively stable distribution, while other features, such as Fetal Movement, Light Decelerations, Prolonged Decelerations, and Histogram Variance, appear to have much higher variability accompanied by many outliers. This condition indicates significant data heterogeneity in the physiological signals of pregnant women and fetal activity. Overall, this boxplot analysis provides important insights for researchers to understand data distribution patterns, identify features with extreme value ranges, and determine the need for normalization, transformation, or outlier handling before the machine learning model training process is carried out.

The correlation heatmap provides a comprehensive representation of the linear relationships among all numerical features within the fetal health dataset derived from Cardiotocography (CTG) signals. This analysis aims to elucidate the dependency structure between variables and to identify features with meaningful predictive value for fetal health classification. The correlation coefficients are visualized through a color gradient in which red tones denote positive correlations, blue tones represent negative correlations, and the intensity of the color reflects the magnitude of the linear association. The results indicate that the group of histogram-based features, histogram_mean, histogram_median, histogram_mode, and histogram_variance, exhibits strong positive correlations ($r > 0.80$). This pattern suggests that these parameters capture highly related statistical characteristics of the underlying CTG signal distribution. The substantial inter-feature correlations also highlight potential redundancy, which is an important consideration for feature selection strategies aimed at minimizing multicollinearity in machine learning models. Several features demonstrate moderate correlations with the target variable fetal_health, with coefficients generally ranging between $r = 0.20$ and 0.30. Among these, histogram_variance, histogram_mean, and prolonged_decelerations appear most relevant for distinguishing fetal health states. Although the magnitude of these correlations is not high in absolute terms, such values are common in complex physiological data, where clinical phenomena are typically influenced by non-linear interactions and combinations of multiple parameters. Consequently, these features retain significant predictive potential, particularly when used in conjunction with machine learning algorithms capable of capturing non-linear patterns.

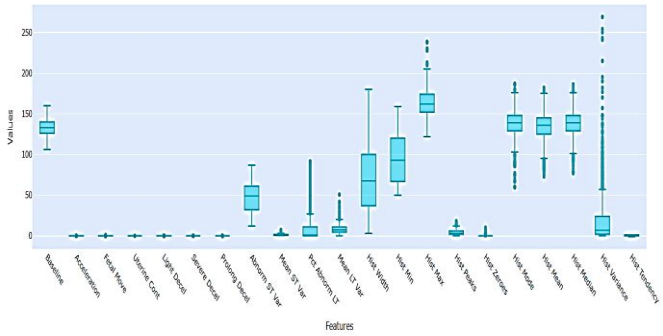

Fig. 7. Boxplot of fetal health data features.

Other features, such as accelerations, fetal_movement, and uterine_contractions, show low correlations with most histogram-based variables. This indicates that these features represent different physiological domains, specifically fetal behavioral responses and uterine activity, rather than statistical characteristics of the CTG signal. Their distinct informational contribution underscores the importance of retaining these features during the modeling process. Overall, the correlation patterns observed in the heatmap provide an empirical foundation for informed feature selection and predictive modeling. Identifying clusters of highly correlated variables enables the reduction of redundancy, while features exhibiting notable correlations with fetal_health serve as key candidates for developing more accurate, stable, and interpretable classification models. These findings also enhance the understanding of the interplay between physiological parameters and CTG signal characteristics, thereby strengthening the scientific contribution of this study in the domain of data-driven fetal health assessment (Fig. 8)

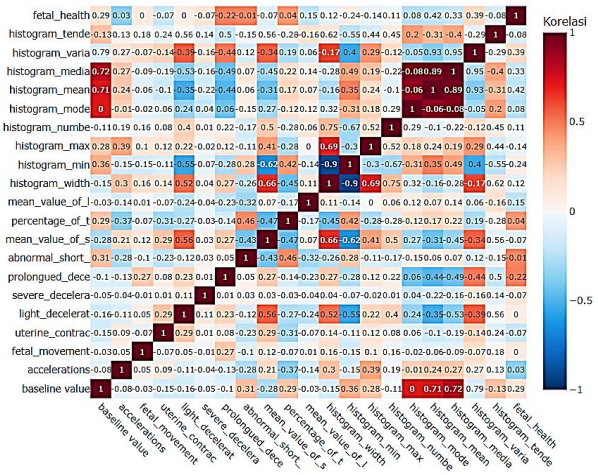

Fig. 8. Fetal health correlation heat map.

The Random Forest model achieved 92.7% accuracy and 85.9% macro F1-score, outperforming SVM's 88.97% accuracy and 79.85% macro F1-score. RF showed better sensitivity to minority classes and maintained low false-negative rates, which is crucial for clinical reliability. Feature importance analysis identified Mean Value of Short-Term Variability and Accelerations as the strongest indicators of fetal health.

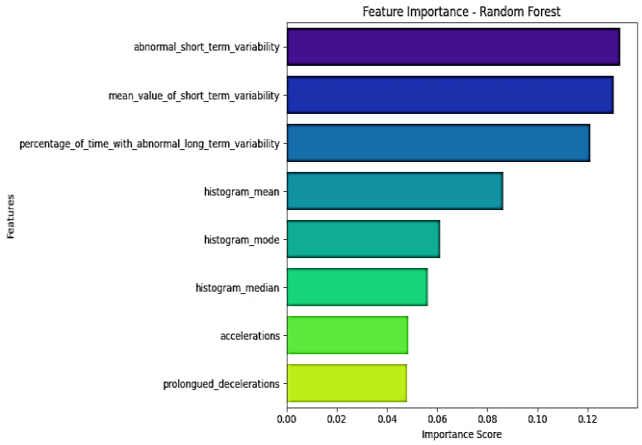

Fig. 9. Feature Importance.

Fig. 9 illustrates the contribution of each feature to the performance of the Random Forest model in predicting fetal health based on cardiotocography (CTG) data. The feature importance analysis indicates that abnormal short-term variability and the mean value of short-term variability are the most influential predictors, highlighting the critical role of fetal heart rate variability in fetal health assessment. In addition, the percentage of time with abnormal long-term variability contributes substantially, reflecting irregular fetal physiological responses to intrauterine conditions. Histogram-based features, including the histogram mean, mode, and median, support the model by characterizing the overall distribution of fetal heart rate patterns. Meanwhile, accelerations and prolonged decelerations, although less influential, remain relevant as they represent the reactivity of the fetal nervous system to internal and external stimuli.

Here is the explanation of Table V. Model Performance Comparison between Random Forest and Support Vector Machine (SVM) models:

TABLE V. MODEL PERFORMANCE COMPARISON

Class	Precision	Recall	F1-Score	Support	Model
1.0	0.9420	0.9789	0.9601	332	Random Forest
2.0	0.8863	0.6610	0.7573	59	Random Forest
3.0	0.8378	0.8857	0.8611	35	Random Forest
macro avg	0.8887	0.8418	0.8595	426	Random Forest
weighted avg	0.9258	0.9272	0.9239	426	Random Forest
1.0	0.9345	0.9457	0.9401	332	SVM
2.0	0.6500	0.6610	0.6555	59	SVM
3.0	0.8667	0.7429	0.8000	35	SVM
macro avg	0.8171	0.7832	0.7985	426	SVM
weighted avg	0.8895	0.8897	0.8892	426	SVM

Presents the comparative performance of two machine learning models, Random Forest and Support Vector Machine (SVM), in predicting fetal health conditions based on CTG (Cardiotocography) data. The evaluation metrics used include Precision, Recall, and F1-Score, which collectively assess the balance between classification accuracy and reliability across different fetal health classes (1.0 = Normal, 2.0 = Suspect, 3.0 = Pathological).

1) Class-wise performance

a) Class 1.0 (Normal Fetal Health*): The Random Forest model achieved* the highest performance with a Precision of 0.9420, Recall of 0.9789, and F1-Score of 0.9601, outperforming SVM (F1 = 0.9401). This shows that Random Forest effectively identifies normal fetal conditions with fewer misclassifications.

b) Class 2.0 (Suspect Fetal Health): Both models exhibited moderate results, but Random Forest (F1 = 0.7573) performed better than SVM (F1 = 0.6555). The lower recall values (0.6610 for both) indicate that the models struggled to correctly identify all suspect cases, possibly due to the limited number of samples (59 instances) and overlapping feature distributions.

c) Class 3.0 (Pathological Fetal Health): Random Forest again outperformed SVM, with F1 = 0.8611 compared to 0.8000. This suggests that Random Forest has a stronger ability to detect pathological (high-risk) cases, which is critical in medical diagnosis to minimize false negatives.

2) Overall model comparison

a) Macro average: Random Forest achieved F1 = 0.8595, higher than SVM's F1 = 0.7985, showing that overall, Random Forest maintains more consistent performance across all classes.

b) Weighted average: When weighted by class distribution, Random Forest reached F1 = 0.9239, outperforming SVM's F1 = 0.8892. This indicates that Random

Forest provides more robust and balanced predictions, even when class imbalance exists in the dataset.

3) Interpretation: The results demonstrate that Random Forest consistently outperforms SVM in almost all metrics and across all fetal health categories. Its ensemble nature allows it to capture complex nonlinear relationships and handle noisy medical data effectively. Although SVM remains competitive, especially for Class 1.0, its performance drops significantly for minority classes (2.0 and 3.0), suggesting limitations in generalization under imbalanced data conditions.

Overall, the Random Forest model provides the most reliable classification performance for fetal health prediction, achieving superior precision, recall, and F1-scores compared to SVM. This finding supports the selection of Random Forest as a robust baseline model for real-time fetal health monitoring and decision-support systems in obstetrics.

B. Discussion

The confusion matrix presented in Table VI provides a detailed evaluation of the Random Forest classifier's performance in predicting fetal health status across three categories: Normal, Suspect, and Pathological. The model demonstrates strong discriminative ability, particularly for the Normal class, with 325 instances correctly classified and only a small number of misclassifications (4 as Suspect and 3 as Pathological). This indicates that the feature set used captures the physiological patterns of normal fetal conditions effectively. For the Suspect class, the model correctly identifies 39 cases; however, 17 instances are misclassified as Normal, and 3 as Pathological. The moderate number of misclassifications in this class is consistent with findings in CTG-based studies, where Suspect cases tend to exhibit overlapping characteristics between healthy and pathological patterns, making the class inherently more challenging to classify. The Pathological class shows satisfactory performance with 31 correctly identified cases and only minimal misclassification (3 as Normal and 1 as Suspect). This indicates that the model is capable of recognizing clinically significant deviations in fetal heart rate variability and deceleration patterns that are characteristic of pathological cases. Overall, the Random Forest classifier demonstrates strong predictive reliability, particularly for identifying Normal and Pathological fetal states. The majority of errors occur in the Suspect class, which aligns with clinical realities wherein borderline physiological patterns create ambiguity. These results validate the effectiveness of the selected features and the model's robustness, suggesting its potential use as a supportive tool for automated fetal health assessment based on CTG signals.

The confusion matrix (Fig. 10) in Table VII presents the classification performance of the Support Vector Machine (SVM) model (Fig. 11) on the fetal health dataset. The SVM classifier exhibits strong performance in predicting the *Normal* class, successfully identifying 314 samples, although 15 cases were misclassified as *Suspect* and 3 as *Pathological*. These misclassifications are expected in CTG-based assessments, as mild irregularities in fetal heart rate signals [34] may overlap with characteristics found in *Suspect* recordings. For the Suspect class, the model correctly classified 39 instances, but 19 samples were incorrectly predicted as Normal and 1 as Pathological. This pattern highlights the inherent ambiguity of the Suspect class, which often contains borderline physiological patterns that lie between healthy and pathological states, making it one of the most difficult categories to classify accurately. The performance on the Pathological class shows that 26 cases were classified correctly, while 3 were misclassified as Normal and 6 as Suspect. Although the SVM successfully captures a substantial portion of pathological signals, the misclassification of several Pathological cases into the Suspect group indicates that the model may require further optimization, potentially through kernel selection or class-weight adjustment, to better handle samples that exhibit severe but variable abnormalities. Overall, while the SVM model performs reliably in identifying Normal and Suspect cases, its performance on Pathological cases is comparatively lower than that of the Random Forest model. This suggests that SVM may be more sensitive to overlapping feature distributions and may benefit from hyperparameter tuning to improve margin separation in the multiclass CTG classification problem. Nonetheless, the classifier still demonstrates competitive performance and contributes valuable comparative insights into the strengths and limitations of different machine learning approaches for fetal health prediction.

TABLE VI. CONFUSION MATRIX FOR RANDOM FOREST CLASSIFIER

True / Predicted	Normal	Suspect	Pathological
Normal	325	4	3
Suspect	17	39	3
Pathological	3	1	31

V. Conclusion

This study proposed a robust end-to-end machine learning pipeline for fetal health prediction using features derived from cardiotocography signals and inputs representative of biocompatible sensor data. By integrating RobustScaler-based preprocessing, Random Forest feature selection, and comparative evaluation of Random Forest (RF) and Support Vector Machine (SVM) models, the proposed approach effectively addresses key challenges in fetal health datasets, including class imbalance and outlier-prone physiological signals. From a scientific standpoint, the results demonstrate that robust preprocessing combined with feature optimization significantly improves model stability and minority-class detection. The Random Forest model consistently outperformed SVM, achieving higher accuracy and macro F1-score while maintaining better sensitivity to clinically critical Suspect and Pathological cases. These findings highlight the suitability of ensemble-based learning for reliable fetal health classification under imbalanced conditions. In terms of applicability, the proposed pipeline is computationally efficient and designed with deployment in mind, making it suitable for integration into real-time prenatal monitoring systems based on wearable and biocompatible sensors. This supports early risk screening and has the potential to assist clinical decision-making in both hospital and remote-care settings. Nevertheless, this study is limited by the use of a public CTG dataset rather than real-time data acquired directly from wearable sensors, and by the exclusive evaluation of classical machine learning models. Future work will focus on validation using live sensor data, exploration of deep learning models to capture temporal dynamics, and further clinical validation to ensure safe and effective real-world deployment.

Acknowledgment

This doctoral dissertation research was supported by a scholarship from the National Research and Innovation Agency (BRIN). The author expresses sincere gratitude to the promoter and co-promoters for their guidance, constructive feedback, and valuable insights that greatly contributed to the completion of this publication.

***Abstract*—As the world move beyond the 5G era, the emergence of 6G promises a significant integration with innovative communication paradigms and burgeoning technology trends, actualizing previously utopian concepts alongside increased technical complexities. Analytical models offer basic frameworks, but ML and AI now outperform them in solving complex problems, either by augmenting or supplanting model-based methodologies. The predominant focus of data-driven wireless research is on discriminative AI (DAI), which necessitates extensive real-world datasets. In contrast to DAI, Generative AI (GenAI) refers to generative models (GMs) that can identify the fundamental data circulation, patterns, and characteristics of the incoming data. Given these attractive characteristics, GenAI can either substitute or augment DAI methodologies in multiple contexts. This comprehensive tutorial-survey article begins with an overview of 6G and wireless intellectual ability by delineating potential 6G applications and services. The aspects presented in this paper support the internet of things integration with 6G networks with the support of the AI as intelligent systems. This review paper concentrates on fundamental wireless research domains, encompassing network optimization, organization, and management. It examines the foundational learning principles of DAI and its methodologies, the application of DAI in wireless networks, and the utilization of GMs in 6G networks. Due to its comprehensive nature, this paper will act as a crucial reference for researchers and professionals exploring this dynamic and promising field.**

***Keywords*—GenAI; 6G; generative models; intelligent systems; wireless communication**

I. Introduction

The evolution of wireless networks has been characterized by significant innovations, with each generation introducing dramatic changes that redefine our interaction with digital environments. As we move beyond the 5G era, defined by remarkable data speeds and strong connectivity [1], a new vista emerges with the introduction of 6G. Although 5G was lauded for its massive machine-type communications (mMTC), ultra-reliable low-latency communications (URLLC), and enhanced mobile broadband (eMBB), 6G transcends being a mere enhancement of its predecessor; it signifies a fundamental transformation aimed at redefining the principles of wireless connectivity. The anticipated 6G aspires not only to enhance key performance indicators (KPIs) but also to integrate with innovative communication paradigms and future technical pathways, actualizing previously utopian concepts [2].

6G represents a major step toward a more connected and intelligent future, not just an incremental upgrade. We highlight innovative technologies that pave the way for an era when communication transcends mere connectivity, enabling deeper, more meaningful, and intelligent interactions in an increasingly digital landscape. Exploring the potential technological advancements of 6G, semantic communications stand out as a fundamental element, striving to surpass traditional data transfer models by facilitating networks that understand and interpret content semantics, thereby ensuring communication that is not only ultra-fast but also contextually astute [3]. In the past decade, articles have highlighted the possibility of data-driven methodologies to supplement or replace model-based approaches. Analytical models provide foundational insights, while AI models use real-life datasets for exact adaptation to complicated situations.

Most modern wireless data research relies on DAI models, which prioritize identifying distinctions between data types. Three fundamental learning paradigms are commonly used in DAI models, as shown in Fig. 1. These principles will be discussed in Section II.

While these learning paradigms are versatile, obtaining large real-world training datasets can be costly in terms of money, effort, and computer resources. In addition to performing ML tasks (e.g., classification, regression, clustering, pattern search, dimensionality reduction). DAI models may struggle to interpret data and miss subtle patterns/states, presenting challenges in complex real-world scenarios. Unlike DAI, GenAI refers to GMs that can identify the distribution, patterns, and properties of incoming data [4].

*Corresponding author.

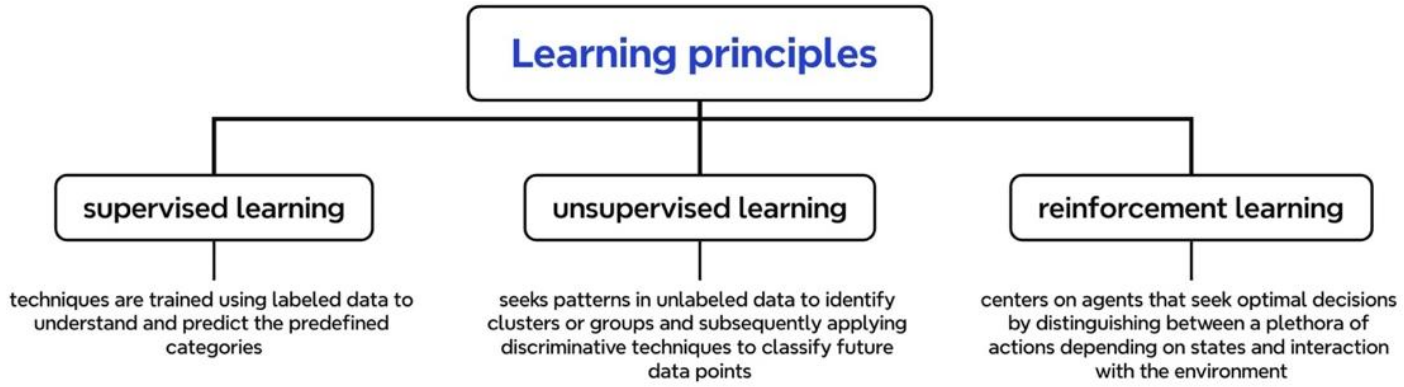

Fig. 1. Fundamental learning principles used in DAI.

After modelling the data distribution, GMs can produce new instances that are similar to the training data and examples. This is crucial in wireless domains where real-world data is limited, fragmentary, costly, and difficult to understand or grasp. It is essential for data augmentation, imputation, disentanglement, anomaly detection, and more. Despite the idea that GenAI is a new trend, our study of 120 technical articles highlights the extensive research across key wireless research pathways. GenAI gained attention after the release of big language model-based chatbots by tech heavyweights such as OpenAI's ChatGPT in Nov. 2022, Google's BARD in Mar. 2023, and Microsoft's Bing Chat in Feb. 2023. These developments sparked attention in both the industrial and intellectual sectors. With renewed attention, GenAI-driven wireless communication and networking research is poised for growth. Our study is comprehensive and rich in material, making it a valuable reference for scholars and professionals in this important and growing field.

GMs are gaining popularity in wireless telecommunication and networking. The research in [5] explores the benefits and drawbacks of using GMs for wireless channel modelling. Traditional channel modelling requires special skill and is technically demanding. To solve this problem, they developed a Generative Adversarial Network (GAN) technique to model wireless channels autonomously from raw data. GenAI for wireless networks is covered in [6], with an emphasis on three sample GMs: GANs, variational autoencoders (VAEs), and diffusion-based generative models (DGMs). A GenAI-based paradigm for wireless network management is developed, challenging established approaches, and promoting GM solutions. This case study optimizes contracts in mobile AI-Generated Content (AIGC) services using DGMs. A recent assessment highlights the growth of mobile AIGC networks, emphasizing real-time, tailored services that prioritize user privacy.

In response to DAI model issues in industrial IoT, [7] recommends GM adoption and examines current GMs for IIoT-related tasks such as anomaly detection, trust-boundary protection, network traffic prediction, and platform monitoring. According to [8], GANs have great potential for privacy and security due to their ability to produce realistic data. The authors analyze the merits, weaknesses, and future trajectories of GANs, addressing the lack of thorough surveys in this area. According to [9], GANs can be used for tasks such as spectrum sharing, anomaly detection, and security threat mitigation. The study highlights the benefits of GANs, including synthesising field data and recovering corrupted spectrum bits. GANs are rapidly being used in cybersecurity, particularly for jobs involving imbalanced datasets. The IoT applications hold potential for commercialization through the deployment of 6G communication networks.

The lack of studies on reviewing the wireless communications, especially the 6G networks, in the Generative AI era is the main motivation for this study. For autonomy and context, we begin with 6G network and wireless intelligence foundations in Section I. Section II provides a brief introduction of 6G communications and networking trends, including their numerous uses and offerings. Considering that we established the context with the requisite background knowledge, GenAI for wireless networks' optimization, organization, and administration is presented in Section III. Section IV outlines the strategic significance of GMs for emerging domains of 6G network research. Finally, the conclusion is shown in Section V.

II. The Role of Discriminative AI in 6G Networks

This section highlights developing trends in 6G communications and networking technology, followed by problems faced in achieving 6G implementation. Key concepts of DAI approaches are also covered. Here, we simply discuss how DAI approaches have been used to address key wireless network issues. This article explains use cases of DAI in wireless networks. The parts that are included in this section are illustrated in Fig. 2.

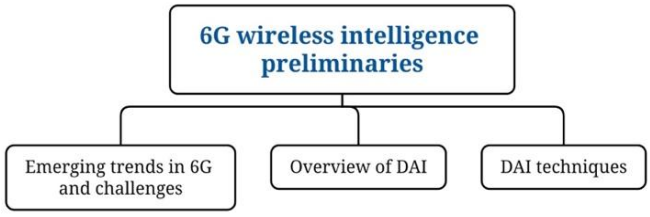

Fig. 2. 6G wireless intelligence preliminaries.

The emergence of 6G networks will revolutionize technology, introducing new applications and offerings beyond 5G capabilities.

TABLE I. COMPARISON OF SL, USL, AND RL

	Supervised Learning	Unsupervised Learning	Reinforcement Learning
Pros	1. Effective for well-defined tasks with labelled data 2. Good performance in classification and regression tasks	1. Does not require labelled data - Can discover hidden patterns and structures in data 2. Useful for data pre-processing, dimensionality reduction, and clustering	1. Suitable for sequential decision-making problems 2. Can learn from delayed feedback. 3. Capable of dealing with dynamic environments
Cons	1. Requires labelled data - Prone to overfitting if not properly regularized 2. May not generalize well to new tasks or domains	1. No explicit target labels, making evaluation challenging 2. May require more complex models and training techniques	1. Can be computationally expensive 2. Requires exploration 3. exploitation trade-off - Sensitive to reward function design
Preferred	1. When labelled data is available 2. For tasks with clear input output relationships 3. When the goal is prediction or classification	1. When labelled data is scarce or unavailable. 2. For tasks focused on discovering hidden patterns or relationships. 3. When the goal is data analysis or pre-processing	1. When the problem involves sequential decision-making. 2. In dynamic environments with delayed feedback. 3. When the goal is to learn an optimal policy or strategy

These innovations aim to establish an increasingly connected and productive world by integrating growing technologies. Terahertz (THz) communications, a fundamental element of 6G, offer ultra-high-speed data transfer and sophisticated sensing uses with better bandwidth and spatial accuracy than existing technologies. Ultra-Large Antenna Arrays (ULAA) and Near-Field Communications (NFC) offer more spatial multiplexing and reduced interference, but architecture and operational issues remain [10].

6G networks require semantic interaction, which shifts from data transfer to valuable knowledge sharing. Consider context, receiver knowledge, and data intent to improve network efficiency and intelligence. Optical Wireless Communications (OWC) [11], [12], [13] provides a spectrum-rich replacement to RF communications, resistant to electromagnetic noise but affected by meteorological conditions and line-of-sight restrictions [14], [15], [16]. Parallel to this, 6G will apply AI to improve user experiences [17] in material recommendation, smart infrastructure [18], and wellness.

Large-scale IoT installations and digital twins will benefit from 6G, enabling real-time synchronization and better decision-making across industries. 6G will enhance the metaverse by enabling adaptive and reactive engagements via digital twins, edge AI (EAI), and holographic telecommunications [19]. Even with technological breakthroughs, 6G networks confront considerable obstacles. Spectrum management is vital as the radio spectrum grows scarce and new frequency bands like THz require research. Meeting varied QoS needs requires advanced resource management and traffic methods. Flexible network architectures and protocols are necessary for 6G networks due to the diversity of devices, technology, and services. Scalability is crucial for managing the expanding number of connected devices and services. Energy efficiency is crucial for IoT deployments using battery-powered devices. Finally, comprehensive security and privacy protection are crucial as networks become more complicated and large. Successfully implementing and operating 6G networks requires addressing these problems, where AI/ML can play a crucial role.

DAI techniques have improved significantly in complicated network settings by filling gaps in analytical methodologies. While their deployment relies on real-life data, it might be challenging in terms of time and expense. There are basic kinds of ML techniques: supervised learning, unsupervised learning, and reinforcement Learning, which includes generative models. Each ML class has unique techniques and strategies for various tasks. We analyze the pros and cons of different ML types in Table I and explain their suitable use based on situations and goals. The specific characteristics of each ML class offer advantageous solutions for various wireless network difficulties. Summarised as follows:

1) Supervised Learning (SL): A dataset of input-output pairings, marked output, is used for training models. To generalize and predict unknown data, the model must learn a mapping from inputs to outputs. The SL is commonly used for classification and regression applications, including Support Vector Machine (SVM), decision trees, naive Bayes, k-Nearest Neighbors (K-NN), and linear/ridge/lasso analysis.

2) Unsupervised Learning (USL): Models learn from unlabelled datasets. The aim is to discover hidden patterns, structures, or correlations in the data. Some unsupervised learning tasks are:

a) Clustering and pattern search: Use K-means and fuzzy C-means clustering.

b) Dimensionality reduction: Analyses include Principal Component Analysis (PCA), t-stochastic neighbour embedding, and linear discriminant evaluation.

3) Reinforcement Learning (RL): Using environmental interactions, agents learn to make decisions. While receiving rewards or penalties, the agent aims to learn a policy that maximizes cumulative return over time. RL functions differently from SL and USL by addressing sequential decision-making challenges and operating in delayed feedback environments.

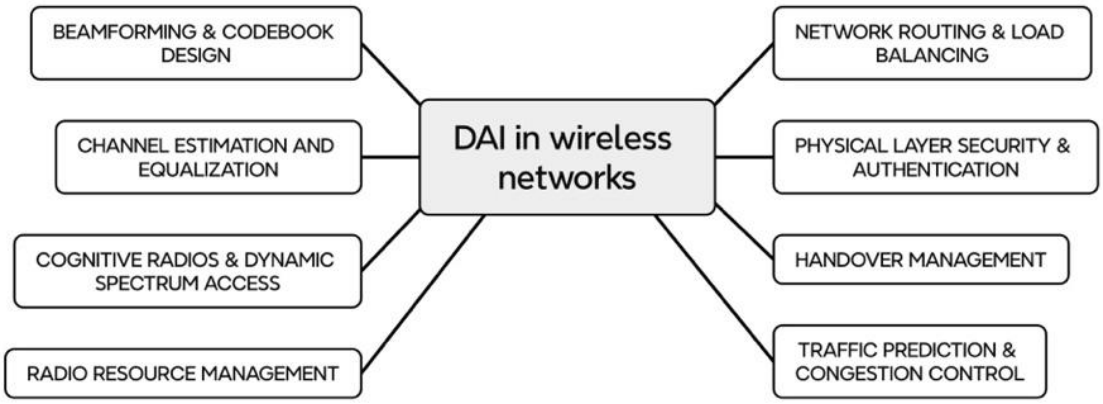

Fig. 3. The use of DAI in wireless networks.

RL algorithms include Q-learning, state-action-reward-state-action, Deep Q-Learning (DQN), Deep Deterministic Policy Gradient (DDPG), and Twin Delayed DDPG (TD3), arranged by development time.

Deep neural networks (DNNs) [20] provide superior performance in generalization, prediction, and classification compared to classic ML techniques due to their capacity to learn complicated and hierarchical data representations. A DNN architecture typically includes an input layer, hidden layers, and an output layer. The input layer accepts raw data, whereas the output layer produces the final prediction or representation. Hidden layers change data, acquiring complex features and high abstraction levels as it flows through the network. include Feedforward Neural Networks (FNNs), Multilayer Perceptrons (MLPs), Convolutional Neural Networks (CNNs), Recurrent Neural Networks (RNNs), and Autoencoders (AEs). GMs and transformers are classified as DNNs/DL and will be elaborated in later parts.

The intrinsic DL features eliminate manual feature engineering and enhance model performance across many tasks. DL models are made to scale with huge datasets and utilize modern hardware processing capability. DL models can learn end-to-end mappings from input data to desired output, simplifying the learning process and enabling smooth integration into multiple applications. Due to their fundamental properties, DL models are becoming a popular research tool for solving complex wireless communication and networking issues. Recently, wireless network performance has been improved using DAI models. Fig. 3 shows the usage of DAI in wireless networks that are explained in this section.

The two SL and USL algorithms, especially DL, are capable of learning to estimate channel state information (CSI) and executing equalization. Precise Channel State Information estimation is essential for numerous activities, including beamforming, resource allocation, and link adaption. Conventional pilot-based methods may prove inefficient for intricate and non-linear channels in dynamic environments, whereas deep neural networks can be trained on previous data to properly forecast channel state information.

DL algorithms can adjust beamforming parameters accordingly to CSI and other external parameters using archived and real-time data. To address CSI acquisition issues, pre-defined beamforming codebooks are used for initial access and data transfer [21]. Instead of relying on conventional codebooks, DL models could analyze huge quantities of data from an operational site to create adapted codebooks that accurately reflect the site's distinctive characteristics. Hybrid architectures manage hardware complexity with MIMO gain, allowing DL algorithms to optimize analog and digital beamforming weights, resulting in enhanced system performance and energy economy.

RL agents can optimize spectrum assignments in unpredictable contexts, determining optimal communication bands with little interference and maximum use. RL enables smart radios to adjust parameters like transmit power, modulation initiatives, and coding rates to enhance communication performance and coexist with other radio systems in a joint spectrum.

In wireless networks, ML may optimize resource allocation, power control, and network setup, enhancing radio asset administration and energy conservation [22]. DL models anticipate user behaviour and traffic sequences, while deep RL (DRL) methods aid in resource allocation decisions. In dynamic network systems, SL techniques can simulate power levels and performance measures, while RL methods can identify ideal power control rules. Fig. 4 shows a DRL hosted in a cloud where a DRL optimization procedure (DRL-OP) will be started on the cloud, requiring negotiation where the elements and the flow of the process are illustrated.

SL helps detect and prevent eavesdropping and jamming attacks by recognizing and classifying hostile network events [23]. SL may enable RF signal fingerprinting for user authentication or geolocation by identifying unique properties. USL detects network breaches and abnormalities by identifying unexpected traffic patterns at an early stage, preventing cyber risks, network outages, and performance deterioration. Integrating SL and USL techniques improves wireless communication security, confidentiality, integrity, and overall security.

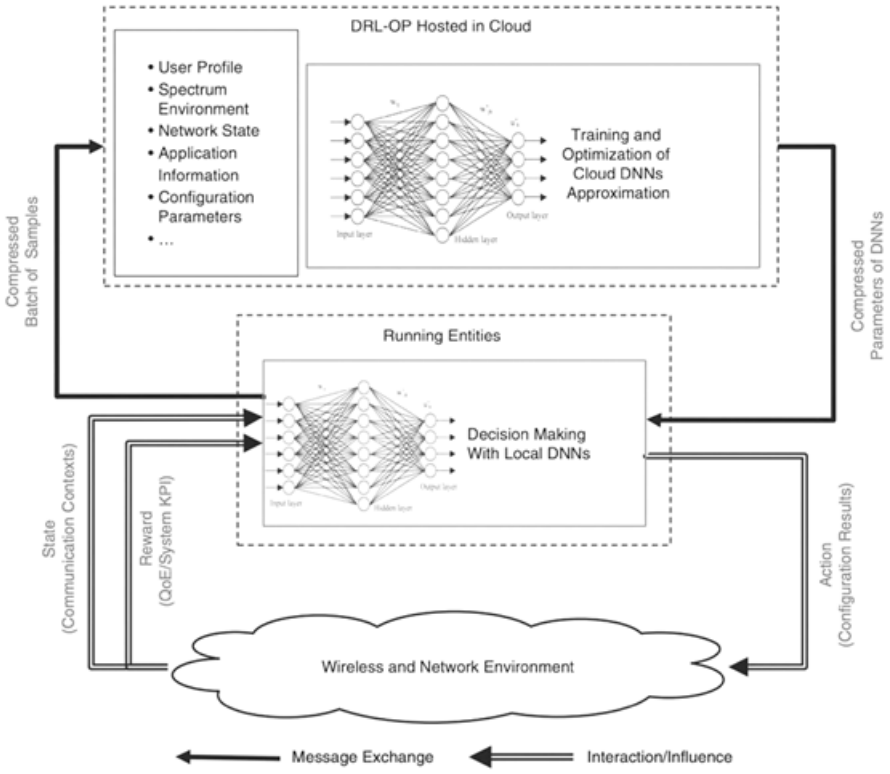

Fig. 4. The interactive DRL loops.

ML enhances handover handling by optimizing decision-making and ensuring smooth connectivity and QoS for mobile users across different cells or access points [24]. Handover control can benefit from ML techniques for projection, decision-making, and optimization. Digital neural networks can forecast handovers by examining historical data, user movement patterns, and network conditions, enabling proactive handovers, lowering delays and increasing user experience. In contrast, DRL agents can improve handover decisions by considering user movement, signal strength, network load, and QoS needs, determining the optimal target cell or access point for every user.

SL algorithms anticipate future traffic trends using marked training data, while USL algorithms detect underlying patterns and structures in network traffic data for prediction [25]. Network traffic forecasting can benefit from time series prediction methods developed for temporal data. By training on historical data with labeled congestion conditions, SL algorithms can forecast levels and take necessary actions to address the issue. USL methods, including clustering and dimensionality reduction, can uncover patterns, analyze congestion reasons, and develop mitigation strategies.

USL approaches like clustering and anomaly detection can organize network elements with similar properties and find novel traffic trends or activities. This information aids in establishing effective routing tactics, optimizing load circulation, and preserving network performance under dynamic situations. However, RL enables network agents to learn from their surroundings and adjust routing and load balancing techniques gradually. RL algorithms enable network agents to maximize load distribution, identify optimal pathways, and make better judgments in dynamic settings like shifting traffic loads and connection capacity. Fig. 5 depicts a centralized DL-based load balancing model [26] for heterogeneous networks. Data from the network is sent into the DL model, which processes information and applies it to the network.

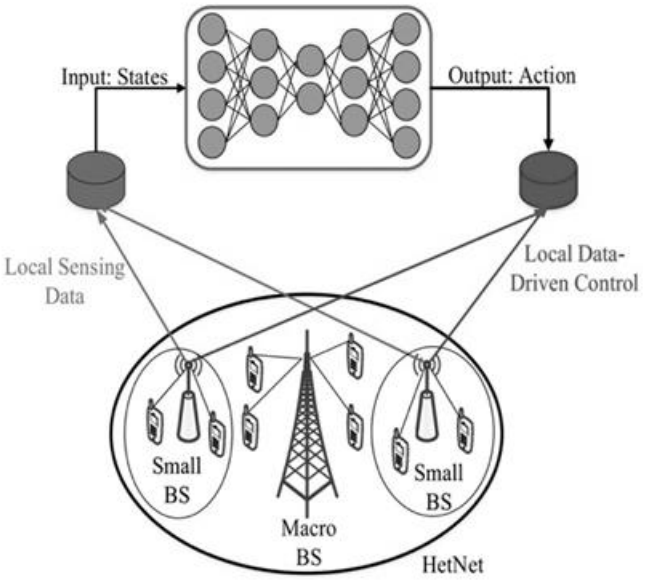

Fig. 5. A DL-based centralized load balancing mechanism in a heterogeneous network. After feeding cell data into the DL model, the HO variables are determined based on its result.

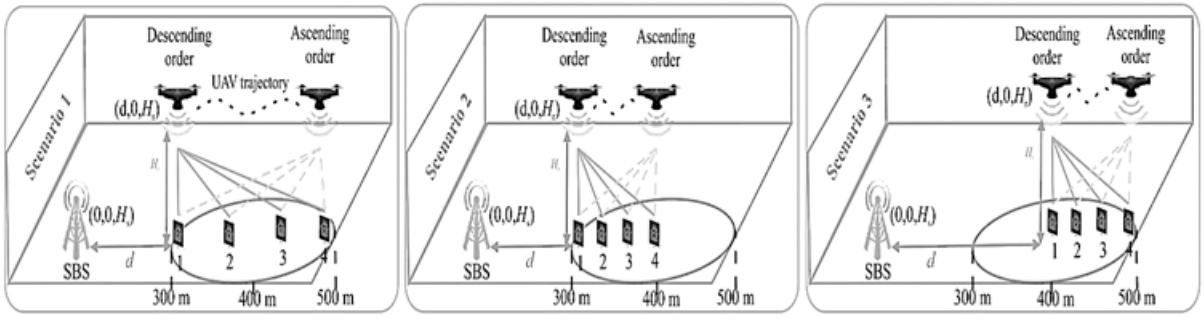

Fig. 6. Various hot-spot user distribution cases.

III. Generative AI for Wireless Networks

GMs demonstrate potential in tackling network optimization, organization, and resource management issues. GANs and other GMs can improve wireless network efficiency, mobile network slicing, and self-organization by producing artificial data and enhancing learning algorithms. This section shows how GMs effectively address resource allocation, network management, and performance optimization in various communication settings. GMs enhance RL/DRL agent learning by generating samples that demonstrate state-action value variation [27]. This reduces acquiring effects in nonstationary situations, minimizes action-value exaggeration and underestimation, and improves network improvement.

The work in [28] introduced a GAN-based Deep Distributional Q Network (GAN-DDQN) to tackle demand-aware resource allotment in 5G network segmentation. The GAN-DDQN model creates action tests, reflecting state-action values, and addresses nonstationary learning difficulties. The authors offer a reward-clipping approach to address training instability.

GMs can forecast user desires for resources, enabling efficient and adaptable network, computation, and storage control. Utilizing these estimates in dynamic service-oriented network slicing methods enhances resource provisioning and user experience (QoE). For allocation of resources forecasting in IoT usage, [29] introduced GANSlicing, a flexible service-oriented software-defined mobile network slicing scheme. This strategy prioritizes efficiency and flexibility in resource allocation to enhance user experience. GANs are used in GANSlicing to estimate user resource needs, enabling efficient and flexible control of network, compute, and storage equipment. Furthermore, in [30], Shahid et al. propose the production of realistic IoT network traffic utilizing a combination of AEs and GANs to enhance network-based intrusion detection systems (NIDS) and assess their effectiveness. The authors train an autoencoder to acquire the latent representation of actual sequences of packet sizes, thereafter training a WGAN in the latent space to provide latent vectors that can be decoded into realistic sequences. The artificial bidirectional flows produced by this technology closely mimic the actual traffic generated by a Google Home Mini, effectively deceiving anomaly detectors into perceiving them as valid traffic.

Recently, DL approaches have gained popularity for solving assignment issues. Additionally, VAE variations can be used to address linear sum allocation issues, a widely studied topic in wireless allocation of resources. A VAE variation can be used to tackle linear sum allocation issues, which are frequent in wireless resource allocation. This approach can replace the Hungarian algorithm and quickly and accurately solve huge cost matrices, as shown by simulation results in [31]. Fig. 6 shows the distribution of users in different scenarios where four NOMA users are positioned differently in each scenario. Users are scattered across the hot-spot region in Scenario 1, but before and after the center in Scenarios 2 and 3.

To overcome data shortage and imbalance in SONs, GMs can generate realistic artificial data for training powerful ML algorithms as shown [32], the authors propose a new cell outage detection approach for SONs using GAN and Adaboost to solve imbalanced data. GAN pre-processes imbalanced data, creating synthetic data for the minority class, while Adaboost classifies the balanced dataset. This method accurately detects cell outages in cellular networks, surpassing existing classification algorithms' limits in imbalanced data. The approach improves classification performance significantly, as measured by metrics like ROC, precision, recall rate, and F-value. Fig. 7 illustrates how the generator generates bogus samples from randomized noise samples. The discriminator determines if synthetic samples are authentic or not. If the discriminator finds synthetic samples more similar to real data, they are included in the minority group to create a fair dataset X'.

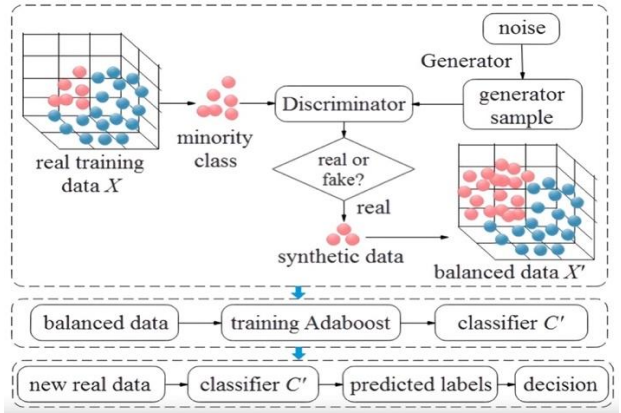

Fig. 7. Cell outage detection workflow using GAN and Adaboost [32].

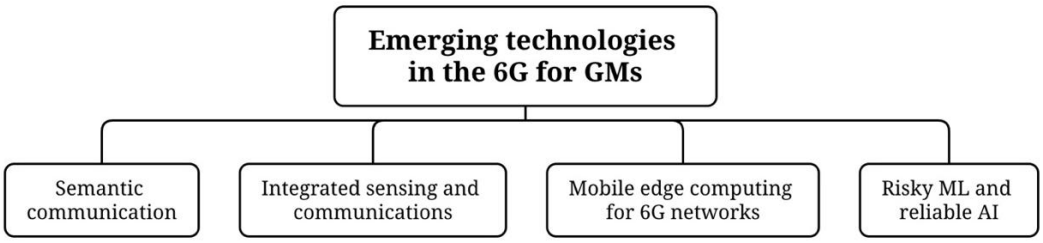

Fig. 8. Content of this section showing the technologies considered as the possibilities in the 6G for the GMs.

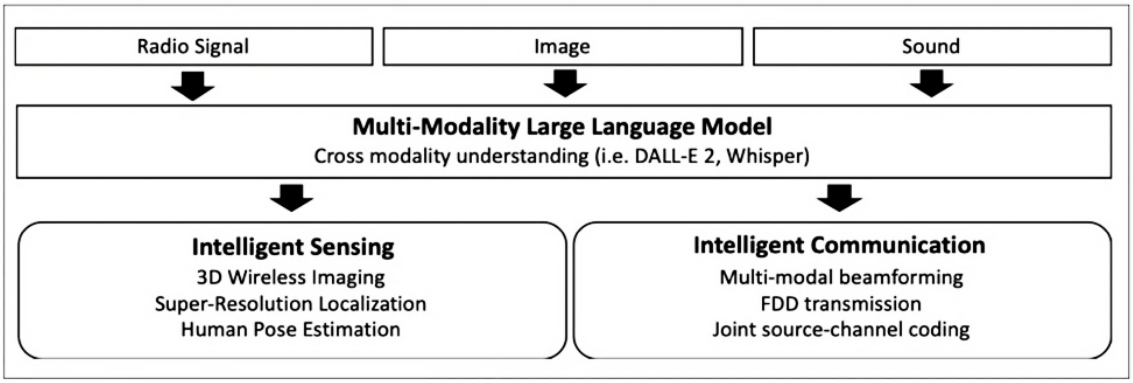

Fig. 9. Example on wireless sensor and communication LLM applications.

To improve algorithm flexibility to network shifts like UAV movement trends or infrequent URLLC events, GMs can generate synthetic data that records the basic architecture of these patterns. According to study [33], WS-GAN is a weakly-supervised GAN that uses additional data to predict wireless coverage using randomly distributed samples of received signal intensity. In contrast to standard methods like kNN or matrix finish, WS-GANs increase prediction effectiveness by including auxiliary information like terrain and building data, which greatly affects signal strength variation. In tests on an actual LTE dataset, WS-GAN demonstrated superior estimation accuracy and produced more practical wireless coverage maps compared to baseline approaches. In addition, [34] introduces a simpler approach for small cell coverage optimization utilizing GAN to obtain knowledge and transfer it to local SDN controllers. This approach focuses on creating effective GAN training for diverse topologies, even with insufficient data on network behavior and performance.

GANs and VAEs show potential for network administration and optimization. From improved learning algorithms to assignment solutions, GMs provide a versatile and effective toolkit for network researchers and practitioners. In non-stationary situations, GMs excel at forecasting user resource needs, handling imbalanced and sparse data, and adjusting to dynamic network conditions. GMs enhance network adaptability, efficiency, and robustness. By generating synthetic data, GMs can enhance actual information for training ML algorithms, enhancing performance in tasks like resource allocation and outage detection. Additionally, GMs improve the reliability of RL/DRL algorithms in non-stationary situations, enabling them more suitable for real-world deployments. Combining GMs with existing technology could change next-generation networks.

IV. The Role of Generative Models in Emerging 6G Capabilities

This section talks about emerging 6G capabilities included in the use of semantic communication, integrated sensing and communications (ISAC), mobile edge computing (MEC) and EAI for 6G networks, and Risky ML (RML) and reliable AI. Fig. 8 shows the content of this section.

Semantic communication (SC) is set to be a fundamental innovation in the advancement of 6G networks. In contrast to conventional communication models that emphasize the delivery of unadulterated bits with minimal distortion or data loss, semantic communication seeks to convey "meaningful" information, taking into account elements such as setting, the receiver's prior knowledge, and the transmission's intended purpose. This sophisticated technique designates SM as an essential element of forthcoming 6G networks, anticipated to utilize GenAI for comprehending, interpreting, and responding to extensive heterogeneous data flows.

Large Language Models (LLMs) are crucial in transforming the landscape of supply chains, ushering in an era of advanced, intelligent, and contextually aware data flows. LLMs are anticipated to provide as the foundation for developing self-governing, interacting AI agents that comprehend telecommunications language, ultimately guiding humanity towards collective intelligence, as opposed to the earlier notion of linked intelligence. Furthermore, LLMs can be developed as multimodal big models trained on telecommunications data and fine-tuned to execute various downstream tasks, thereby obviating the necessity for specialized models and facilitating the realization of artificial general intelligence (AGI)-enhanced wireless networks. LLMs can enhance wireless networks by providing predictability

features, hence facilitating enhanced and proactive localization, beamforming, power allocation, transition, and spectrum administration, even in hitherto unencountered network conditions, as shown in Fig. 9. Conversely, wireless networks can link many GenAI models using innovative communication methods at both semantic and effectiveness levels, facilitating expedited detecting, inference, and action while minimizing the usage of resources.

With strong natural language comprehension potential, LLMs provide powerful database querying interfaces. Users can ask questions in normal language, and the system will understand and retrieve the desired data, instead of using structured searches. GANs are revolutionizing SM by producing more effective, flexible, and perceptive results. Additionally, GANs may simplify complex data into understandable visual illustrations, guaranteeing that the transmitted information is received and understood by the recipient. Using picture translations helps improve understanding and overcome the gap between raw data and actionable insights.

DGMs offer a unique technique to SM, tackling data transport and interpretation difficulties. DGMs can improve signal quality, preserving valuable data even in unfavourable situations. This feature is crucial when signal loss may obfuscate the meaning of communicated data. DGMs enable variable-rate communication for dynamic communication. As data complexity varies, DGMs can adjust transmission rates to ensure efficient data transfer without overburdening communication links. This allows DGMs to convey semantic depth despite data complexity.

ISAC brings new opportunities for network solutions by combining sensing and communication capabilities to react to shifts in the environment, resulting in improved effectiveness and intelligent processes. For ISAC, few factors can be considered important to discuss:

1) Data augmentation: the task involves creating synthetic, compelling sensor data to enhance real-world data repositories and provide a solid foundation for training. GANs excel in creating realistic and accurate data, making them ideal for augmentation jobs.

2) Anomaly detection: The objective is to identify data trends or spots that significantly depart from norms, ensuring fast notifications and system dependability. GANs have improved in identifying irregularities in sensor data spread. DGMs enhance anomaly identification by incorporating uncertainty quantification into their iterative approach.

3) Resource optimization: This involves simulating network settings and predicting future states to allocate resources efficiently. GANs excel at simulating various network contexts, enabling efficient model training for resource optimization. FGM's standardizing flows, which accurately describe complex network state distributions, are essential tools for decision-making in this environment.

4) Sensor/Data fusion: This responsibility involves combining data from several sensors to provide a comprehensive and accurate environment depiction. VAEs simplify complex tasks by reducing data into a simplified hidden space . Standardizing flows can improve this process by accurately simulating complex data patterns.

5) Decision making: This job supports consecutive decision-making based on sensor and communication data. GTMs excel at handling large data sets, making them useful in sequential decision-making situations. LSTMs, designed for data patterns, are essential for situations requiring a strong temporal or sequential backdrop.

MEC and EAI change 6G networks by decentralizing data execution. Standard models, relying on central servers or cloud computing, caused latency and inefficiencies, especially for time-sensitive operations or remote devices. Integrating compute and AI/ML capabilities at the network edge enables real-time data processing and decision-making for devices. This change is essential for meeting the needs of 6G and its various uses. GANs may reproduce real-world data through generated samples. GANs can enhance data at the edge in MEC contexts, particularly when significant datasets are unavailable for training or assessment.

Bayesian VAE models may estimate ambiguity, making them essential for edge devices [35]. Serial data is essential for edge applications like VR and AR. LSTMs and GTMs efficiently evaluate patterns, enabling real-time improvements in AR encounters based on user motions and activities. Edge devices frequently face complex data distributions, particularly in multi-modal or multi-sensor settings. Standardizing Flows models complex distributions, enabling localized AI to comprehend and respond to nuanced input. In cases of noisy or uncertain edge data, DGMs can be crucial. Their repeated output refinement improves accuracy continuously, making it useful for advanced robotics with unpredictable environmental variations.

RML studies how AI models can be deceived by particularly constructed inputs, leading to inaccurate predictions or classifications. Adversarial instances include modest, unnoticeable modifications to input data and manipulating model output, which may appear unmodified to humans. Studying AML is critical for understanding vulnerabilities and developing responses against prospective attacks.

GANs can be used to create antagonistic samples that deceive classifiers. The producer in GANs can produce fake samples that mislead a target classifier into making incorrect conclusions [36]. Conversely, GMs are able to identify and counter aggressive attacks. In GAN training, the generator generates adversarial instances and the discriminator learns to differentiate between authentic and adversarial samples. With proper training, the discriminator can identify adversarial samples in real-world settings.

AML handles adversarial assaults, enhancing AI system resilience and robustness. Although protections against adversarial attacks are being created, openness is needed to understand how they work and how the model processes data, which lies within trustworthy AI (TAI). Numerous frameworks have been suggested to direct the advancement of TAI, with the European Commission’s High-Level Expert Group on

Artificial Intelligence being one of the most notable entities to have formalized TAI as a theory cantered on seven pillars that encompass diverse aspects of AI ethics and durability.

V. CONCLUSIONS

As the age of 6G begins, the amalgamation of innovative communication paradigms and nascent innovations is swiftly revolutionizing wireless communications, with machine learning and artificial intelligence proving to be pivotal in tackling intricate difficulties. Although DAI prevails in the AI-driven wireless scientific domain, the potential of GenAI to augment and enhance DAI methodologies is becoming increasingly apparent, particularly in contexts characterized by insufficient or partial data. This study offered insights into the principles of 6G and explored the critical function of GMs in diverse areas of wireless research. Moreover, by identifying potential problems and proposing effective techniques, we argue that our research offers scholars and industry professionals valuable insights, thereby positioning itself as a guide resource in this rapidly developing field.

ACKNOWLEDGMENT

The authors would like to express their gratitude to UNITAR International University for supporting this research.

***Abstract*—Effective prioritization of software requirements is essential for reducing project risks, optimizing resource allocation, and ensuring timely delivery. Conventional approaches such as Analytic Hierarchy Process (AHP) and MoSCoW often suffer from subjectivity, inefficiency, and poor scalability, making them unsuitable for large-scale projects. Although machine learning (ML) based methods improve scalability, they frequently overlook critical contextual factors such as risk, urgency, implementation effort, and inter-requirement dependencies. To address this gap, this study proposes a new machine learning based context aware software requirements prioritization system. In the proposed system, a pre-trained RoBERTa model and an ordinal neural regression model are employed to infer contextual features including technical risk, complexity, urgency, business value, implementation effort, requirement stability, stakeholder criticality, security sensitivity, and inter-requirement dependencies directly from requirement statements. These inferred features are then used as inputs to a supervised multiple regression model (XGBoost), which generates continuous priority scores for each requirement, with higher scores reflecting higher implementation priority. To ensure transparency, SHAP-based feature attribution is applied for feature importance analysis, and a feedback integration mechanism allows stakeholders to iteratively refine prioritization outcomes, thus in-turn retraining the core prioritization model. Empirical validation against three domain experts across five projects from different application domains demonstrates strong alignment, with Spearman rank correlations between 0.6 and 0.75, Mean Absolute Error (MAE) around 0.10, and Top 5 Match Rates up to 0.80. The results confirm that the proposed system provides a scalable, explainable, and context aware requirements prioritization mechanism suitable for real-world software engineering projects.**

I. Introduction

Contemporary software projects exhibit increasing complexity as application priorities shift during development and as requirements interact through technical and organizational dependencies [1]. In such environments, the ordering of requirements functions as a determinant of system risk, resource contention, and delivery reliability; inappropriate ordering propagates bottlenecks, extends schedules, and can precipitate project failure. Practice often adopts structured techniques such as Analytic Hierarchy Process, MoSCoW, and case-based ranking to introduce discipline into decision making; however, these techniques depend heavily on judgments elicited from experts at specific points in time and require substantial manual effort, which constrains reproducibility and scalability when the requirement set is large or volatile [1]. Related work on interactive optimization for the Next Release Problem also shows how optimization and learning can be combined for release planning [2]. A further limitation is the absence of a formal representation of project specific context. Urgency, failure risk, technical constraints, and operational dependencies are frequently handled implicitly or retrospectively, producing priority lists that appear consistent during elicitation yet diverge from the evolving state of the project [3]. Structured prioritization has also been reviewed at the use-case level, extending the evidence base beyond requirements lists [4]. Recent systematic literature reviews (SLRs) consolidate more than one hundred and forty requirements prioritization techniques from 2000 to 2021, highlighting that both traditional approaches (AHP, MoSCoW, numerical assignment) and modern AI-based methods (fuzzy logic, genetic algorithms, machine learning) still face persistent challenges in scalability, stakeholder coordination, dependency handling, and automation [3][5][6][32]. Thus, there is an evident need for development of scalable, empirically validated ML models that support can real-world prioritization workflows.

Within such contexts, machine learning models for requirements prioritization offer a scalable and objective alternative by analyzing historical data together with project specific contextual information to automate prioritization [7] [30]. This approach reduces continuous reliance on expert intervention, thereby lowering subjectivity and improving the consistency of decisions. In practice, machine learning methods have been shown to increase efficiency while decreasing manual effort in prioritization tasks [7][8][9]. Recent machine learning surveys on requirements prioritization identify scalable, data-driven approaches including case-based ranking, classification-based methods, clustering algorithms (k-means, Fuzzy C-Means), and semi-automated frameworks such as SRP Tackle, which demonstrate strong performance on large-scale requirement sets while reducing expert elicitation burden [9][10]. Additionally, several works now incorporate semi-automated and interactive mechanisms where stakeholders provide feedback to refine prioritization outcomes, partially

*Corresponding author.

addressing human-in-the-loop and iterative refinement challenges [2][9][10] [11] [31].

Although machine learning approaches improve scalability and objectivity relative to manual methods, a persistent gap is their limited treatment of context [5]. Automated models frequently omit the intent and contextual cues embedded in requirements statements. When project-specific factors such as urgency, risk, complexity, resource needs and availability, and dependencies are not represented, the resulting priority order may diverge from project goals and constraints. For example, selecting a low-risk item with no dependencies ahead of a high risk, mission critical item can increase cost and delay delivery. In such cases, the prioritization output no longer serves the project's objectives and weakens the value of the process. At the same time, several recent strands of research address parts of this gap: 1) Natural language processing (NLP) in requirements engineering uses deep language models and dependency parsing to extract requirement attributes, risk indicators, and structural properties directly from textual requirements, enabling more precise feature engineering [12] [13] [14]; 2) Dependency-aware prioritization techniques such as DRank and CDBR explicitly model and exploit requirement dependency graphs, using graph-based ranking, execute-before-after relationships, and collaborative filtering to propagate priority signals across dependent items [9][11][15][16]. 3) Recent machine learning surveys document growing adoption of supervised classification, clustering, ranking algorithms, and swarm optimization approaches that incorporate dependencies, though often in isolation and not jointly optimized [5][9] and 4) Explainability and interpretability methods are increasingly discussed as essential for understanding and validating AI-based prioritization decisions, though their application to requirements prioritization pipelines remains limited [5][9][17]. However, these approaches typically address specific factors or mechanisms (e.g., dependency graphs alone, or NLP for classification only) and often require substantial elicitation effort, manual configuration, or separate treatment of contextual signals, leaving room for more integrated, end-to-end frameworks that jointly infer multiple contextual features from requirement text, model dependencies explicitly, and provide explainability through a unified prioritization pipeline.

This study addresses these limitations through the following objectives:

- Design and implement a context aware machine learning model that prioritizes software requirements from their descriptions and contextual features, including risk, urgency, and dependencies. In contrast to prior dependency-aware approaches (such as DRank and CDBR) that focus primarily on explicit dependency matrices or pairwise comparisons, and to NLP studies that target isolated feature extraction or classification [9][11][12][15], the proposed model infers a broader integrated set of contextual variables including technical risk, complexity, urgency, implementation effort, stability, stakeholder criticality, security sensitivity, and inter-requirement dependencies directly from requirement text and combines them within a unified regression framework.
- Apply natural language processing techniques, using RoBERTa for risk estimation and dependency analysis, and an ordinal neural regression model for other contextual features such as complexity, urgency, implementation effort, stability, stakeholder criticality, security sensitivity, and business value [12][18]. This design builds on recent advances in using deep NLP models and interpretable machine learning for requirements classification, attribute extraction, and dependency identification [12][13][14][19][20], while extending them beyond isolated classification tasks to multi-feature context inference optimized specifically for downstream prioritization.
- Use a supervised multiple regression model (XGBoost) to generate continuous priority scores. Regression-based integration of contextual features aligns with recent automated prioritization frameworks and machine learning surveys that recommend ensemble methods for requirements ranking [9][21]; however, in this work the regressor operates over features that are explicitly inferred from requirement text via NLP and evaluated for importance through explainability analysis, rather than relying solely on manually annotated attributes or any ad-hoc feature engineering process.
- Establish a mechanism to collect and integrate stakeholder feedback, including revised priority scores and contextual feature values, to update the training data and improve model adaptability and accuracy over time. This feedback-driven retraining mechanism is consistent with semi-automated and human-in-the-loop prioritization techniques reported in recent literature [9][10] and aligns with the push toward interactive ML in requirements engineering; however, this work uniquely applies the feedback loop to an explicitly context-aware, explainability-informed feature space shaped by SHAP-based feature selection during design time, enabling both transparency and iterative refinement.

This study contributes the following to requirements engineering:

- Context aware framework: A scalable and automated requirements prioritization system that integrates machine learning and natural language processing to infer contextual features from requirement statements, providing a foundation for informed and efficient prioritization [21]. Semi-automated techniques reported in prior work also motivate the integration of human feedback into prioritization pipelines [10]. By jointly modeling textual features, inferred contextual signals (risk, complexity, effort, stability, security, stakeholder importance), inferred dependencies, and learned dependencies within a single end-to-end pipeline, the framework addresses research gaps identified in recent SLRs and complements existing context-aware, dependency-aware, and ML-based RP approaches, thereby clarifying the boundary between earlier techniques and this present work [5][6][9][11][15].

- Contextual feature inference: Use of RoBERTa for risk estimation and dependency analysis, together with an ordinal neural regression model for additional contextual features, and integration of these values into a unified prioritization pipeline [19]. Unlike prior NLP-based efforts in requirements engineering that focus mainly on requirement classification, non-functional requirement type detection, or structural complexity assessment [12][13][14], the feature inference layer here is explicitly optimized via supervised learning to feed a downstream prioritization regressor, enabling true end-to-end learning from requirement text to priority scores without intermediate manual steps.
- Regression-based integration: Combination of inferred and annotated contextual features within a supervised multiple regression model (XGBoost) to produce continuous priority scores and improve predictive performance [20] . This extends earlier regression and optimization-based prioritization models by incorporating explainability-informed feature selection (via SHAP) and text-derived dependency signals, which recent surveys indicate have not yet been jointly exploited in existing AI-based and machine learning-based RP studies [5][9][15][21].
- Design time SHAP feature selection: Application of Shapley Additive Explanations once during model design to select influential features for the final training dataset, ensuring consistent training and retraining while excluding SHAP from the runtime pipeline [17]. SHAP and related explainability methods are increasingly used to analyze and interpret complex ML models in various domains [17], and their application to model development (feature selection, model debugging) is well established; however, their use to deliberately shape the feature space of a requirements prioritization pipeline selecting only the most impactful features informed by explanations remains underexplored in the requirements engineering literature, particularly in conjunction with NLP-based contextual feature inference.
- Feedback driven retraining: A mechanism for stakeholders to review and adjust prioritization outputs; the collected feedback updates the training data using the same SHAP selected feature set to improve adaptability and maintain accuracy over time [12]. This human-in-the-loop mechanism complements existing interactive and semi-automated approaches such as SRP Tackle (which uses semi-automation to reduce expert burden), DRank (which resolves conflicts via dependency propagation), CDBR (which integrates stakeholder and developer preferences with dependency-based optimization), and interactive genetic algorithms discussed in recent surveys [9][10][11][15], by embedding explicit human feedback directly into the retraining cycle of a context-aware, explainability-informed model and enabling stakeholders to influence the feature importance profile over time.
- Empirical validation: The system is evaluated with multiple domain experts across diverse projects, showing reduced manual workload and improved alignment of priorities with risk mitigation and resource allocation objectives [16]. The evaluation design aligns with recommendations from recent AI-based and machine learning SLRs on requirements prioritization, which emphasize the importance of empirical assessment across diverse projects, evaluation of scalability with large requirement sets, validation of dependency handling, and measurement of stakeholder satisfaction and usability in realistic industrial settings [5][6][9].

The remainder of the paper is organized as follows. Section II presents the methodology: requirement data preparation, contextual feature inference with RoBERTa and ordinal neural regression, SHAP feature selection, and development of the core regression prioritization model. Section III describes the system design and implementation, including the architecture, integration of contextual feature estimators, dependency analysis, backend services, and the user interface. Section IV reports empirical validation with expert evaluation and performance analysis using mean absolute error, Spearman rank correlation, and Top 5 match rate. Discussion is given in Section V. Section VI concludes with a summary of contributions and directions for future work aimed at improving scalability, adaptability, and applicability in practice.

II. Methodology

This study employs a structured methodology with five sequential phases to develop and evaluate a context aware, machine learning based requirements prioritization system. The complete workflow is shown in Fig. 1.

A. Phase 1: Requirement Data Preparation

Requirement statements were collected from publicly available Software Requirements Specification (SRS) documents of multiple open-source projects. The documents were processed to construct a dataset for training and testing the prioritization models. Preprocessing included tokenization, vectorization, lemmatization, removal of special characters, and lowercasing. These steps standardize the text and prepare it for use in the natural language processing and machine learning models employed in subsequent phases of the study [22].

B. Phase 2: Contextual Feature Estimation

Each contextual feature was modeled with a dedicated machine learning pipeline appropriate to its data type and structure. The training data consisted of requirement statements from open-source SRS documents, which were annotated for contextual feature values and binary dependency [16]. The accompanying table summarizes the specification and characteristics of the estimation and inference models. Coupling preferences with dependency information has been shown to improve prioritization quality in semi-automated and dependency aware settings [11] [16] [23]. SHAP (Shapley Additive Explanations) was then applied to a subset of the labeled data to identify the features with the greatest influence on the output of the core prioritization model; a basic random forest regressor was used only for this SHAP analysis step [24]. The most influential features were selected and fixed for training the prioritization model. Finally, all trained inference models, together with configuration files, tokenizers, and vectorizers,

were saved for use by the backend API of the core prioritization system.

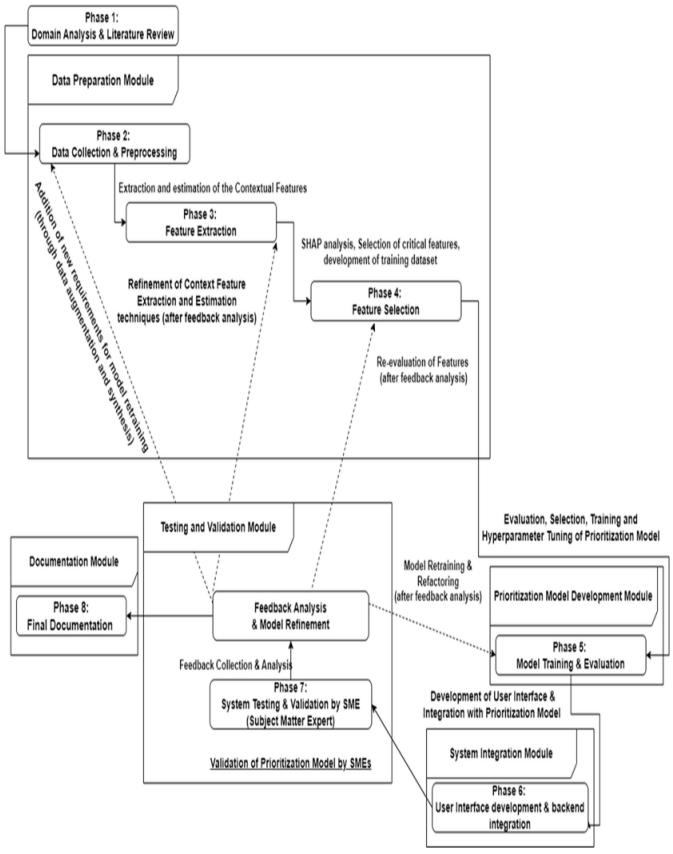

Fig. 1. Methodology workflow diagram.

C. Phase 3: Requirements Prioritization Model

The requirement prioritization pipeline begins by estimating contextual features from requirement statements using the inference models developed in Phase 2. Next, the expert labeled training data are augmented to create the initial training set for the core prioritization model. Augmentation injects small Gaussian noise into sentence embeddings derived from the requirement text, as well as into priority scores and contextual feature values scaled from 0 to 1, while preserving the original dependency labels to maintain structural consistency. A subset of the augmented data is then used to train multiple supervised regression models, including Random Forest, Gradient Boosting Regressor, Support Vector Regressor, and XGBoost Regressor. Model performance is evaluated with fivefold cross validation using Root Mean Squared Error, Mean Bias Error, Mean Absolute Error, Mean Bias Ratio, and the coefficient of determination R2 as metrics. Across these comparisons, the XGBoost Regressor shows the strongest accuracy and generalization [25].

After selecting XGBoost as the core prioritization model, hyperparameter tuning was conducted using two strategies: randomized search cross validation and Bayesian optimization [26]. The search covered learning rate, maximum tree depth, number of estimators, L1 and L2 regularization strengths, and subsampling ratio [29]. In comparison, Bayesian optimization produced lower root mean squared error and higher overall performance while exploring the search space more efficiently [26]. The final XGBoost model, trained on the selected feature set with the best parameters from Bayesian optimization, was exported together with the TF IDF vectorizer. These components were integrated into the backend application programming interface of the prioritization system, which prioritizes new software requirements. The main stakeholder interactions are illustrated within the use case diagram shown within Fig. 2.

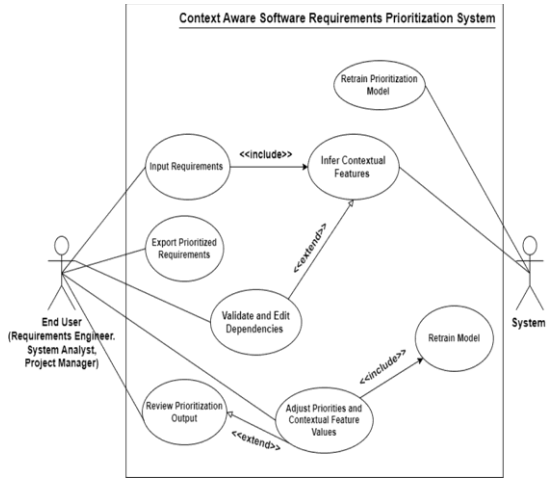

Fig. 2. Use case diagram (core priorization).

D. Phase 4: Model Validation and Interpretability

After tuning and finalizing the core prioritization model, an empirical study is conducted to assess its applicability in real settings. The model's predicted priority scores and ordering are compared with the judgments of three domain experts on a new set of requirement statements and project contexts. Performance is measured using Spearman rank correlation, Top 5 match rate, and mean absolute error. Two evaluation modes are used. In the end-to-end automated mode, the inference models estimate contextual feature values and binary dependencies. In the manual mode, domain experts provide contextual feature and dependency values after reviewing the project contexts. The results provide quantitative evidence of the applicability and effectiveness of the machine learning based prioritization system and address the study objective of reducing subjectivity and improving scalability in requirements prioritization [5][9].

E. Phase 5: System Deployment

The system is deployed with Fast API to provide backend services and programmatic access to the core prioritization models through HTTP endpoints. A user interface enables nontechnical users to submit requirement statements and view the resulting priority scores and ordering.

III. Implementation

A. Data Acquisition and Preparation

The first step is the search and collection of software requirement statements from Software Requirements Specification (SRS) documents associated with open source or declassified projects. To support contextual diversity and generalizability of the machine learning models, SRS documents were drawn from a range of project domains,

including telecommunication, healthcare, finance, and education.

After extracting the requirement statements, a domain expert manually annotated contextual feature values for each statement in the context of its source project. The features included technical implementation risk, complexity, urgency, stability across the project lifecycle, implementation effort, security sensitivity, and stakeholder criticality. Prior work has used NLP to assess structural properties and complexity of requirements, supporting the inclusion of such signals in our feature set [14]. Each feature was rated on a five-point ordinal scale from 1 (lowest) to 5 (highest) with respect to the corresponding SRS. In addition, inter requirement dependencies were annotated within each project using a binary label (dependent or independent) based on structural relationships observed in the SRS. Graph-based representations capture inter-sentence dependencies relevant to inferring such links [27]. These annotations constitute the ground truth for training the contextual feature inference models and the core requirements prioritization model used in this study.

Before training the machine learning models, the requirement text was preprocessed to standardize format by lowercasing, removing special characters, and normalizing whitespace. The semantic content of the statements was preserved without paraphrasing to remain consistent with the expert annotations. Contextual feature values were normalized to the interval [0,1] (for example, 2 maps to 0.4). Requirement statements were then vectorized with the all-mpnet-base-v2 Sentence Transformer, yielding 768 dimensional embeddings that capture the meaning and nuances of each statement.

To address the sparsity of expert labeled training data and to improve the robustness of the contextual feature estimators, the dependency detector, and the core prioritization model, a controlled data augmentation procedure is applied. The procedure injects Gaussian noise into the sentence embeddings and the normalized contextual feature values while leaving the dependency labels unchanged to preserve logical correctness. This emulates minor contextual and semantic variations that arise in practice [28]. Gaussian noise is applied to each input element, including normalized feature values and the 768-dimensional embedding that represents each requirement statement, using the formula given below.

$$x^j = x + \varepsilon,\ \varepsilon \sim N(\mu, \sigma^2) \quad (1)$$

x: Original data point (scalar or vector).

x^j: jth augmented sample generated from x.

ε: Additive Gaussian noise.

μ: Mean of the Gaussian noise (often 0).

σ: Standard deviation of the Gaussian noise; the variance is σ^2.

Here, gaussian noise is sampled from the probability density function given below:

The Gaussian probability density function specifies the distribution of the noise introduced during data augmentation and enables controlled simulation of stochastic fluctuations around a chosen mean. This supports more robust estimation of contextual features and dependencies and improves the generalizability of the core prioritization model. The augmented samples were then combined with the original expert labeled data to form a more comprehensive and balanced training set. Finally, the target variable Priority Score was perturbed with Gaussian noise using a separate standard deviation σ priority and then clipped to the interval [0.5,1.0] to keep augmented labels within realistic scoring ranges.

B. SHAP Analysis for Contextual Feature Evaluation

To examine the effect of contextual features on the output of the core prioritization model, Shapley Additive Explanations (SHAP) are used to decompose each prediction into additive contributions from individual features. SHAP supports global and local interpretation, which allows quantification of feature importance, assessment of average directional effects, and inspection of instance level behavior for each contextual feature [24]. The following subsections present visualizations of the SHAP analysis performed on the initial augmented training data with a basic random forest regressor.

Fig. 2 ranks the features by their mean absolute SHAP value, which reflects overall influence on the model output irrespective of sign. For each feature, the mean of the absolute Shapley values is computed across all test instances, providing an aggregate measure of the extent to which the feature moves predictions away from the base value. Requirements stability shows the highest mean absolute SHAP value (0.035), indicating the strongest contribution to the predicted priority scores. Complexity (0.028) and urgency (0.020) follow, suggesting that anticipated implementation difficulty and time sensitivity also have substantial impact. Implementation effort (0.018) and stakeholder criticality (0.016) form a middle group with moderate effects. Business value, security sensitivity, and technical risk have lower values (0.010 to 0.012), indicating less consistent contributions across the dataset.

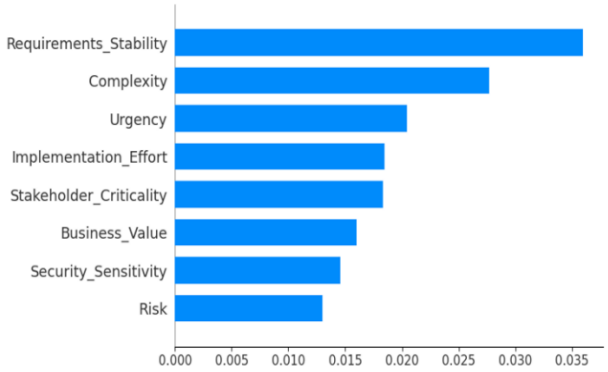

Fig. 3. Outcome of SHAP analysis.

This observation raises the possibility of under representation or collinearity with other features. Whereas the previous figure reports the absolute magnitude of feature importance, the current Fig. 3 presents signed mean SHAP values, which indicate whether a feature increases or decreases the predicted priority on average. The signed mean is obtained by averaging the raw Shapley values, including their signs, across all samples in the training data. In this analysis,

requirements stability shows a small negative mean (approximately −0.0010), indicating that higher stability is associated with lower predicted priority. These average directional effects of each contextual feature on the predicted priority scores are illustrated in Fig. 4.

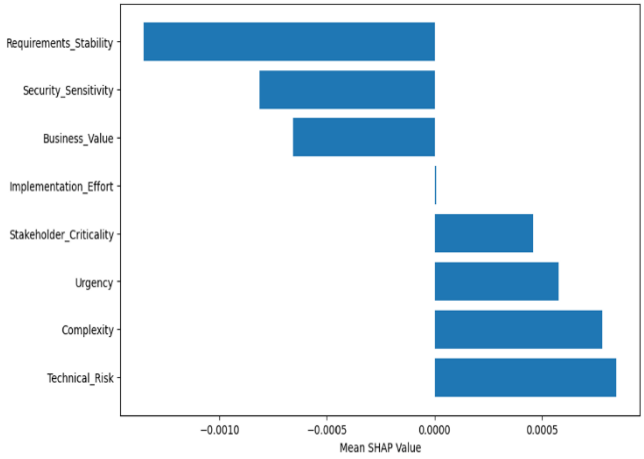

Fig. 4. Average Directional Effects (SHAP analysis).

This pattern is consistent with the local rationale that stable requirements are less urgent and can be deferred without jeopardizing schedules or increasing the risk of implementation failure. Security sensitivity (approximately −0.0007) and business value (approximately −0.0005) also show negative means, suggesting that highly valuable or sensitive items may be deprioritized relative to volatile tasks, possibly reflecting a trade off with complexity or risk. In contrast, technical risk exhibits a positive mean effect (approximately +0.0005), indicating that riskier requirements tend to receive higher priority, which aligns with a mitigation first strategy that addresses components prone to failure early in the lifecycle. Urgency, stakeholder criticality, and complexity show positive average contributions (approximately +0.0004 to +0.0008), reinforcing their influence in increasing the priority score. Taken together, the directional analysis indicates an implicit policy to defer stable, even high value, requirements while advancing urgent, complex, or risky items. Based on the SHAP analysis, requirements stability, complexity, and urgency are retained for their strong mean absolute contributions, and technical risk, implementation effort, and stakeholder criticality are included for their consistent directional effects, which capture risk mitigation, resource demand and allocation, and stakeholder influence in prioritization. This feature subset is expected to preserve predictive accuracy, improve interpretability, and reduce the risk of overfitting.

C. Model Evaluation and Metrics

The dataset refined through augmentation was used to train four machine learning models: Random Forest, Gradient Boosting, XGBoost, and a multilayer perceptron. Model performance was assessed with K fold cross validation using root mean square error (RMSE), mean bias error (MBE), mean absolute error (MAE), mean bias ratio (MBR), and the coefficient of determination R^2. Brief descriptions of these metrics are provided in Table I. The corresponding formulas are presented below.

TABLE I. MODEL EVALUATION METRICS

Model Evaluation Metrics	
Evaluation Metrics	***Description***
Root Mean Square Error	The Root Mean Square Error metric measures the average magnitude of error (net difference) between the actual values (within the training subset of data) and predicted values (actual values predicted by the regression learning models). This approach typically penalizes larger errors (difference in prediction) more than smaller errors due to the squaring operation before averaging. So, lower root means square error signifies better model accuracy as it quantifies comparatively lower prediction error.
Mean Bias Error	The Mean Bias Error actually measures the average difference between the actual and predicted values, which takes a bit different approach than RMSE where more focus is given only on measuring magnitude 78 of prediction error, whereas MBE also takes signs of the absolute difference into consideration. Considering the sign of the difference in predicted and actual values, MBE signifies positive and negative biases in prediction. This approach aids in identifying systemic bias, where positive MBE indicates model is under predicting (model output lower than actual values) and negative MBE indicates the model is over predicting (model output higher than actual values) than the actual values
Mean Absolute Error	The mean absolute error (MAE) is a popular metric for evaluation of regression models, which measures the average magnitude of the prediction error without considering the direction. This approach of evaluating only the net difference in predictive error, makes MAE a more direct and explainable error metric, which neither allows errors to cancel out like MBE.
Mean Bias Ratio	This evaluation metric like the MBE is also focused on evaluation of the bias (over and under prediction) within a model's prediction. However, MBR focuses on determining whether a model systematically over predicts or under predicts outcomes. Similarly, a positive mean bias ratio signifies that the model underestimates values and a negative mean bias ratio signifies that the model overestimates values. So, mean bias ratio closer to zero signifies overall lower or minimal bias in predictions made by model.
R2 (R-squared coefficient of determination)	The R2 is a metric that quantifies how well the regression learning model explains the variability of the actual data (.i.e. How well does the regression model's prediction match the actual data). If the model predicts perfectly, the numerator (sum of squared errors) becomes zero, then . But if the model can't explain variance well, the numerator will be larger making it closer to zero or even negative in some cases

R-squared coefficient of determination

$$R^2 = 1 - \frac{\sum_{i=1}^{n}(y_i - \hat{y}_i)^2}{\sum_{i=1}^{n}(y_i - \bar{y})^2} \quad (2)$$

Mean Bias Ratio

$$MBR = \frac{\sum_{i=1}^{n}(y_i - \hat{y}_i)}{\sum_{i=1}^{n} y_i} \quad (3)$$

Mean Absolute Error

$$MAE = \left(\frac{1}{n}\right)\sum_{i=1}^{n}|y_i - \hat{y}_i| \quad (4)$$

The evaluation results of the model after K - cross fold validation using the above-mentioned metrics are illustrated within the graphs provided within Fig. 4, 5 and 6 where Fig. 4, Fig. 5 and Fig. 6 refer to average directional effects (SHAP Analysis), Test RMSE, and Test MBE respectively.

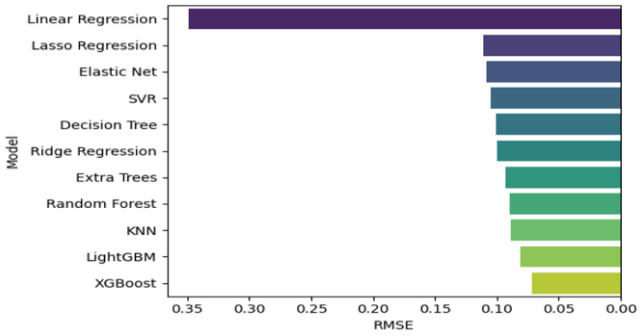

Fig. 5. Test RMSE.

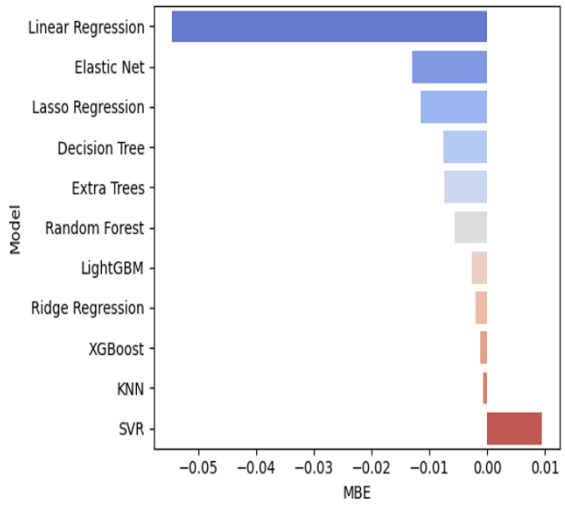

Fig. 6. Test MBE.

Mean Bias Error

$$MBE = \left(\frac{1}{n}\right)\sum_{i=1}^{n}(\hat{y}_i - y_i) \quad (5)$$

Root Mean Square Error

$$RMSE = \sqrt{\left(\frac{1}{n}\right)\sum_{i=1}^{n}(y_i - \hat{y}_i)^2} \quad (6)$$

The results show that XGBoost outperformed the other models. It achieved the lowest root mean square error (0.0718), the highest coefficient of determination R^2 (0.7991), and near zero bias (MBE = −0.0011, MBR = −0.0013). Light GBM and k nearest neighbors were the next best models but with slightly lower accuracy and consistency. Linear regression performed poorly, with higher error and a negative R^2, indicating that it did not capture the structure of the data. Plots comparing the models across all metrics corroborate these findings. Test RMSE, cross validation RMSE, R^2, MBE, and MBR were all lowest or closest to ideal for XGBoost, supporting its better generalization, stability, and low bias. The cross-validation RMSE values for the candidate models are reported in Fig. 7 and distribution of test mean bias ratio in Fig. 8.

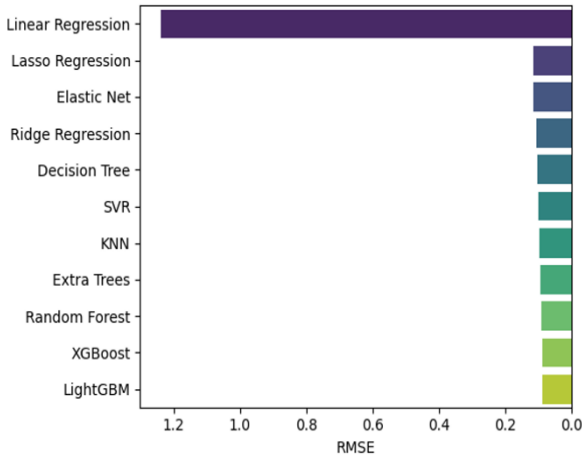

Fig. 7. Cross-Validation RMSE (Train).

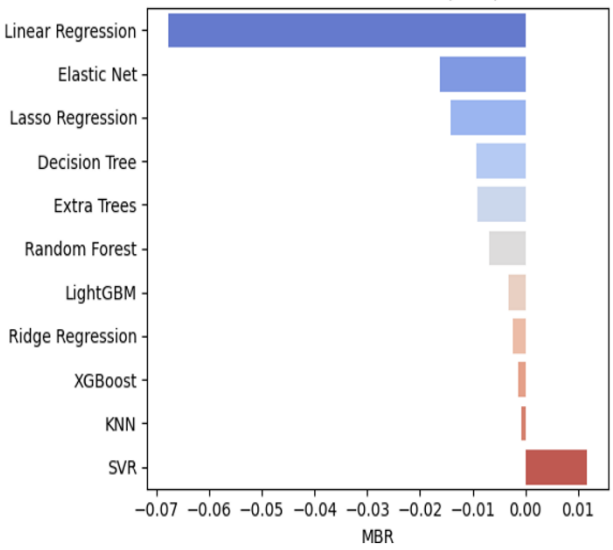

Fig. 8. Test Mean Bias Ratio (MBR).

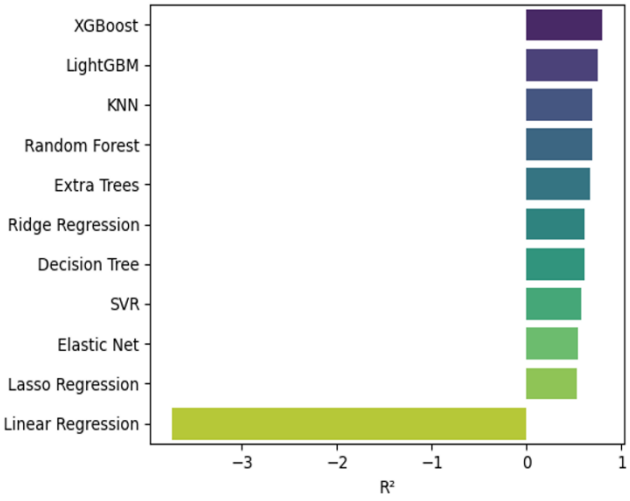

Fig. 9. Coefficient of determination (R2).

Furthermore, the corresponding coefficients of determination for the evaluated models are presented in Fig. 9.

D. Hyperparameter Tuning Process

After selecting XGBoost as the best performing model, we refined it through hyperparameter tuning using two techniques: randomized search cross-validation and Bayesian optimization. Both procedures were implemented and evaluated using the study's core metrics, and the tuned configurations were compared on the same validation protocol. The results of the two hyperparameter tuning approaches for XGBoost are as follows:

TABLE II. HYPERPARAMETER PROCESS

Outcome of Hyperparameter Tunning			
Method	***Best RMSE***	***Best R2***	***Best MBE***
Bayesian Optimization	0.074881	0.781547	0.000841
Randomized Search	0.078633	0.759108	–0.002580

The model tuned with Bayesian optimization produced a lower root mean square error (0.07488 versus 0.07863), a higher coefficient of determination R^2 (0.78155 versus 0.75911), and a mean bias error closer to zero and positive (0.00084 versus −0.00258), indicating lower and more balanced bias. The tuning results are summarized in Table II. These results support Bayesian optimization as the preferred hyperparameter tuning strategy for the XGBoost model used for contextual requirements prioritization. The tuned model was then retrained on the full training set, excluding the portion reserved for evaluation, and both the final model and the TF IDF vectorizer were saved for deployment within the prioritization system.

E. Implementation and Validation of Core Prioritization Model

The system architecture consists of a ReactJS frontend and a Fast API backend. Fast API is used to implement RESTful endpoints with asynchronous request handling and data validation. The endpoints support requirement submission, prioritization, editing of contextual features, dependency analysis, and retrieval of prioritization results. The frontend provides modular components for user interaction and communicates with the backend through HTTP POST and GET requests. The High-Level overview of the prioritization model's architecture is shown in Fig. 10 and details of API endpoints are summarized in Table III.

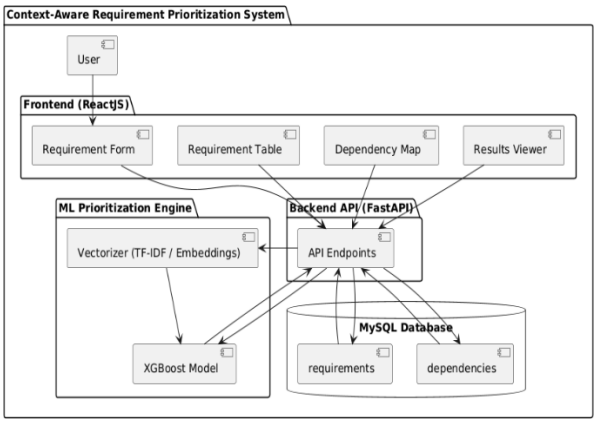

Fig. 10. Prioritization model architecture.

TABLE III. API ENDPOINTS DESCRIPTION

API endpoints description				
Endpoint	***Purpose***	***Method***	***Input***	***Output***

IV. RESULTS

This section reports the results of expert-based validation of the core prioritization model, an XGBoost model optimized with Bayesian optimization. Performance is summarized for five projects from different domains and compared with the judgments of three domain experts. The analysis focuses on alignment between the model and the experts using three metrics: Spearman rank correlation, Top 5 match rate, and mean absolute error.

Fig. 11 summarizes mean absolute error results across projects and experts. Excluding three specified instances, namely Expert 1 in Project 5 with MAE 0.07, Expert 2 in Project 4 with MAE 0.06, and Expert 3 in Project 3 with MAE 0.07, the model maintains low error across the remaining evaluations, with MAE values between 0.06 and 0.11 and an average near 0.10. The agreement is strongest in logistics, where Project 2 shows MAE 0.06 for all experts, and in telecommunications, where Project 1 reports MAE 0.08 for Expert 1, 0.07 for Expert 2, and 0.11 for Expert 3. Minor variations, such as the higher MAE of 0.11 for Expert 3 in Project 1, indicate deviations in some project contexts.

Fig. 12 reports Spearman rank correlation outcomes. Across projects, the model shows consistent ranking agreement, with average Spearman rank correlation between 0.6 and 0.7. The strongest agreement is observed with Expert 2, particularly in

healthcare (Project 5) and logistics (Project 2), where Spearman rank correlation reaches 0.75 and 0.70 respectively.

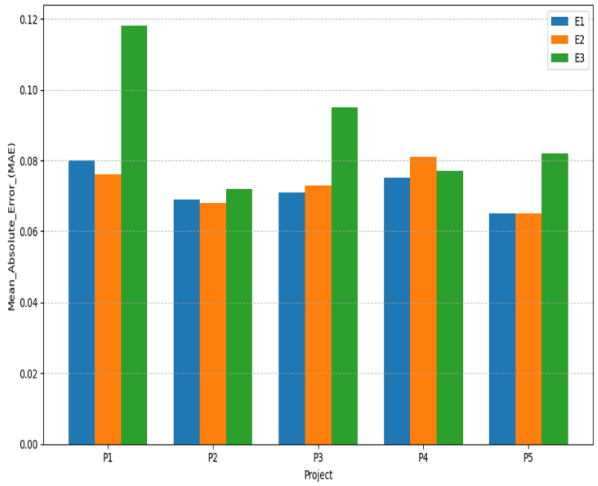

Fig. 11. Mean Absolute Error (MAE) values.

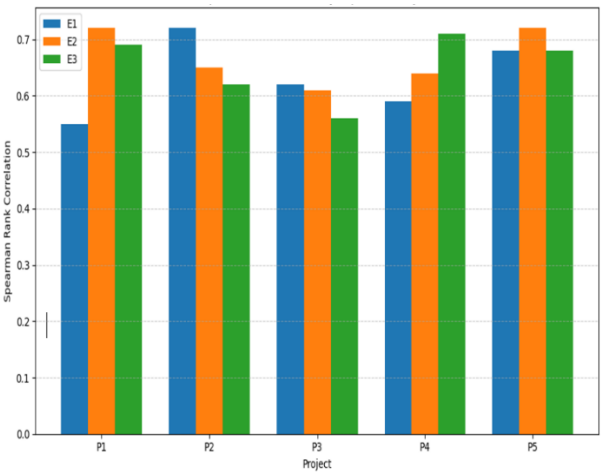

Fig. 12. Spearman rank correlation outcomes.

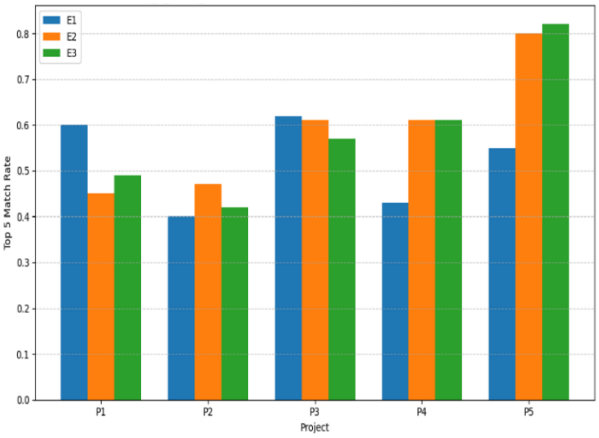

Fig. 13. Top 5 match rate values.

Fig. 13 presents Top 5 match rate values, with average Top 5 match rate between 0.5 and 0.55. In Project 5, the Top 5 match rate attains 0.80 for Expert 2, indicating close agreement on the highest-priority items. In Project 3, Spearman rank correlation is 0.60 for Experts 1 and 2 and the Top 5 match rate is 0.60 for both.

Additional results include Project 4 with Spearman rank correlation 0.60 for Expert 1 and 0.40 for Expert 3, and Top 5 match rates of 0.40 and 0.60 respectively. In Project 4, mean absolute error is 0.07 for Expert 1 and 0.09 for Expert 3. In Project 1, MAE is 0.08 for Expert 1, 0.07 for Expert 2, and 0.11 for Expert 3. In Project 5, MAE is 0.08 for Experts 2 and 3. The absence of measurements for Expert 3 in Project 3 limits a complete assessment for that project.

V. Discussion

The results indicate that the model can align closely with expert judgments in domains where requirements are well defined and evaluation criteria are relatively consistent. The strongest agreement with Expert 2 in healthcare and logistics suggests that the inferred contextual representation supports reliable prioritization in such settings, including for critical non-functional requirements.

Performance varies across domains, particularly in e-commerce (Project 4) and smart city (Project 3), where agreement is weaker for some experts. This variability is consistent with domains that exhibit stronger context dependence and greater divergence in expert preferences, which can reduce rank agreement even when absolute score differences remain small. The missing Expert 3 measurements in Project 3 further limits the interpretation of results for that domain.

This study has several limitations that should be considered when interpreting the findings. First, the datasets were derived primarily from open-source Software Requirements Specification documents, which may not fully represent industrial requirements practices, particularly in regulated or safety critical environments. Second, contextual feature values and dependency labels were annotated by a limited number of domain experts, and expert judgments can vary across projects and domains. This variability may influence both the learned mapping between contextual features and priority scores and the observed agreement metrics. Third, the approach infers contextual features from requirement statements, and the inference quality depends on the clarity and completeness of the textual descriptions. Requirements that are underspecified, ambiguous, or strongly dependent on external project context can reduce inference accuracy and, in turn, affect prioritization performance. Fourth, although cross validation and held out expert evaluation were used, the training data remains limited in scale. Data augmentation improves robustness, but it cannot substitute for broader real-world coverage, and generalization to unseen domains may require additional calibration. Finally, the system evaluates agreement against expert prioritizations rather than measuring downstream project outcomes. Therefore, the reported improvements reflect alignment with expert judgment and do not directly quantify impacts on delivery time, defect reduction, or operational risk.

Overall, the findings support robustness in critical domains while indicating the need for targeted improvements to address inconsistencies in subjective or complex project contexts. In practice, the model can reduce manual effort and provide decision support in resource constrained settings, but it should

be used to assist expert decision making rather than replace expert judgment, particularly in domains with high subjectivity.

A. Comparison with Existing Approaches

Existing machine learning based requirements prioritization techniques report improved scalability and reduced elicitation effort, but often without rich contextual features or explicit dependency handling [5] [9]. Semi-automated models such as SRP Tackle achieve high prioritization accuracy on large requirement sets but focus mainly on multi criteria scoring and clustering, with limited attention to fine grained dependency and risk signals [10]. Dependency aware approaches like DRank and CDBR show that incorporating requirement graphs and execution order improves prioritization quality, yet they typically rely on manually specified dependencies and do not infer contextual attributes directly from requirement text [11][16][23].

Within this landscape, the proposed model attains Spearman rank correlations between 0.6 and 0.75, Top 5 match rates up to 0.80, and mean absolute errors around 0.10 across diverse domains, which is consistent with or better than performance ranges reported for recent ML based RP methods when evaluated against expert judgments [7] [9]. The main added value lies in jointly modeling contextual factors such as stability, urgency, risk, and stakeholder criticality, inferring dependencies from SRS text, and providing SHAP based explanations, which extend prior dependency awareness and semi-automated frameworks while maintaining competitive predictive accuracy [5] [16] [24].

B. Limitations and Threats to Validity

The empirical evaluation is based on requirement statements drawn from publicly available or declassified SRS documents across a limited set of domains, including telecommunications, healthcare, finance, and education. This dataset may not fully represent industrial projects with different documentation styles, regulatory constraints, or safety critical requirements, which restricts the generalizability of the findings to other contexts. In addition, the number of projects and requirements per project is modest compared with large scale industrial portfolios, so scalability to very large backlogs remain to be confirmed empirically.

The expert-based validation involves three domain experts whose judgments reflect individual preferences, experience, and familiarity with specific domains. While multiple experts and projects were used to mitigate individual bias, differences in their rankings, particularly in e-commerce and smart city domains, indicate that part of the observed disagreement arises from variability in human judgments rather than model error alone. The study also focuses on Spearman rank correlation, mean absolute error, and Top 5 match rate as evaluation metrics, which capture ordering and score alignment but do not fully reflect all project level outcomes such as business value realization, downstream defect reduction, or stakeholder satisfaction.

From a modeling perspective, there is a risk of overfitting or tuning bias because the XGBoost model and its hyperparameters were selected based on cross validation performance on an augmented dataset. Although K fold cross validation and data augmentation were used to improve robustness, the same family of metrics guides both model selection and evaluation, which may overestimate performance relative to unseen industrial data. Furthermore, the contextual feature estimators and dependency detectors are trained on annotations produced within this study, so systematic biases or inconsistencies in the labeling process could propagate into the final prioritization outputs.

VI. Conclusion and Future Work

This research developed a context-aware requirements prioritization framework using machine learning, centered on an XGBoost regression model optimized with Bayesian optimization. The system automates and improves prioritization by integrating contextual factors such as technical risk, urgency, complexity, requirement stability, implementation effort, security sensitivity, stakeholder criticality, business value, and inter-requirement dependencies, which are inferred from requirement statements in SRS documents or provided through user input. In doing so, the framework addresses limitations of traditional approaches such as Analytic Hierarchy Process and MoSCoW that are sensitive to subjectivity, scale poorly, and depend heavily on expert availability.

The methodology combines fine-tuned RoBERTa models for risk and dependency estimation with sentence transformer embeddings and Coral Ordinal models for complexity and related features. At design time, a feature selection step is performed using the Shapley Additive Explanations (SHAP) process to retain the most influential contextual variables for consistent training and retraining, thereby enhancing interpretability and transparency. Empirical evaluation across five projects with three domain experts demonstrates consistent alignment between model outputs and expert prioritizations, as reflected by Spearman rank correlation, Top 5 match rate, and low mean absolute error across projects.

In practice, the system supports prioritization in dynamic development settings by enabling iterative refinement through stakeholder feedback and by providing structured prioritization outputs that can assist decision-making. The approach is intended to support expert judgment by producing an initial ordering and exposing the contextual basis of priority scores rather than replacing expert decision-making.

Despite the contributions of this study, the evaluation remains limited to open-source and declassified SRS documents, a modest number of projects, and expert validation in selected domains. Future work will expand the annotated training data with larger industrial case studies to increase stakeholder and domain diversity, refine contextual inference using more advanced natural language processing techniques, and strengthen dependency modeling for complex requirement networks. Additional evaluation criteria will be incorporated to improve external validity and assess downstream project outcomes such as delivery efficiency and risk reduction. Continued attention to interpretability, transparency, and ethical scaling is essential for deployment in sensitive domains such as healthcare and other mission-critical systems. Overall, this research contributes to machine learning-assisted software engineering by providing a practical and scalable foundation for context-aware requirements prioritization and management.

Functions Inverse Using Neural Networks via Branch-Wise Decomposition and Newton Refinement

Abdullah Balamash
Electrical and Computer Engineering-Faculty of Engineering, King Abdulaziz University, Jeddah, Saudi Arabia

***Abstract*—In this work, a unified framework (using Neural Networks) is proposed to find the inverse of mathematical functions, spanning both simple one-to-one mapping and complex multivalued relations. The approach uses standard multilayer Neural Networks (NN) to approximate the functions' inverse and introduces a deterministic branch-wise decomposition to handle multi-valued inverses. For single-valued (one-to-one) functions, a NN is directly trained on input-output pairs to learn the inverse mapping. For multi-valued functions, the function domain is decomposed into one-to-one branches, and a dedicated NN is trained for each branch. A refinement step using Newton's method is applied to the NN output to further improve inversion accuracy. Across a broad set of benchmark functions, the proposed approach achieved low mean absolute error (MAE) and mean squared error (MSE) in recovering the true inverse, with high round-trip consistency. Newton refinement further reduces inversion error by rapidly converging to higher precision solutions. Notably, even for multi-valued inverse functions, each branch-specific NN can accurately recover the true inverse. Accordingly, standard NN, when combined with branch-wise decomposition and Newton refinement, can serve as an effective universal approximator for the inverse of functions across a spectrum of complexities.**

***Keywords*—Neural networks; function inverse; Newton method; branch-wise decomposition**

I. Introduction

A. Background and Related Works

Finding the inverse function is a fundamental problem in many domains, from control systems and robotics to scientific computing and optimization. Traditional analytical or numerical methods can be challenging to apply when the function is complex or not single-valued. Neural networks offer a powerful alternative, since when they are provided with sufficient training data, they can approximate any well-behaved and invertible continuous function to an arbitrary accuracy [1]. In practice, inversion using NN has been explored in control systems and other fields [2], but significant challenges remain when the inverse mapping is multi-valued [3]. Recent advances in physics-informed neural networks (PINNs) have demonstrated remarkable capability in solving both forward and inverse problems by embedding physical laws directly into the learning process [4], although these approaches primarily address parameter identification rather than multi-valued function inversion.

If the forward function is $y = f(x)$ is not one-to-one, then the inverse relation $x = f^{-1}(y)$ is multi-valued, meaning a single y corresponds to multiple valid solutions (x). For example, both $y = x^2$ and $y = \sin(x)$ have two or more inverse values for a given y. Standard neural regression fails in this setting because training data is not a single-valued mapping: the same input y appears with different target x, leading to contradictory samples [5]. A conventional NN trained on such data will tend to predict the average of the contradictory samples [6]. Previous studies have shown that multi-valuedness can hinder learning [3]. It has been shown in robotics that a standard NN cannot learn a multi-valued kinematics function, necessitating specialized solutions [7]. Recent work using deep learning for inverse kinematics in robotic manipulators has demonstrated both the potential and limitations of various neural architectures in handling such non-unique mappings [8].

Several schemes were explored to cope with multi-valued inverses. Mixture Density Networks (MDNs) model the inverse distribution as a mixture of Gaussian distributions, where each Gaussian component corresponds to a single outcome. MDN minimizes the log-likelihood of the observed data under the predicted mixture model, which allows the model to fit all possible outcomes [9]. While MDNs are powerful, they are complex, hard to train, and less interpretable in practice. They are difficult to train since they need to learn several things at once, such as means, variances, and mixing weights for each Gaussian component. They also need a careful initialization and regularization to avoid both overfitting and underfitting. Recent applications of MDNs in photonic inverse design have shown their effectiveness in handling non-uniqueness, through the challenges of specifying the number of mixture components and joint parameter optimization persist [10]. Transfer learning approaches have been proposed to mitigate some of these training difficulties [11].

The modular neural networks (mixtures of experts) method was explored, where each expert network learns one branch of the inverse mapping, and a gating network decides which expert network to activate for a given input [12], [13]. While such gating architectures can handle multi-valued mappings, they add an extra layer of complexity, as the gating layer must be trained and tuned, and performance can be sensitive to the partitioning of the input space.

Multi-headed neural networks provide another approach, in which a single network outputs several possible inverse candidates (heads) simultaneously [14], [15]. While this approach allows multiple solutions, it still couples all outputs into one model, requiring complex loss functions and additional mechanisms to ensure that each head specializes in a distinct branch. For example, a multiple-choice learning strategy can be employed, wherein for each training example, only the output head closest to the ground truth is updated, forcing other heads

to diverge [16]. This added training complexity is necessary to prevent the heads from collapsing to the output. The work in [15] demonstrated a multi-headed tandem neural network approach for non-uniqueness in inverse design of layered photonic structures, utilizing a self-attention mechanism to constrain and separate multiple outputs.

Beyond these mainstream methods, researchers have explored other techniques for multi-valued inversion. One idea is to provide the network with additional inputs or context to disambiguate the inverse. In study [3], the authors proposed a state-regulated NN that augments a multilayer perceptron with a discrete state variable to indicate different branches of the inverse. This effectively transforms a one-to-many mapping to multiple one-to-one mappings, provided the correct state is supplied during the inference. Some researchers have approached the one-to-many mapping using manifolds or piecewise mappings. In study [17], the researchers present a method that learns locally linear maps on different regions of a data manifold to represent multiple outputs for a given input.

In photonic design, generative models have been leveraged to address the inverse problem of non-unique solutions. For example, conditional generative adversarial networks have been used to generate multiple candidate structures that all produce the same target optical spectrum [18], and conditional variational autoencoders have been applied to learn the distribution of possible inputs that yield a given output [19]. More recently, diffusion models have emerged as a powerful alternative for inverse design problems, demonstrating superior performance in capturing complex distributions and naturally handling one-to-many mappings [20]. In [21], the authors proposed DiffMat, a diffusion model-based framework for energy-absorbing mathematical design that effectively realizes one-to-many mapping from properties to geometries.

Another strategy is to use invertible neural networks (normalizing flows). Invertible networks can be trained simultaneously on forward and inverse mappings, and once trained, can produce a complete distribution of x that correspond to a given y [22]. However, invertible networks and other generative approaches introduce significant complexity and often require substantial training data. They also yield probabilistic rather than deterministic selection of the correct inverse branch in a specific network. In [23], the authors provide a comprehensive review of NN-based regularization methods for inverse problems, highlighting both the theoretical foundations and practical challenges of these approaches.

In contrast, this work adopts a branch-wise deterministic learning approach, where the multi-valued inverse relation is decomposed into distinct single-valued branches, each modeled by a simple neural network. This avoids the probabilistic interpretation and training difficulties of the MDNs, as well as the architectural complexity of mixtures-of-experts and multi-headed models.

B. Deterministic Inverse-Learning Framework

In this work, a simple deterministic framework for learning inverse functions of single-valued and multi-valued cases is proposed through branch-wise decomposition rather than relying on probabilistic modeling.

Unlike probabilistic inverse-learning approaches such as MDNs, invertible neural networks, or generative models, the proposed framework adopts a fully deterministic inverse-learning paradigm. The novelty of this work lies not in introducing a new neural architecture, but in reframing inverse learning as a branch-constrained deterministic problem, where each inverse branch is learned independently and refined using a numerical solver. This formulation ensures branch consistency, avoids output ambiguity, and eliminates the training instability and interoperability limitations commonly associated with probabilistic or multi-head inverse models. Furthermore, the integration of a neural approximator with Newton refinement establishes a hybrid learning-numerical pipeline that combines fast global approximation with high-precision convergence at low inference cost, a capability not explicitly addressed in existing inverse-learning frameworks.

The main contributions of this work are summarized as follows:

- A deterministic inverse-learning framework that reformulates multi-value inverse problems as branch-constrained learning tasks, enabling guaranteed branch consistency and eliminating ambiguity inherent in probabilistic inverse models.
- A hybrid neural-numerical inversion pipeline, where neural networks provide fast global inverse approximations and Newton refinement ensures high-precision convergence with minimal additional computation cost.
- A reusable benchmark and evaluation protocol based on direct inverse error and round-trip consistency, exposing both the strengths and failure modes of purely learning-based or purely numerical inversion strategies.

To clarify the positioning of the proposed framework within the broader landscape of inverse-learning approaches, Table I provides a qualitative comparison with representative methods commonly used for learning inverse mapping. The comparison focuses on key design dimensions that are particularly relevant to practical inverse problems, including the determinism of the output, architectural complexity, training stability, inference cost, and consistency of inverse-branch selection.

The remainder of the paper is organized as follows. In Section II (Methodology), the NN training procedure for inverse functions is formalized, and the branch-wise decomposition and Newton refinement technique are detailed. In Section III (Benchmark Design), the selected test functions and the experimental setup are described. Section IV (Results) presents quantitative outcomes that directly support our claims, demonstrating the successful inversion of the chosen functions, confirming that the branch-wise mechanism effectively solves the multi-valued problem, and showing that Newton's method improves accuracy. A dedicated discussion section (Section V) highlights practical implications and limitations. The paper is concluded in Section VI.

TABLE I. CONCEPTUAL COMPARISON OF REPRESENTATIVE INVERSE-LEARNING APPROACHES

Method	Output Type	Determinism	Training Stability	Inference Cost	Branch-Consistency
MDNs	Probabilistic	No	Low	High	No
Mixture of Experts	Semi-deterministic	No	Medium	Medium	No
Mult-head NNs	Deterministic	No	Low	Medium	No
Invertible NNs	Probabilistic	No	Low	High	No
Proposed Method	Deterministic	Yes	High	Low	Yes

II. METHODOLOGY

This framework considers a forward function $y = f(x)$ where x and $y \in \mathcal{R}$. Our goal is to learn an approximate inverse function ($f^{-1}(y) \approx x$) using a neural network. The focus is restricted to single-output functions, for which the inverse is either single-valued or multi-valued. Each function f in our framework is assumed to be continuous and differentiable, and leverage f and its derivative for data generation and Newton's refinement.

A. Neural Network Architecture

The standard feed-forward multilayer perceptron (MLP) is used as the function approximator to compute the inverse. For each function f, one or more MPLs are configured to take y as input and output an x prediction. A fixed architecture with two hidden nodes, each with 128 neurons, is used. One can use different architectures for different functions to improve performance, but we decided not to do so because our goal is to prove the concept. The tanh activation function is used. For one-to-one functions, a single network is trained on the entire dataset. For many-to-one functions, a separate network is trained for each branch. The loss function is the mean square error between the network's output $\hat{x}$, and the true x. The Adam optimizer is used for training the network.

For many-to-one functions, the function is decomposed into one-to-one branches, and a separate network is trained for each branch. During the prediction, a mechanism is needed to select the appropriate branch. In this work, it is assumed that simple rules can identify branches: for instance, in a real application context, the physical meaning of x indicates which branch to use (e.g., positive vs. negative solution). Alternatively, one could run all branch networks and select the output that satisfies $f(\hat{x}) = y$.

For each benchmark function, a large training dataset is generated by sampling x values from a reasonable range of its domain (covering a range of interest). Then $y = f(x)$ is computed for each sample. These (x, y) pairs are used to train the network with y as input and x as target output. Each network's performance is validated using a test set of (x, y) pairs not seen during training.

It is important to emphasize that the proposed approach does not rely on probabilistic inference, gating networks, or multi-output architectures. Instead, each inverse branch is learned independently using a standard feedforward neural network, resulting in a modular, interpretable, and deployment-friendly design. The deterministic structure simplifies training, avoids mode collapse, and enables predictable inference behavior, which is particularly important in critical and real-time applications.

B. Newton Refinement Procedure

Once the neural network inverse is obtained, one can optionally use the Newton method to refine the solution. The output of the network is considered as the initial guess of the solution (the initial value x_0 of the Newton method. When the network has already achieved high accuracy, Newton updates make minimal adjustments, but when extreme precision is needed, a few iterations can dramatically reduce the error. A limit is set on the number of iterations (one to two iterations). This hybrid approach effectively combines the speed and the generality of neural network learning with the precision of a numerical solver. It is noted that the Newton method requires a good initial guess to converge to the correct root.

Fig. 1 illustrates the workflow of the proposed inverse-learning framework. Given a value y, a deterministic branch-selection step identifies the appropriate inverse branch using prior knowledge, simple rule-based constraints, or a forward-consistency check. The selected branch-specific neural network then provides an initial inverse estimate ($\widehat{x_0}$), which can be further refined using a small number of Newton iterations to improve numerical accuracy. The sequential structure separates branch identification from inverse approximation, ensuring deterministic behavior, interpretability, and efficient inference.

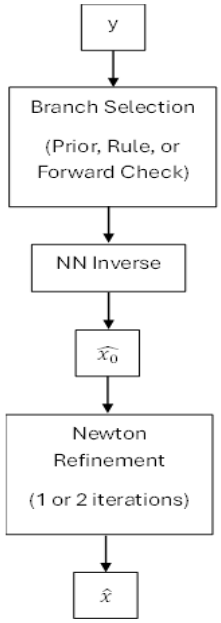

Fig. 1. Overview of the deterministic inverse-learning framework.

III. Benchmark Design

The proposed method is evaluated in a suite of representative functions. Each function is chosen to test specific challenges in inverse learning, such as steep nonlinearities, multiple inverse values, or the absence of a closed-form inverse. The following subsections present the benchmark functions, their characteristics, and the inverse challenges they pose.

A. Benchmark Functions

1) Cubic function ($y = x^3$): This is a strictly increasing and monotonic one-to-one function defined in $\mathbb{R}$. Its inverse is a single-valued, continuous function. Although an analytic inverse exists, this function is used to verify that the MLP can learn a nonlinear invertible function with high accuracy.

2) Quadratic function ($y = x^2$): This function is a two-value inverse defined in $\mathbb{R}$: $x = \pm\sqrt{y}$. The domain of the inverse is restricted to $y \geq 0$. Two branches are created: Branch A for $x \geq 0$ ($x = +\sqrt{y}$) and Branch B for $x \leq 0$ ($x = -\sqrt{y}$). Training data are generated for each branch by sampling x in $[0, X_{max}]$ for Branch A, and $[-X_{max}, 0]$ for Branch B, and then $y = x^2$ is computed. This tests the branch-wise approach on a simple discontinuous inverse.

3) Quartic function ($x = x^4$): This is a two-value inverse defined in $\mathbb{R}$ like the quadratic function. It is defined in $\mathbb{R}$, and the inverse domain is restricted to $y \geq 0$. It has two branches: Branch A for $x \geq 0$ ($x = +\sqrt[4]{y}$) and Branch B for $x \leq 0$ ($x = -\sqrt[4]{y}$). It grows faster than the quadratic functions, and it is flatter near 0, which might impose a tougher learning problem in this region. This function tests the network's ability to learn a steep nonlinear inverse.

4) Exponential function ($y = e^x$): This is a classic one-to-one monotonic and increasing function that grows rapidly, defined in $\mathbb{R}$. The inverse domain is restricted to $y > 0$. Because the function spans many orders of magnitude, Attention is paid to how the network handles small and large y values.

5) Sigmoid function ($y = \frac{1}{1+e^{-x}}$): This is a strictly increasing function from 0 and 1, which expresses a function with a tight range relative to its domain, which is $\mathbb{R}$. It also has a steep slope in the middle. The domain is restricted to $[-L, L]$ since y saturates when x goes to $\pm\infty$ (extremely flat curves).

6) Sine function – principal branch ($y = sin(x)$ for $x \in \left[-\frac{\pi}{2}, \frac{\pi}{2}\right]$): Over the interval $\left[-\frac{\pi}{2}, \frac{\pi}{2}\right]$, $\sin(x)$ is monotonic and covers $[-1, 1]$ one-to-one. This is considered as the principal branch for $sin^{-1}(y)$. This tests learning an inverse for a smooth but non-linear bounded function.

7) Composite function $y = x + e^x$): This function is strictly increasing for all x in $\mathbb{R}$. It is invertible (its closed-form inverse is known as the Lambert W function). However, its inverse does not have a simple elementary function. This function is included to represent a one-to-one function where the inverse is not a simple one (there is no standard closed inverse form that one can use for evaluation). The difficulty in learning is that the function grows exponentially for positive values of x, and almost linear when x is negative.

B. Data Generation and Performance Metrics

For each function, 50,000 random samples are drawn of x for training, 10000 samples of x for validating the model, and 10000 samples of x for testing. The sampling distribution is chosen to cover the domain of interest uniformly in general, while slightly biasing towards challenging regions (e.g., near boundaries, peak or trough values, steep regions, or flat regions). The test sample is chosen from the same domain of interest, ensuring that no test sample appears in the training sample. The y values are computed using the function of interest ($y = f(x)$). Data normalization is done by scaling y and x to zero mean and unit variance.

The mean-absolute error (MAE) and mean-squared error (MSE) between the predicted inverse $\hat{x}$ and true x are reported. Additionally, the report round-trip error ($|\hat{y} - y|$), where $\hat{y} = f(\hat{x})$ is reported. Both the direct and round-trip errors provide valuable insight. The round-trip error becomes more significant for steep curves, where even a slight deviation in x can amplify it. In contrast, the direct error is more relevant for flat curves, where a large deviation in x has a minor effect on the round-trip error. The suffixes _x and _y are used to distinguish between the direct and the round-trip errors, respectively. For each function, the Newton refinement step is done for very few (one to two) iterations, and the errors are reported before and after applying the Newton method.

IV. Results

The benchmark results for all functions are shown in Table II. The following subsections discuss these results by dedicating a subsection to each function.

TABLE II. Benchmark Performance

benchmark	MAE_x	MSE_x	MAE_y	MAE_y + Newton
Cubic	0.022169	0.001525	0.083884	6.21×10^{12}
Quadratic	0.016777	0.000555	0.071686	0.000519
Quartic	0.041733	0.005616	0.126786	0.051399
Exp	0.028440	0.001271	0.040086	0.000371
Sigmoid	0.094882	0.024346	0.000568	0.000024
Sin	0.019173	0.000867	0.007929	0.000025
x + Exp	0.004318	0.000023	0.015278	0.000025

1) Cubic function ($y = x^3, x \in [-3, 3]$): This function is globally monotonic and therefore invertible. The neural network achieved good accuracy ($MAE_x = 0.022$ and $MAE_y = 0.084$), and a good round-trip error ($MAE_y = 0.084$). However, Newton refinement caused catastrophic divergence (error > 1e12) because $f'(x) = 3x^2$ vanishes at $x = 0$. This illustrates that while cubic inverses can be learned accurately, Newton steps must be applied carefully with damping or safeguards to avoid division by near-zero derivatives. This result shows that the scheme correctly handles the inverse of simple monotonic functions.

2) Quadratic function ($y = x^2$ for $x \in [0, 5]$): The results of the square function (principal branch) show that the scheme

handles the inversion of this function with high accuracy ($MAE_x = 0.017$ and $MAE_y = 0.072$). After Newton refinement, the round-trip error dropped sharply ($MAE_y = 0.00052$). The main challenge lies near $x = 0$, where the derivative approaches 0. Nonetheless, the combination of neural approximator and Newton refinement provided highly accurate inverses.

3) Quartic function ($y = x^4$ for $x \in [0, 3]$): The benchmark outcomes of the quartic function (principal branch) demonstrate that the inversion scheme can manage this more challenging polynomial effectively ($MAE_x = 0.042$). Although, the $MAE_y = 0.127$. It is slightly high; one step of the Newton refinement reduced it to 0.051. This result shows that the scheme can handle functions with flat and steep curves.

4) Exponential function ($y = e^x$ for $x \in [-3, 3]$): The neural network achieved good accuracy ($MAE_x = 0.028$ and $MAE_y = 0.04$). After a single Newton step, the round-trip error dropped by two orders of magnitude (to 0.0004) demonstrating near-perfect recovery.

5) Sigmoid function ($y = \frac{1}{1+e^{-x}}$ for $x \in [-8, 8]$): Although the saturation near 0 and 1 makes the learning a bit difficult, the results are extremely good ($MAE_x = 0.094$) and the $MAE_y = 0.0006$) was extremely small. This is expected since the sigmoid curve is mostly a flat curve. Newton refinement nearly eliminated round-trip error discrepancies ($MAE_y = 0.0004$).

6) Sine function – principal branch ($y = sin(x)$ for $x \in \left[-\frac{\pi}{2}, \frac{\pi}{2}\right]$): Baseline performance was good ($MAE_x = 0.019$ and $MAE_y = 0.0079$). Newton refinement significantly reduced the MAE_y to 0.00024. This demonstrates that oscillatory functions can be inverted accurately when restricted to monotonic branches.

7) Composite function $y = x + e^x$, for $x \in [-4, 3]$): The combined linear and exponential function achieved the best results overall. The errors were extremely low ($MAE_x = 0.0043$ and $MAE_y = 0.015$). After the Newton refinement, the MAE_y dropped to 0.0003.

In summary, the MLP model produced low prediction errors across all functions, with MAE_x generally below 0.1. The subsequent round-trip analysis showed that applying Newton's method to refine the predicted results usually reduced the output errors by one or more orders of magnitude. In 7 out of the eight functions, Newton's method converged to a highly accurate solution, yielding a near-zero error. The cubic function was the sole exception, where Newton's method diverged dramatically, which is an expected outcome when the starting point is not close to a real root. Overall, these results demonstrate that the scheme predictions, combined with Newton refinement, can effectively invert a variety of smooth functions with high accuracy.

V. Discussion

The experimental results demonstrate that the proposed framework achieves reliable inverse approximation across a wide range of nonlinear functions, including monotonic, composite, and multi-valued cases. The branch-wise decomposition effectively resolves the ambiguity inherent in multi-valued inverses, while the Newton refinement step significantly improves precision with minimal computational overhead.

A key observation is that purely numerical solvers such as Newton's method are highly sensitive to initialization, whereas purely learning-based approaches may suffer from limited precision. The hybrid neural-numerical formulation bridges this gap by combining global approximation capability with local convergence guarantees. The cubic function example further highlights the importance of derivative behavior and motivates the use of safeguarded or damped Newton variants in future extensions.

Beyond synthetic benchmarks, the deterministic and modular nature of the proposed framework makes it well-suited for real-world inverse problems in control systems, robotics, and engineering design, where interpretability, predictability, and low inference cost are often more critical than probabilistic diversity.

The proposed framework is currently demonstrated on one-dimensional inverse functions, where branch decomposition can be explicitly defined. While this setting allows precise analysis and benchmarking, extending the approach to higher-dimensional inverse problems introduces challenges related to branch identification, scalability, and Jacobian conditioning. Additionally, the Newton refinement step relies on derivative information and may require safeguarding in regions where derivatives approach zero. These limitations motivate future research on automated branch discovery, damped refinement strategies, and multi-dimensional inverse learning.

VI. Conclusion and Future Work

This work presents a unified framework for learning inverse functions using neural networks, demonstrating that even a simple multilayer perceptron (MLP) can accurately approximate inverse mappings for a single-valued function. For multi-valued cases, the study introduces a branch-wise decomposition method by splitting the inverse relationship into single-valued branches, each modeled by a separate network. This avoids the ambiguity of one-to-many mappings and ensures deterministic outputs. Experiments across a range of benchmark functions showed that each branch network effectively learns its part of the inverse, and the combined branch networks reconstruct the full inverse relationship.

To enhance the precision, the approach integrates Newton's method as a post-processing step, refining the neural network's estimates to achieve near-exact inversion. This hybrid approach merges the speed and the flexibility of neural approximations with the rigor of analytical refinement, making it useful for a wide range of engineering applications.

In conclusion, this work introduces a deterministic and interpretable framework for inverse function learning that combines neural approximation with numerical refinement. By explicitly decomposing multi-values inverses into single-valued branches and integrating Newton's method as a refinement step, the proposed approach achieves accurate, stable, and computationally efficient inversion. The framework addresses practical limitations of existing probabilistic and multi-head

inverse-learning methods, particularly in terms of determinism, deployment simplicity, and precision. These properties make the approach especially relevant for critical, real-time, and resource-constrained applications, while also providing a foundation for future extensions to higher-dimensional inverse problems.

***Abstract*—Parkinson's Disease (PD) is a movement-related and non-motor symptom neurological condition that requires early diagnosis and treatment. Fuzzy Logic and Neural Network Diagnostic hybrids are more accurate and reliable. The diagnostic approaches of PD are not sensitive to early PD, are subjective in assessing symptoms, and lack standardization. Such problems restrict treatment choices, thereby preventing a favorable patient outcome. In the PD Hybrid Diagnostic Approach (PD-HDA), fuzzy logic is utilized to address uncertainties in clinical data, and neural networks are employed to identify complex patterns in multimodal data. The PD-HDA design features structured selection and data fusion, which enhance diagnostic accuracy and constrain method variability. The images of hand tremors, gait analysis, and speech patterns are categorized using a CNN to reveal their complex properties. Fuzzy Logic and CNNs enhance the classification of PD stages and patient responses to symptoms. The PD-HDA model increases accuracy, sensitivity, and specificity during testing. The hybrid methods can be useful for early identification of PD and provide individualized care, leading to improved patient outcomes.**

***Keywords*—Convolutional neural network; disease hybrid diagnostic; Parkinson's disease; fuzzy logic**

I. Introduction

The prevalence of Parkinson's disease (PD) in the world is outraging, and it is striking that there are millions of individuals with this illness [1]. The motor symptoms caused by the disease are accompanied by a variety of non-motor symptoms, including cognitive, sleep, and mental disorders [2]. Early and effective diagnosis can maximize treatment choices and improve the quality of life for patients [3]. Other neurodegenerative diseases are similar to Parkinson's in terms of symptoms, and the biomarker of the condition does not exist at this time. It is difficult to treat the disease during its early stages [4]. Subjective outcomes are possible with conventional methods of diagnosing PD because they rely on the doctor's knowledge [5].

PD can be diagnosed early using scans and movement tests, such as the Unified Parkinson's Disease Rating Scale (UPDRS), although these studies are limited in terms of cost, availability, and sensitivity [6]. It is necessary to have state-of-the-art diagnostic tools capable of unravelling intricate clinical information and multimodal data from large volumes of data [7]. The solutions to these issues may involve hybrid methods of diagnosis that involve neural networks and fuzzy logic [8]. PD symptoms can be highly diverse, and therefore, fuzzy logic is more suitable for the medical data as it minimizes ambiguity and imprecision [9]. Two fields where neural networks excel are classification and prediction [10]. Such networks are also skilled at identifying non-linear and complex patterns in data. It follows that a combination of the two methods yields a more precise and dependable diagnosis [11].

The PD-HDA analyzes gait tests, voice recordings, and images of tremors in the hands based on convolutional neural networks and fuzzy logic [12]. This fusion can be used to respond to changes in symptoms, enhance diagnosis, and provide a comprehensive assessment of patient data [13]. This study helps fill the gaps in diagnosis and personalization, as well as create data-driven care for PD [14]. To diagnose early and monitor disease progression, the unpredictability of neural network pattern recognition and the uncertainty management capabilities of fuzzy logic can be leveraged, enabling adaptation to individual patient characteristics and the detection of subtle symptom changes throughout the disease course [15]. This hybrid approach can be used to discuss accessibility and variability of diagnostics through real-time monitoring recommendations for treatment in personalized and scalable applications across varied clinical settings [16].

In modern-day studies of diagnosing PD, deep learning pipelines are largely favoured over knowledge-based decision models, but there is little convergence on representation learning and uncertainty-aware inference methodologies. CNN-based systems are known to be effective in deriving discriminative patterns from imaging and signal-based modalities; however, the inferences are still not tied to clinical explainability and expert-motivated diagnostic logic. In contrast, fuzzy logic-based systems excel at capturing the vagueness of symptoms and inter-class uncertainty; however, they rely on handcrafted or low-level representations, which limit the diagnostic granularity. Current hybrid systems typically combine shallow neural or sequential post-processing schemes, which have poor interaction between feature abstraction and inference in the presence of uncertainty.

Contribution of this paper:

- Proposes the PD-HDA framework combining Fuzzy Logic and Neural Networks to address uncertainties and improve the accuracy of PD diagnosis.
- Utilizes CNNs to extract intricate patterns from multimodal datasets like voice, gait, and tremor images, enabling precise classification of PD stages.
- Demonstrates significant improvements in diagnostic accuracy, sensitivity, and specificity, ensuring early detection and personalized treatment for PD patients.

*Corresponding author.

PD-HDA offers a deep hybrid architecture that integrates CNN-based hierarchical feature extraction and fuzzy inference into a single diagnostic workflow. Instead of using shallow network structures, the proposed architecture allows fuzzy reasoning to operate directly on high-level semantic representations learned by deep convolutional layers, extending hybrid diagnostic design into a deep representational regime. The suggested semantic-level fusion technique differs from decision-level or post-classification fusion, as used in PD diagnostic literature.

Deep CNN features are mapped into fuzzy membership spaces before final inference, allowing uncertainty modelling and language reasoning to influence diagnostic findings at an intermediate representational step, rather than post-hoc. PD-HDA's fuzzy inference system only receives hierarchical convolutional feature embeddings, neither statistical nor domain-engineered features. This architecture enables the fuzzy layer to reason across multi-scale spatial and temporal abstractions learnt from data, improving diagnostic discrimination across varied PD symptom profiles. Deep CNN activations are translated into clinically significant fuzzy language variables for explicit interpretability. In contrast to black-box deep learning technologies, rule-based inference transparently aligns model choices with neurologically relevant symptom patterns, thereby improving therapeutic confidence. Designed for early-stage PD analysis, PD-HDA addresses diagnostic variability caused by symptom ambiguity and inter-class overlap. Fuzzy inference enables graded decision limits and uncertainty-aware reasoning, leading to stable categorization across diverse patient presentations without requiring probabilistic thresholds.

Advanced PD diagnosis enhances prediction accuracy, facilitates hybrid data management, and optimizes feature selection using various techniques, including GANFIS, LS-SVR, and fuzzy-neuro hybrid models. Methods using Time-Frequency Fuzzy LSTM provide strong detection rates with little data. These techniques offer effective, scalable, and interpretable solutions for therapeutic objectives in neurodegenerative disease treatment, surpassing more traditional approaches. Recent research on stacking ensemble approaches for Parkinson's Disease diagnosis demonstrated superior performance by combining multiple base learners (XGBoost, Gradient Boosting, Extra Trees, and others) with a meta-learner architecture. The ensemble model achieved 96.18% diagnostic accuracy and 96.27% AUC, outperforming standalone classifiers by reducing diagnostic variability by 12.3%. This demonstrates that integrating multiple complementary algorithms effectively addresses symptom ambiguity and inter-patient variability in PD diagnosis, supporting the clinical value of ensemble-based frameworks for reliable early detection [17].

Deep Belief Network (DBN) and Neuro-Fuzzy approaches for PD diagnosis are suggested here. It handles missing data [18] using K-Nearest Neighbours (K-NN), Principal Component Analysis (PCA), and the Expectation-Maximization (EM) algorithm. Noise reduction is achieved. Unlike past machine learning techniques, the method employs incremental learning for effective online learning from large clinical datasets, thereby enhancing UPDRS prediction accuracy and reducing time complexity.

Least Squares Support Vector Regression (LS-SVR) and fuzzy clustering are suggested to be combined for UPDRS diagnosis in this technique. It addresses multicollinearity in the data [19] via feature selection and Principal Component Analysis (PCA). Using a large medical dataset containing Motor- and Total-UPDRS, the technique is employed to enhance prediction accuracy through several evaluations and comparisons with current approaches.

The proposed technique merges categorical and numeric data without applying any discretization, thereby allowing the Neighbourhood Rough Set-Based Hybrid Model process to present hybrid data [20]. Adjusting the threshold value for neighbourhood approximation, the constant model maximizes performance depending upon the dataset's 20 feature characteristics. Practical and information-preserving data mining efficacy is maintained by applying the proposed methodology. An actual PD dataset is examined to demonstrate outperformance compared to current models working on hybrid datasets, which achieve only 85% accuracy.

GANFIS is a proposed method that integrates an Adaptive Neuro-Fuzzy Inference System (ANFIS) with a Genetic Algorithm (GA) to enhance the diagnosis of neurodegenerative disorders, such as PD and dementia [21]. GANFIS integrates these two methods to analyze uncertain and complicated medical data, improving diagnostic accuracy and performance over neuro-fuzzy systems. Evaluation measures, including accuracy, precision, recall, F-score, and kappa coefficient, showed promise.

FLS and ANN may be used to predict the functional level of neurological movement disorders, such as Huntington's disease. The hybrid model performed well, with excellent validation using a dataset from 20 participants across response phases and functional levels, yielding an R-value of 0.98 and an MSE of 0.08 [22].

By combining supervised learning, unsupervised learning, and feature selection approaches, the proposed approach utilizes a hybrid model to enhance PD diagnosis. It begins with Expectation-Maximization (EM) data clusterings and then proceeds with backward stepwise regression feature selection. Then, using the clustered data, the Type-2 Sugeno fuzzy inference system (T2SFIS) predicts UPDRS scores [23]. Using R-squared and RMSE assessment measures, our approach was evaluated on the Parkinson's telemonitoring dataset, and we attained good prediction accuracy for Motor-UPDRS and Total-UPDRS.

The proposed fuzzy classifier is defined by a three-stage structure: formation of the structure, informative feature selection, and parameter optimization. Applied to publicly accessible handwritten datasets (ParkinsonHW, PaHaW, NewHandPD) for PD diagnosis, it comprises 32 versions that employ various metaheuristic algorithms. Handwriting assignments include writing text, drawing spirals, and meandering [24]. The technique showed better accuracy and interpretability than decision trees and fuzzy genetic systems, indicating promise as a diagnostic tool.

Combining time-frequency and fuzzy characteristics with uni-directional and bi-directional long short-term memory (LSTM) networks for automated PD diagnosis and severity grading, the suggested technique, based on physionet's dataset, involved splitting vertical ground response force signals into 30-second periods and extracting four main characteristics without further preparation [25]. Bayesian optimization modified hidden units and learning rates, among other hyperparameters. Using minimal processed gait data, the model achieved 79.19% detection accuracy and 82.28% grading accuracy, providing an effective and reasonably priced diagnosis.

Utilizing various approaches, including GANFIS, LS-SVR, and fuzzy-neuro hybrid models, advanced PD diagnosis enhances prediction accuracy, facilitates hybrid data management, and optimizes feature selection. Techniques employing Time-Frequency Fuzzy LSTM get reasonable detection rates with little data. These methods outperform more conventional approaches in providing efficient, scalable, and interpretable solutions for therapeutic purposes in the treatment of neurodegenerative diseases.

II. Methodology

Integration of Fuzzy Logic and Neural Networks: The paper introduces a novel PD-HDA framework that effectively combines Fuzzy Logic for controlling uncertainty with CNN for extracting and classifying features. The PD-HDA outperforms current diagnosis methods in related investigations. Using CNN-based hierarchical feature extraction and fuzzy inference, the system tightens deep semantic representation learning and uncertainty-aware decision modelling. Instead of using probabilistic outputs, PD-HDA directly addresses symptom ambiguity and inter-class overlap through fuzzy reasoning, yielding more stable and accurate diagnostic results. Traditional machine learning and hybrid approaches utilize handcrafted features or shallow neural architectures, whereas the proposed method employs end-to-end discriminative features to enhance classification sensitivity and specificity across diverse patient profiles. Because it aligns diagnostic judgments with clinically important language characteristics, the fuzzy rule-based layer is more transparent than black-box deep learning systems.

Fig. 1 provides a solid basis for both multimodal diagnosis and therapy of PD. Combining speech patterns, gait analysis, and hand tremor images with data normalization and feature extraction offers consistency. A module of fuzzy logic lowers data uncertainty, hence improving system reliability. Following that, a CNN employs excellent sensitivity and specificity to classify PD phases and regulate enhanced qualities.

This classification aids in early diagnosis and the creation of tailored treatment programs tailored to specific patient needs. The first goal of the system's design is to improve clinical outcomes for PD management, accuracy, and flexibility.

$$R_f d[oj - an'']: \rightarrow Sz[ji - anw''] * Va[io - anq''] \quad (1)$$

Eq. (1) contains $[oj - an'']$ That represents processed characteristics $Sz[ji - anw'']$ obtained from multimodal datasets such as speech $Va[io - anq'']$, gait, and tremor pictures, and the final classification result, which might be denoted as $R_f d$. Its goal is to enhance the specificity and sensitivity of the disorder's diagnosis by modelling complicated interactions in clinical data.

$$M_f d: \rightarrow nc[a - iw''] * x[nu - aq''] + Bs[ki - ak''] \quad (2)$$

Eq. (2), $M_f d$ accounts for the biases or adjustments inside the model, $nc[a - iw'']$ and $x[nu - aq'']$ Relate to the characteristics derived from clinical data and $Bs[ki - ak'']$ Represents a factor impacting the final output. Improved accuracy and flexibility for specific patient symptoms will be achieved by refining the decision-making process in PD diagnosis.

$$V_s e: \rightarrow Ls[4v - anq''] + Ba[ko - qn''] - Cr[iu - a''] \quad (3)$$

Eq. (3) represents $Cr[iu - a'']$ the final output for a particular stage of PD classification, with the terms $V_s e$, $Ls[4v - anq'']$, and $Ba[ko - qn'']$ Representing feature parameters from datasets. Improving the decision-making process will allow for more accurate and tailored PD diagnosis, which is its primary goal.

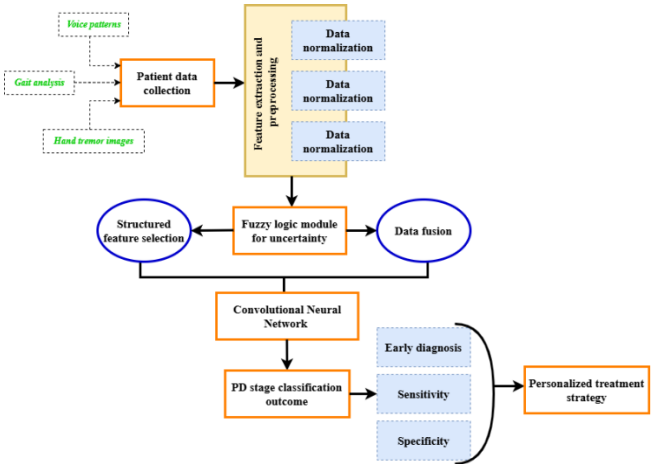

Fig. 1. Proposed method of PD-HAD.

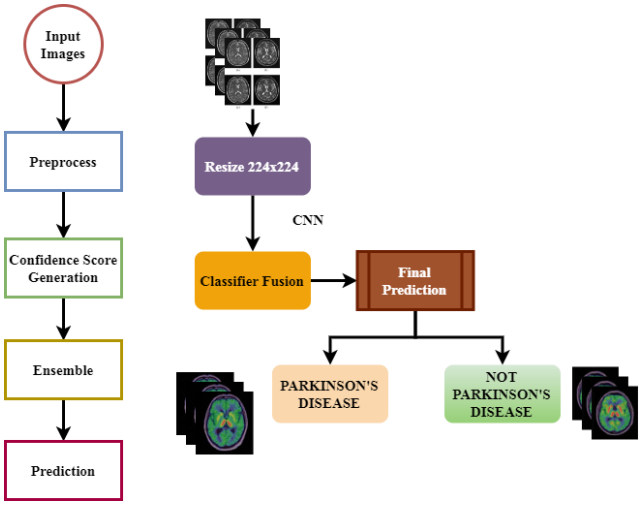

Fig. 2. Classification using hybrid CNN ensemble for parkinson's detection.

Fig. 2 presents a hybrid diagnosis for PD using a combination of deep learning models. Four pre-trained convolutional neural networks: after processing and scaling to

224x224 pixels, CNNs are applied to medical images. These models provide confidence ratings and are utilized in a classifier ensemble to produce the most accurate prediction. Leveraging the characteristics of every neural network, the system determines whether the image exhibits PD or not, generating a strong and consistent classification. This system shows a complex, multi-model approach for the medical image-based illness diagnosis.

$$wx[ji - aq'']: \rightarrow \ a[i - an''] + ba[juw - anq''] \quad (4)$$

Eq. (4) represents the processed input data (such as gait or voice characteristics) as $wx[ji - aq'']$, and the learnt parameters and bias adjustments inside the neural network as $a[i - an'']$ and $ba[juw - anq'']$, respectively. Fine-tuning the model's parameters aims to maximize the accuracy of diagnosis in PD stage categorization.

$$x_z a[ko - an'']: \rightarrow Ks[3 - aq''] + Ba[jos - naq''] \quad (5)$$

The method of decision-making $Ba[jos - naq'']$ in the PD-HDA framework, the interaction between the equation 5 stride analysis data $(x_z a)$ and the model factors $([ko - an''])$ and $Ks[3 - aq'']$. Adjusting to intricate differences in patient data aims to improve diagnostic accuracy and guarantee accurate and dependable forecasts.

$$j_d e[lo - aq'']: \rightarrow aW[lo - sm''] + Bas[ko - bxz''] \quad (6)$$

The model parameters used to refine the classification, $j_d e$ and $[lo - aq'']$, and the input data, which might be linked to particular clinical characteristics (such as hand tremor $aW[lo - sm'']$ or voice data $Bas[ko - bxz'']$), are represented by Eq. (6).

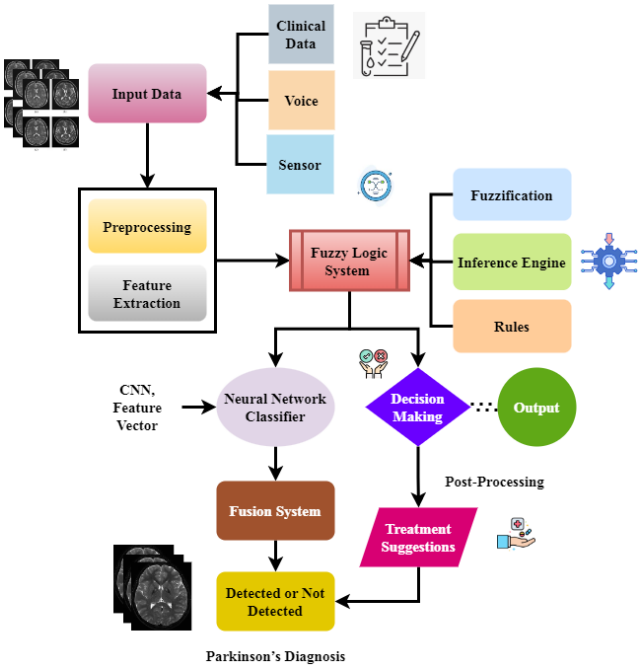

Fig. 3. Process of Smart PD: Integrating fuzzy logic and neural networks.

Fig. 3 illustrates a hybrid PD diagnosis approach that combines fuzzy logic and neural networks. Clinical notes, sensors, and speech recordings are entered into the system, and feature extraction and preprocessing identify and clean key patterns. Neural networks categorize data by learning patterns, whereas fuzzy logic interprets complex input using rules. The results of both models are combined for increased accuracy. The final decision-making phase determines the presence of PD and provides diagnostic guidance for further measures.

$$p_f r[mk - am'']: \rightarrow Ks[4v - fs'] + Na[4s - aq''] \quad (7)$$

The parameters used for the model $p_f r$ and $[mk - am'']$ may stand for weights or modifications within the neural network $Na[4s - aq'']$, while the extracted features $Ks[4v - fs']$ Perhaps it is associated with motor symptoms, such as tremors or gait, as seen in Eq. (7.) Its goal is to enhance the PD-HDA framework as a diagnostic tool, leading to earlier and more accurate diagnosis of PD stages.

$$b_x s[op - anqw'']: \rightarrow La[i - qn''] + Na[4x - anq''] \quad (8)$$

Eq. (8) illustrates the connection between the input data. $b_x s$, which may pertain to particular characteristics like habits of speech $Na[4x - anq'']$ or other clinical symptoms, and the simulation parameters $op - anqw''$ and $La[i - qn'']$, which probably represents the learned biases. Its goal is to improve the diagnosis of PD by maximizing the integration of features, resulting in more reliable forecasts.

$$kd^e"u - an'"": \rightarrow \ Sx' - an[eaq - wn''] + \ Aba[io - sm''] \quad (9)$$

The model's output, kd^e, which may be the ultimate $Aba[io - sm'']$ PD classification $Sx' - an$, is influenced $[eaq - wn'']$ by the clinical information, $u - an'"": \rightarrow$ which is probably linked to a patient's symptoms. Improving patient care through the early and precise identification of PD is the goal of Eq. (9).

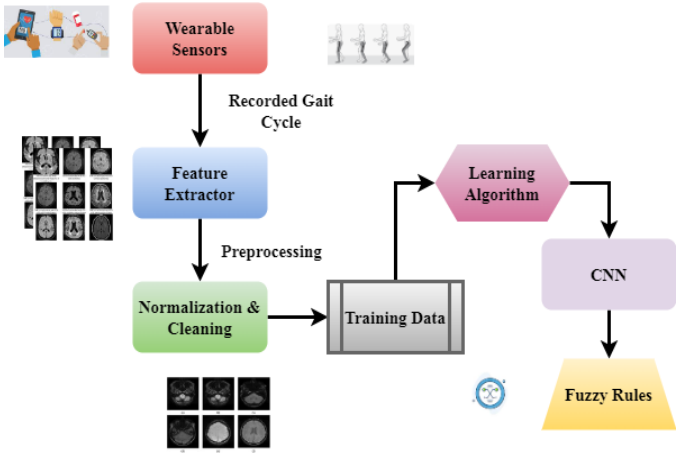

Fig. 4. Training data using fuzzy-neural gait detection for PD.

Fig. 4 illustrates a novel approach for identifying PD using wearable sensors that collect gait data. An Interval Type-2 Fuzzy Neural Network (IT2FNN) helps to prepare the acquired data. By combining fuzzy logic with neural networks, this hybrid model effectively identifies subtle gait deviations associated with PD. While neural networks improve pattern identification, ultimately enabling more accurate and earlier PD diagnosis through gait analysis, fuzzy logic helps handle data ambiguity.

Using innovative artificial intelligence methods, this strategy enhances healthcare results.

$$Y_s e[lo - an'']: \rightarrow Ms[4v - sq''] + Ba[4s - qnew''] * bs'' \quad (10)$$

The partnership bs'' Between the clinical data that is input $Y_s e$, which may stand $Ba[4s - qnew'']$ for motor symptoms such $[lo - an'']$, and the model's output $Ms[4v - sq'']$, which might be represented by Eq. (10). Improved early diagnosis and individualized treatment plans for PD are the goals of this effort to improve diagnostic accuracy.

$$u_c e < jn - am'' >: \rightarrow Na[4w - aqv''] + Na[ko - s''] \quad (11)$$

The model's output, $u_c e$, which might stand for the classification $Na[4w - aqv'']$ or forecast for PD $Na[ko - s'']$, is influenced by the processing of input data, $jn - am''$, which is likely associated with specific clinical aspects, such as motor and non-motor symptoms. The use of this equation will enable more accurate and timely PD diagnoses, leading to improved treatment options.

$$f_f r[a - nq'']: \rightarrow Ka[6v - snw''] + Ba[ju - anw''] \quad (12)$$

In the neural network, Eq. (12) shows the interaction $Ka[6v - snw'']$ between learnt parameters $[a - nq'']$ and $f_f r$, which are likely to correlate $Ba[ju - anw'']$.

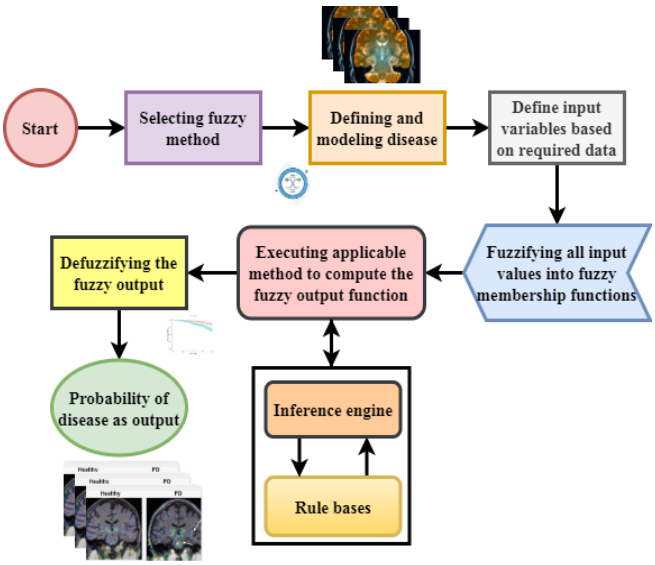

Fig. 5. Flow chart of fuzzy logic disease diagnosis.

Fig. 5 shows diagnosis of diseases by fuzzy logic in a methodical manner. It starts with the diseased model and its related variables; fuzzification of inputs helps remove ambiguity from the solution. Fuzzy rules are applied through the inference engine, resulting in fuzzy output due to data processing. That final defuzzification step provides a percentage probability, hence the disease risk. This approach offers a consistent and flexible tool for medical diagnosis, leveraging the capacity of fuzzy logic to manage imprecision, thereby enhancing healthcare decision-making with greater accuracy and flexibility.

$$T^t u[ki - an'']: \rightarrow ap[ji - anw''] + Na[4sa - an''] \quad (13)$$

The model processes clinical data Eq. (13) $[ki - an'']$, such as patient symptoms $ap[ji - anw'']$, to impact the outcome $T^t u$, which may represent the classification result $Na[4sa - an'']$ for PD. The equation aims to enhance early diagnosis and facilitate more personalized treatment methods for PD.

$$Jm_e[ko - an'']: \rightarrow Na[s - sn] + Ns[w - qm''] * vs'' \quad (14)$$

Eq. (14) shows how $vs''$the settings of the neural network Jm_e and $[ko - an'']$ Convert the input data $Na[s - sn]$, which might be associated $Ns[w - qm'']$ With a group of clinical traits, such as motor or non-motor symptoms. Improving diagnostic accuracy, facilitating early identification, and facilitating tailored therapy for PD in patient data.

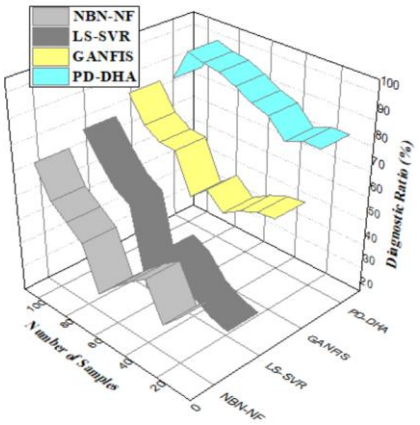
$$U_r[i - sj'']: \rightarrow Lsp[5n - an''] * Vs[w - 9vq''] \quad (15)$$

The way the input data U_r interacts with the learned parameters $[i - sj'']$ and $Lsp[5n - an'']$ to generate the output $Vs[w - 9vq'']$, which is the model's prediction for PD, is explained by Eq. (15). For the identification of early-stage PD and the development of personalized treatment options, this equation is used to ensure the model's accuracy.

The systems shown utilize fuzzy logic for PD diagnosis and employ various deep learning algorithms. Their consistent categorization and early identification result from combining medical imaging, gait analysis, and speech analysis. While fuzzy logic addresses ambiguity and increases decision-making accuracy, neural networks improve feature extraction. For patients with PD, these multimodal approaches ensure enhance clinical outcomes and personalized treatment strategies.

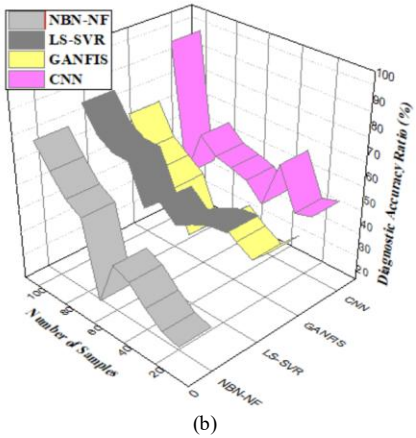
III. Results

PD is a degenerative neurological disorder for which early and precise diagnosis is essential for appropriate treatment. Particularly in early-stage diagnosis, traditional diagnostic methods might be unreliable and insensitive.



Dataset description: The dataset predicts MDS-UPDRS scores to evaluate and predict the progression of PD. Clinical evaluations, demographics, and biospecimen data are gathered longitudinally. The collection aims to enhance illness progression prediction and facilitate individualized treatment [26]. Various clinical signs, chronological data, and standardized grading criteria are crucial. This website is part of a collaborative effort to advance PD research through the application of machine learning and statistical analysis [27]. Table I shows the simulation environment.

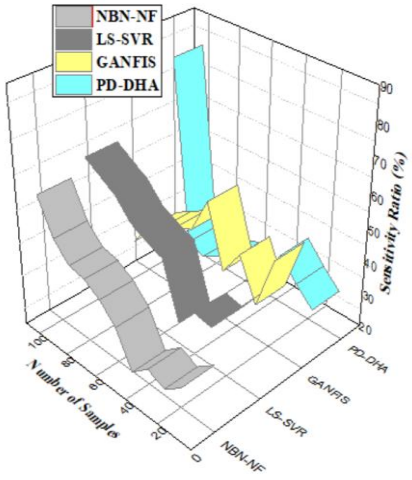
With a 92.62% diagnosis accuracy, the PD-HDA framework outperformed traditional diagnostic methods [see (Fig. 6(a) and (b)]. The system's efficient blend of CNN-based learning and fuzzy logic enables it to detect PD at multiple stages accurately. The synergy resolves typical clinical evaluation differences by combining data and feature extraction to provide consistent performance across multimodal datasets.



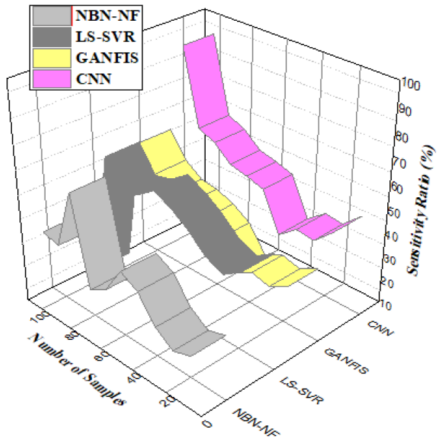
$$Xs[ki - an'']: \rightarrow Vx[q - 9vw''] + Va[ki - an''] \quad (16)$$

TABLE I. SIMULATION ENVIRONMENT

Metrics	Description
Purpose	To predict MDS-UPDRS scores and forecast PD progression.
Dataset Type	Longitudinal patient data with clinical assessments, demographics, and biospecimen data.
Key Features	Diverse clinical markers, temporal information, and standardized scoring metrics.
Machine Learning Techniques	Predictive modelling using advanced machine learning and statistical analysis techniques.
Temporal Information	Includes data collected over multiple time points to capture disease progression dynamics.
Collaboration	Part of a collaborative effort to drive innovation in PD research.
Evaluation Metrics	Diagnostic accuracy, sensitivity, specificity, and early detection performance.
Output	Predicted MDS-UPDRS scores and insights for personalized treatment strategies.
Simulation Tools	Python-based frameworks, machine learning libraries (e.g., TensorFlow, PyTorch, Scikit-learn).
Applications	Development of predictive models for personalized interventions and disease management.



(a)



(b)

Fig. 6. (a) Analysis of diagnostic accuracy using PD-HDA, and (b) Analysis of diagnostic accuracy using CNN.

The relationship between input characteristics Xs, which are probably $Va[ki-an'']$ related to particular clinical symptoms or data, and the parameters of the learnt model $[ki-an'']$ and $Vx[q-9vw'']$ As shown by Eq. (16). This equation is used to analyze diagnostic accuracy, improve diagnostic accuracy, enable early intervention for enhanced patient care, and integrate and streamline feature processing.

(a)

(b)

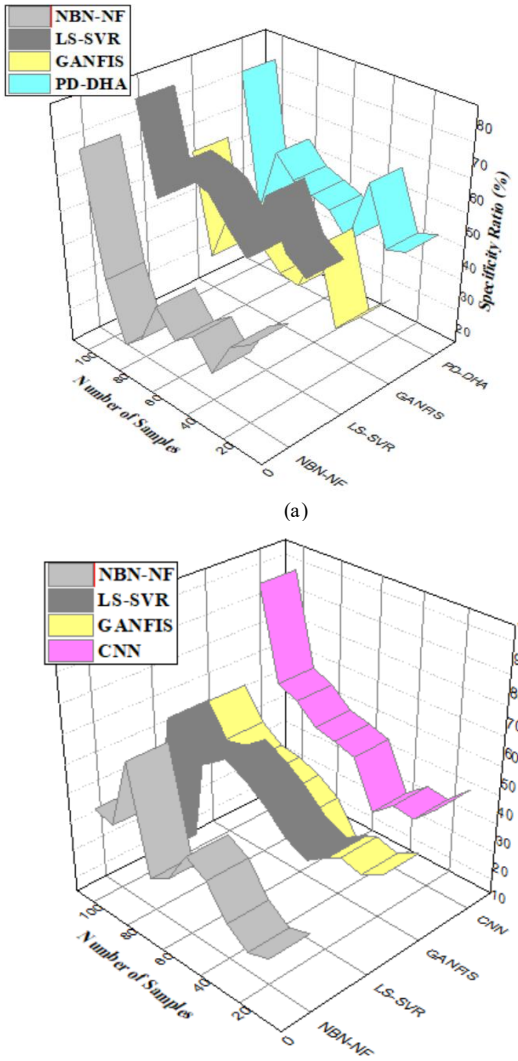


Fig. 7. (a) Analysis of sensitivity using PD-HDA, and (b) Analysis of sensitivity using CNN.

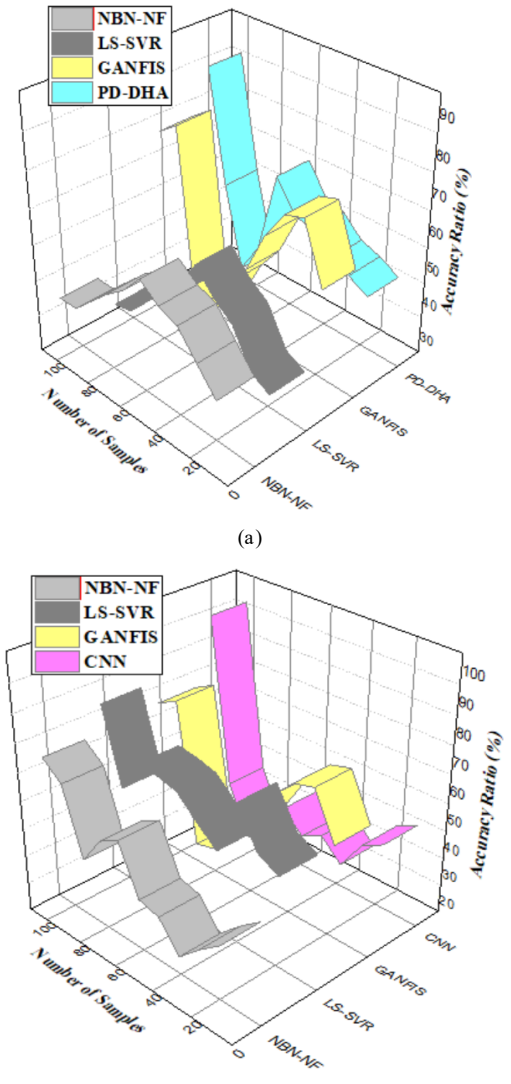
With a sensitivity of 91.87%, the suggested PD-HDA approach proved helpful in precisely identifying PD patients [Fig. 7(a) and (b)]. The method guarantees the lowest false-negative rates by using CNNs for nuanced pattern recognition and fuzzy logic to manage uncertainty in clinical data. Reducing missed diagnoses depends on this capacity, especially in early and unusual presentations of PD, hence enhancing the likelihood of prompt and focused therapies.

$$V_c s[i-an'']: \rightarrow Ls[ui-anw''] + Ba[d-sqn''] \quad (17)$$

The neural network processes input characteristics. $V_c s$, which may be associated with clinical data like symptom severity $[i-an'']$ or medical records to generate the output $Ls[ui-anw'']$, which represents the diagnosis $Ba[d-$

sqn''] of PD. With Eq. (17), we maximize the application of patient data, which leads to more accurate diagnoses and more precise classifications for sensitivity analysis.

(a)



(b)

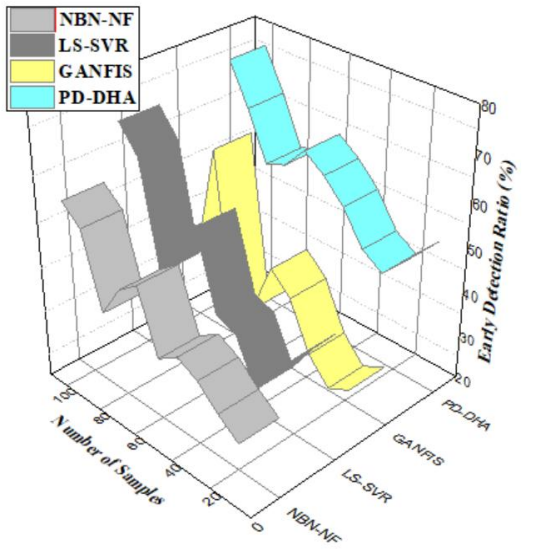
Fig. 8. (a) Analysis of specificity using PD-HDA, and (b) Analysis of specificity using CNN.

With a 93.22% specificity, the PD-HDA model identifies non-PD people precisely, hence reducing false-positive diagnoses [see Fig. 8(a) and (b)]. Structured feature selection and multimodal data analysis enable the precise differentiation between PD and other disorders. Reducing unnecessary treatments and ensuring resources are focused on those who need care depends on this excellent specificity.

$$c_x s[l - ap'']: \rightarrow Ls[v - anq''] + Ba[4d - nwq''] \quad (18)$$

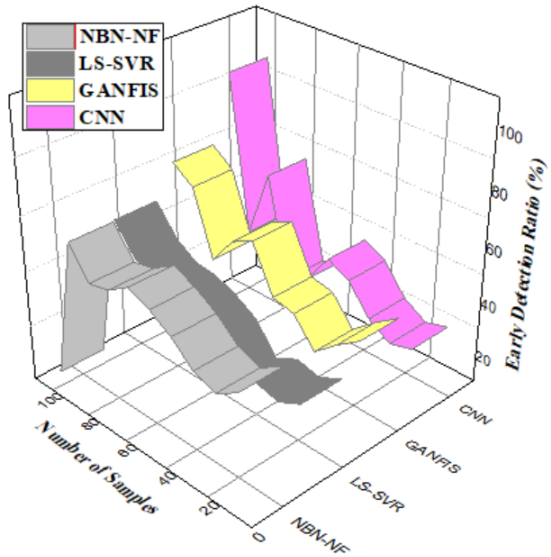
The output $c_x s$, which is the classification or prediction of PD, is obtained by processing the clinical input data $[l - ap'']$ through the settings of the model $Ls[v - anq'']$ and $Ba[4d - nwq'']$. The goal of Eq. (18) is to improve diagnostic accuracy by enhancing the model's ability to integrate and evaluate data for analysis of specificity.

(a)



(b)

Fig. 9. (a) Analysis of accuracy using PD-HDA and (b) Analysis of accuracy using CNN



The PD-HDA framework was effective in differentiating PD from non-PD cases, with an overall accuracy of 97.24% [see Fig. 9(a) and (b)]. This statistic demonstrates the model's durability and its ability to generalize across multiple datasets by utilizing speech patterns, gait analysis, and tremor photos. Such high accuracy highlights how consistently hybrid methods provide precise diagnostic information for clinicians, as seen in Eq. (19).

$$k_d r[ki - an'']: \rightarrow Ks[ki - qm''] + Bs[ko - sme''] \quad (19)$$

Eq. (19) shows the model's parameters. $k_d r$, which modifies the internal weights and biases of the model, processes the input feature $[ki - an'']$, which is probably related to clinical data like symptom severity, by adjusting the parameters $Ks[ki - qm'']$ and $Bs[ko - sme'']$. The goal of this equation is to facilitate early identification of PD by optimizing the integration of several clinical characteristics to ensure the accuracy of the analysis.

(a)

(b)

Fig. 10. (a) Analysis of early detection using PD-HDA, and (b) Analysis of early detection using CNN

The early detection accuracy of 95.76% emphasizes the framework's ability to identify PD in its early stages [see (Fig. 10(a) and (b)]. CNNs paired with fuzzy logic help detect often-overlooked minor clinical signs and trends. This skill determines if starting timely treatment measures slows down the progression of illnesses and improves long-term patient outcomes.

$$k_r r[ju - n'']: \rightarrow Ns\left[rs'' * Vs[ko - amw'']\right] + Nsf'' \quad (20)$$

An extra adjustment term $k_r r$ and a mixture of network parameters $[ju - n'']$ are used to analyze the input data $Ns\left[rs'' * Vs[ko - amw'']\right]$, which may be associated Nsf'' With patient-specific symptoms or data points. Equation aims to represent the complex correlations observed in multimodal clinical data for early detection analysis. Table II presents a comparison of the existing method and the proposed method.

TABLE II. COMPARISON OF THE EXISTING METHOD AND PROPOSED METHOD

Aspects	Existing Method in Ratio	Proposed Method in Ratio	Key features
Diagnostic Accuracy	80.85%	92.62%	Enhanced feature extraction via CNN and data fusion for accurate classification.
Sensitivity	78.82%	91.87%	Improved detection of PD cases using Fuzzy Logic for uncertainty management.
Specificity	81.86%	93.22%	Better differentiation between PD and non-PD cases through multimodal data analysis.
Overall Accuracy	85.90%	97.24%	Robust performance leveraging structured feature selection and advanced algorithms.
Early Detection	75.88%	95.76%	High early detection rates using subtle pattern recognition in clinical data.

IV. DISCUSSION

This work advances hybrid diagnostic modelling by formalizing a deep semantic learning–reasoning pipeline in which CNN-derived hierarchical representations are directly coupled with fuzzy inference. This connection enhances performance by transforming discriminative convolutional features into uncertainty-aware language variables prior to classification, enabling data-driven abstraction and rule-based reasoning to inform diagnostic conclusions. This approach explains reported advantages by attributing enhanced stability and sensitivity to deep feature hierarchies and graded fuzzy decision boundaries rather than network depth. The semantic representation-level uncertainty-handling method in the PD-HDA framework is organized. The fuzzy inference layer compares the ambiguity of symptoms and the overlap of classes through membership functions between deep feature spaces, which contrasts with probabilistic classifiers that tend to provide a clear judgment basis. This formalization provides an analytical model of dealing with the ambiguity in diagnosing the PD, especially in borderline and early-stage patients. High-dimensional CNN activation mapping is used to transform into fuzzy language entities of clinical significance, forming an interpretable diagnostic reasoning layer in PD-HDA. The built-in rule base provides clear inference paths that relate diagnostic findings to neurologically relevant patterns of symptoms, extending the hybrid modelling beyond the optimization of accuracy to provide explainable clinical decision support. This layer of interpretability indicates the impact of feature abstractions on diagnostics. The paradigm facilitates graded diagnostic thinking in cases of symptom variability during the analysis of early-stage PD. Fuzzy inference makes it less vulnerable to variations in features at early stages by smoothing disease class transitions. Diagnostic consistency across diverse patient demographics is achieved without rigid categories. In addition to application-level validation, the proposed hybrid

diagnostic paradigm can be applied to other neural and uncertainty-driven clinical cases. Deep feature learning and fuzzy reasoning are modular, allowing for adaptation to various data modalities and illness conditions without compromising interpretability and uncertainty modelling. This makes PD-HDA a transferable diagnostic architecture rather than a task-specific empirical solution.

V. Conclusion

The PD-HDA uses CNNs and fuzzy logic to address PD diagnostic problems. By utilizing CNNs to evaluate challenging multimodal datasets and employing fuzzy logic to mitigate clinical data ambiguity, the framework achieves 92.62% diagnostic accuracy, 91.87% sensitivity, 93.22% specificity, and 95.76% early detection accuracy. Usually, the PD-HDA method is more effective than conventional diagnostic tools in the initial stages of PD, albeit erratically and subjectively. Elaborate and intricate patterns that emerge from data relating to speech, gait, and tremor analysis facilitate the accurate and reliable identification of the progression stages of PD. Rapid therapeutic interventions resulting from such findings reduce the span and improve the prognosis of patients autonomously. The results highlight the potential of hybrid diagnostic methods to overcome the limitations of current methods, enhance the reliability of diagnosis, and establish a new standard for PD diagnosis. The next research focus will be to extend the PD-HDA framework to include a more diverse range of information, such as real-time monitoring and biomarkers, to achieve the best accuracy.

Additionally, efforts will be made to optimize the model for clinical use, ensuring both scalability and user-friendliness. The method's practicality is shown by its improved classification accuracy, sensitivity, and resilience compared to standard machine learning models, standalone CNN architectures, and hybrid techniques. This study employs a single data modality and a specified fuzzy rule basis, which restricts adaptation to changing clinical patterns and acquisition situations. Future research will apply the framework to imaging, voice, and sensor-based clinical data, examining adaptive fuzzy rule optimization and attention-guided feature selection to enhance generalization and clinical interpretability.

Acknowledgment

The authors would like to thank Prof. Dr. Sujatha Krishnamoorthy for her contribution to this work.

***Abstract*—The increasing scarcity and sensitivity of clinical data necessitate the development of high-quality synthetic datasets. This study evaluated the ability of Conditional Tabular GAN (CTGAN) to generate synthetic heart disease data that preserves the statistical properties and predictive patterns of the Cleveland Heart Disease dataset. It assessed the fidelity of numerical and categorical features, preservation of pairwise correlations, and predictive utility using Logistic Regression and Random Forest classifiers. Dimensionality reduction analysis using PCA and t-SNE further measured the global similarity between the real and synthetic datasets. The results obtained show that CTGAN successfully reproduces the general distribution and correlations, especially for key features such as age, talach, and old peak. However, some discrepancies remain in categorical attributes. Predictive modeling shows moderate transferability, indicating that synthetic data captures important patterns without completely replicating the original labels. These findings highlight the potential of CTGAN-generated synthetic data as a privacy-preserving alternative for benchmarking and early algorithm development, while emphasizing the importance of feature-level and prediction validation in synthetic data research.**

I. Introduction

Cardiovascular diseases, particularly heart disease, remain a leading cause of global mortality, accounting for approximately 17.9 million deaths annually according to the World Health Organization. Early identification and timely intervention are essential to reducing morbidity and mortality associated with these conditions. In recent years, machine learning (ML) techniques have attracted significant attention for their potential to support heart disease diagnosis and risk prediction, thereby enabling data-driven clinical decision-making [1].

Despite these advances, the robustness and generalizability of ML models in healthcare are often constrained by limitations inherent to real-world clinical data [2]. One of the primary challenges is the scarcity of large-scale, high-quality, and representative datasets. Publicly available resources, such as the UCI Heart Disease dataset, are typically limited in size and frequently exhibit class imbalance, which restricts their suitability for training reliable predictive models [3]. In addition, patient privacy regulations and ethical considerations impose further restrictions on data sharing and reuse [4]. These challenges collectively hinder reproducibility and limit the practical deployment of ML-based solutions in clinical settings [5].

To address data scarcity while mitigating privacy concerns, synthetic data generation has emerged as a promising alternative. Among existing approaches, Generative Adversarial Networks (GANs) have demonstrated strong capability in modeling complex data distributions. In particular, Conditional Tabular GAN (CTGAN) is designed to handle tabular datasets with both continuous and categorical variables, as well as class imbalance. These characteristics make CTGAN especially suitable for healthcare applications [6], where heterogeneous feature types and skewed data distributions are common.

Although GAN-based synthetic data generation has been widely explored, most existing studies primarily emphasize downstream model performance, such as classification accuracy, while providing limited systematic evaluation of artificial data fidelity. In particular, the preservation of statistical properties and feature-level relationships in synthetic tabular data is often under-examined. Furthermore, there is insufficient empirical evidence regarding whether synthetic tabular data generated for heart disease prediction can offer comparable predictive utility to real clinical data while maintaining essential statistical and structural characteristics.

To address these gaps, this study evaluates the quality and fidelity of CTGAN-generated synthetic heart disease data through a comprehensive assessment framework. The evaluation includes descriptive statistical comparisons, correlation structure analysis, distributional similarity testing, and utility-based evaluation using a logistic regression classifier implemented in Python. Rather than augmenting predictive pipelines, the study assesses whether synthetic data can serve as a statistically reliable substitute for real clinical data in downstream machine learning tasks.

By integrating statistical fidelity analysis with predictive utility evaluation, this work provides empirical insights into the suitability of CTGAN-generated synthetic data for healthcare machine learning applications. The findings contribute to ongoing discussions on the role of synthetic data in clinical

artificial intelligence, particularly in scenarios involving sensitive or limited-access tabular datasets.

The remainder of this paper is organized as follows. Section II reviews related work on synthetic data generation and evaluation in healthcare. Section III describes the dataset, CTGAN configuration, and the methodology for synthetic data generation and evaluation. Section IV presents the experimental results. Section V discusses the findings in relation to existing studies and outlines the limitations. Finally, Section VI concludes the paper and suggests directions for future research, followed by the Acknowledgments and References.

II. Literature Review

Heart disease prediction increasingly relies on machine learning (ML) and deep learning (DL), offering potential for timely diagnosis and improved clinical decision-making. However, challenges such as limited high-quality clinical data and persistent class imbalances drive the use of synthetic data generation. Generative Adversarial Networks (GANs) have emerged as a promising approach to generate realistic tabular datasets while preserving patient privacy. This literature review focuses on three areas: (1) ML and DL approaches for heart disease prediction, (2) GAN-based synthetic data generation in healthcare, and (3) assessment of the quality, utility, and privacy of synthetic data. Across these themes, this review highlights methodological advances, benchmarking strategies, and remaining gaps, thereby providing a foundation for this study.

A. Heart Disease Prediction Using Deep Learning and Machine Learning

Traditional machine learning (ML) models, such as logistic regression, decision trees, support vector machines (SVMs), k-nearest neighbors (KNN), and random forests (RFs), have been widely used for heart disease prediction due to their interpretability and computational simplicity [7,8]. Recent studies demonstrate that classical ML models, particularly tree-based methods, achieve high predictive performance across diverse datasets. For instance, Random Forest and Bagged Trees consistently produced 94–99% accuracy in multi-site validations, highlighting their reliability [15,16]. Nevertheless, these approaches often depend on manual feature engineering and may struggle to capture nonlinear relationships inherent in high-dimensional clinical data.

To address these limitations, deep learning (DL) models, intense neural networks (DNNs), and backpropagation neural networks (BP-NNs) have been increasingly employed. When combined with feature selection techniques such as L1-regularized LinearSVC or minimum redundancy maximum relevance (mRmR), these models consistently demonstrate improved predictive accuracy, often exceeding 98% [9,10]. These findings emphasize the importance of intelligent feature selection to optimize DL performance.

DL models have also been applied to non-tabular data, such as cardiac sound signals. Using Mel-frequency cepstral coefficients (MFCC) extracted from heart sounds, DL classifiers achieved near-perfect test accuracy and F1-scores [11]. Similarly, mobile-based cardiac screening employing DL has shown promising results for accessible, non-invasive diagnosis [12]. These studies illustrate the potential of incorporating alternative data modalities to complement traditional clinical predictors.

Ensemble and hybrid models have further enhanced prediction accuracy by combining multiple algorithms or data sources. For example, a DL ensemble integrating electronic medical record (EMR) and sensor data achieved 98.5% accuracy using information gain weighting [13]. Stacked ensembles of Extra Trees, XGBoost, and RF yielded robust accuracy around 92–95% [14]. Hybrid frameworks combining KNN, XGBoost, and LSTM also outperformed individual classifiers across multiple datasets [20]. These results underscore the effectiveness of multi-model strategies in capturing complementary predictive patterns.

Recent studies have explored additional predictors beyond standard clinical features. For example, SHAP analysis applied to Random Forest models identified novel biochemical markers, such as calcium and inflammation indicators, as relevant for cardiovascular risk [17]. Similarly, genomic data and psychological variables have been integrated within ML frameworks, improving predictive performance from 71.3% to 85.1% [18, 19]. These findings suggest that incorporating diverse data types can enhance model generalizability and interpretability.

Despite these promising results, generalizability remains limited. A systematic review found that only 10 out of 486 AI-based cardiovascular models underwent meaningful external validation [21]. Common limitations include small sample sizes, class imbalance, and strict privacy regulations, which hinder robust training and evaluation. These challenges highlight the need for data augmentation strategies, such as synthetic data generation via Generative Adversarial Networks (GANs), to address data scarcity while maintaining privacy. The following sections explore recent advances in GAN-based tabular synthesis, benchmarking approaches for evaluating fidelity and fairness, and real-world applications of synthetic clinical data.

B. Synthetic Data Generation in Healthcare using GANs, Disease Prediction using Deep Learning, and Machine Learning

Recent work has introduced enhanced GAN variants tailored for the unique characteristics of clinical tabular datasets. CTAB-GAN+ [22] incorporates task-aware loss functions, mixed-type variable encoders, and optional differential privacy mechanisms, improving F1-score performance under privacy constraints. STNG [23] integrates multiple generative approaches (Gaussian Copula, CopulaGAN, TVAE, Conditional GAN) with downstream validation via AutoML, demonstrating high fidelity across diverse medical datasets. SMOOTH-GAN [24] emphasizes clinically valid synthetic distributions while balancing privacy. In contrast, transformer-based models such as TT GAN [25] and FCT GAN [26] further improve the modeling of complex inter-variable dependencies in heterogeneous datasets. These studies collectively highlight the trend toward domain-aware, privacy-conscious GAN architectures capable of generating realistic clinical data.

To ensure synthetic data is not only realistic but also practical, several benchmarking frameworks have emerged. End-to-end pipelines [27] evaluate fidelity, privacy, and utility,

revealing that GANs remain competitive even compared to diffusion-based models. Comparative studies [28–30] have consistently shown that CTGAN and WGAN-GP preserve inter-variable correlations and downstream classifier performance, while hybrid methods such as CTGAN-ENN [31] and BT-GAN [32] address class imbalance and subgroup fairness. Overall, these evaluations emphasize the need for multi-dimensional assessment (fidelity, utility, fairness) to validate synthetic tabular data for healthcare applications.

Practical deployment of synthetic data requires attention to privacy and regulatory alignment. Studies using Bayesian networks and GANs on large datasets (e.g., CPRD) [33] stress ethical deployment with privacy risk mitigation, such as k-anonymity and differential privacy. Alternative approaches generate synthetic data from summary statistics to avoid direct access to patient-level data [34], while pipelines such as EMR-WGAN [35] provide hands-on workflows for real-world model development. Advanced models such as IGAMT [36] and DP-CGANs [37] further ensure privacy, fairness, and high downstream utility, particularly for heterogeneous and irregular clinical tabular data. These studies highlight a growing emphasis on ethically aligned, privacy-preserving synthetic data generation suitable for clinical AI research.

Despite the development of sophisticated GAN architectures and benchmarking strategies, questions remain regarding how to rigorously evaluate synthetic data quality and ensure it is both valuable and privacy-preserving in clinical contexts. The following section discusses evaluation frameworks, performance metrics, and architectural innovations that address these challenges.

C. Evaluation of Synthetic Data Quality and Utility in Healthcare

The evaluation of synthetic healthcare data revolves around three foundational pillars: fidelity, utility, and privacy. Fidelity ensures that synthetic data accurately replicates real-world distributions, utility reflects its usefulness in downstream analyses, and confidentiality safeguards sensitive patient information [38]. These dimensions were formalized in early frameworks and have since guided multiple evaluation standards. Preserving inter-variable correlations in time-series health data [39] and implementing domain-aware pipelines for EHRs [40] demonstrate practical strategies to maintain these dimensions. Comprehensive benchmarking studies [41,42] combine statistical similarity metrics (e.g., KS tests, Chi-square tests) with privacy assessments, such as membership inference attacks. SynthRO [43], using MIMIC-III/IV datasets, highlights the trade-offs between fidelity, utility, and privacy, emphasizing the need for balanced optimization in synthetic data generation.

Performance of synthetic data varies across clinical domains, making context-aware evaluation essential. In oncology and diabetes datasets, a divide-and-conquer CTGAN approach achieved high fidelity (97.65% shape score) and strong classification metrics [44]. Conditional GANs tailored for cardiovascular data outperformed standard CTGAN and TVAE models in fidelity measures such as the Jaccard index and KS statistic [45]. Modeling survival curves in oncology trials further illustrates the challenge of replicating censored time-to-event data [46]. Comparative analyses [47,48] highlight that no single model universally outperforms others, reinforcing the importance of domain-specific benchmarks. Broader evaluation frameworks [49] also incorporate fairness and environmental cost alongside fidelity and utility, underscoring the increasing complexity of evaluation metrics in clinical applications.

Architectural improvements in GAN-based models have targeted fidelity, usability, and privacy. Divide-and-conquer CTGAN [50] and MargCTGAN [51] enhance downstream classification performance and preserve marginal distributions, particularly for small clinical datasets. DP-CTGAN [52] integrates differential privacy directly into training to ensure privacy-conscious generation. Memory-efficient models such as MeTGAN [53] address high-cardinality categorical features while reducing computational overhead, and OCT-GAN [54] incorporates neural ordinary differential equations (NODEs) to handle class imbalance and multimodal distributions. Collectively, these innovations reflect a trend toward modular, scalable, and ethically aligned generative frameworks that meet the complex demands of healthcare data.

Although Generative Adversarial Networks (GANs) have gained traction as a solution for data scarcity in healthcare, most existing studies focus primarily on augmenting training datasets to improve predictive model performance. While this utility-based approach has achieved notable improvements in classification accuracy and robustness, there remains a lack of systematic assessment of GAN-generated data as a stand-alone substitute for real patient data. Evaluations frequently prioritize high-level utility metrics without thoroughly examining whether synthetic data preserves the intricate statistical and structural patterns inherent in clinical datasets. CTGAN, a GAN variant designed for mixed-type tabular data, shows promise in handling categorical and continuous variables with imbalanced distributions.

However, limited studies have rigorously assessed its ability to maintain clinically meaningful inter-feature relationships, such as those among chest pain, ECG readings, and heart disease diagnosis, which are critical for interpretability and real-world applicability. This study addresses these gaps by conducting a comprehensive evaluation of CTGAN-generated synthetic data for heart disease prediction, focusing on statistical fidelity, multivariate structure, and downstream classification performance. By doing so, it provides deeper insights into the reliability and limitations of CTGAN in generating synthetic clinical data for sensitive domains like cardiovascular healthcare.

III. Methodology

To address the challenges posed by scarce and sensitive clinical datasets, synthetic data generation using Generative Adversarial Networks (GANs) has gained prominence in clinical research. Further leveraging Conditional Tabular GAN (CTGAN) models, this study generates synthetic medical data from benchmark datasets to evaluate heart disease prediction performance. The primary objective is to assess the quality of the artificial data by comparing its statistical properties and predictive utility with those of the original dataset.

A. Data Source and Preprocessing

The Cleveland Heart Disease dataset was retrieved from the UCI Machine Learning Repository using the ucimlrepo Python package. This dataset [55] contains 303 patient records with 14 attributes (13 features and one target). The target column, `num`, indicates heart disease diagnosis:

- 0: Absence.
- 1-4: Presence with increasing severity.

The dataset contains 13 features and one target variable relevant to cardiac health (Table I).

TABLE I CLEVELAND HEART DISEASE DATASET FEATURES

Feature	Type	Description
age	Integer	Age in years
sex	Categorical	Sex (1=male, 0=female)
cp	Categorical	Chest pain type (1–4)
trestbps	Integer	Resting blood pressure (mm Hg)
chol	Integer	Serum cholesterol (mg/dl)
fbs	Categorical	Fasting blood sugar >120 mg/dl
restecg	Categorical	Resting ECG results (0–2)
thalach	Integer	Maximum heart rate achieved
exang	Categorical	Exercise-induced angina (1=yes, 0=no)
oldpeak	Integer	ST depression induced by exercise
slope	Categorical	Slope of peak exercise ST segment
ca	Integer	Number of major vessels (0–3)
thal	Categorical	Thalassemia (3=normal, 6=fixed defect, 7=reversible defect)
num	Target Integer	Diagnosis of heart disease

Two columns, ca and thal, contained missing values, which were imputed using the mode of each column. Numerical features (age, trestbps, chol, thalach, oldpeak) were preserved in their original scale. In contrast, categorical features (sex, cp, fbs, restecg, exang, slope, ca, thal) were encoded to facilitate synthetic data generation. The missing values were handled as follows:

```
df['ca'].fillna(df['ca'].mode()[0], inplace=True)
df['thal'].fillna(df['thal'].mode()[0], inplace=True)
```

B. Synthetic Data Generation Using CTGAN

The CTGAN model was employed to generate synthetic medical records from the cleaned and preprocessed dataset (`df_v2`). This dataset consisted of 303 patient instances, 13 predictive features, and one target variable. All preprocessing steps, including missing value imputation, categorical encoding, and 1st-to-99th percentile clipping, were completed before training.

1) CTGAN configuration: Fig. 1 shows a screenshot of the Jupyter Notebook code used to train the CTGAN model on the Cleveland Heart Disease dataset. The figure illustrates the setup of model parameters, categorical feature specification, and the output progress of generator and discriminator losses during training.

```
from ctgan import CTGAN
import pandas as pd

df_v2 = pd.read_csv("heart_clean_v2_clipped.csv")

categorical_columns = ['sex','cp','fbs','restecg','exang','slope','ca','thal']

ctgan = CTGAN(
    epochs=1200,
    batch_size=256,
    embedding_dim=256,
    generator_lr=2e-4,
    discriminator_lr=2e-4,
    verbose=True,
    pac=1  # fixes the AssertionError for small datasets
)

ctgan.fit(df_v2)
```

```
Gen. (-0.85) | Discrim. (-0.04): 100%|██████████| 1200/1200 [00:58<00:00, 20.57it/s]
```

Fig. 1. Screenshot of CTGAN training code and output progress for the cleveland heart disease dataset.

2) Model training: The CTGAN was trained directly on the cleaned dataset. Since categorical variables in `df_v2` were encoded as integers, CTGAN automatically inferred their discrete nature during training. Training completed successfully, with stable Wasserstein losses for both the generator (≈ –0.85) and discriminator (≈ –0.04), indicating balanced adversarial optimization without signs of divergence or mode collapse.

3) Synthetic data generation: After training, a synthetic dataset of equal size to the original (`n = 303`) was generated. Matching the sample size allowed direct pairwise comparison of statistical properties and predictive utility between real and synthetic datasets. The synthetic data was generated as follows:

```
num_samples = df_v2.shape[0]
synthetic_data = ctgan.sample(num_samples)
synthetic_df = pd.DataFrame(synthetic_data, columns=df_v2.columns)
```

To ensure structural and semantic consistency with the real dataset, categorical variables were rounded and cast to integer types. At the same time, numeric features (e.g., chol, oldpeak) were clipped to medically valid ranges to prevent unrealistic values. These adjustments ensured that the synthetic dataset adhered to clinically plausible ranges while preserving statistical fidelity.

C. Statistical Evaluation of Synthetic Data

To assess the fidelity of the synthetic dataset, multiple statistical analyses were performed to compare distributions and inter-feature relationships between the real and synthetic datasets, as detailed below.

Kolmogorov–Smirnov (KS) tests and Wasserstein distances were computed for continuous features (age, trestbps, chol, thalach, oldpeak) to quantify distributional differences between real and synthetic datasets. Features with significant KS p-values (<0.05) or elevated Wasserstein distances were flagged as exhibiting moderate deviations.

Correlation analysis was performed to compare pairwise feature relationships between the real and synthetic datasets. Features showing substantial deviations in Pearson correlation coefficients were highlighted to identify potential discrepancies in the underlying structure.

Exploratory Data Analysis (EDA) was conducted to identify features with moderate or significant deviations based on distributional and proportional differences.

These analyses provide a quantitative foundation for evaluating whether the synthetic data preserves the statistical characteristics of the original dataset.

D. Utility Evaluation of Synthetic Data

To assess the practical utility of the synthetic dataset, predictive models were trained and evaluated on both the real and synthetic datasets. This evaluation measures whether the synthetic data preserves the predictive patterns present in the real dataset.

1) Restoring target column for predictive modeling: The target column (num) was restored in both the real and synthetic datasets to enable predictive evaluation. Features and target were separated as follows:

$$X_real, y_real \text{ and } X_synth, y_synth$$

Where *X_real* contains all feature columns from the real dataset, *y_real* contains the target column (num) from the real dataset, *X_synth* contains all feature columns from the synthetic dataset, and *y_synth* contains the target column (num) from the artificial dataset.

2) Dataset splitting: Both datasets were split into training and testing subsets using a 70:30 ratio to enable unbiased evaluation. Stratified sampling was applied to maintain the proportion of patients with and without heart disease (num) across subsets. The training data was used to fit the classifiers, and the testing data was used to evaluate predictive performance. The dataset splitting was implemented as follows:

```
From sklearn.model_selection import train_test_split
X_train, X_test, y_train, y_test = train_test_split(
X, y, test_size=0.3, random_state=42, stratify=y)
```

3) Predictive modeling: Two classifiers were employed:

a) Logistic Regression (LR): A linear baseline model for binary classification.

a) *Random Forest (RF):* an ensemble tree-based model capable of capturing non-linear relationships. Each model was incorporated into a pipeline with preprocessing for categorical and numerical features. Models were trained on the training subset and evaluated on the testing subset to ensure reproducible performance assessment.

4) Performance metrics: Model performance was assessed using standard classification metrics: Accuracy, Precision, Recall (Sensitivity), F1-score, ROC-AUC, and the Confusion Matrix. This procedure provides a reproducible framework to quantify the predictive utility of the synthetic data. Results and corresponding visualizations are presented in the Results section.

IV. Result

A. Numerical Feature Fidelity

The CTGAN-generated synthetic dataset was first evaluated for the fidelity of continuous features relative to the original Cleveland Heart Disease dataset. Table II presents a comparison of numeric features, including mean, standard deviation, percentage difference, and overall fidelity rating for each feature.

TABLE II Comparison of Numeric Features Between Real and Synthetic Data

Feature	Real μ[a]	Synth μ[a]	Real σ[a]	Synth σ[a]	Δ%[b]	Fidelity[c]
age	54.42	51.68	8.88	8.55	5.04%	M
trestbps	131.62	124.78	17.17	20.99	5.20%	M
chol	246.29	207.42	48.82	46.49	15.78%	W
thalach	149.68	162.95	22.44	19.96	8.87%	M
oldpeak	1.03	0.99	1.12	1.06	3.53%	S

[a]μ and σ denote the mean and standard deviation of the respective datasets.
[b]Δ% represents the percentage difference between the real and synthetic mean values.
[c]Fidelity ratings are categorized as Strong (S), Moderate (M), or Weak (W).

Fig. 2 presents kernel density estimates (KDEs) of numeric features, comparing real and synthetic datasets.

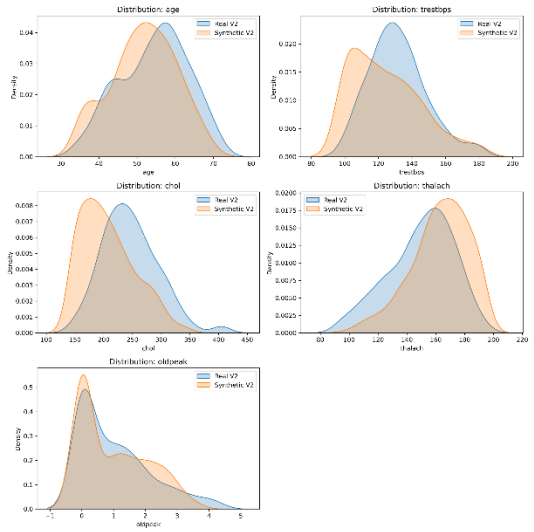

Fig. 2. KDE comparison of numeric feature distributions (real vs. synthetic).

B. Categorical Feature Fidelity

Categorical features were evaluated for fidelity by calculating the maximum proportional differences between the real and synthetic datasets. Table III highlights the top features with their corresponding fidelity assessments, indicating which variables were well-preserved and which exhibited larger deviations.

TABLE III Categorical Feature Fidelity Between Real and Synthetic Datasets

Feature	Max % Difference	Fidelity
sex	3.96%	Strong
cp	7.59%	Moderate
fbs	22.11%	Weak
restecg	10.56%	Weak
exang	0.33%	Strong
slope	17.16%	Weak
ca	11.22%	Weak
thal	11.88%	Weak

C. Distributional Similarity

To further evaluate the fidelity of numeric features, Kolmogorov–Smirnov (KS) tests and Wasserstein distances were calculated, providing quantitative measures of distributional similarity between the real and synthetic datasets. Table IV summarizes these results, highlighting features with the most significant discrepancies.

TABLE IV DISTRIBUTIONAL SIMILARITY OF NUMERIC FEATURES BETWEEN REAL AND SYNTHETIC DATASETS

Feature	KS Statistic	KS p-value	Wasserstein Distance
age	0.1782	0.0001	2.74
trestbps	0.2937	0.0000	7.17
chol	0.3597	0.0000	38.87
thalach	0.2607	0.0000	13.27

D. Feature Correlation Analysis

Pairwise feature correlations were analyzed to assess whether the CTGAN-generated synthetic dataset preserved the relationships observed in the original dataset. Table V lists the top five feature pairs exhibiting the most considerable absolute differences in correlation.

TABLE V COMPARISON OF PAIRWISE FEATURE CORRELATIONS BETWEEN REAL AND SYNTHETIC DATASETS

Feature 1	Feature 2	Real Corr	Synthetic Corr	|Δ|[a]
age	ca	0.365	-0.042	0.41
oldpeak	slope	0.575	0.273	0.30
restecg	chol	0.166	0.442	0.28
trestbps	fbs	0.170	-0.104	0.27
ca	num	0.521	0.288	0.23

[a]|Δ| = absolute difference in means

Fig. 3 visualizes these differences in a heatmap, providing an intuitive overview of how inter-feature relationships are maintained or altered in the synthetic dataset.

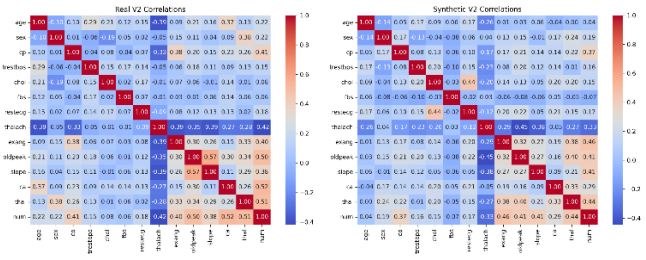

Fig. 3. Heatmap of correlation differences between real and synthetic datasets.

E. Predictive Utility Evaluation

To evaluate the predictive utility of the CTGAN-generated synthetic dataset, Logistic Regression and Random Forest classifiers were trained on one dataset and tested on the other. This setup assesses whether the synthetic data preserves the predictive patterns of the original dataset. Table VI summarizes the classification performance metrics (Accuracy, Precision, Recall, F1-score) for each training-testing scenario.

TABLE VI PREDICTIVE PERFORMANCE OF CLASSIFIERS TRAINED ON SYNTHETIC VS. REAL DATASETS

Train → Test	Model	Accuracy	Precision	Recall	F1
Synthetic → Real	Logistic Regression	0.560	0.566	0.560	0.561
Synthetic → Real	Random Forest	0.560	0.608	0.560	0.561
Real → Synthetic	Logistic Regression	0.615	0.557	0.615	0.571
Real → Synthetic	Random Forest	0.582	0.464	0.582	0.500
Train → Test	Model	Accuracy	Precision	Recall	F1

To demonstrate the evaluation procedures used in this study, confusion matrices were generated programmatically in Python within a Jupyter Notebook environment. The implementation includes model predictions, confusion matrix computation, and visualization using Seaborn heatmaps. Fig. 4 provides a snapshot of the evaluation code, illustrating the end-to-end process used to assess classifier performance across real and synthetic datasets.

```python
import matplotlib.pyplot as plt
import seaborn as sns
from sklearn.metrics import confusion_matrix

# Function to plot and save confusion matrix as heatmap
def plot_confusion_matrix(y_true, y_pred, classes, title, filename):
    cm = confusion_matrix(y_true, y_pred, labels=classes)
    plt.figure(figsize=(6,5))
    sns.heatmap(cm, annot=True, fmt="d", cmap="Blues", xticklabels=classes, yticklabels=classes)
    plt.xlabel("Predicted Label")
    plt.ylabel("True Label")
    plt.title(title)
    plt.tight_layout()
    plt.savefig(filename, dpi=300)
    plt.show()

# Define class labels
classes = sorted(y_real.unique())

# Dictionary of models
models = {
    "Logistic Regression": pipe_lr,
    "Random Forest": pipe_rf
}

# 🔁 Train on Synthetic → Test on Real
for name, model in models.items():
    y_pred = model.predict(X_test_real)
    plot_confusion_matrix(
        y_test_real,
        y_pred,
        classes=classes,
        title=f"{name}: Train on Synthetic → Test on Real",
        filename=f"cm_{name.replace(' ','_')}_syn2real.png"
    )

# 🔁 Train on Real → Test on Synthetic
for name, model in models.items():
    y_pred = model.predict(X_test_syn)
    plot_confusion_matrix(
        y_test_syn,
        y_pred,
        classes=classes,
        title=f"{name}: Train on Real → Test on Synthetic",
        filename=f"cm_{name.replace(' ','_')}_real2syn.png"
    )
```

Fig. 4. Code snippet used to generate confusion matrices for real and synthetic dataset evaluation.

The resulting confusion matrices for both Logistic Regression and Random Forest classifiers, trained and evaluated on real and synthetic datasets, are presented in Fig. 5 and Fig. 6. These matrices provide a clear visualization of correct versus incorrect predictions for each class, allowing detailed inspection of model behavior and cross-domain generalization (synthetic→real and real→synthetic). They serve as direct evidence of the evaluation phase and illustrates how well predictive patterns are preserved in the synthetic data.

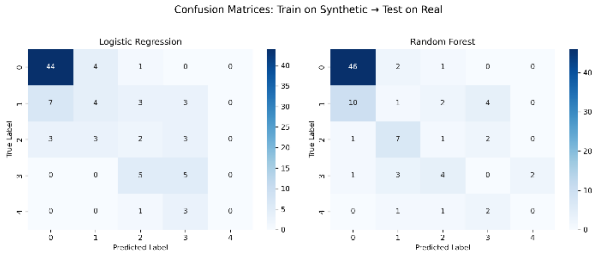

Fig. 5. Confusion matrices for Logistic Regression and Random Forest classifiers (TSTR).

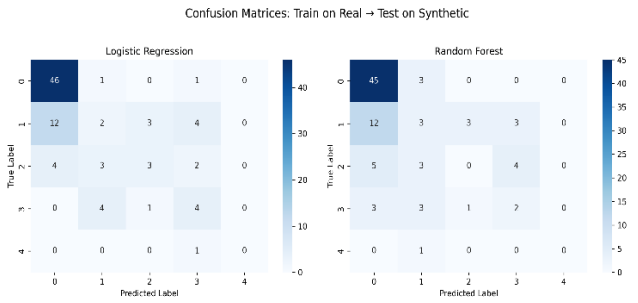

Fig. 6. Confusion matrices for Logistic Regression and Random Forest classifiers (TRTS).

E. Feature Importance Comparison

Random Forest feature importance was computed independently for the real and synthetic datasets to evaluate whether CTGAN preserved the relative influence of key predictive features. Fig. 7 and Fig. 8 depict the comparison, allowing assessment of how closely the synthetic data replicates feature-level patterns learned from the real dataset.

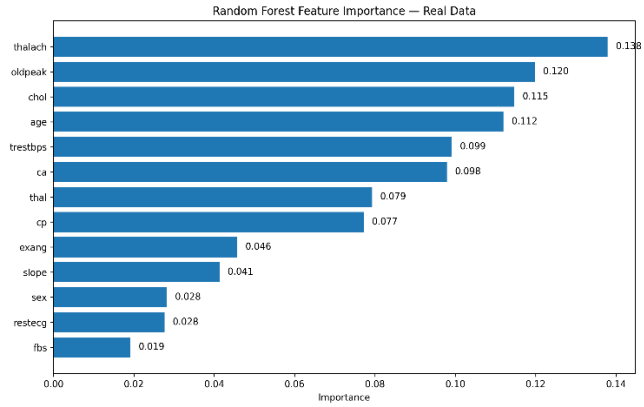

Fig. 7. Random forest feature importance on real data.

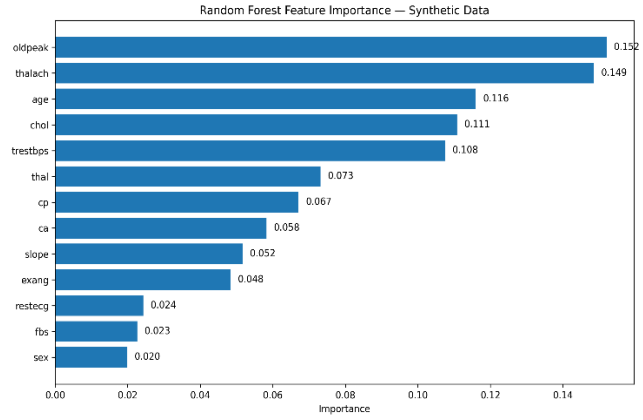

Fig. 8. Random forest feature importance on synthetic data.

F. Dimensionality Reduction Analysis

Table VII summarizes quantitative distance metrics derived from PCA and t-SNE embeddings, while Fig. 9 and Fig. 10 present scatter plots illustrating the spatial overlap between synthetic and real samples in the reduced feature space.

TABLE VII DIMENSIONALITY REDUCTION-BASED SIMILARITY BETWEEN REAL AND SYNTHETIC DATASETS

Method	Distance
PCA	1.013
t-SNE	6.952
Avg min dist (synthetic → real)	2.022

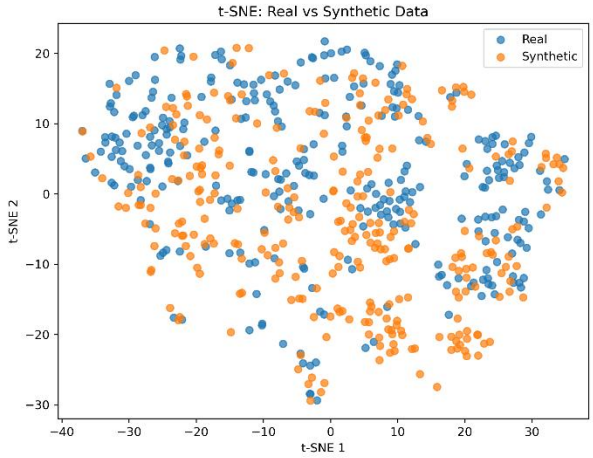

Fig. 9. t-SNE scatter plots showing synthetic and real samples in feature space.

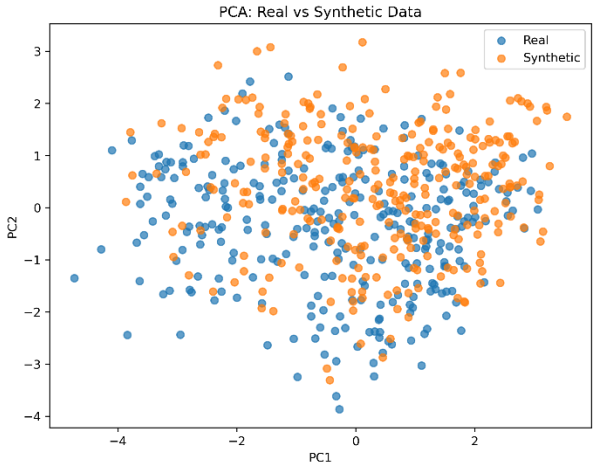

Fig. 10. PCA scatter plots showing synthetic and real samples in feature space.

V. Discussion

The present study evaluated how effectively CTGAN-generated synthetic data replicates the statistical structure, feature relationships, and predictive utility of the Cleveland Heart Disease dataset. Findings indicate that, although CTGAN preserves several overarching patterns, particularly in continuous variables, it does not fully reproduce finer-grained distributional characteristics or certain categorical feature relationships. These discrepancies affect downstream model performance and indicate areas where synthetic data diverges most from clinical signals.

Numerical features such as age, trestbps, and oldpeak exhibited moderate to strong fidelity, with percentage

differences in means generally below 6%, whereas features such as cholesterol (chol) demonstrated weaker fidelity. Categorical features, including fbs, slope, ca, and thal, exhibited higher variability, reflecting the challenges of modeling sparse or complex discrete distributions in tabular GANs. Similar challenges in preserving categorical distributions and marginal fidelity have been reported in CTGAN-based studies on clinical tabular data in papers 44 and 45, suggesting that these limitations are not dataset-specific but intrinsic to current GAN-based tabular synthesis approaches.

Correlation analyses further indicated that, although significant pairwise relationships were preserved, some feature interactions deviated in synthetic data, particularly those involving high-variance or multi-level categorical variables. This finding aligns with prior comparative evaluations, which show that no single synthetic data generator consistently preserves all inter-feature dependencies across domains and datasets in papers 47 and 48. Importantly, this contextualizes the observed correlation drift as a known trade-off rather than an implementation flaw.

Predictive evaluations demonstrated that classifiers trained on synthetic data partially generalized to real data, and vice versa. Logistic Regression and Random Forest classifiers achieved moderate accuracy (≈56–61%) when cross-tested between real and synthetic datasets. Although predictive performance did not fully match that of models trained and tested on the original dataset, these results indicate that synthetic data retains essential structure relevant to downstream modeling. Similar observations have been reported in clinical benchmarking studies, where high fidelity does not always translate into equivalent downstream performance, as reported in paper 44. Confusion matrices highlight that synthetic data remains somewhat distinguishable from real data, reflecting subtle discrepancies that warrant further improvement.

PCA and t-SNE analyses suggests that synthetic samples occupy a feature space broadly similar to real data, although differences remain. Random Forest feature importance comparisons indicate that the most influential predictors, thalach, oldpeak, age, and cholesterol (chol), are consistently identified in both datasets. This consistency suggests that CTGAN preserves dominant predictive signals even when fine-grained distributions differ, supporting its utility for exploratory analysis and preliminary modeling tasks.

Despite these encouraging results, several limitations were noted. Discrete or sparse categorical features were reproduced less faithfully, resulting in reduced predictive alignment for some combinations of features. Additionally, multi-class ROC AUC metrics were not consistently computable, limiting certain aspects of discrimination evaluation. These challenges reflect broader issues reported in synthetic healthcare data evaluation, where fidelity and utility must be balanced and remain sensitive to feature type and dataset complexity in paper 49.

These limitations also highlight potential avenues for future improvement. Hybrid architectures, conditional GAN variants, and feature-specific regularization approaches may enhance fidelity for challenging features. Integrating domain knowledge into the generation process may further reduce discrepancies, particularly for clinically relevant variables.

This study provides a systematic, multi-faceted evaluation of CTGAN-generated synthetic heart disease data, encompassing feature-level fidelity, correlation preservation, predictive utility, and global feature-space similarity. The findings provide practical guidance for researchers aiming to leverage synthetic data for privacy-preserving modeling or for augmenting limited clinical datasets. By situating the observed strengths and limitations within established comparative findings in papers 44, 45, 47, 48, and 49, this work offers practical guidance for researchers considering synthetic tabular data for privacy-preserving modeling or data augmentation, while maintaining transparency about current methodological constraints.

VI. Conclusion

CTGAN demonstrated potential for generating synthetic tabular data suitable for preliminary modeling and exploratory analysis in privacy-sensitive contexts. The synthetic dataset retained many essential characteristics of the original data and supported predictive performance within a comparable range, indicating its usefulness for low-risk, non-diagnostic applications. Despite observable limitations, the results suggest that CTGAN can serve as a supportive tool for data augmentation, early-stage model development, and constrained-data environments.

While certain categorical features and multi-feature interactions exhibited lower fidelity, the synthetic data preserved sufficient structure to support exploratory modeling, feature importance analysis, and preliminary predictive tasks, cross-dataset evaluations using Logistic Regression and Random Forest indicated that synthetic samples retained meaningful relationships with the target variable, offering practical utility when access to real clinical data is limited or restricted.

Importantly, this work presents a transparent and reproducible framework for evaluating synthetic tabular data in healthcare that integrates feature-level fidelity analysis, correlation preservation, predictive utility assessment, and dimensionality reduction techniques. The findings highlight the role of CTGAN-generated data as a complementary resource for dataset augmentation, algorithm benchmarking, and exploratory research under privacy constraints.

Future work may further enhance data fidelity through hybrid GAN architectures, domain-informed conditional generation, and targeted improvements for sparse or complex categorical features. Overall, this study demonstrates that GAN-based synthetic data can provide a practical balance between data utility and privacy considerations for healthcare analytics.

Acknowledgment

A sincere thanks to the Center of Research and Innovation Management (CREIM) at UniSZA for facilitating this publication. Heartfelt appreciation to the UniSZA team, especially Miss Nur Laila Najwa Josdi, PhD candidate, for her contributions to the project's technical setup, and to Dr. Wan Aezwani Wan Abu Bakar, her supervisor, for valuable guidance, conceptual input, and meticulous review of the manuscript. Special acknowledgment to Assoc. Prof. Ts. Dr. Mustafa Man from UMT for his assistance with network integration and helpful recommendations during the review process.

Additionally, the team expresses gratitude to the international collaborator and the insights provided by Dr. Evizal Abdul Kadir, research fellow at Universitas Islam Riau, Indonesia, which significantly enhanced this work.

Epidemic Modeling with a Hybrid RF-LSTM Method for Healthcare Demand Prediction

Budor Alshammari[1], Bassam Zafar[2]
Department of Computing and Information Systems, King Abdulaziz University, Jeddah, 22252, Saudi Arabia [1]
Department of Management Information Systems, University of Hail, Hail, 81411, Saudi Arabia[1]
Department of Computing and Information Systems, King Abdulaziz University, Jeddah, 22252, Saudi Arabia [2]

***Abstract*—Accurate resource demand forecasts are necessary for sustainable healthcare systems to preserve flexibility and efficiency as well as to provide services in a professional manner. In this work, we propose an integrated Random Forest/Long Short-Term Memory (RF-LSTM) model for predicting Saudi Arabia's national healthcare resource demand. It combines non-linear feature extraction and temporal sequence learning. The integrated model employs governmental epidemiological and operational data from 2020 to 2024 to capture both short-term and long-term volatility and sustainability trends. The results demonstrate significant improvements in predictive accuracy compared with single-model baselines, such as Autoregressive Integrated Moving Average (ARIMA), Random Forest (RF), and Long Short Term Memory (LSTM), with reductions in Mean Absolute Error (MAE) and Root Mean Square Error (RMSE) for up to 22% and 18% compared with ARIMA, and by 12% and 9% relative to the best single model, which is LSTM, respectively A statistical analysis using one-way ANOVA confirmed the robustness of the hybrid method. Furthermore, residual plots were examined to verify model assumptions and visually assess the uniformity of prediction errors, thereby validating the results. These findings suggest that integrated AI-based prediction models can effectively facilitate capacity planning, enhance resource allocation, and contribute to achieving the objectives of Saudi Vision 2030 for a resilient, data-driven healthcare system.**

I. INTRODUCTION

The COVID-19 pandemic has driven increased use of predictive analytics in the healthcare sector, underscoring the importance of data-driven decision-making to enhance efficiency and resilience [1]. Prediction models and decision support systems have become essential tools for predicting healthcare demand and providing operational sustainability [2]. During the pandemic, machine learning (ML) and combined artificial intelligence (AI) approaches, such as Random Forest (RF) and Long Short-Term Memory (LSTM) networks, demonstrated promising results in estimating healthcare resource requirements [3]. These techniques align with the digital-health transformation targets and the broader sustainability objectives outlined in Saudi Vision 2030. [4].

This paper introduces a hybrid Random Forest-Long Short-Term Memory (RF-LSTM) model that predicts healthcare demand in Saudi Arabia by combining non-linear feature extraction with sequential learning. The model, which uses local data from 2020 to 2024 [5], aims to facilitate future capacity planning aligned with the digital health transformation objectives outlined in Saudi Vision 2030. Governmental platforms, such as Tawakkalna and Seha, have enabled large-scale data collection, patient monitoring, and healthcare management. These national digital efforts laid the framework for implementing AI-based decision support systems and data-driven healthcare [6]. The abbreviations are given in Table I.

Although predicting healthcare demand in a pandemic context remains challenging, standard models, such as ARIMA and SARIMAX, properly account for seasonality but often fail to capture complex nonlinear patterns. On the other hand, regression models, like Random Forest (RF) and XGBoost, may not effectively exploit temporal relationships when trained on independent and identically distributed data [7].

Several studies have been conducted during the COVID-19 pandemic to achieve optimal predictive outcomes; however, only a limited number have offered a comprehensive analysis of integrating various ML algorithms to enhance results and improve prediction accuracy. In other words, by integrating the essential and practical characteristics of multiple algorithms, it is possible to improve model performance and achieve superior results.

To address these limitations, researchers have introduced a novel hybrid machine learning algorithm, the Random Forest Long Short-Term Memory (RF-LSTM) model, that combines

the strengths of both approaches. The RF feature identifies non-linear relationships among epidemiological and contextual variables, whereas the LSTM component handles sequential patterns and temporal dependencies [8,9]. This proposed model has the advantage of being applied to various time-series data.

Unlike existing hybrid approaches, this study provides a distinctive methodological contribution using national-level data in Saudi Arabia that merges ML and deep-learning models in parallel or through residual correction. The proposed framework introduces a sequential RF-to-LSTM integration, where Random Forest outputs are engineered as temporal features and injected directly into the LSTM sequence-learning stage. This design enhances the model's ability to capture short-term nonlinear interactions and long-term temporal dependencies simultaneously. In addition, the study utilizes an exclusively Saudi, multivariate national dataset (2020–2024) that incorporates epidemiological indicators, ICU and bed utilization, vaccination progress, mobility patterns, and policy-response variables. No previous research has integrated this combination within a unified, sustainability-driven prediction pipeline. The framework is supported through lag-window engineering, rolling statistical smoothing, and rigorous statistical validation (ANOVA, Tukey HSD), offering a transparent and reproducible methodological advancement. It introduces a sequential feature-injection architecture, in which Random Forest is employed as a nonlinear feature transformation mechanism rather than a parallel predictor or ensemble component. Specifically, RF-derived representations are generated from multivariate epidemiological and operational indicators and subsequently restructured into temporally ordered sequences that serve as inputs to the LSTM network. This design enables the LSTM to simultaneously learn long-range temporal dependencies and nonlinear cross-sectional interactions—capabilities that are not fully captured by existing parallel or ensemble-based RF–LSTM approaches reported in the literature. By embedding RF outputs directly within the temporal learning pipeline, the proposed model establishes a structurally distinct hybrid architecture explicitly tailored to national-level healthcare demand forecasting under high volatility and resource-constrained conditions.

II. Related Work and Research Gaps

Research on epidemic and healthcare prediction has progressed from traditional statistical models to hybrid AI approaches that emphasize both predictive accuracy and operational sustainability [10].

Traditional time-series models such as ARIMA and SARIMA have been widely used for COVID-19 forecasting due to their simplicity and interpretability. However, their performance significantly deteriorates when dealing with nonlinear dynamics, sudden structural changes, and multivariate dependencies in healthcare indicators. Kufel et al. [10] and Roy et al. [11] demonstrated that while ARIMA models can capture seasonality, they fail to adapt to regime changes and complex epidemic waves. Logistic Patient Information-Based Algorithm (LPIBA) is a sophisticated algorithm employed to forecast the number of coronavirus mortalities and infections. Although LPIBA demonstrated superior performance compared to ARIMA, it exhibits limitations when comprehensive data is lacking or when collecting certain features is impractical [12]. Another model, the Prophet model, is a robust algorithm when data is missing. It is an open-source model that exhibits strong performance with time-series data [13].

Traditional models, such as ARIMA and SARIMA, have failed to capture the nonlinear relationships and dynamic shifts present in epidemiological data. In contrast, Hybrid models that combine ensemble learners such as Random Forest with sequential deep learning techniques like LSTM have shown strong potential due to their enhanced accuracy and resilience [11]. Logistic Patient Information-Based Algorithm (LPIBA) is a sophisticated algorithm employed to forecast the number of coronavirus mortalities and infections. Although LPIBA demonstrated superior performance compared to ARIMA, it exhibits limitations when comprehensive data is lacking or when collecting certain features is impractical [12]. Another model, the Prophet model, is a robust algorithm when data is missing. It is an open-source model that exhibits strong performance with time-series data [13].

A. Hybrid AI-Based Forecasting Models

Recent studies have explored hybrid architecture integrating ensemble learning and deep neural networks. Borges and Nascimento (2022) proposed a two-stage Prophet–LSTM model for ICU demand forecasting during COVID-19. Their model improved short-term prediction accuracy by combining Prophet's trend extraction with LSTM's temporal learning. However, a major limitation was the high sensitivity of Prophet to sudden policy changes and under-reporting issues, which caused reduced performance during extreme outbreak waves [14]. Punia et al. (2020) developed a Random Forest–LSTM hybrid architecture, where RF was used for nonlinear feature extraction and LSTM for sequence modeling. Their approach significantly improved demand forecasting accuracy across multiple datasets. Nevertheless, the model showed limited generalization capability when applied to new regions with different healthcare dynamics, highlighting a lack of regional adaptability [15]. Furthermore, Kaur and Singh (2023) proposed a hybrid CNN–LSTM model focused on sustainable healthcare management. Although their model captured spatial and temporal patterns effectively, it struggled with real-world missing data and exhibited instability when trained on noisy policy-related variables [16].

Similarly, Rahman and Lee (2024) introduced an RF–GRU hybrid model for sustainable healthcare demand prediction in Asian countries. Their results demonstrated improved performance over standalone models; however, their framework required extensive hyperparameter tuning and suffered from high computational complexity, making large-scale deployment challenging [17]. In Saudi Arabia, Alabbad et al. (2022) developed a machine learning model for ICU length-of-stay prediction using Saudi Arabian clinical data. Although their work highlighted the importance of local datasets, their model was limited to a single outcome variable and did not address broader national healthcare capacity forecasting [18]. International efforts, such as the COVID-19 Forecast Hub, have also demonstrated the effectiveness of ensemble models in predicting mortality and hospitalisation rates [19].

Overall, these studies indicate the growing awareness of sustainability-driven forecasting in the healthcare industry. Hybrid ML models, including those that integrate ensemble and sequential learning, improve their strength and comprehension in the presence of real-world uncertainty. However, their potential for long-term healthcare prediction at the national level is underexplored, emphasizing the importance of integrated frameworks that incorporate predictive analytics into national healthcare decision-support systems [20].

[24] Alshammari et al., 2024	RF	0.214	0.809	Baseline random forest model with strong interpretability but limited temporal adaptability.
[25] Li et al., 2024	LSTM	0.230	0.900	Temporal dependencies were captured but showed higher error variance during non-stationary periods.
This work (RF-LSTM)	Hybrid AI Forecasting	0.188	0.737	Achieved the lowest MAE (0.188) and RMSE (0.737), indicating superior accuracy and variance stability across national healthcare datasets.

In Table II, a comparative analysis with other hybrid predicting studies was summarized to complement the baseline model comparison presented earlier.

The comparison results further validate that the proposed hybrid RF-LSTM framework attains substantial enhancements in both predictive accuracy and robustness, surpassing prior methodologies by adeptly merging short-term dynamics with long-term sustainability factors.

B. Identified Weaknesses in Existing Hybrid Studies

Most hybrid models focus on regional or hospital-level datasets. Few studies attempt national healthcare demand forecasting using government operational data, which limits scalability for policy-level planning. Moreover, many hybrid approaches use parallel architecture, where ML and DL components run independently. This limits deep integration between nonlinear feature extraction and temporal sequence learning. In addition, several models assume smooth data patterns, while real-world healthcare data includes reporting delays, missing values, and abrupt policy shifts. Existing models often lack robust preprocessing pipelines to handle these challenges.

According to the cost and complexity, Hybrid deep architectures (CNN-LSTM, RF-GRU) frequently require extensive training time and computational resources, which limit their deploy ability in real-time healthcare decision-support systems. A significant number of studies focus on short-term forecasting without integrating sustainability indicators and long-term healthcare system resilience.

C. Research Gap and Motivation

From the previous studies, it becomes clear that although hybrid models such as Prophet–LSTM, CNN–LSTM, and RF–GRU have improved forecasting accuracy, they still face critical limitations in terms of national scalability, long-term sustainability, and operational integration.

Therefore, there exists a clear research gap in developing a sequential hybrid model that:

- Integrates static nonlinear learning with temporal sequence modeling,
- Utilizes large scale national healthcare datasets, and
- Supports sustainable healthcare planning within the context of Saudi Vision.

This study addresses these gaps by proposing a sequential RF-LSTM architecture, where Random Forest outputs are embedded as engineered features into the LSTM network. This ensures stronger integration between spatial-contextual learning and temporal dynamics while maintaining interpretability and operational feasibility.

III. MATERIALS AND METHODS

A. Dataset

The database consists of local-level daily healthcare indicators in Saudi Arabia during the period (2020–2024). It is generated by the Ministry of Health (MOH) Coronavirus Open Data Portal, and the World Health Organization (WHO) Dashboard was used as a secondary source to support the dataset, as it provides regularly updated healthcare indicators [5, 21].

- The dataset comprises the following information:
- Confirmed COVID-19 cases and recovery rates.
- ICU and hospital bed occupancy rates.
- Vaccination rates.
- Policy and mobility indicators.

Additional variables such as holidays and weather information.

B. Data Preprocessing

Linear interpolation was used to supplement missing data points. Outliers were identified and excluded using the interquartile range (IQR) approach and eliminating all

observations below Q1 - 1.5 × IQR or above Q3 + 1.5 × IQR. The process thoroughly addressed errors, including reporting spikes and inconsistencies, ensuring consistent data for model training. Continuous data were normalized to the [0, 1] interval, whereas categorical variables (e.g., policy constraints and weather conditions) were one-hot encoded. Additionally, lagged features were generated with delays of 1 to 14 days to record temporal dependencies, representing short-term effects [22]. 7 and 14-day rolling averages recognized medium-term trends and minimized daily fluctuations. Lagged transformations are also applied to ICU capacity and vaccination rates to preserve the temporal structure and enhance sequential learning in the hybrid model.

1) Handling missing values: As shown in Eq. (1), missing values are estimated using linear interpolation by assuming a linear trend between the previous and next observations.

$$\hat{x}_t = x + \left(\frac{x_{t+1} - x_{t-1}}{2}\right) \quad (1)$$

Where:

- $\hat{x}_t$ is the interpolated value at time t
- x_{t-1} is the previous known observation
- $x_{t+1}$is the next known observation
- t represents the current time index

This method was selected due to its effectiveness in preserving temporal continuity in epidemiological time-series data.

Outlier Detection:

$$\text{Lower Bound} = Q1 - 1.5 \times IQR \quad (2)$$

$$\text{Upper Bound} = Q3 + 1.5 \times IQR \quad (3)$$

$$\text{Where: } IQR = Q3 - Q1 \quad (4)$$

The Interquartile Range (IQR) method was applied to detect and remove extreme outliers, Eq. (2), and Eq. (3).

Where:

- Q1: First quartile (25th percentile)
- Q3: Third quartile (75th percentile)
- IQR: Interquartile range, representing the spread of the middle 50% of the data

The 1.5 multiplier was adopted as the standard threshold for statistical outlier detection, based on Tukey's conventional method. The interpolation process [Eq. (1)] and the IQR-based outlier detection [Eq. (2–4)] contribute to stabilizing the dataset before training the RF–LSTM model.

2) Normalization and encoding: As shown in Equation (5), Min–Max normalization rescales the variables into the range [0,1] to ensure uniform feature scaling and improve training stability.

$$x' = \frac{x - x_{min}}{(x_{max} - x_{min})} \quad (5)$$

Categorical weather/policy indicators were one-hot encoded.

Where:

- X is the original feature value
- Xmin and Xmax are the minimum and maximum values of the feature
- X' is the normalized value

3) Lag and rolling features: Lagged features preserve short-term temporal dependencies by directly shifting past values into the current input space. In this study, lag orders k = 1 to 14 days were used to capture immediate epidemiological dynamics and short-term variations in healthcare demand, where Xt-k denotes the observation at time step t-k as shown in Eq. (6).

$$X_{t,k}^{(lag)} = x_{t-k} \qquad K=1,..,14 \quad (6)$$

The rolling mean in Equation (7) was applied to smooth short-term fluctuations and captured medium-term trends. Here, (w) denotes the window size, which was set to 7 and 14 days in this study, and Xt-i represents the previous observations within the defined window. This transformation reduces noise and enhances the stability of the learning process for the sequential RF-LSTM framework.

$$X_t^{(w)} = \left(\frac{1}{w}\right) \Sigma_{i=0}^{w^{-1}} X_{t-i} \quad (7)$$

C. Model Architecture

The proposed hybrid framework operates in two sequential stages, summarized in Algorithm 1: RF for static feature learning and LSTM for sequence modeling.

1) Random Forest (RF) regressor: The Random Forest regressor predicts healthcare demand by averaging the outputs of multiple decision trees, as expressed in Equation (8). At each time step t, the feature vector Xt, including lagged and rolling statistical features, is provided to all B trees. Each tree generates a prediction $h_{b(X_t)}$, and the final RF prediction $\hat{Y}_{RFt} =$ is obtained by computing their Mean. In the proposed hybrid framework, these RF predictions serve as engineered static features. They are subsequently injected into the LSTM network to enhance temporal learning and improve the stability of long-horizon forecasting.

RF regression:

$$\hat{Y}_{RF,t} = \left(\frac{1}{B}\right) \Sigma\, h_{b(X_t)} \quad (8)$$

Where:

B is the number of trees

hb (.) is the prediction of tree b

This integration allows the model to combine the non-linear representational power of ensemble learning with the sequential modeling capability of LSTM networks.

2) Long Short-Term Memory (LSTM) network: To model temporal dependencies, the LSTM network links residual and RF prediction sequences. The Adam Optimiser is used for training, with early termination to prevent overfitting. Additionally, sequence normalisation and dropout regularisation improve model generalisation [23].

The LSTM captures sequential dependencies using the following equations:

$$f_t = \sigma\left(W_{f\,[h_t^{-1}, x_t]} + b_f\right) \quad (9)$$

$$i_t = \sigma\left(W_{i\,[h_t^{-1}, x_t]} + b_i\right) \quad (10)$$

$$\tilde{C}_t = \tanh\left(W_{C[h_{t-1}, x_t]}\right] + b_c \quad (11)$$

LSTM Prediction:

$$\hat{Y}_{LSTM,t} =: g(h_t) \quad (12)$$

The LSTM network was employed to model complex temporal dependencies within the healthcare demand data. At each time step t, the input vector xt includes temporal features and the Random Forest prediction $\hat{Y}_{RF,t}$, which is treated as an additional engineered feature. The forget gate in Eq. (9) controls the retention of historical information, while the input gate in Eq. (10) regulates the incorporation of new temporal patterns and external signals. The candidate memory state in Eq. (11) updates the internal memory based on current and previous inputs. Finally, the output layer generates the predicted healthcare demand $\hat{Y}_{LSTM,t}$as described in Eq. (12). This mechanism enables the proposed hybrid model to effectively capture both short-term dynamics and long-term dependencies in national healthcare demand patterns.

Algorithm 1: Sequential RF-LSTM Hybrid Framework

Input:
xt ← Preprocessed feature matrix at time t
yt ← Target healthcare demand variable
Output:
ŷt ← Final hybrid forecast
Stage 1: Data Preparation
1: Generate lagged features (t − 1 … t − 14)
2: Compute rolling statistics (7-day and 14-day windows)
3: Apply Min–Max normalization to continuous variables
4: Encode categorical variables using one-hot encoding
Stage 2: Random Forest Feature Learning
5: Initialize Random Forest regressor
6: Train RF on (xt, yt)
7: Generate static predictions:
ŷRF,t = RF(xt)
Stage 3: Sequential Data Construction
8: Augment features:
St = [xt , ŷRF,t]
9: Construct time-series sequences:
for t = 1 to T − L do
Create input sequence S_(t:t+L)
Assign target y_(t+L)
end for
Stage 4: LSTM Sequence Learning
10: Initialize LSTM model
11: Configure hyperparameters:
- Hidden units = 64
- Dropout = 0.2
- Optimizer = Adam
12: Train LSTM on constructed sequences
13: Apply early stopping based on validation loss
Stage 5: Hybrid Prediction
14: Predict final output:
ŷt = LSTM(St)
Return:
ŷt

Algorithm 1 summarizes the sequential workflow of the proposed RF-LSTM hybrid framework for national healthcare demand forecasting. In Stage 1, the raw epidemiological and operational indicators are transformed into a learning-ready feature set through lag generation, rolling-window statistics, normalization, and one-hot encoding. This step ensures that both short-term dynamics (through lagged features) and medium-term trends (through rolling averages) are explicitly represented. In Stage 2, a Random Forest regressor is trained on these features to capture nonlinear interactions among the input variables, yielding static predictions that reflect the baseline healthcare demand.

In Stage 3, the Random Forest predictions are concatenated with the original preprocessed features to construct enriched sequences that combine both engineered static information and temporal patterns. These augmented sequences are then reshaped into input windows suitable for sequence learning. In Stage 4, an LSTM network is trained on these sequences using the Adam optimizer, early stopping, and dropout regularization to learn long-range temporal dependencies while preventing overfitting. Finally, in Stage 5, the trained LSTM model produces the hybrid forecast ŷ, which integrates the strengths of both components: the interpretability and robustness of Random Forest and the temporal adaptability of LSTM. This sequential design is particularly suitable for national-level healthcare forecasting, where complex nonlinear relationships and time-dependent dynamics must be modeled simultaneously.

where, L represents the sequence length (look-back window), which defines the number of past time steps used as input to the LSTM, in this study, L = 14 days was selected based on epidemiological considerations and prior forecasting literature.

This hybrid architecture enhances prediction stability and responsiveness to changes in national healthcare data by leveraging the complementary advantages of both components,

the LSTM for dynamic sequence modeling and the RF for interpretable static learning. This kind of combination is consistent with the latest advances in time-series prediction that adopt explainable ML. The sequential RF-LSTM method is described in Algorithm 1, which begins with preprocessing and lag creation, followed by model training and residual integration.

Fig. 1 illustrates the complete architecture of the proposed sequential RF–LSTM hybrid model, designed specifically to address the complex, nonlinear, and time-dependent nature of national healthcare demand in Saudi Arabia. This architecture stems from its structured, task-specific division of learning responsibilities across model stages.

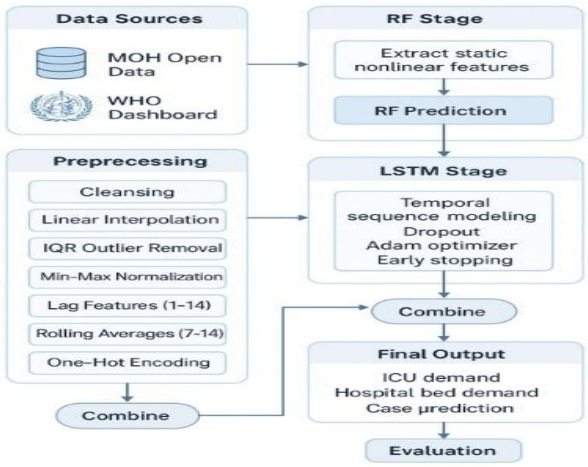

Fig. 1. The structure of the proposed RF-LSTM hybrid model for healthcare demand forecasting.

In the first stage, the Random Forest (RF) module extracts nonlinear and static patterns from heterogeneous healthcare indicators, including ICU occupancy, hospital bed utilization, vaccination rates, mobility signals, and policy measures. This is particularly important because healthcare systems' data exhibit irregular interactions and nonlinear dependencies across variables, which traditional linear or purely sequential models fail to represent adequately.

D. Training and Evaluation Protocol

1) Loss function for training: The hybrid RF–LSTM model was trained using the Mean Squared Error (MSE) as the objective function, defined as:

$$MSE = \left(\frac{1}{n}\right) \Sigma \, (y_t - \hat{y}_t)^2 \tag{13}$$

where, yt and $\hat{y}_t$ represent the actual and predicted healthcare demand at time t, respectively, and n is the total number of observations. The Adam optimizer was employed to minimize the loss function in (13), enabling stable, efficient convergence during training while preventing overfitting through early stopping mechanisms.

2) Performance evaluation metrics: After training, the proposed model's performance was assessed using three standard forecasting metrics: Mean Absolute Error (MAE), Root Mean Square Error (RMSE), and Coefficient of Determination (R2).

The Mean Absolute Error (MAE) is expressed as:

$$MAE = \left(\frac{1}{n}\right) \Sigma \, |y_t - \hat{y}_t| \tag{14}$$

The Root Mean Square Error (RMSE) is defined as:

$$RMSE = sqrt\left(\left(\frac{1}{n}\right) \Sigma \, (y_t - \hat{y}_t)^2\right) \tag{15}$$

In addition, the coefficient of determination (R2) is given by:

$$R^2 = 1 - \frac{\Sigma (y_t - \hat{y}_t)^2}{\Sigma (y_t - \bar{y})^2} \tag{16}$$

where denotes the mean of the observed healthcare demand values.

Eq. (13) was used as the loss function during the training phase to minimize the squared difference between actual and forecast healthcare demand values. Subsequently, Eq. (14)–(16) were applied for post-training evaluation. MAE provides an intuitive measure of average prediction error, RMSE emphasizes large deviations, which are critical in healthcare resource planning, and R2 quantifies the model's explanatory power in capturing variations in national healthcare demand patterns.

3) Statistical testing: To statistically validate the observed performance differences among the compared forecasting models, a one-way Analysis of Variance (ANOVA) was conducted using the F-statistic defined in Equation (17). The test examined whether variations in predictive errors across models were statistically significant at $\alpha = 0.05$. Following ANOVA, a Tukey HSD post hoc test was applied to identify pairwise differences among individual models. This statistical framework ensured that the superior performance of the proposed RF–LSTM hybrid model was not due to random variation but represented a statistically significant improvement over benchmark models.:

$$F = \frac{\frac{SS_{between}}{k}}{\frac{SS_{within}}{N-k}} \tag{17}$$

followed by Tukey HSD for pairwise comparison.

Baseline comparators included:

ARIMA/SARIMAX (statistical models)

Random Forest (RF) (tree ensemble)

Long Short-Term Memory (LSTM) (deep learning).

Residual analysis was employed to evaluate the errors and their distribution over prediction horizons. Moreover, Residual diagrams demonstrate the differences between predicted and observed values, while error variance measures the strength under variable demand conditions. These analyses provided valuable insights into the model's reliability during both outbreak peaks and intervals of stability.

IV. RESULTS

A. Quantitative Performance

The RF-LSTM hybrid model achieved the lowest MAE and RMSE, and a near-perfect R2 of 0.9995. The MAE and RMSE (Table III) values represent the average and squared variances between the expected and actual healthcare demand, however. Lower values indicate more accurate and consistent predictions, whereas higher R2 values indicate a more precise overall model fit.

Moreover, the RF-LSTM achieved the lowest RMSE (0.737), demonstrating enhanced robustness against demand fluctuations. Lower RMSE values further reflect greater forecast stability and reduced sensitivity to demand fluctuations, reaffirming the model's advantage in dynamic healthcare environments.

TABLE III. CORE PERFORMANCE METRICS

Model	MAE	RMSE	R2
ARIMA	0.265	0.955	0.9978
RF	0.214	0.809	0.9990
LSTM	0.245	0.910	0.9985
RF–LSTM (proposed)	0.188	0.737	0.9995

The hybrid RF-LSTM model achieved the lowest MAE (0.188), indicating minimal average discrepancy between predicted and actual healthcare demand. (Fig. 2) illustrates performance enhancements of 22% and 12% compared to the ARIMA and LSTM models, thereby validating the hybrid model's superior predictive accuracy.

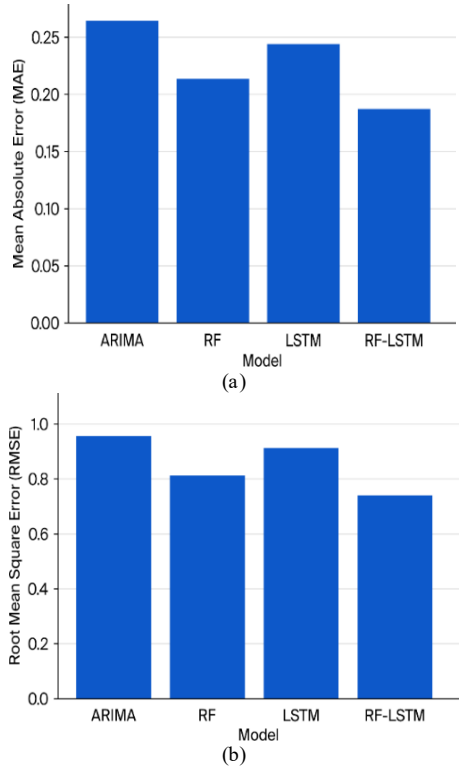

Fig. 2. Comparison of MAE (a) and RMSE (b) Across the proposed hybrid RF-LSTM model and other models.

B. Model Performance During Peak Demand

To further evaluate the robustness of the proposed model under critical stress conditions, its behavior during a simulated peak healthcare demand period was analyzed. Fig. 3 illustrates the temporal prediction performance of all models during a 30-day high-demand interval. The RF–LSTM hybrid model exhibits stronger stability and closer alignment with the actual demand curve compared with ARIMA, standalone RF, and standalone LSTM models.

Unlike ARIMA, which shows delayed adaptation to sudden demand spikes, and LSTM, which occasionally overshoots in highly volatile phases, the proposed hybrid model maintains smoother and more accurate tracking of temporal changes. This improved performance is attributed to the integration of nonlinear feature extraction from the RF stage with the temporal learning capacity of the LSTM stage.

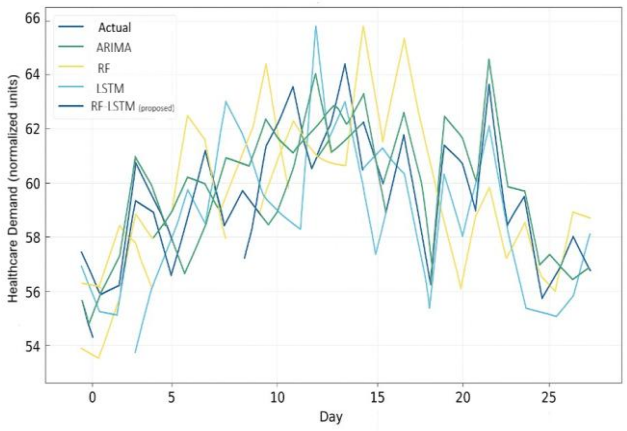

Fig. 3. Model behavior during a simulated peak demand period.

C. Hyperparameter Sensitivity Analysis

1) Effect of RF ensemble size: The impact of the Random Forest ensemble size on the hybrid model performance is shown in (Fig. 4). As the number of trees increases from 100 to 200, a clear decreasing trend in RMSE is observed, indicating improved stability and reduced variance. Beyond 200 trees, only marginal improvements were observed while computational cost increased significantly. Therefore, an ensemble sized 200 trees was selected for the final model configuration.

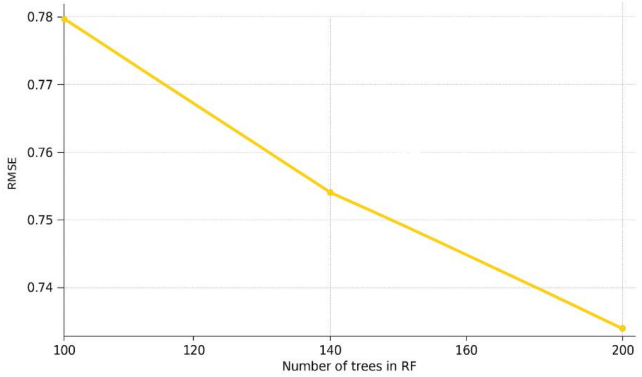

Fig. 4. Effect of RF ensemble size on hybrid RF–LSTM RMSE.

2) Effect of sequence length L on hybrid RF–LSTM MAE performance: To analyze the influence of sequence length on temporal modeling, experiments were conducted using sequence lengths of 7, 10, and 14 days.

As shown in Fig. 5, increasing the sequence length results in a consistent reduction in MAE. Shorter sequences limit the model's ability to capture medium-term dependencies, whereas longer sequences allowing L = 14 significantly enhance temporal learning. A sequence length of 14 days was selected as the optimal input configuration, balancing prediction accuracy and computational efficiency.

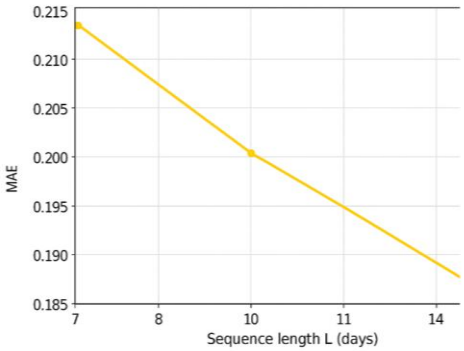

Fig. 5. Effect of sequence length L on hybrid RF–LSTM MAE performance.

D. Error Distribution and Robustness

Analysis of the error distribution and variance revealed that the hybrid approach reduces variability compared to individual models. Residual plots showed narrower confidence intervals, thereby verifying enhanced stability during both outbreak surges and low rates. These results support previous studies on hybrid models, explaining that they are strong enough to manage changes in systems [2,15,20]. The suggested framework demonstrated superior performance relative to both regional and global standards while maintaining clarity and scalability.

V. Discussion

The hybrid RF-LSTM model efficiently integrates two complementary methodologies: ensemble feature extraction and advanced sequence modelling, allowing the system to manage complex, non-linear, and non-stationary healthcare data. From a healthcare perspective, implementing these models into local health visualizations enables the immediate detection of ICU incidents, facilitates flexible resource allocation, and supports strategic planning. This approach supports data-driven governance and long-lasting digital health systems. These findings are also consistent with worldwide trends, where hybrid ensemble and deep learning architectures are improving pandemic preparedness and operational resilience.

The above approaches correspond with the latest international initiatives to utilise AI-based prediction in healthcare systems. The suggested RF-LSTM framework fits with this model because it combines explainable ensemble learning (RF) with temporal adaptability (LSTM). This makes it a good compromise between ease of understanding and predictive accuracy. This combination enables the model to leverage Random Forests' feature-level transparency and LSTMs' sequential learning capabilities, making it especially suitable for healthcare systems characterized by dynamic, diverse data sources.

Fig. 6 demonstrates the variation in MAE over time for ARIMA, RF, LSTM, and RF-LSTM models at different prediction horizons (7, 10, and 14 days). It shows that the prediction errors of all models gradually increase as the prediction horizon lengthens. Nonetheless, the hybrid RF-LSTM consistently maintains the lowest MAE and displays a more natural decline in performance. This indicates that the hybrid model can effectively handle longer prediction periods, providing better reliability and resilience against cumulative errors, thereby enhancing its robustness. The distinct separation between the curves indicates that the hybrid model generalizes more effectively in unstable healthcare scenarios.

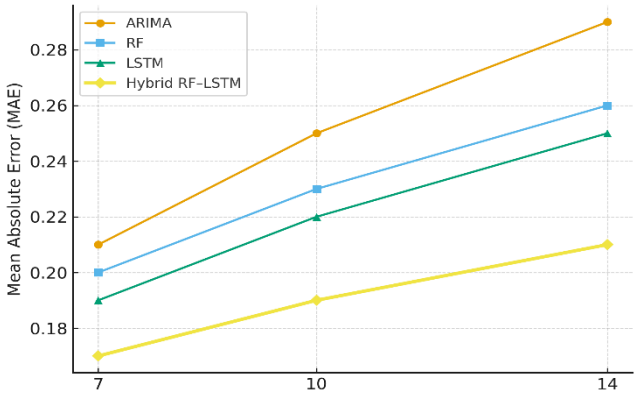

Fig. 6. Temporal variation of MAE across forecasting horizons (7-day, 10-day, and 14-day ahead) for ARIMA, RF, LSTM, and RF-LSTM models, showing the superior stability and accuracy of the hybrid approach.

The RF-LSTM model is more stable and can be applied in a broader range of situations due to its hybrid architecture. Random Forest reduces non-linear variance, and LSTM detects temporal consistency. In combination, they reduce overfitting and adapt to changes in epidemic and operational dynamics. In practical healthcare environments, this improvement can help hospital administrators prepare for surges in ICU demand, use staff effectively, and balance national medical resources during crises.

Overall, the results show that the proposed RF-LSTM model not only enhances predictive accuracy but also helps healthcare operations stay resilient and sustainable. The model demonstrates both technical dependability and practical value for national healthcare forecasting by enhancing data utilization, resource management, and the operation of early warning systems.

A. Limitations and Future Work

Although the suggested model performs well, several limitations require attention. First, it depends on continuous and accurate updates from national health datasets for optimal performance, which may not always be complete or timely. Second, the model's two-stage training process increases computational costs. Third, the RF-LSTM captures complex temporal dynamics; however, its ability to handle larger, more diverse regional datasets remains to be confirmed.

On the other Hand, Future research may target these limitations by exploring an advanced ensemble method that combines attention techniques with Graph Neural Networks (GNNs) to capture correlations across multidimensional healthcare data more effectively. The goal of this approach is to enhance the model's generalizability and interpretability across a broader range of healthcare settings within the Gulf Cooperation Council (GCC) region. Incorporating additional sustainability criteria, both environmental and operational, could also help optimize predictive analytics to better align with Saudi Arabia's Vision 2030 objectives.

VI. Conclusion

This study presented a hybrid Random Forest–Long Short-Term Memory (RF–LSTM) model designed to improve national healthcare demand forecasting in Saudi Arabia through an integrated approach that combines non-linear feature extraction with advanced sequence learning. Motivated by the data-driven transformation goals of Saudi Vision 2030, the proposed model leverages a comprehensive, exclusively Saudi dataset (2020–2024) that includes epidemiological indicators, ICU and bed utilization, vaccination progress, mobility metrics, and policy-response variables. By engineering Random Forest outputs as temporal features and feeding them directly into the LSTM architecture, the framework captures both short-term non-linear interactions and long-term temporal dependencies in a unified predictive pipeline.

The findings demonstrate that the hybrid RF–LSTM model consistently outperforms traditional and single-model baselines—including ARIMA, RF, and LSTM—across multiple forecasting horizons. The model maintains lower error rates and enhanced stability as prediction windows lengthen, highlighting its robustness against cumulative uncertainty and rapidly changing healthcare conditions. From an operational standpoint, the model offers practical value for strategic planning, enabling earlier detection of ICU trends, more flexible allocation of healthcare resources, and improved resilience of national decision-support systems. Its alignment with international AI-healthcare initiatives reinforces its relevance within broader global efforts to strengthen pandemic preparedness and digital-health infrastructure. While the model achieves strong performance, certain limitations remain, including reliance on continuous dataset updates, increased computational requirements due to its two-stage architecture, and the need to validate performance across more diverse regional datasets. Future research should explore integrating attention mechanisms, graph neural networks, and expanded sustainability metrics to enhance generalizability, interpretability, and alignment with Vision 2030 objectives.

Overall, the proposed RF–LSTM framework provides both methodological innovation and operational significance, offering a scalable and data-driven solution for national healthcare forecasting. It represents a meaningful contribution toward building resilient, intelligent, and sustainable healthcare systems in Saudi Arabia and beyond.

Acknowledgment

The author is grateful to all the journal editors and anonymous reviewers for their time and effort. The author is also thankful to the Deanship of Scientific Research at the University of Hail for its continuous support and collaboration. This manuscript's English translation and proofreading were assisted by 'Grammarly'. All responsibility for the content of this paper rests solely with the authors.

Funding Statement

This work has no funding, unless the acceptance letter is received. King Abdulaziz University will provide financial support.

Availability of Data and Materials

The data supporting the findings of this study are openly available in the following repository: Ministry of Health (Saudi Arabia). COVID-19 Open Data Portal [5]: Open Data - Open Data Library (accessed on Jan 2025). the World Health Organization (WHO). COVID-19 Dashboard [21]: Saudi Arabia. (accessed on May 2025).

Ethics Approval

This study did not require ethics approval, as it used only publicly available, anonymized datasets and collected no new data from human subjects.

Conflicts of Interest

The authors declare no conflicts of interest to report regarding the present study.

Intelligent Platform for Employee Retention Prediction

Medha Wyawahare, Milind Rane, Ashish Rodi, Samarth Arole, Aryan Mundra
Electronics and Telecommunication Engineering, Vishwakarma Institute of Technology, Pune, India

***Abstract*—Employee retention is a very important challenge to the organizations since it raises the cost of recruitment, affects domain knowledge retention, and impacts workforce stability. Presented here is a platform-based intelligent employee retention prediction system as a real-time HR decision support tool. As a part of the research, Feedforward Neural Network was initially trained and tested with structured employee data to confirm the relevance of the features and predictive viability, which had recorded an accuracy of 88.7%. This final implementation will integrate an AI-based Chat Widget with a modular pipeline system that will utilize an LLM for performing analytical reasoning on employee attributes and provide human-understandable explanations that will aid the HR decisions. The architecture separates the user interaction layer (Agent) from the prediction and reasoning logic (Pipeline), which makes the system scalable, interpretable, and easily integrable with the workflows of an organization. The proposed platform will show how validated predictive models and LLM-provided reasoning can be integrated in order to provide actionable and explainable employee retention insights.**

***Keywords*—Employee retention; feedforward neural network; Large Language Model; HR analytics; intelligent platform**

I. Introduction

Current organisations have been facing serious employee retention issues due to increase in recruitment costs, onboarding, and the loss of organisational knowledge that comes with employee turnover. High rates of attrition have adverse effects on productivity, team building, and long-term strategic planning. Consequently, more organizations are turning to data-based methods to identify employees who are vulnerable to turnover and develop proactive retention plans.

Deep learning and machine learning methods have gained popularity in predicting employee attrition in recent years. Conventional approaches like decision trees, logistic regression, and ensemble are mainly based on structured historical data and provide little interpretability to HR professionals. Even though neural network-based models enhance predictive accuracy by modeling non-linear relationships among employee attributes, they are typically black boxes and cannot be easily incorporated into real-time HR processes. Also, the majority of available solutions have difficulties integrating unstructured or semi-structured data, including employee feedback or qualitative measures of work attitude.

To overcome these shortcomings, this paper introduces an intelligent, platform-based employee retention prediction system that integrates tested predictive modeling with explainable AI-driven reasoning. In the research stage, a Feedforward Neural Network (FNN) was constructed with structured employee information to confirm the relevance of features and determine predictive ability. The information gained through this model was used in the design of the solution eventually deployed. Predictive intelligence has been integrated into an AI Chat Widget in the operational system, which communicates with a modular GenAI pipeline. A Large Language Model (LLM) serves as an analytical reasoning tool over employee data and is capable of providing human-interpretable explanations to enable HR teams to make informed decisions based on risk factors.

The proposed architecture distinguishes between user interaction (Agent) and prediction and reasoning logic (Pipeline) to provide scalability, modularity, and easy deployment. The system combines predictive modeling with LLM-based explainability to provide an interface between high-accuracy attrition prediction and HR decision support. The design enables organizations to move beyond fixed prediction models to interactive, explainable, and scalable retention analytics platforms.

This paper is organised in the following way. Section II is a literature review on employee attrition prediction and current ML models. Sections III and IV address the research gap and problem formulation. Section V introduces the proposed methodology, which involves the FNN-based validation step and the LLM-based platform architecture. Section VI explains the experimental design and the findings of the predictive model. Section VII explains the implications of the findings and the role of explainability in HR decision-making. Lastly, Section VIII summarizes the paper and provides future research directions.

II. Literature Review

One of the most important workforce analytics is employee turnover prediction because of its financial and operational repercussions on an organization. Different deep learning and machine learning methods have been utilized to perform the analysis of the attrition patterns and come up with prediction methods. This section will examine research literature and will categorize the studies in terms of the methods used.

Pioneering researches used the conventional statistical models like logistic regression (LR) and the ordinary least squares (OLS) regression to forecast turnover. Logistic regression has been extensively used in determining the important attributes of attrition which include salary, job satisfaction, and tenure [15][16][19][20][27][29]. Other studies included regression analysis using employee biodata and

predictive personality which emphasized the significance of predicting job retention [21][34]. In other studies, the survival models and discrete choice analysis were used to distinguish voluntary and involuntary turnover [25]. Its performance in OLS regression coupled with neural networks was established in the analysis of workforce attrition [41]. Logistic regression in HR analytics was also studied, using it on the data of various organizations [30][35].

Decision tree-based models like Gradient Boosting (GB), Random Forest (RF) and XGBoost have gained wide popularity because they provide the capability to model high-order interactions between features [9][17][23][28][32][33]. Ensemble techniques were compared and the findings showed that XGBoost has always been better than other classifiers in turnover prediction [38][43][51]. Other studies suggested combining decision trees with SVM, Naive Bayes, and AdaBoost to enhance their accuracy [7][45][47]. Combination of uplift modeling with retention prediction demonstrated that the other conventional classifiers performed better but uplift modeling offered more precise interventions [55]. Also, other studies were able to combine features selection techniques like Chi-Square and Information Gain to improve the performance of the decision trees [54].

Employee retention prediction has strongly embraced the use of DL techniques, especially the Artificial Neural Networks (ANNs). Research concluded that DL models such as the feedforward neural networks (FNN) and convolutional neural networks (CNN) performed better than traditional machine learning models [8][13][14]. Other studies used a multi-layered deep learning model, which combined demographic factors and measures of employee engagement to enhance the accuracy of predictions [26][31]. Deep autoencoders were used with genetic algorithms (GA) to optimize feature selection in other studies [40]. Solutions based on neural networks, like Brownian Motion Butterfly Optimization have also been suggested to minimize overfitting and better turnover prediction [11][10][53]. Explainable AI methods like SHAP and LIME were also included in the research to understand deep learning models [7].

Certain researches touched upon alternative predictive models, such as uplift model and organizational network model. The uplift modeling that targets employees who are most likely to react to retention-related interventions proved to be more effective in intervention than the traditional classifiers [55]. Besides, Organizational Network Analysis (ONA) was also used to examine the level of employee connectivity within firms and found out that the network structures greatly influence turnover behavior [52].

Some studies combined a number of ML methods to enhance the accuracy of prediction. Employee retention analysis has been suggested to use hybrid models with decision trees and SVM, Naive Bayes, and AdaBoost [7][47]. In other studies, model fusion models have been used, which combines a number of classifiers with the aim of attaining an improved performance in prediction [50]. One research presented a weighted quadratic random forest (WQRF) model, which has improved the classification based on weighted decision trees [50]. Other studies used clustering techniques alongside ANNs and data augmentation, including CTGAN, to enhance the strength of models [42]. Researchers also investigated the stacking, and optimization models to improve the precision of the prediction [48].

Several studies have explored alternative approaches to employee retention prediction. Yanamala (2020) emphasized on the value of big data and machine learning in evaluating the working class [1], while it was Yahia et al. who further went up and introduced a deep data dimension for better predictions [4]. Authors Sexton et al. (2005) and Pérez-Campdesuñer et al. established that neural networks are better than traditional models [5][6]. Rane et al. investigated the applications of AI, machine learning, and deep learning in businesses to retain HRs [18][39]. Shafie et al. were working on ANNs with data augmentation to use in clustering, and El-Rayes et al. (2020) were working on trees to identify useful features to use in turnover analysis [22][24]. Lim et al. proposed a novel approach that uses a deep autoencoder and KNN, to enhance the prediction of the employee turnover [36]. On the same token, Park et al. used advanced ML techniques to predict employee retention by reviewing new trends in the workforce [37][2][39]. Examples of deep learning progress are Al-Darraji et al.'s practice for predicting worker attrition [44] and Cheng's method for HR predictive analytics [49]. In their study, Zhang et al. used machine learning to discover main reasons for attrition [56].

Artificial Neural Networks (ANNs) are recognized by several studies for their strong abilities in predicting if an employee will remain with the company. In Dubey et al.'s (2018) and Al-Darraji et al.'s (2021) studies, it was found that using ANN-based models helped overcome the restrictions of traditional machine learning, since they can show how non-linear relationships shape the patterns of workers [3][44]. Yahia et al. proposed a deep data framework that improves the effectiveness of ANNs in analyzing workforce data [46]. In 2024, Shafie et al. investigated using ANN to cluster data and use data augmentation to boost accuracy [42][12]. Although XGBoost and Random Forest are high in accuracy, ANNs show exceptional performance when trying to model tougher patterns, features, and forms of data. While LSTM only works with sequential information, FNNs are more flexible and scalable, allowing them to handle HR data that can be structured, like employee feedback, or unstructured, like how engaged employees feel. As our dataset doesn't change over time, LSTM models cannot be used. ANNs work better in various industries and are still understandable with explanation techniques such as SHAP and LIME. Given these advantages, our research builds upon ANN-based methodologies to develop a robust, commercially viable employee retention prediction model that enhances HR decision-making.

III. Research Gap

Most of the available methods are focused on increasing accuracy by improving classification based on structured historical data, but they do not put sufficient interest in interpretability and real-time interaction. Because of this, most predictions are often made without enough explanation or actionable context for HR professionals.

Another important factor is that most of the predictive models are developed as stand-alone analytical applications and

are not designed to be integrated into enterprise systems. This limits their operational usage in HR departments because these departments require interactive systems that could respond dynamically to user requests and changing organizational information. There is also a lack of discussion in current literature on how unstructured or semi-structured information, such as qualitative employee feedback or situational indicators of the workplace, is managed.

While these models are capable of producing superior predictive performances, their black-box character implies a challenge for trust and adoption in HR applications. The research gap lies in the development of intelligent platforms which can integrate proven predictive modeling together with explainable and user-friendly AI interfaces to be used for devising retention strategies. This work fills this gap by combining predictive validation with an LLM-powered reasoning layer into a platform-based modular architecture.

IV. Problem Statement

The problem of employee churn is a big hurdle for organizations because the interaction of demographic, professional, and behavioral factors that cause attrition is complex. Though predictive models can be used to estimate turnover risk, in practice, HR teams view them as a challenge to interpreting the predictions and converting them into practical retention measures. This is the point at which the disconnect between prediction and decision-making makes the tools of attrition analysis currently in use less practical.

This needs to be engaging, insightful at a human level, and fit within organisational processes. This proposal is based on the gap that exists between effective attrition prediction and viable HR decision support through integrating predictive intelligence into an AI Chat Widget and a modular pipeline architecture.

V. Methodology

The proposed employee retention prediction system is structured into two stages: predictive model validation methodology coupled with a platform-based deployment that is oriented towards explainable and interactive HR decision support. The general system workflow is represented by the Agent and Pipeline structures depicted in Fig. 1 and Fig. 2 respectively.

A. Understanding and Preprocessing Data

The methodology begins with understanding the nature of data and attributes leading to employee attrition. The dataset contains employee data, which includes demographic data, job-related parameters, and behavioral information. Data is to be pre-processed before feeding into the model in order to ensure the quality and consistency of the data. This involves filling in missing or inconsistent values, encoding categorical variables into numerical forms, and normalizing numerical variables onto a standard scale. These are the preprocessing steps used to guarantee that the data is learning-ready, and feature contributions can therefore be analyzed meaningfully. Because of restrictions of data privacy and confidentiality, a synthetic employee dataset was created in order to try and represent realistic HR attributes and attrition trends while maintaining the statistical properties needed for validating the model.

B. Feedforward Neural Network Predictive Validation

An FNN is designed at the research stage-after preprocessing-to investigate predictive feasibility and authenticate the importance of the selected features. The FNN is selected since it can be used for modeling nonlinear relationships in structured data and it can be utilized for situations with no temporal dependencies. While FNN is the proposed model, additional classical ML models were implemented for comparative evaluation.

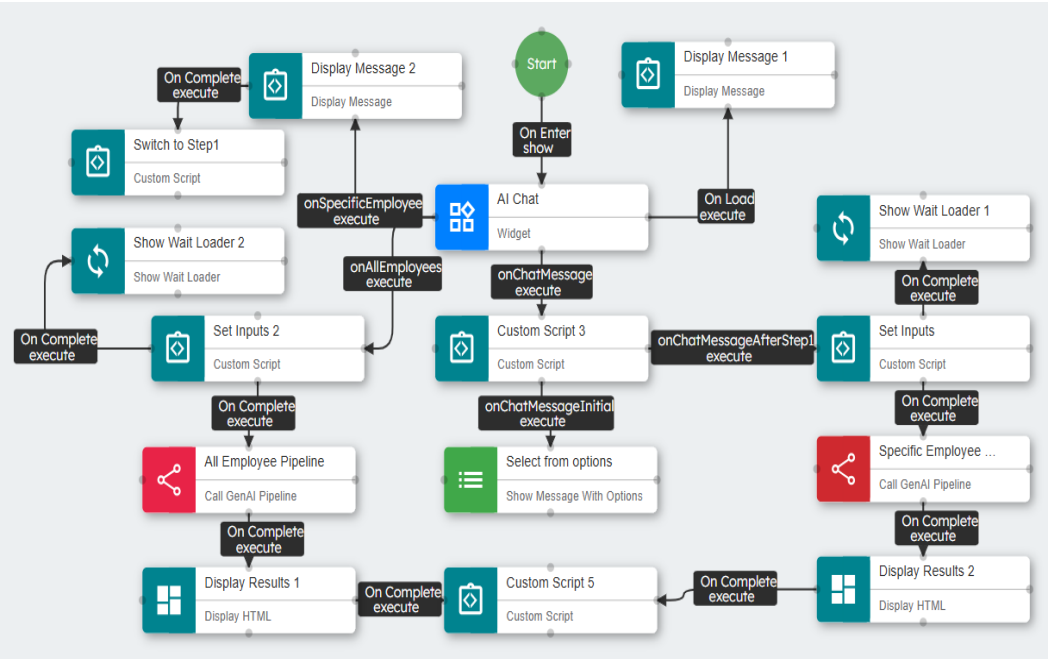

Fig. 1. Workflow of the agent.

The whole network architecture comprises several fully connected layers activated by the Rectified Linear Unit and one output layer activated by the sigmoid function for binary classification. The Adam optimizer trains the model and provides stable convergence with adaptive learning rates. Hyperparameters such as batch size, learning rate, and numbers of neurons were tuned experimentally. The FNN performs with an accuracy of 88.7%, which indicates how well this model achieves the mapping of attrition-related patterns. This model is not deployed as a stand-alone production classifier; nonetheless, it provides a tested predictive basis. The knowledge gained in this step contributes to the design of the system put into practice, especially with respect to the characteristics that substantially support employee retention.

C. Integration-Based Platform Implementation on the LLM.

Once the predictive feasibility has been established with the FNN-based assessment, the system is extended to a platform-based implementation targeted at operational use. This implementation is designed into two main parts, namely the Agent and the Pipeline, as shown in Fig. 1 and Fig. 2.

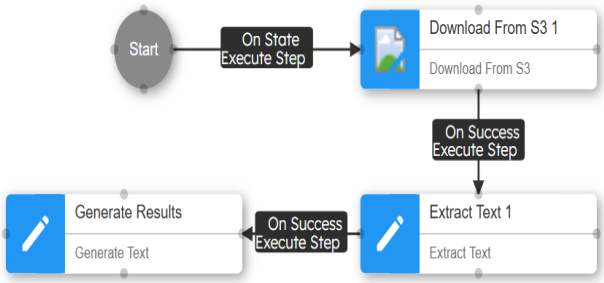

Fig. 2. Workflow of the pipeline.

Accordingly, the Pipeline component is responsible for handling analysis processing and the controlled execution of analytical operations. It reaches out to cloud storage for the employee data uploaded to the system. The pipeline expects structured inputs regarding the approved set of features and invokes a Large Language Model-Gemini 2.0 Flash-through secure API calls. Instead of being a classifier, it conducts analytical reasoning on employee characteristics and issues interpretations regarding attrition risk, accompanied by human-readable explanations. To make the presentation of its results consistent, a fixed structure is applied to the output.

D. AI Chat Widget and User Interaction

This Agent component, illustrated in Fig. 1, is implemented as an AI Chat Widget that represents the main interface of HR professionals. Through this interface, the user can upload employee datasets, select options for analyses, and ask for predictions without directly being involved with models that underlie these operations. In the case that such a request is triggered, the Agent communicates with the Pipeline of Fig. 2, invoking the respective analytical workflow.

The answers that the Pipeline provides are nicely formatted as HTML and then displayed in the Chat Widget. This output will provide insights into the factors of attrition risk, causes, and recommendations to help with HR decision-making. AI Chat Widget reduces the overall complexity of the system and allows a non-technical user to interact with advanced AI capabilities in a straightforward and understandable way. The advanced AI features in an understandable and clear manner.

E. Methodology Summary

In summary, the suggested methodology can be summarized as a two-step procedure: a predictive validation step with the assistance of a Feedforward Neural Network to check the relevance of the features and frame a baseline performance and a deployment-focused architecture, which transfers this intelligence to an LLM-based AI Chat Widget and a system pipeline.

VI. Results

This section contains the quantitative findings obtained during the predictive validation stage and the outputs provided by the implemented AI-based platform.

A. Predictive Model Performance

Table I summarizes the performance of various machine learning models that were used to predict employee attrition. Conventional classifiers like Logistic Regression, Naive Bayes, KNN, Decision Tree, and Random Forest exhibit competitive levels of accuracy on the structured employee data. The Feedforward Neural Network (FNN) proposed in this paper achieves the highest accuracy of 88.7%, which means that it is more accurate in capturing non-linear relationships among employee attributes.

Table I provides results that prove the efficacy of the chosen set of features and the appropriateness of neural network-based models for structured HR data. This assessment is conducted during the research and validation stage to determine predictive feasibility and benchmark model performance. It is not the implemented inference mechanism of the end platform, which focuses on interpretability and decision support.

TABLE I. Comparison of FNN Model with Classical Machine Learning Models

Model	Accuracy (%)
Logistic regression	87.4
Naïve Bayes	85.6
Decision Tree	78.5
KNN	84.3
Random Forest	85.9
Proposed FNN	88.7

B. Platform Outputs and User Interaction

The operational outputs of the deployed system are illustrated in Fig. 3 to Fig. 5. Fig. 3 shows the AI Chat Widget interface through which HR professionals interact with the system. After uploading the employee dataset, users are presented with multiple options, enabling both individual-level and organization-wide retention analysis in an interactive manner.

Fig. 3 presents the output generated for a specific employee analysis. The system provides an assessment of attrition risk along with factors contributing to the identified risk. These

outputs aim to support decision-making by highlighting key attributes influencing the prediction.

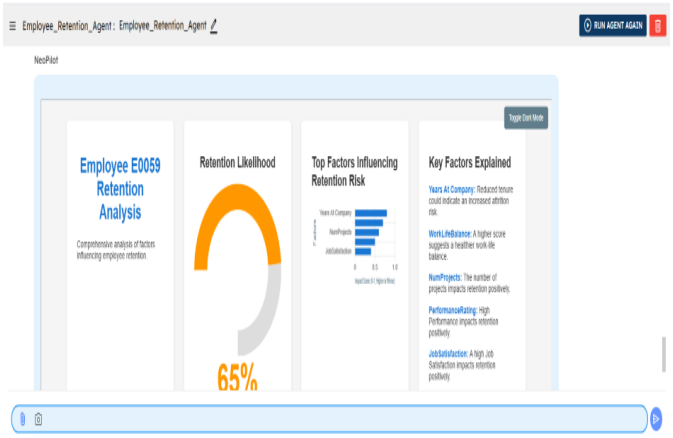

Fig. 3. Output for analysis on a specific employee.

Fig. 4 shows overall analysis of employee retention. This view depicts the risk distribution by departments, major factors causing attrition, and aggregated insights from the organization. Such a result will enable the HR teams to identify retention issues and prioritize intervention strategies at an organizational level.

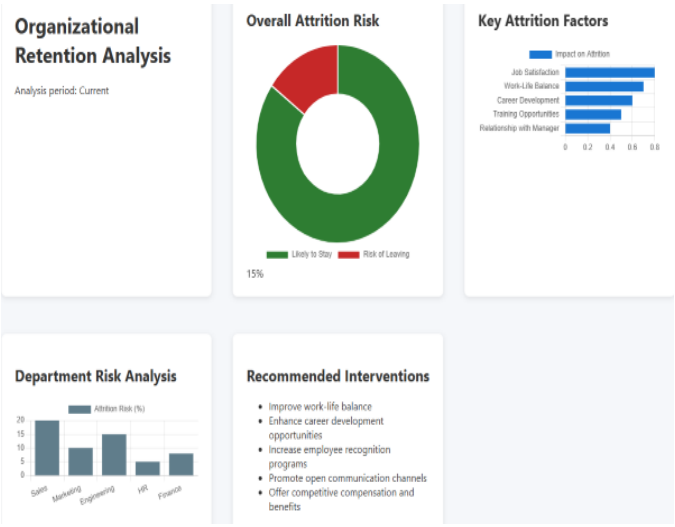

Fig. 4. Overall employee retention analysis.

VII. Discussion

The findings indicate that the neural network-based solutions are more effective than the conventional ML models in predicting employee turnover with using structured HR data. Out of the various models tested, Feedforward Neural Network was the most effective as it gave a firm predictive background and demonstrated the applicability of the features chosen.

Predictive accuracy is, however, not sufficient in practice in HR. Prediction systems of attrition should also be able to facilitate interpretability, trust, and action. Considering this need, the presented system goes beyond prediction to introduce an architecture with proven predictive intelligence into an architecture powered by LLM. The Large Language Model does not substitute the predictive foundation but instead operates as a reasoning and explanation interface which extrapolates predictive signals into interpretation accessible to humans.

The AI Chat Widget and modular GenAI pipeline enables a natural communication process of the HR professionals with the system and abstracts the underlying complexity of the analytical process. The individual and organizational analysis depicted in Fig. 4 and Fig. 5, respectively, indicate the usefulness of this methodology because it involves a combination of risk indicators and explanatory context, which, in turn, champions the proactive retention strategies. The use of the Agent and Pipeline components further increases the scalability of the system and makes easy future system extensions.

The suggested platform does not compare the Large Language Model as an independent predictive classifier. Rather it considers the efficiency of the LLM on the basis of explanation consistency, which is the capacity of the model to offer coherent, human comprehensible explanations to aid HR in decision-making. In this regard, 25 cases of employees were chosen randomly and asked several times. In repeated queries, there was a consistent focus on dominant contributing factors (e.g., job satisfaction, workload, tenure) that the LLM focuses on that are aligned with the FNN output. The plausible explanations that were generated were found to have the right attributes of employees that led to the attrition risk, without bringing on board unfounded or contradictory variables, and therefore, guaranteeing the consistency between the prediction and the rationale.

The LLM-generated explanations are made easy to understand by the HR professionals who do not have a technical background as per the usability considerations. Clarity in the presentation of the risk indicators, contributing factors and the recommendations increases transparency and trust, consequently allowing informed and proactive decisions to be made in regard to retention. These observations affirm the appropriateness of the LLM as an explainability and decision-support subsystem to the proposed system.

VIII. Conclusion

This paper proposes the design of an intelligent employee retention prediction system, based on a platform integrating predictive model validation with explainable AI-driven decision support. The work overcomes one of the major limitations of traditional approaches to predict attrition: the gap existing between high performing predictive models and their practical usability by HR. Testing of the system was conducted using a synthetic employee dataset, generated to simulate realistic HR attributes and attrition patterns for enabling model validation in a way that avoids data privacy and confidentiality concerns.

During the research phase, a Feedforward Neural Network was developed on structured employee data and evaluated to validate feature relevance and predictive feasibility. The accuracy achieved is 88.7%. This outcome established a sound predictive basis for the project and informed the design of the deployed system. In its final form, rather than being a standalone classification, the predictive intelligence has been embedded in an AI Chat Widget and a GenAI pipeline.

The deployed platform applies a Large Language Model to reason analytically and provide human-understandable explanations of its reasoning to support decisions made by HR. By abstracting the analytical complexity and providing interpretable insights through an interactive interface, the system empowers HR professionals to predict attrition risks at both the individual and organizational levels and develop proactive strategies for retention.

Overall, the proposed architecture represents an illustration of how validated predictive modeling and explainable AI can be combined into one scalable, enterprise-ready platform for workforce analytics. Further research would extend the system to include unstructured data sources, such as employee feedback and surveys, and evaluate the platform across a wide range of organizational datasets to further improve generalizability and impact.

Spatial Classification of Fertilizer Requirements Using Fuzzy C-Means on Shallot Agricultural Land

Roghib Muhammad Hujja, Ahmad Ashari, Danang Lelono, Agus Prasekti
Dept. Computer Science and Electronics, Universitas Gadjah Mada, Yogyakarta, Indonesia

***Abstract*—Spatial variability in soil fertility constrains productivity in intensive shallot farming, yet fertilizer is frequently applied uniformly across fields. This practice results in nutrient inefficiencies, increased costs, and heightened environmental risks. This study introduces a fertilizer requirement mapping framework utilizing Fuzzy C-Means (FCM) clustering, a machine learning technique for data grouping, applied to in-situ measurements of soil Nitrogen (N), Phosphorus (P), and Potassium (K). The framework was evaluated in a 500 × 500 m shallot field in Srikayangan, Kulon Progo, Indonesia, subdivided into 10 × 10 m management blocks suitable for smallholder operations. Soil NPK levels were measured using IoT sensor nodes and georeferenced with GNSS, while high-resolution RGB imagery from a UAV provided spatial context. Normalized NPK data were clustered with FCM to delineate fertility zones exhibiting nutrient differences. To operationalize clustering results, a nutrient-priority decision logic identified the most limiting nutrient (N, P, or K) for each block. Fertilizer recommendation points were visualized on a UAV-derived orthomosaic map to facilitate interpretation and field application. The results indicate that this approach effectively captures gradual fertility transitions and produces actionable fertilizer zones for site-specific nutrient management (SSNM) in smallholder systems. The study demonstrates the practical integration of fuzzy clustering, IoT-based soil sensing, and UAV mapping to inform precision agriculture decisions.**

Keywords*—Fuzzy C-Means (FCM); soil fertility zoning; NPK (Nitrogen, Phosphorus, Potassium); fertilizer recommendation; precision agriculture; Site-Specific Nutrient Management (SSNM); IoT (Internet of Things); UAV (Unmanned Aerial Vehicle)

I. Introduction

Soil fertility variability represents a significant constraint to productivity and sustainability in intensive vegetable farming. In many fields, soil properties such as nutrient availability, texture, and organic matter content exhibit substantial variation over short distances. Despite this, fertilizer is typically applied uniformly. This disconnect between spatial variability and uniform management leads to inefficient nutrient use, increased costs, and elevated risks of environmental impacts, including nutrient leaching and accumulation [1], [2].

Shallot (Allium cepa var. aggregatum) cultivation, prevalent in Indonesia and Southeast Asia, depends on effective fertilizer management to achieve optimal yield and bulb quality. Grown in narrow beds with intensive inputs, shallots are particularly sensitive to nutrient imbalances. Nitrogen (N), Phosphorus (P), and Potassium (K) are the primary drivers of growth, root development, bulb formation, and stress resistance. The distribution of these nutrients varies according to soil conditions, irrigation practices, and fertilization history, resulting in significant variability even within smallholder plots [1].

Precision agriculture and site-specific nutrient management (SSNM) address this challenge by tailoring fertilizer inputs to spatially variable soil and crop conditions. A central aspect of SSNM involves delineating relatively homogeneous management zones to enable differentiated fertilizer application [1], [3]. Early research employed dense grid-based soil sampling and geostatistical interpolation to generate continuous fertility maps. Although effective, these methods often demand considerable sampling effort and may not readily translate into fertilizer decision rules that are easily adopted by farmers [3].

Clustering-based methods group spatial units—defined areas within a field—into management zones based on similar soil or crop attributes. Fuzzy C-Means (FCM) clustering, a technique that allows data points to partially belong to multiple groups, is widely used in soil fertility assessment, as it captures gradual transitions and inherent uncertainty in soil properties. Unlike hard clustering (which assigns each spatial unit to only one group), FCM gives each spatial unit a degree of membership in multiple clusters, reflecting spatial continuity. Studies have used FCM to delineate management zones based on soil chemical properties (e.g., nutrient levels), electrical conductivity, yield data, and remote sensing (data collected from satellite or aerial images) across cropping systems [3], [8], [9].

Recent research extends FCM zoning by adding multi-nutrient data, principal component analysis, and geospatial techniques. These support variable-rate fertilization and site-specific management. For example, fuzzy clustering has generated nutrient-based zones that capture macro- and micronutrient variability, thereby improving fertilizer targeting [4]-[7]. These studies confirm FCM's suitability for capturing soil heterogeneity and supporting differentiated management. However, most prior work focuses on general fertility zones or composite indices rather than nutrient-specific fertilizer priorities.

At the same time, advances in agricultural sensing technology enable higher-resolution data for precision agriculture [20]. Internet of Things (IoT)-based soil sensors [14] provide near-real-time soil measurements at fine spatial resolution, reducing reliance on labor-intensive laboratory analyses [10], [15], [19]. Unmanned aerial vehicle (UAV) remote sensing also supplies high-resolution information on field structure and crop condition, supporting detailed mapping at the scale of individual beds or plots [11]-[13], [18]. Recent studies highlight the promise of integrating IoT sensing, UAV

imagery, and data analytics into decision-support systems for precision agriculture [17], [18].

Despite these advancements, a gap remains between soil data analysis and the generation of actionable fertilizer recommendations. Few studies have demonstrated direct integration of fuzzy clustering with nutrient-priority logic for N, P, or K at the level of individual spatial units. Additionally, most existing applications operate at coarse spatial scales, which limits their applicability in smallholder vegetable systems where management occurs at the bed scale.

This study addresses these gaps by proposing a spatial classification and decision-support method for mapping fertilizer needs. The method uses Fuzzy C-Means clustering of soil NPK data. It is applied to a 500 × 500 m shallot field in Srikayangan, Kulon Progo, Indonesia. The field is divided into 10 × 10 m blocks for smallholder bed-scale use. Soil N, P, and K were measured with IoT sensors and combined with high-resolution UAV imagery. FCM clustering on normalized NPK data created fertility zones. A nutrient-priority logic then found the most limiting nutrient (N, P, or K) at each block.

This study offers three primary contributions. First, it develops a nutrient-priority logic that translates fuzzy membership degrees into actionable recommendations. Second, it applies FCM clustering at a fine spatial scale consistent with smallholder bed operations. Third, it integrates IoT-based soil sensing and UAV imagery into a straightforward, map-based decision-support output.

This study does not introduce a new clustering algorithm. Rather, it enhances the practicality of FCM-based soil fertility zones by linking fuzzy clustering results with site-specific fertilizer prescriptions. The proposed approach is adaptable to various crops, regions, and sensor configurations where soil nutrient variability necessitates more efficient fertilizer management.

II. Methodology

A. Study Area and Data Acquisition

The study was conducted in an intensively cultivated vegetable field used for seasonal shallot and leafy vegetable production in Desa Srikayangan, Kecamatan Sentolo, Kabupaten Kulon Progo, Yogyakarta, Indonesia. The field in our experiment spans approximately 500 × 500 m and is subdivided into narrow beds and furrows, following local farming practices. The objective of the data acquisition campaign was to capture the spatial variability of soil macronutrients—Nitrogen (N) [16], Phosphorus (P), and Potassium (K), which are essential nutrients plants require in relatively large amounts—and relate it to crop-condition patterns observable from high-resolution UAV (unmanned aerial vehicle) imagery.

A regular sampling grid with a nominal spacing of 10 × 10 m was designed to cover the entire field. Each grid cell (block) was represented by a single sampling point located near the center of the crop bed. At every sampling point, an in-situ NPK soil sensor probe was inserted vertically into the topsoil (0–20 cm) after removing surface residues and ensuring good contact between the probe and the soil [10].

For each point, the probe was held in place until the readings stabilized, and the values of N, P, and K were recorded. To reduce random noise, the insertion and reading process was repeated two or three times within a radius of about 1 m, and the average of these readings was used as the NPK value for the corresponding block. Between sampling points, the probe was cleaned to avoid cross-contamination.

To obtain reference values and assess the consistency of sensor readings, composite soil samples were collected from a subset of grid points. These samples were air-dried and analyzed in the laboratory using standard procedures [4], [5]. The resulting dataset thus consists of triplets, each associated with georeferenced coordinates for a sampling location.

The geographic coordinates of all sampling points were measured using a GNSS receiver mounted on a survey pole, ensuring sub-meter positional accuracy. The in-field NPK sensing and GNSS positioning procedure is illustrated in Fig. 1.

Fig. 1. In-situ soil NPK data acquisition and GNSS-based georeferencing during field sampling.

To obtain a spatially continuous representation of crop condition and field structure, aerial images of the study area were acquired using a fixed-wing unmanned aerial vehicle (UAV) equipped with a nadir-looking RGB camera (Fig. 2). The UAV was programmed to fly an autonomous mission over the 500 × 500 m field along parallel flight lines. The flight altitude was set to approximately 100–120 m above ground level, resulting in a ground sampling distance of a few centimeters per pixel [11],[13].

Forward and side overlaps were configured to at least 70% and 60%, respectively, to ensure reliable image matching. Several ground control points (GCPs) were placed at clearly visible locations within and around the field and surveyed using the same GNSS equipment as the soil sampling points. These GCPs were later used to improve the geometric accuracy of the photogrammetric products.

The raw UAV images were processed using a standard structure-from-motion (SfM) photogrammetry workflow, which includes feature detection and matching, bundle adjustment,

dense point cloud generation, and orthorectification. The resulting orthomosaic was georeferenced in the same projected coordinate system as the GNSS measurements. The georeferenced soil NPK points were then overlaid on the orthomosaic in a geographic information system (GIS), and each 10 × 10 m block was associated with both its NPK values and its corresponding location in the UAV image. This integration enabled subsequent Fuzzy C-Means clustering on the block-level NPK data and the visualization of fertilizer recommendation points directly on the high-resolution UAV map.

Fig. 2. Fixed-wing UAV platform used for high-resolution RGB image acquisition.

B. Data Preprocessing and Block Generation

To support block-level decision making, the study area was discretized into a regular grid of 10 × 10 m cells, hereafter referred to as blocks. Each soil sampling point was assigned to its corresponding block based on spatial location. For blocks with more than one sample, the average values of N, P, and K were computed. Blocks without observations were either excluded from the analysis or filled using simple spatial interpolation (nearest neighbor), depending on their position and the density of surrounding samples.

The raw N, P, and K values may have different units and numerical ranges. To prevent any single nutrient from dominating the clustering process, all variables were normalized prior to analysis. In this study, min–max normalization was used:

$x'_{ij} = \frac{x_{ij} - \min(x_j)}{\max(x_j) - \min(x_j)}$ Where x_{ij} is the original value of nutrient $j \in \{N, P, K\}$ in block i, and x'_{ij} is the normalized value within the interval $[0,1]$. Each block is then represented as a three-dimensional feature vector.

$$\boldsymbol{x}_i = [N'_i, P'_i, K'_i]$$

Basic quality control was applied to detect and handle outliers (e.g., physically unrealistic values due to sensor error). Outliers were inspected against the laboratory reference data and field notes. If a value was clearly erroneous and could not be confirmed, the corresponding block was removed from further analysis.

C. Fuzzy C-Means Clustering

The core of the proposed approach is the use of the Fuzzy C-Means (FCM) algorithm to partition the blocks into a set of soil fertility clusters based on their normalized N, P, and K values. FCM seeks to minimize the following objective function:

$$J_m = \sum_{i=1}^{n} \sum_{k=1}^{c} u_{ik}^m \parallel \mathbf{x}_i - \mathbf{v}_k \parallel^2$$

where,

- n is the number of blocks,
- c is the number of clusters,
- u_{ik} is the membership degree of block i in cluster k,
- $m > 1$ is the fuzziness exponent (typically $m = 2$),
- $\boldsymbol{v}_k$ is the center of cluster k, and
- $\|\cdot\|$ denotes the Euclidean norm.

In this study, the number of clusters (c) was chosen to represent distinct patterns of nutrient status in the field (e.g., three clusters to capture relatively low, medium, and high fertility combinations or characteristic N–P–K imbalances). The algorithm proceeds iteratively as follows:

- Initialization: Initialize the membership matrix $U[= u_{ik}]$ with random values such that $\sum_{k=1}^{c} u_{ik} = 1$ for all i.
- Cluster center update: Compute cluster centers

$$\mathbf{v}_k = \frac{\sum_{i=1}^{n} u_{ik}^m \mathbf{x}_i}{\sum_{i=1}^{n} u_{ik}^m}$$

for each cluster k.

- Core Membership update: Update membership degrees

$$u_{ik} = \frac{1}{\sum_{j=1}^{c} \left(\frac{\parallel \mathbf{x}_i - \mathbf{v}_k \parallel}{\parallel \mathbf{x}_i - \mathbf{v}_j \parallel} \right)^{\frac{2}{m-1}}}$$

for all blocks i and clusters k.

- Stopping criterion: Repeat steps 2–3 until the change in the membership matrix between two successive iterations falls below a small threshold ε(e.g., 10^{-5}) or a maximum number of iterations is reached.

The implementation was carried out in Python using a custom FCM routine and executed in Google Colab. The output of this step is a set of cluster centers $\{\mathbf{v}_k\}$and a membership matrix that describes the degree to which each block belongs to each cluster.

D. Derivation of Nutrient Priority Classes

To transform the fuzzy clusters into actionable fertilizer recommendations, the nutrient composition of each cluster

center was analyzed. For each cluster k, the relative status of N, P, and K was assessed by comparing the normalized values N'_k, P'_k, and K'_k in v_k to the field-wide distribution or target fertility levels. Clusters in which a particular nutrient exhibits comparatively low values were interpreted as zones where that nutrient is more likely to be limiting.

A simple decision rule was then defined to assign a nutrient priority to each block:

- For each cluster k, determine the "most limiting" nutrient j_k, which is the nutrient with the lowest normalized value in $\mathbf{v}_k$.
- For each block i, compute a nutrient priority score by combining its membership degrees with the cluster-level limiting nutrients. For example, the priority score for nutrient j in block i can be defined as,

$$S_{ij} = \sum_{k:j_k=j} u_{ik}$$

- Assign block i to the nutrient with the highest score $\arg\max_j S_{ij}$, yielding one of three recommendation classes: N-priority, P-priority, or K-priority.

This procedure preserves the fuzzy nature of the underlying clusters while providing a crisp, interpretable label for operational use. Blocks with similar scores for multiple nutrients can be flagged as mixed or flexible zones for further agronomic evaluation if needed.

E. Spatial Mapping and Visualization

The FCM cluster labels (dominant cluster per block) and the nutrient-priority classes were joined back to the 10 × 10 m spatial grid and visualized in a GIS. The fertility clusters were displayed as a zonation map of the shallot field. At the same time, the nutrient-priority classes were represented in a separate map showing whether N, P, or K should be emphasized in each block.

To make the output usable in the field, representative fertilizer recommendation points were selected from within contiguous patches of each nutrient-priority class. In each patch, a few blocks with the highest nutrient-priority scores were chosen as application points. These points were then overlaid on the UAV orthomosaic, allowing farmers and field technicians to locate the recommended areas directly on a detailed image of the shallot beds. The final maps form the basis for suggesting differentiated fertilizer rates (e.g., higher urea doses at N-priority points, higher SP-36 at P-priority points, and higher KCl at K-priority points) instead of a single uniform NPK recommendation for the whole field.

III. Results and Analysis

A. Fuzzy C-Means Zoning of Soil Fertility

The Fuzzy C-Means (FCM) algorithm successfully partitioned the 500 × 500 m field into three main fertility zones based on the N, P, and K measurements at each 10 × 10 m block. Visual inspection of the resulting clusters (Fig. 3) shows that the field is clearly structured into red, green, and blue zones with gradual transitions rather than abrupt boundaries.

Cluster-level analysis indicates that:

- Cluster 1 (Red) corresponds to blocks with high N and relatively low K.
- Cluster 2 (Green) represents blocks with high K but lower N.
- Cluster 3 (Blue) is characterized by relatively high P with more balanced N and K values.

These patterns align with the agronomic interpretation in the field, where some areas receive high N fertilization but remain undersupplied with P and K. In contrast, other areas have accumulated K from previous applications.

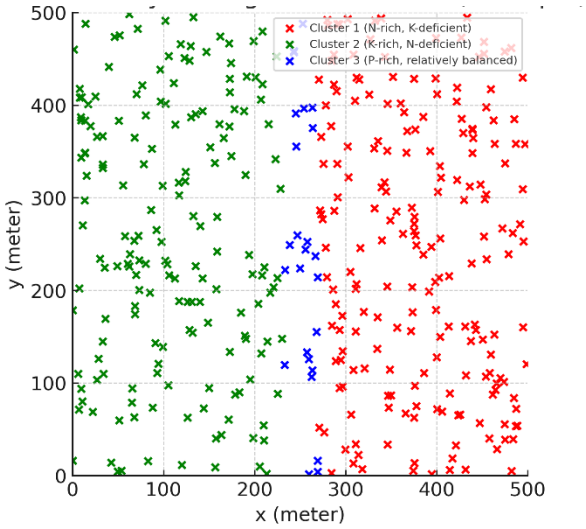

Fig. 3. Soil fertility zoning based on Fuzzy C-Means clustering.

The quality of the clustering was evaluated using two internal indices. The Silhouette Score of 0.61 and Dunn Index of 0.03 suggest that the three clusters are reasonably well separated while still capturing the gradual variability that exists in real soil conditions. These values suggest that FCM offers a reliable representation of the underlying fertility structure and is suitable as a basis for informed spatial decision-making.

B. Spatial Pattern of Nutrient Deficiencies

By comparing the cluster centers with the most fertile reference condition, it is possible to identify which parts of the field are more likely to be deficient in specific nutrients. The cluster map in Fig. 4 shows that:

- The western part of the field is dominated by Cluster 2 (green), indicating high K but relatively low N, and simultaneously showing P deficiency in some blocks.
- The eastern part of the field is dominated by Cluster 1 (red), where N is high but P and K are lower, suggesting a need to supplement P and K rather than N.
- Cluster 3 (blue) appears in intermediate zones with higher P and relatively balanced N and K, acting as a transition between the red and green zones.

This pattern confirms that nutrient limitations are not uniform: the west is mainly limited by P and K, whereas the east

is more constrained by N. Such differences justify the need for site-specific fertilizer management instead of uniform application. Table I summarizes the qualitative interpretation of each cluster based on the N, P, and K status.

TABLE I. INTERPRETATION OF FCM FERTILITY CLUSTERS

Cluster	Dominant color	N status	P status	K status	Interpretation
C1	Red	High	Low–medium	Low	N-rich, K-deficient zone (needs P and K)
C2	Green	Low–medium	Low–medium	High	K-rich, N-deficient zone
C3	Blue	Medium	High	Medium	P-rich, relatively balanced, and stable zone

C. Fertilizer Recommendation Points

To translate the cluster information into operational recommendations, fertilizer application points were determined by selecting blocks with the highest nutrient-priority scores inside each deficiency zone. These points are located near the centers of areas with the strongest shortage, representing locations where additional fertilizer will have the most significant effect while still covering surrounding blocks.

The resulting fertilizer recommendation map is shown in Fig. 4. The background colors represent the FCM clusters as in Fig. 3, while overlaid symbols indicate specific application points for each nutrient:

- Red squares mark N application points, where additional urea is recommended.
- Blue triangles mark P application points, where SP-36 is prioritized.
- Green circles mark K application points, where KCl is prioritized.

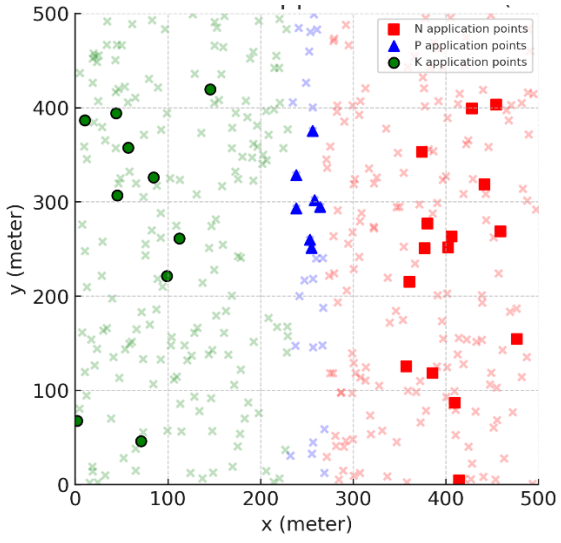

Fig. 4. Fertilizer recommendation points over the FCM zonation map.

Based on the nutrient-priority classification, the corresponding fertilizer types and application rates are summarized in Table II.

TABLE II. FERTILIZER RECOMMENDATION RATES BY NUTRIENT PRIORITY

Nutrient priority	Symbol/color in Fig. 4	Recommended fertilizer and rate (per ha)
N-priority	Red square	Urea 300–350 kg/ha
P-priority	Blue triangle	SP-36 100–120 kg/ha
K-priority	Green circle	KCl 150–200 kg/ha

These recommended doses are intended for the core application points and can be adjusted proportionally for the surrounding blocks, depending on equipment capability and field conditions.

D. Visualization on High-Resolution Spatial Agricultural Map

To make the results directly interpretable by farmers and local extension workers, the nutrient-priority recommendation points were finally overlaid on a high-resolution aerial orthomosaic of the study area (Fig. 5). The orthomosaic was generated from UAV imagery and represents individual crop beds and management units within the 500 × 500 m field.

The coordinates of the 10 × 10 m blocks and the selected fertilizer application points (Section III-C) were transformed into the same spatial reference system as the orthomosaic. Each point was then plotted on top of the image and symbolized according to its recommended nutrient:

- blocks with N-priority were marked as N application points,
- blocks with P-priority were marked as P application points, and
- Blocks with K-priority were marked as K application points.

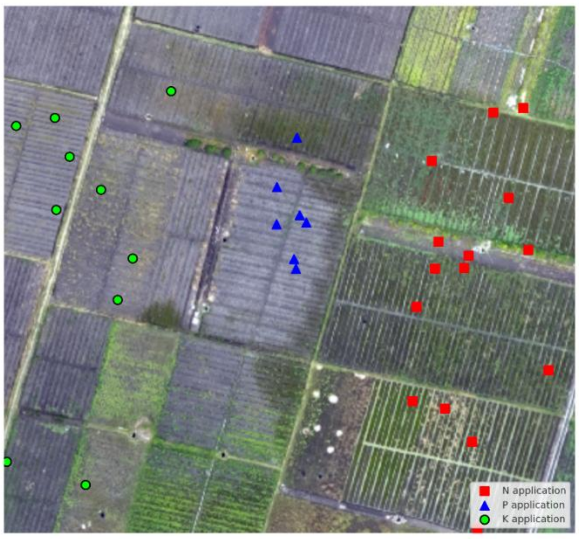

Fig. 5. UAV orthomosaic with FCM-based fertilizer recommendation points.

Fig. 5 shows that many N-priority points coincide with visually lighter or less vigorous plots in the eastern portion of the field. In contrast, P- and K-priority points are concentrated in the western and central plots where crop growth appears uneven or patchy. This spatial correspondence between visual crop condition and the FCM-based nutrient recommendations provides an additional qualitative validation of the proposed method.

By combining the orthomosaic with the fertilizer recommendation points, the resulting map becomes a practical tool for field operations: farmers can visually locate specific beds or parcels that require N, P, or K and adjust their applications accordingly. The map can also be integrated into mobile or web-based interfaces, allowing operators to navigate to the recommended positions using GPS while viewing the underlying UAV image.

E. Discussion

The FCM-based spatial classification clearly revealed that the 500 × 500 m field cannot be treated as a uniform management unit. The three clusters obtained from NPK data describe distinct fertility regimes that are consistent with both the historical fertilization practices and the visual crop patterns observed in the UAV imagery. Cluster 1 (red) represents blocks with relatively high N. However, Cluster 2 (green) corresponds to blocks with high K but lower N, and Cluster 3 (blue) contains blocks with relatively high P and more balanced N and K. These patterns suggest that the field has experienced heterogeneous nutrient accumulation, with specific areas receiving repeated N applications while others have accumulated K or P.

When the cluster information is translated into nutrient-priority classes, a transparent spatial gradient emerges: the western part of the field is dominated by blocks that require additional phosphorus (P) and potassium (K). In contrast, the eastern part shows a concentration of N-priority blocks. The central area is characterized by P-priority points associated with Cluster 3, which has a higher P. However, only moderate N and K. This configuration implies that a uniform NPK recommendation would inevitably over-fertilize some zones (e.g., N in the western plots) and under-fertilize others (e.g., P and K in the west, N in the east). Instead, the proposed method provides differentiated targets: more P and K in the west, more N in the east, and fine-tuned doses in the transition zones.

A key advantage of FCM in this context is its ability to handle gradual transitions and uncertainty. Traditional hard clustering or simple thresholding of nutrient values would force each block into a single, crisp category, creating sharp boundaries between zones that may not exist in reality. In contrast, FCM assigns membership degrees to multiple clusters for each block. The nutrient-priority scores derived from these memberships enable the method to highlight "core" deficiency zones, where a single nutrient is clearly limiting, while also acknowledging mixed or ambiguous areas. This is reflected in the placement of fertilizer recommendation points, which tend to appear in the centers of homogeneous patches, rather than directly on the boundaries between different fertility regimes. This is agronomically reasonable because edge blocks can often be managed with intermediate or blended doses.

The overlay of fertilizer recommendation points on the UAV orthomosaic further strengthens the interpretation. In the eastern plots where N-priority points cluster, the imagery shows lighter coloration and less vigorous canopy growth, typical of N deficiency. Conversely, several P- and K-priority points are located in western or central plots, where the vegetation pattern is patchy or where crop rows appear uneven. The spatial agreement between model-derived recommendations and visual symptoms from high-resolution imagery serves as an independent, qualitative validation of the approach. It also demonstrates how proximal sensing (soil sampling and FCM analysis) and remote sensing (UAV imagery) can be combined into a single, intuitive decision-support product for farmers.

From a management perspective, the generated maps enable site-specific fertilization at a resolution that is compatible with the scale of individual beds or farmer-owned subplots. By applying urea only around the N-priority points in the east (300–350 kg/ha), and focusing SP-36 and KCl around P- and K-priority points in the west and center, the farmer can reallocate a fixed fertilizer budget more efficiently rather than increasing total input. This has two important implications: 1) potential economic benefits, through savings in fertilizer where it is not needed and yield gains where deficiencies are corrected; and 2) environmental benefits, by reducing the risk of nitrate leaching and K or P accumulation in already fertile zones. Although yield measurements are not yet included in this study, the spatial pattern of recommendations is consistent with these expected outcomes.

At the same time, several limitations should be acknowledged. First, the analysis is based on a single sampling campaign, which captures spatial but not temporal variability; nutrient dynamics across seasons or cropping cycles are not yet modeled. Second, the block size of 10 × 10 m represents a compromise between spatial detail and sampling feasibility. Smaller blocks could reveal finer heterogeneity but would require more intensive sampling, while larger blocks might mask important within-block variability. Third, the fertilizer doses used in the recommendation map are derived from general agronomic guidelines; they would ideally be adjusted using response curves or economic optimization to quantify the benefits of site-specific management fully. Finally, the clustering quality, although supported by the Silhouette Score (0.61) and Dunn Index (0.03), could be further evaluated by comparing alternative clustering methods (e.g., k-means, Gaussian mixture models) and by validating the zones against actual yield data.

Despite these limitations, the study demonstrates that integrating FCM clustering with nutrient-priority analysis and UAV imagery can produce operationally meaningful fertilizer recommendation maps. The methodology is generic and can be extended to other fields, additional nutrients, or different sensor sources, and can be embedded into an IoT-based platform, such as Agri Watch Net, to support near-real-time decision-making. Future work will focus on multi-seasonal data, yield-based validation, and coupling the nutrient-priority maps with variable-rate application technologies to quantify the economic and environmental benefits of adopting this approach.

Although this study is demonstrated using a shallot field in Srikayangan, Indonesia, the contribution of this work is not limited to a specific crop or geographic context. The proposed framework is methodologically generic and can be applied to any agricultural system where 1) soil macronutrients can be measured at spatial sampling points (via sensors or laboratory analysis), 2) a management grid can be defined according to operational field units, and 3) spatial transitions in soil fertility are expected. The use of Fuzzy C-Means clustering combined with nutrient-priority decision logic is independent of crop type and location, and therefore transferable to other horticultural crops, cereal systems, and smallholder or commercial farming contexts. In this sense, the Srikayangan field serves as a representative testbed to demonstrate the operational feasibility of translating fuzzy soil fertility classification into actionable fertilizer recommendations, rather than as a location-specific solution.

IV. Conclusion

This study presented a spatial classification and decision-support framework for fertilizer requirement mapping based on Fuzzy C-Means clustering of soil NPK data integrated with IoT-based sensing and UAV imagery. By applying the proposed approach at a fine spatial resolution compatible with smallholder bed-scale management, the results demonstrate that soil fertility within a single field can exhibit substantial spatial differentiation, making uniform fertilizer application inefficient and potentially wasteful.

The use of fuzzy clustering enables the representation of gradual transitions in soil nutrient availability, while the introduced nutrient-priority decision logic bridges the gap between fuzzy classification outputs and actionable fertilizer recommendations. Rather than producing only generalized fertility zones, the proposed framework identifies which macronutrient—Nitrogen, Phosphorus, or Potassium—should be prioritized at each management block, thereby enhancing the operational relevance of site-specific nutrient management.

Although the framework was demonstrated using a shallot field in Srikayangan, Indonesia, its contribution lies in the methodological integration and decision-support logic rather than the specific field context. The approach is generic and transferable to other crops, regions, and agricultural systems where spatial variability in soil nutrients necessitates more targeted fertilizer management. By combining fuzzy clustering with high-resolution sensing and intuitive spatial visualization, this work provides a practical pathway for translating soil data into actionable management decisions.

Overall, the proposed framework advances the practical usability of FCM-based soil fertility zonation for precision agriculture by linking data-driven spatial analysis with fertilizer decision-making, thereby supporting more efficient, economical, and sustainable nutrient management practices.

V. Future Work

Future research will focus on extending the proposed framework in several directions. First, multi-season soil and crop data will be incorporated to capture temporal nutrient dynamics and improve the robustness of fertilizer recommendations. Second, the derived nutrient-priority zones will be validated against measured yield and economic return data to quantify agronomic and financial benefits. Third, comparative experiments with alternative clustering and interpolation methods, such as k-means and geostatistical kriging, will be conducted to evaluate methodological trade-offs. Finally, the integration of the proposed approach with variable-rate fertilizer application technologies and mobile decision-support interfaces will be explored to facilitate real-time, data-driven nutrient management at scale.

IT, Adventist University of Central Africa, Kigali, Rwanda[1]

***Abstract*—Urban air pollution is a growing public-health challenge in African cities, yet traditional monitoring stations are sparse and expensive. The paper presents CleanCity IoT, a deployed, low-cost, vehicle-mounted air-quality platform that combines IoT sensors, GSM connectivity, cloud aggregation, and machine learning to produce near-real-time exposure maps and 2-hour forecasts for multiple pollutants. Each device integrates low-cost sensors for PM2.5, PM10, NO_2, O_3, SO_2, and CO_2, alongside temperature and humidity. Measurements are geotagged and transmitted over mobile networks form vehicles to a cloud backend, where data are validated, stored, and visualized through a user-friendly dashboard that also issues automated alerts and periodic reports. Using a dataset collected in Kigali and secondary cities via routine vehicular routes, the paper introduces the training of a multivariate time-series model to forecast short-horizon pollutant levels, supporting proactive health guidance and regulatory action. The system reports a performance in terms of latency, uptime, coverage, and data quality, and evaluate forecast accuracy using MAE/RMSE/MAPE and event-oriented metrics for spike prediction. Results indicate that CleanCity IoT provides reliable, scalable, and cost-effective urban air-quality intelligence, closing key gaps in spatiotemporal coverage while enabling citizen access, policy support, and social impact. The platform demonstrates a practical blueprint for African cities to operationalize air-quality intelligence using existing mobile infrastructure and locally developed technology.**

Keywords*—CleanCity IoT; air quality; mobile sensing; multivariate forecasting; spike detection

I. Introduction

Urban air pollution has emerged as one of the fastest-growing environmental and public-health threats in African cities such as Kigali, Rwanda, driven by rapid urbanization, motorization, and industrial expansion [1][2]. The World Health Organization (WHO) reports that air pollution causes over seven million premature deaths annually, while nearly 90% of the global population is exposed to pollutant concentrations exceeding recommended limits. In many low- and middle-income countries, fine particulate matter ($PM_{2.5}$ and PM_{10}) and gaseous pollutants such as nitrogen dioxide (NO_2), sulfur dioxide (SO_2), ozone (O_3), and carbon dioxide (CO_2) remain poorly monitored, limiting the capacity for evidence-based policymaking and citizen awareness [3]. Recent environmental assessments in Kigali have revealed that $PM_{2.5}$ concentrations during peak hours often surpass 50 µg/m³, nearly double the WHO 24-hour guideline, highlighting an urgent need for high-resolution, real-time monitoring systems [4].

Conventional air-quality monitoring infrastructures, which depend on fixed high-precision stations, provide accurate but spatially limited data. Their high installation and maintenance costs prevent widespread deployment across large or topographically diverse urban areas. Consequently, most African cities rely on sparse or intermittent measurements that fail to capture micro-scale variations and short-term pollution spikes. In response, researchers have turned to low-cost Internet of Things (IoT)–based sensing networks that offer dense, distributed data acquisition at a fraction of the traditional cost [4], [5]. Among the most effective configurations are vehicle-mounted sensor systems, which leverage the mobility of public-service vehicles, taxis, and buses to achieve city-wide spatial coverage without constructing new fixed stations [5] [6] [7].

Earlier studies such as [8] on affordable vehicle-mounted monitoring, [9] on IoT devices for municipal vehicles, and [6] on bus-based monitoring platforms have demonstrated the technical feasibility of mobile air-quality mapping and visualization. These systems collect particulate and gaseous pollutants while traversing city corridors, producing near-real-time datasets for spatial pattern analysis. However, most prior implementations primarily focused on measurement and visualization, offering limited integration of predictive analytics, alert systems, and policy-support mechanisms—features crucial for proactive environmental management, especially in data-scarce regions.

Building upon these efforts, this study introduces CleanCity IoT, a low-cost, scalable, and mobile air-quality monitoring and forecasting platform developed at the University of Rwanda in collaboration with national and regional partners. Each CleanCity IoT unit integrates low-cost sensors for $PM_{2.5}$, PM_{10}, NO_2, SO_2, O_3, and CO_2, along with temperature and humidity modules, controlled by an ESP32 microcontroller equipped with

This work was supported by a generous grant from PASET/RSIF, without whom this project would not have been possible.

GSM connectivity. The devices are mounted on moving vehicles, enabling spatially continuous air-quality sampling across Kigali and secondary cities. Data are transmitted via mobile networks to a cloud server (ThingSpeak), where they are cleaned, stored, and visualized through a real-time web dashboard featuring pollution heat maps, alert notifications, and automated reporting tools. Fig. 1 illustrates the overall CleanCity IoT ecosystem, including its sensing, communication, and analytics layers.

A distinctive feature of CleanCity IoT is the inclusion of a machine-learning forecasting module that predicts pollutant levels up to two hours ahead based on multivariate time-series data. This capability enables early warnings and supports informed interventions by environmental authorities, health agencies, and city planners. Furthermore, by making air-quality information publicly accessible through a user-friendly dashboard, the system strengthens community engagement and promotes citizen science, aligning with Rwanda's Smart-City and environmental-sustainability initiatives.

The proposed study builds upon the foundational work by [10], [11], who developed an IoT-edge-based prototype for detecting transportation-related pollution spikes in Kigali. Their system demonstrated the feasibility of using low-cost IoT networks for real-time air-quality monitoring in urban transport corridors. However, while the earlier prototype focused primarily on localized pollution detection and data transmission through edge networks, the present research extends this framework into a fully integrated CleanCity IoT system that includes mobile GSM-based data collection, cloud dashboard visualization, and machine-learning-driven forecasting. Thus, this study represents both continuation and enhancement of the ACEIoT initiative's earlier work, translating edge-level monitoring into a scalable, citizen-centered solution for smart urban management.

A. Contributions

The key contributions of this work are as follows:

- Design and deployment of a vehicle-mounted IoT device integrating multi-pollutant gas and particulate sensors with GSM-based real-time communication.
- Implementation of a cloud-hosted dashboard providing visualization, alerting, and reporting functionalities for stakeholders.
- Development of a multivariate machine-learning model for two-hour-ahead pollutant prediction, supporting proactive urban-health responses.
- Field validation of the system in Kigali and secondary cities, demonstrating low-cost scalability, data reliability, and practical usability.
- Promotion of local innovation and social impact, reinforcing Rwanda's vision for smart and sustainable urban management.

Through these contributions, CleanCity IoT establishes a practical, home-grown framework for real-time, predictive, and socially inclusive air-quality intelligence applicable to cities across Africa.

B. Paper Organization

The remainder of this paper is structured as follows: Section II reviews related work on mobile air-quality sensing and forecasting techniques. Section III describes the system design, algorithm construction and hardware implementation. Section IV presents data-processing and machine-learning methodologies. Section V discusses experimental results and performance evaluation, and Section VI concludes with key findings and future research directions.

II. Related Work

A. Conventional and Fixed-Station Monitoring

Traditional air-quality surveillance depends on reference-grade analyzers that provide highly accurate but spatially limited data. These stations, typically operated by environmental agencies, can cost more than USD 50,000 per unit, with significant yearly maintenance expenses [8]. Such systems monitor only a few fixed locations, resulting in low spatial coverage that fails to capture localized variations in pollutants caused by traffic density, topography, or industrial activities. While essential for calibration and regulatory baselines, fixed networks are financially unsustainable for widespread deployment in developing countries.

B. Emergence of Low-Cost IoT Sensor Networks

Advances in sensor miniaturization, embedded microcontrollers, and cloud connectivity have led to low-cost IoT-based monitoring systems [12], [13]. These frameworks employ microcontrollers such as Arduino or ESP32 and communication technologies including Wi-Fi, GSM, or LoRa to transmit environmental data in real time. Gubbi *et al.* (2013) outlined a scalable IoT architecture for smart environments that has since inspired numerous urban-sensing deployments. Although low-cost sensors are less accurate than reference analyzers, they enable dense spatial coverage, data fusion, and temporal tracking when coupled with calibration algorithms or machine learning [5], [14].

C. Mobile and Vehicle-Mounted Sensing Approaches

To improve spatial resolution, several researchers have adopted mobile sensing using vehicles as carriers. The paper [12] designed an affordable vehicle-mounted system for dynamic air-quality mapping. In the papers [6] implemented a bus-based monitoring platform integrated with cloud dashboards for real-time visualization. The paper [9] deployed IoT modules on municipally governed vehicles to track NO_2 and particulate matter across city zones. The paper in [7] proposed a vehicular sensor network architecture for real-time pollution analysis, while the paper [15] validated low-cost mobile sensors for hyperlocal monitoring in London. These projects proved the feasibility of vehicular IoT systems, but most emphasized data collection and visualization, with limited inclusion of predictive analytics, alerts, or decision-support tools.

A recent Rwandan contribution in the paper [10] introduced an IoT-edge-based system for detecting transportation pollution spikes using embedded edge computing. Their implementation at the Africa Centre of Excellence in Internet of Things (ACEIoT) validated the use of localized edge devices for

vehicular pollution tracking. Building on this foundation, the current CleanCity IoT framework enhances mobility, scalability, and predictive intelligence through GSM-based data transmission and cloud-integrated analytics.

D. Cloud-Based Data Aggregation and Visualization

Cloud computing has become central to IoT ecosystems for environmental data management. Platforms such as ThingSpeak, AWS IoT Core, and Azure IoT Hub support data ingestion, storage, and visualization in real time [1], [6], [13], [14], [16], [17]. The papers [2], [18] [6] demonstrated city-wide dashboards for pollutant tracking, and [7] discussed open-source architectures for mobile-data integration with geographic information systems. Nevertheless, most cloud-based implementations stop at visualization, lacking automated alerting, policy analytics, and citizen-accessible interfaces key enablers for social impact.

E. Machine-Learning Forecasting for Air Quality

Accurate short-term forecasting of air pollutants enables preventive interventions. Statistical models such as ARIMA and VAR have been widely used for one-step-ahead predictions, but deep-learning approaches now dominate multivariate time-series forecasting [19]. LSTM and GRU networks, as explored in paper [20] outperform linear models in capturing nonlinear temporal dependencies of $PM_{2.5}$ and NO_2 concentrations. Despite these advances, few studies integrate such predictive analytics directly into mobile, low-cost IoT frameworks, particularly within African contexts where both connectivity and calibration data are limited.

Quantitatively, low-cost sensor units in these studies ranged from USD 150–300 per node, achieved spatial resolutions up to 100m, and showed mean deviations of ±10-20% compared with reference instruments [6], [7], [12]. Such performance is adequate for mapping and trend detection but insufficient for health-critical forecasting without data calibration and model correction.

F. Research Gap and Motivation

Despite the progress summarized above, major limitations persist:

- Lack of integrated forecasting and alerting modules within mobile IoT systems.
- Absence of region-specific deployments in sub-Saharan Africa using GSM infrastructure for scalable connectivity.
- Minimal incorporation of citizen-accessible dashboards and community engagement mechanisms.

The CleanCity IoT platform directly addresses these challenges by combining multi-pollutant IoT sensing, GSM data transmission, cloud-based visualization, and machine-learning-driven forecasting. The project exemplifies a locally developed, cost-effective solution advancing both environmental intelligence and social awareness.

The reviewed literature highlights a steady evolution from fixed-station monitoring toward IoT-enabled, mobile, and data-driven frameworks as shown in Table I. However, none fully integrate predictive analytics, social accessibility, and regional scalability within a single platform. Section III therefore presents the system design and implementation of the proposed CleanCity IoT solution, detailing its hardware architecture, communication model, and cloud-analytics workflow.

TABLE I. COMPARATIVE SUMMARY OF RELATED IOT AND MOBILE AIR-QUALITY MONITORING SYSTEMS

Author & Year	Platform System	Methodology Features	Key Contribution	Identified Limitation
Santana et al. (2021)	Vehicle-mounted AQ mapping	ESP32 + GSM; $PM_{2.5}$ / NO_2 sensing	Affordable mobile monitoring	No predictive analytics
Ivanova et al. (2020)	IoT on municipal vehicles	Wi-Fi IoT nodes; CO PM sensors	Dynamic city-wide mapping	Limited citizen interface
Correia et al. (2023)	Bus-based AQ system	Cloud dashboard visualization	Real-time city dashboards	No forecasting capability
Zherka & Tafa (2023)	Vehicular sensor network	On-board sensors + data fusion	Real-time analysis	Lacks scalability
Zboralski & Kunz (2024)	Mobile GIS framework	Cloud integration	Open-source architecture	No alert or policy module
CleanCity IoT (this work)	Vehicle IoT + GSM + ML	ESP32 + GSM + ThingSpeak + LSTM	Real-time forecasting + dashboard + alerts	-------

III. METHODOLOGY

A. Overview of the Proposed Framework

The CleanCity IoT framework is designed as an end-to-end intelligent air-quality monitoring and forecasting system that leverages Internet of Things (IoT), cloud computing, and machine learning (ML) technologies to provide real-time insights into urban pollution dynamics. The framework aims to transform conventional monitoring often limited to fixed stations into a mobile, scalable, and predictive sensing ecosystem suited for low-resource contexts such as Rwandan cities.

In Fig. 1, the system operates through four tightly integrated layers: 1) sensing and acquisition, 2) communication and transmission, 3) cloud storage and analytics, and 4) visualization and forecasting. Each layer contributes specific functionalities, forming a pipeline that converts raw sensor readings into actionable intelligence for environmental management and policy decision-making.

In the sensing and acquisition layer, a suite of low-cost environmental sensors continuously measures air pollutants including particulate matter ($PM_{2.5}$, PM_{10}), nitrogen dioxide (NO_2), sulfur dioxide (SO_2), ozone (O_3), and carbon dioxide (CO_2), alongside ambient parameters such as temperature and humidity. These sensors are interfaced with an ESP32 microcontroller integrated with a SIM800L GSM module, enabling both data collection and mobile transmission from vehicle-mounted units.

The communication and transmission layer employs GSM/GPRS connectivity for real-time data delivery to cloud infrastructure. This design choice compared to Wi-Fi or LoRa is motivated by the wide availability of mobile networks across Rwandan cities and highways, ensuring scalability and mobility without dependency on fixed infrastructure.

The cloud layer utilizes the ThingSpeak IoT platform, which serves as both a data repository and preliminary analytics engine. Each sensing node transmits periodic measurements (every 30 seconds to 1 minute) to predefined ThingSpeak channels through HTTP POST requests. The platform aggregates, timestamps, and visualizes incoming data streams, while also allowing external APIs for integration with advanced analytical tools such as MATLAB, Python, or Node-RED for extended processing and forecasting.

The visualization and forecasting layer bridge the system's technical outputs with end-user interaction. A custom Air Quality Dashboard accessible via web or mobile interface—displays real-time pollutant levels, temporal trends, and geospatial mapping of emission zones. Historical datasets retrieved from ThingSpeak are used to train a Long Short-Term Memory (LSTM)-based predictive model, which forecasts pollutant concentrations two hours ahead. This predictive feature enhances early-warning capabilities and supports data-driven policy interventions by environmental authorities.

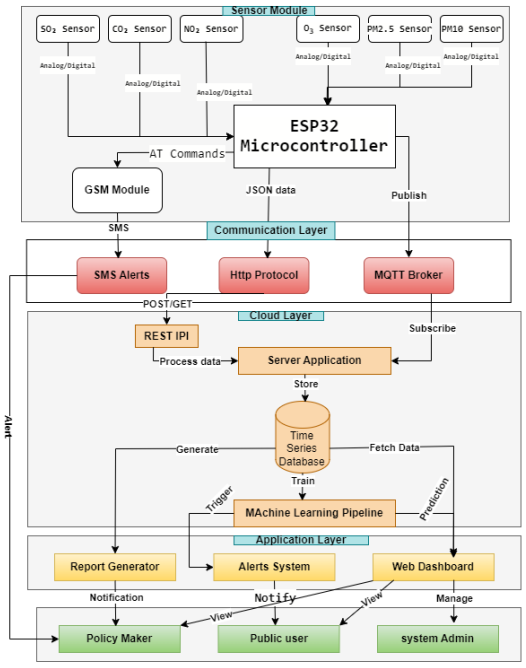

Fig. 1. Proposed framework.

B. Hardware Design and Components

The CleanCity IoT hardware architecture was designed to achieve low-cost, high-mobility, and energy-efficient air-quality monitoring while maintaining compatibility with existing mobile communication networks. The system integrates multiple sensors, a microcontroller unit, and a GSM communication interface, all mounted within a compact enclosure suitable for vehicular deployment.

1) Main controller: ESP32 (LilyGO T-Call SIM800L): At the core of the system lies the LilyGO T-Call ESP32 board on Fig. 2, which combines a dual-core 32-bit Xtensa processor with an embedded SIM800L GSM/GPRS module. The ESP32 manages sensor data acquisition, preprocessing, and transmission, while the GSM modem handles real-time communication with the cloud platform. The built-in UART, ADC, and GPIO interfaces facilitate multi-sensor connectivity, and the board supports 3.3 V logic with a stable 5 V input via USB or Li-ion battery.

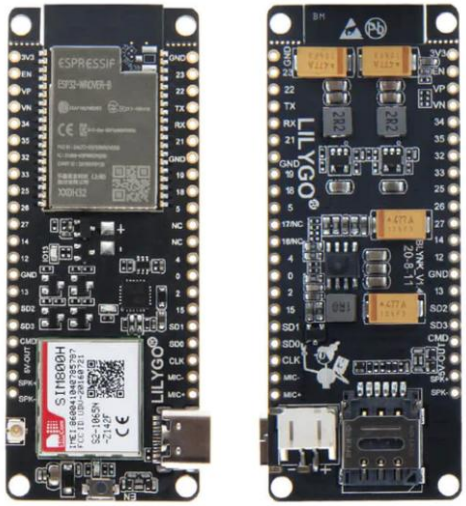

Fig. 2. LilyGO T-Call SIM800L.

The SIM800L module provides reliable 2G cellular connectivity, using HTTP POST requests to upload sensor readings to ThingSpeak channels. The use of GSM ensures that each node remains fully mobile and independent of Wi-Fi coverage, a critical feature for vehicle-mounted monitoring units in Rwandan cities and peri-urban areas.

2) Sensor suite: The CleanCity IoT system employs a diverse set of environmental sensors to capture the most relevant atmospheric parameters affecting air quality. Each sensor was selected for its low cost, stability, and proven performance in mobile IoT applications.

3) PMS5003 – particulate matter ($PM_{2.5}$ and PM_{10}): The Plantower PMS5003 in Fig. 3 is a laser-scattering particulate matter sensor capable of measuring fine and coarse particles ($PM_{2.5}$ and PM_{10}) in real time. It uses a light-scattering principle combined with a digital signal processor to calculate mass concentration in micrograms per cubic meter (µg/m³). The sensor communicates via UART and offers high sensitivity and accuracy suitable for vehicular environments, making it ideal for continuous mobile air-quality monitoring.

4) MQ-131 – Ozone (O_3) sensor: The MQ-131 sensor in Fig. 4 detects ozone concentrations using a tin dioxide (SnO_2)-based semiconductor layer. When O_3 gas contacts the sensitive surface, it alters the material's conductivity proportionally to the gas concentration. The analog output from the sensor is fed to the ESP32's ADC pin, which converts it into a corresponding O_3 level in parts per million (ppm). This sensor was chosen for

its low cost and reasonable response time, essential for detecting short-term pollution spikes.

Fig. 3. Plantower PMS5003.

Fig. 4. MQ-131 sensor.

5) MICS-6814 – Nitrogen Dioxide (NO_2) Sensor: The MICS-6814 in Fig. 5 is a compact three-channel semiconductor gas sensor that simultaneously measures NO_2, CO, and NH_3 gases. It is particularly suitable for mobile IoT applications due to its low power consumption and small form factor. For this project, the NO_2 channel was primarily used, with calibration coefficients adjusted based on the manufacturer's characterization curve. Its analog signal provides ppm-level readings processed by the ESP32's 12-bit ADC.

Fig. 5. Nitrogen Dioxide (NO_2) sensor.

6) AGSM-SO_2-5 Sulfur Dioxide (SO_2) sensor: The AGSM-SO_2-5 in Fig. 6 is an electrochemical-type sensor used to detect sulfur dioxide concentrations in ambient air. The sensor produces a small current proportional to the SO_2 gas concentration, which is converted to voltage using an external resistor circuit and read through an ADC input. This sensor type offers high selectivity and low detection limits, enabling reliable SO_2 measurement even in mixed-gas environments. Its readings are periodically calibrated against baseline voltages under clean-air conditions.

Fig. 6. Sulfur Dioxide (SO_2) sensor.

7) MG-811 Carbon Dioxide (CO_2) sensor: The MG-811 sensor in Fig. 7 measures carbon dioxide (CO_2) concentration using a solid electrolyte cell. The sensor outputs an analog voltage that decreases as CO_2 concentration increases. It operates between 0–10,000 ppm and provides stable performance for mobile applications when coupled with proper temperature compensation. The MG-811 data complements the other gas readings by offering insights into combustion-related emissions.

Fig. 7. Carbon Dioxide (CO_2) sensor.

8) DHT11 temperature and humidity sensor: The DHT11 digital sensor in Fig. 8 monitors ambient temperature and relative humidity, parameters that directly influence gas sensor accuracy and pollutant dispersion. Its single-wire digital output simplifies integration with the ESP32 microcontroller. The temperature and humidity data collected are used to normalize and interpret gas readings, reducing variability due to environmental factors.

Fig. 8. DHT11 temperature and humidity sensor.

C. Custom PCB Design and Circuit Integration

To ensure a compact, reliable, and vibration-resistant mobile sensing unit, the system incorporates a custom-designed PCB, created using EasyEDA and manufactured as a single-layer board. The PCB consolidates all key components including the LilyGO T-Call ESP32, PMS5003 particulate matter sensor, MQ131 ozone module, CJMCU-6814 multi-gas sensor (NO_2 +

SO_2), and analog SO_2 sensor interface into a unified hardware platform optimized for vehicular deployment.

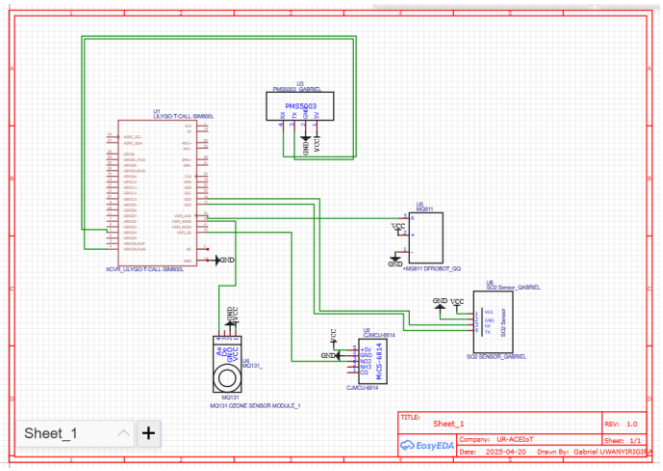

Fig. 9. Schematic diagram of clean city IoT system.

The PCB layout in Fig. 9 follows a structured placement strategy, with the PMS5003 connector positioned on the upper-left side to minimize trace length for the UART interface, while the MQ131 and CJMCU-6814 modules are placed on the right to avoid electromagnetic interference from the GSM modem. Dedicated headers provide labeled terminals for VCC, GND, RX, and TX, ensuring clear wiring during assembly and simplifying sensor maintenance or replacement. The bottom section houses the footprint for the LilyGO T-Call board, providing direct access to GSM, UART, and ADC lines without intermediate wiring.

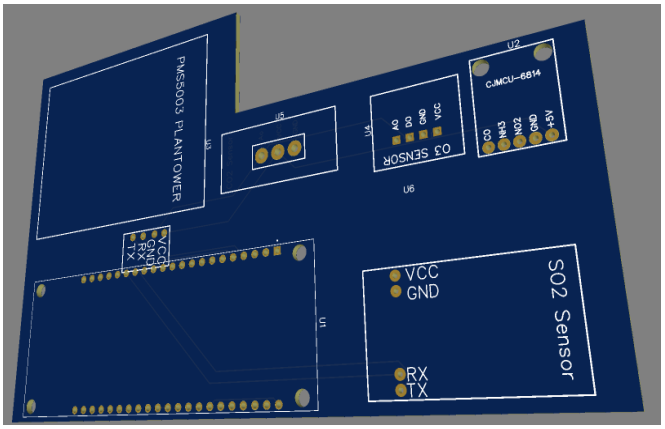

Fig. 10. 3D view of the custom PCB design for the CleanCity IoT device.

The corresponding circuit schematic (Fig. 10) illustrates the electrical interconnections between all sensing modules and the ESP32 controller. UART pins are assigned to the PMS5003 (U3) and SO_2 sensor interface, while the MQ131 analog output is routed to an ADC input. The CJMCU-6814 module is powered by a stable 5V rail, and its NO_2/SO_2 analog channels are fed into separate ADC lines for accurate digital conversion. Ground planes and decoupling capacitors are incorporated to enhance signal stability and reduce noise, which is critical for gas sensor accuracy. The PCB also accommodates optional onboard filtering capacitors for the analog channels, further increasing measurement reliability.

This custom PCB significantly enhances the robustness of the CleanCity IoT device compared to breadboard-based prototypes. By minimizing loose wiring, standardizing sensor interfaces, and optimizing component placement, the board improves electrical reliability, reduces interference from the GSM module, and ensures consistent sensor readings during mobile operation. It also enables rapid replication of the device for larger-scale deployments in Kigali or other Rwandan cities.

D. Data Acquisition and Transmission

The CleanCity IoT system collects, processes, and transmits multi-sensor environmental data in real time through a unified acquisition pipeline. The design ensures synchronized sampling across all sensing modules, reliable communication via GSM, and consistent data formatting for cloud integration.

E. Sensor Data Acquisition Cycle

Each monitoring node performs periodic measurements of particulate matter, gaseous pollutants, and ambient conditions.

- Particulate Matter ($PM_{2.5}$ and PM_{10}): The PMS5003 sensor provides continuous data through a UART interface, reporting particle concentrations in µg/m³.
- Gaseous Pollutants: O_3, NO_2, SO_2, and CO_2 levels are sensed using analog sensors (MQ-131, MICS-6814, AGSM-SO_2-5, and MG-811). Their analog voltages are sampled by the ESP32's 12-bit ADC and converted to concentration values (ppm) using calibration curves derived from reference data.
- Ambient Conditions: The DHT11 sensor provides temperature and relative-humidity readings, which are used for contextual adjustment of gas-sensor responses.

To reduce random noise and ensure stability, multiple readings are averaged within each cycle before transmission. The resulting dataset per interval includes parameters as shown in Table II.

TABLE II. PARAMETERS ACQUIRED DURING EACH SAMPLING CYCLE

Parameter	Symbol	Unit
$PM_{2.5}$ concentration	PM2.5	µg/m³
PM_{10} concentration	PM10	µg/m³
Ozone	O_3	ppm
Nitrogen Dioxide	NO_2	ppm
Sulfur Dioxide	SO_2	ppm
Carbon Dioxide	CO_2	ppm
Temperature	T	°C
Humidity	H	%

F. Data Pre-Processing and Packet Formation

Before transmission, each sensor reading undergoes a lightweight pre-processing pipeline to improve data reliability and ensure consistency across the full dataset. First, a noise-filtering procedure is applied to remove spurious or invalid sensor values. Given a raw reading x_i for pollutant j, the system checks whether it falls within the predefined operational range $[L_j, U_j]$. This filtering step is mathematically expressed as:

$$x_i' = \begin{cases} x_i & \text{ιφ } L_j \le x_i \le U_j \\ \text{NαN} & \text{οτηερωισε} \end{cases} \quad (1)$$

Ensuring that negative values, extreme spikes, and sensor glitches do not propagate into the cloud dataset.

Following outlier removal, each pollutant value is normalized into standard physical units (µg/m³ or ppm) using a linear scaling transformation. This normalization converts raw sensor outputs into a consistent range defined by calibration limits, allowing accurate comparison across sensors. The conversion is achieved using Eq. (2).

$$x_{norm} = \frac{x_i - x_{min}}{x_{max} - x_{min}} \times (S_{max} - S_{min}) + S_{min} \quad (2)$$

where x_{max} and x_{min} are the sensor's calibrated electrical bounds and S_{max} , S_{min} correspond to the standardized environmental scale. This operation ensures homogeneous units throughout the dataset, which is essential for downstream analytics.

Each sanitized and normalized reading is then assigned a timestamp to preserve temporal integrity. The timestamp t_k originates either from the GSM network clock or the ESP32's internal real-time counter. The final structured data packet transmitted at time k is represented as,

$$D_k = \{DeviceID, PM_{2.5}, PM_{10}, O_3, NO_2, SO_2, CO_2, T, H, t_k\} \quad (3)$$

capturing all pollutants, environmental conditions, and metadata in a single, machine-readable structure compatible with ThingSpeak's REST API.

G. GSM-Based Data Transmission

The LilyGO T-Call ESP32 integrates a SIM800L GSM/GPRS modem, allowing each mobile sensing unit to transmit air-quality data directly to the cloud without requiring Wi-Fi or external gateways. Once a complete measurement vector

$$z_t = [PM_{2.5}, PM_{10}, O_3, NO_2, SO_2, CO_2, T, H] \quad (4)$$

is pre-processed, the system encapsulates the data into a structured transmission packet. The full packet sent at time t is expressed as:

$$P_t = \{DeviceID, z_t, t\} \quad (5)$$

Every transmission cycle follows a periodic schedule, where the upload interval is defined as

$$\Delta t = t_k - t_{k-1} \quad (6)$$

and during the experimental deployment, $\Delta t \approx 30$ s, providing a balance between data granularity and power efficiency for vehicular operation. The SIM800L modem performs an HTTP POST request over GPRS, where the payload corresponds to the encoded packet Pt. The uplink transmission can be represented as

$$\mathcal{T}(P_t) \rightarrow \text{ThingSpeak Channel} \quad (7)$$

where $\mathcal{T}(\mathrm{P_t})$ denotes the GSM-based upload operation. Once the server acknowledges receipt, ThingSpeak updates the real-time charts for all monitored pollutants. To ensure time-series completeness, the system incorporates a local retransmission buffer. If a temporary network outage occurs, packets are stored in a local queue

$$Q = \{P_{t_1}, P_{t_2}, \ldots, P_{t_m}\} \quad (8)$$

and are automatically resent once connectivity is restored. Successful transmission empties the queue according to

$$Q \leftarrow Q \setminus P_{t_i} \quad (9)$$

This queue-based recovery mechanism guarantees robustness in urban mobility conditions, where cellular coverage may momentarily fluctuate. As a result, the system achieves reliable, timestamped uploads essential for downstream analytics, ML model training, and spatiotemporal pollution mapping.

H. Cloud Integration and Dashboard Development

The CleanCity IoT system relies on ThingSpeak Cloud as the central platform for ingesting, storing, and visualizing sensor data in real time. Each monitoring node continuously uploads the structured packet Pt to a dedicated ThingSpeak channel, where the information is automatically timestamped and organized across eight data fields. The cloud interface provides dashboards, charts, and API endpoints that support both manual inspection and automated analytical tasks such as forecasting and multi-pollutant correlation studies.

To quantify the data-handling performance of the cloud layer, the expected number of uploaded records over an observation period T is expressed as,

$$N_T = \frac{T}{\Delta t} \quad (10)$$

where, Δt represents the transmission interval (approximately 30 seconds in this deployment). This relation determines the temporal granularity and the total volume of data streamed into the cloud. The corresponding data throughput, crucial for evaluating network and storage efficiency, is computed using

$$R_{up} = \frac{N_T \times P_k}{T} \quad (11)$$

where, P_k denotes the average packet size in bytes. These metrics confirm that the system maintains consistent upload behavior, even under mobile conditions. In ThingSpeak, pollutant concentrations are further processed to compute an Air Quality Index (AQI). For each pollutant iii, the platform evaluates a sub-index using

$$I_i = \frac{I_{high} - I_{low}}{C_{high} - C_{low}} (C_i - C_{low}) + I_{low} \quad (12)$$

where the constants correspond to standard AQI breakpoints.

The overall AQI at time t is determined by,

$$AQI = \max(I_i) \quad (13)$$

allowing the system to categorize air quality levels and support early-warning notifications when thresholds are exceeded.

The cloud platform also enables multi-variable diagnostic analysis, particularly through pollutant correlation. The linear

relationship between any two-pollutant series x_i and x_j is computed using the Pearson coefficient,

$$r_{ij} = \frac{\sum_{k=1}^{n}(x_{i,k}-\overline{x_i})(x_{j,k}-\overline{x_j})}{\sqrt{\sum_{k=1}^{n}(x_{i,k}-\overline{x_i})^2}\sqrt{\sum_{k=1}^{n}(x_{j,k}-\overline{x_j})^2}} \quad (14)$$

This allows identification of pollutant sources with similar temporal behaviors, such as $PM_{2.5}$ and NO_2 often linked to traffic emissions. To ensure reliability, ThingSpeak computes a data completeness index over any period T as,

$$C_T = \frac{N_s}{N_t} \times 100\ \% \quad (15)$$

where Ns and Nt are the numbers of successfully uploaded and total expected packets, respectively. This metric is essential for confirming the robustness of GSM-based data acquisition, especially in mobile environments where connectivity might fluctuate. Through this cloud architecture, CleanCity IoT achieves real-time visualization, long-term storage, and automated analytic capability, making it suitable for continuous urban air-quality monitoring and predictive modeling.

I. Machine Learning Model Development

The dataset collected from the ThingSpeak cloud was used to train a Long Short-Term Memory (LSTM) neural network for short-term air-quality forecasting. The choice of LSTM was motivated by its ability to capture nonlinear temporal dependencies in multivariate time-series data, making it suitable for predicting pollutant levels under changing meteorological and traffic conditions. To prepare the data, each environmental variable was standardized to ensure consistent scaling across all pollutants. This normalization follows the transformation.

$$\hat{z}_t^{(i)} = \frac{z_t^{(i)}-\mu_i}{\sigma_i} \quad (16)$$

where, $\hat{z}_t^{(i)}$ denotes the original reading of feature i at time t, and $\mu_i$and σ_i represent the corresponding mean and standard deviation. A sliding window of length L was then used to construct input sequences for the model. Each multivariate input window is defined as,

$$X_t = [\tilde{z}_{t-L+1}, \tilde{z}_{t-L+2}, \ldots, \tilde{z}_t] \in R^{L\times 8} \quad (17)$$

while the prediction target for horizon H is given by,

$$y_t = z_{t+H} \quad (18)$$

The LSTM learns a nonlinear mapping

$$\hat{y}_t = f_\theta(X_t) \quad (18)$$

where, f_θ denotes the trained neural-network function parameterized by θ. The training objective is to minimize the Mean Squared Error (MSE):

$$\mathcal{L}\mathrm{MSE}(\theta) = \frac{1}{N}\sum_{t=1}^{N}|y_t - \hat{y}_t||_2^2 \quad (19)$$

Model performance was evaluated using Mean Absolute Error (MAE), Root Mean Square Error (RMSE), Mean Absolute Percentage Error (MAPE), and the coefficient of determination R^2, expressed respectively as

$$MAE_j = \frac{1}{N}\sum_{t=1}^{N}\left|y_t^{(j)} - \widehat{y_t^{(j)}}\right| \quad (20)$$

$$RMSE_j = \sqrt{\frac{1}{N}\sum_{t=1}^{N}\left(y_t^{(j)} - \widehat{y_t^{(j)}}\right)^2} \quad (21)$$

$$MAPE_j = \frac{100}{N}\sum_{t=1}^{N}\left|\frac{y_t^{(j)}-\widehat{y_t^{(j)}}}{y_t^{(j)}}\right| \quad (22)$$

$$R_j^2 = 1 - \frac{\sum_{t=1}^{N}\left(y_t^{(j)}-\widehat{y_t^{(j)}}\right)^2}{\sum_{t=1}^{N}\left(y_t^{(j)}-\overline{y^{(j)}}\right)^2} \quad (23)$$

These performance indicators assess the reliability of the LSTM model in forecasting pollutant levels such as $PM_{2.5}$, PM_{10}, NO_2, SO_2, O_3, CO_2, temperature, and humidity. By using standardized inputs and multivariate temporal windows, the model is able to produce stable forecasts up to two hours ahead, enabling early-warning capabilities and supporting real-time decision-making for environmental monitoring.

IV. Results and Discussion

A. Dataset Characteristics

The CleanCity IoT mobile sensing unit collected a total of 6,484 multivariate records during vehicular movement across urban road segments in Kigali. Each record contains synchronized measurements of particulate pollution ($PM_{2.5}$, PM_{10}), gaseous pollutants (NO_2, SO_2, O_3, CO_2), and meteorological variables (temperature and relative humidity). Data were transmitted at an average 30-second sampling interval, resulting in a dense and continuous time-series suitable for both statistical analysis and machine learning–based forecasting.

The temporal behavior of the dataset is illustrated in Fig. 11, which shows the evolution of $PM_{2.5}$, PM_{10}, NO_2, and temperature over several days. The plots reveal clear short-term fluctuations driven by traffic movement, road dust resuspension, and localized emission hotspots commonly encountered during mobile sensing. The temperature curve exhibits a pronounced diurnal cycle, confirming environmental consistency and stable sensor response.

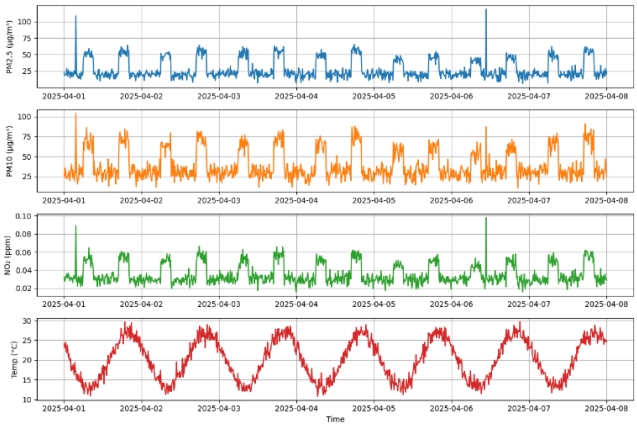

Fig. 11. Time-series variation of key air-quality parameters ($PM_{2.5}$, PM_{10}, NO_2) and meteorological variables collected from the CleanCity IoT mobile sensing system.

To further assess data richness and distributional characteristics, histogram plots for all pollutants and environmental variables are shown in Fig. 12. These distributions demonstrate substantial variability across measured concentrations, with PM_{10} and $PM_{2.5}$ showing multimodal behavior associated with alternating high-traffic and low-traffic conditions. Gaseous pollutants (NO_2, SO_2, O_3) present narrower distributions, typical of background urban air composition, while CO_2 ranges reflect both ambient outdoor levels and intermittent vehicle exhaust influence.

The completeness of the dataset was evaluated using the metric.

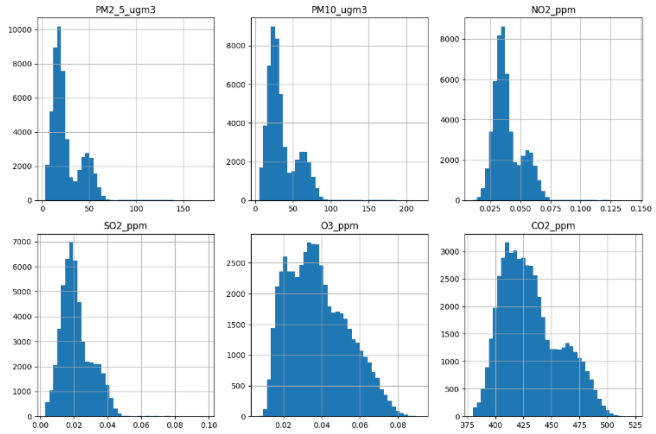

Fig. 12. Distribution of pollutant and environmental variables, illustrating concentration variability and underlying statistical patterns within the dataset.

where, N_S is the number of successfully uploaded samples and N_t is the expected number of samples based on the configured transmission interval. The system maintained high data availability across the monitoring period, confirming robust GSM connectivity and effective packet buffering in the LilyGO T-Call ESP32 board. Collectively, the time-series behavior, variable distributions, and high completeness rate validate the dataset as a reliable basis for subsequent LSTM-based forecasting and statistical analysis of urban air-quality dynamics.

B. System Performance Evaluation

The CleanCity IoT mobile sensing platform was deployed on a vehicle and evaluated under real urban operating conditions to assess communication stability, data reliability, environmental robustness, and cloud-integration performance. The LilyGO T-Call ESP32 board, equipped with the SIM800L GSM/GPRS module, demonstrated stable mobile connectivity throughout the monitoring period. The system achieved a high upload success rate, with most packets reaching the cloud on the first transmission attempt. Occasional GSM signal drops were mitigated by the built-in buffering mechanism, allowing queued packets to be retransmitted automatically once connectivity resumed.

The sensor suite also exhibited consistent and predictable behavior, as demonstrated by the correlation structure among the measured variables in Fig. 13. Strong positive correlations between $PM_{2.5}$ and PM_{10} confirm expected particulate co-variability in traffic-related environments, while moderate relationships between gaseous pollutants reflect common emission sources along the vehicle routes. The negative correlation between temperature and humidity follows typical micro-meteorological conditions in Kigali's urban climate, further validating sensor stability.

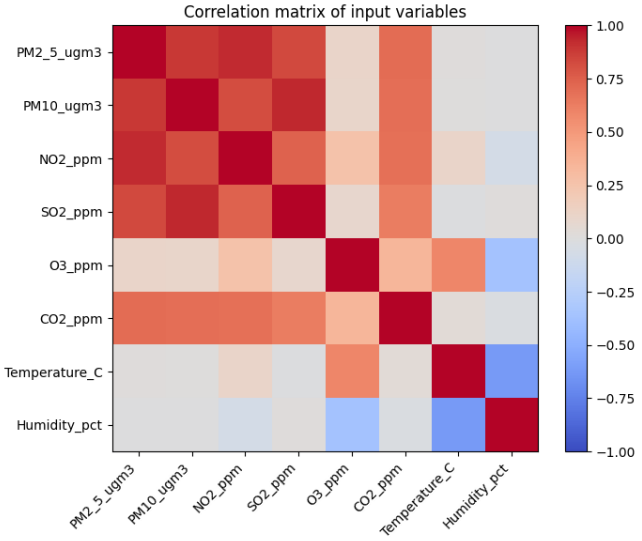

Fig. 13. Correlation matrix illustrating interdependencies between pollutant concentrations and meteorological variables

The data transmission latency averaged 2-4 seconds per packet during motion, consistent with typical GSM-based IoT deployments. The cloud dashboard updated in near real time, enabling effective monitoring of pollutant trends and environmental changes as the vehicle traversed different locations. Additionally, the hardware system demonstrated resilience to vibration, temperature changes, and power fluctuations during mobile operation. Overall, the system performance confirms that the CleanCity IoT platform is reliable for continuous mobile sensing in urban environments, maintaining stable communication, accurate sensing behavior, and real-time cloud integration suitable for further analytics and forecasting applications.

C. Machine Learning Model Performance

The cleaned and preprocessed multivariate dataset was used to train an LSTM-based forecasting model designed to predict short-term pollutant concentrations in real time. Input sequences were constructed using sliding windows of length L, where each window (Eq 16) represents the normalized and filtered sensor readings across all eight variables. The model produces a prediction (Eq 18) where f_θ denotes the LSTM, network parameterized by θ.

Model training converged smoothly, with the mean squared error (MSE) for both training and validation sets decreasing consistently, as shown in Fig. 14. The validation curve remained stable without divergence, indicating good generalization and absence of overfitting.

1) Prediction accuracy on key pollutants: The prediction performance for $PM_{2.5}$ and PM_{10} is shown in Fig. 15, where the predicted values closely follow the temporal structure of the true sensor measurements. The model successfully captures

peaks, transitions, and low-concentration periods, demonstrating strong short-term forecasting capability.

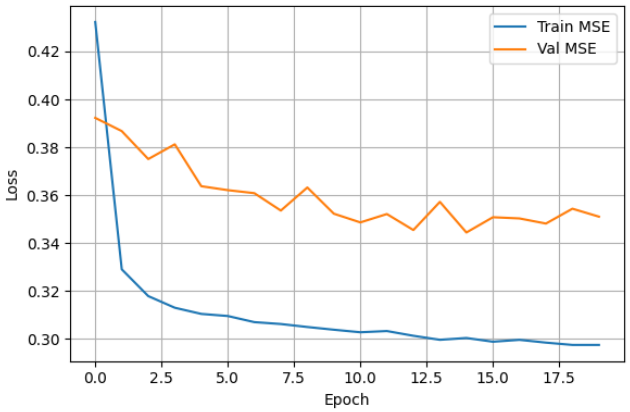

Fig. 14. Training and validation loss curves of the LSTM model, demonstrating convergence behavior and generalization performance.

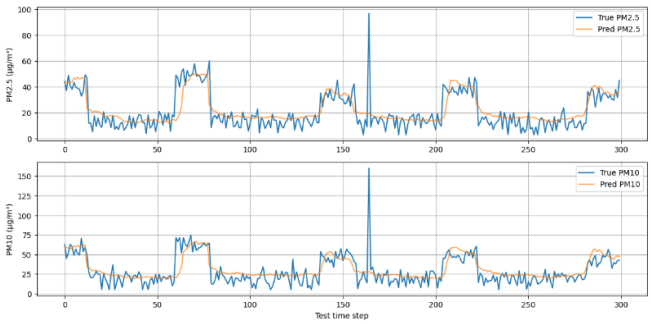

Fig. 15. Comparison between ground-truth and LSTM-predicted concentrations for $PM_{2.5}$ and PM_{10} over selected test windows.

2) Model fit across all variables: Scatter plots comparing predicted versus true values for all pollutants and environmental variables are shown in Fig. 16. The clustering of points around the 1:1 line demonstrates strong model agreement, especially for CO_2, temperature, O_3, and NO_2. Variability in $PM_{2.5}$ and SO_2 predictions reflects the intrinsic noisiness of mobile-sensing particulate measurements.

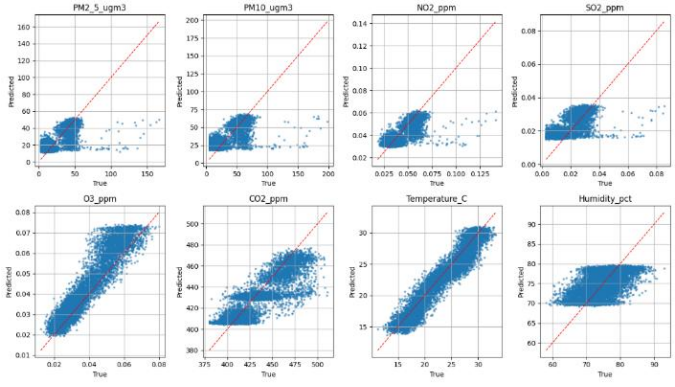

Fig. 16. Scatter plots comparing true and predicted values for all variables, with the 1:1 reference line indicating model accuracy.

3) Error distribution: To further examine predictive behavior, Fig. 17 presents the error distribution for $PM_{2.5}$. The histogram shows a narrow, approximately Gaussian distribution centered close to zero, indicating low systematic bias and moderate variance in short-term particulate predictions.

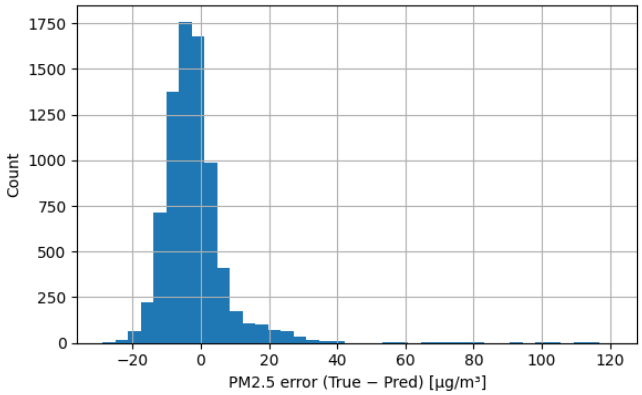

Fig. 17. Error distribution of $PM_{2.5}$ predictions, highlighting bias and variance characteristics of the LSTM model.

4) Quantitative metrics: Summarizes the evaluation metrics for each variable, including MAE, RMSE, and MAPE. The LSTM model achieved strong predictive performance for temperature, CO_2, O_3, and NO_2, while $PM_{2.5}$ and PM_{10} exhibited higher relative errors due to their higher temporal variability and sensitivity to rapid environmental changes (Table III) during vehicle motion.

TABLE III. PERFORMANCE METRICS (MAE, RMSE, MAPE) OF THE LSTM MODEL ACROSS ALL POLLUTANTS AND ENVIRONMENTAL VARIABLES

Variable	MAE	RMSE	MAPE_percent
PM2_5_ugm3	6.83	10.45	61.41
PM10_ugm3	9.26	13.72	56.24
NO2_ppm	0.005	0.007	12.993
SO2_ppm	0.006	0.007	68.230
O3_ppm	0.005	0.006	14.537
CO2_ppm	10.64	14.39	2.42
Temperature_C	1.19	1.49	5.40
Humidity_pct	3.25	4.06	4.40

Overall, the LSTM model demonstrates strong capability in short-term pollutant forecasting across multiple variables. Stability in the loss curve, tight clustering in scatter plots, realistic error distributions, and favorable MAE/RMSE/MAPE scores confirm that the forecasting framework is effective for real-time deployment in mobile urban air-quality monitoring systems.

D. Assembled Edge Device with Deployed Model

The complete air-quality monitoring unit was integrated into a compact, weather-resistant enclosure and mounted on the front of a motorcycle to enable continuous mobile sensing across urban routes. As shown in Fig. 18, the device securely attaches to the motorcycle's suspension frame, ensuring minimal vibration interference while maintaining unobstructed airflow to

the sensing chamber. The embedded ESP32–SIM800L controller executes the trained machine-learning model directly on the edge, enabling on-device preprocessing, anomaly filtering, and real-time prediction without reliance on cloud-based computation.

Fig. 18. Clean city IoT device mounted on motorcycle.

The internal hardware layout, presented in Fig. 19, illustrates the modular arrangement of components including the PM and gas sensors, power system, GSM communication module, and microcontroller. The wiring architecture was optimized to reduce electromagnetic interference and to maintain sensor accuracy during mobile operation. This assembly design ensures robustness under typical road conditions while maintaining low power consumption, making it suitable for long-term vehicular deployments.

Fig. 19. Internal hardware layout of clean city IoT device.

E. Dashboard for Remote Monitoring

A web-based dashboard was developed to provide real-time visualization and remote access to sensor measurements, model inferences, and device status. The interface, shown in Fig. 20, displays pollutant concentrations (PM2.5, PM10, SO_2, NO_2, O_3, CO_2) alongside temperature and humidity, each represented with intuitive color codes and threshold indicators. This enables rapid interpretation of air-quality conditions by operators and supports downstream analytics such as hotspot identification and route-based pollution profiling.

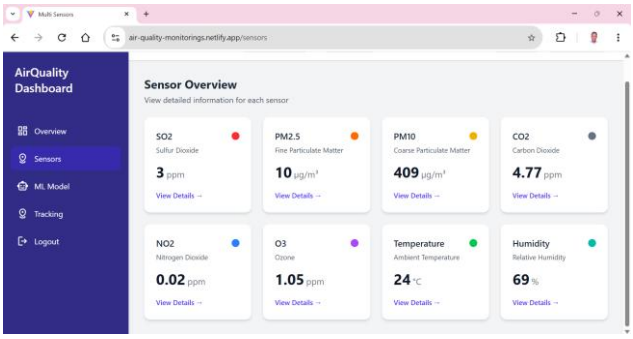

Fig. 20. Web-based remote monitoring dashboard of clean city IoT device.

The dashboard integrates seamlessly with the GSM-enabled edge devices via the cloud backend, allowing continuous updates at fixed intervals. Users may access detailed historical charts, inspect sensor-level readings, or monitor multiple devices simultaneously. This platform improves situational awareness and supports data-driven decision-making for urban air-quality management.

V. Discussion

The results obtained from the mobile air-quality monitoring platform highlight the strong potential of integrating low-cost sensing, edge intelligence, and mobile data acquisition to provide high-resolution pollution insights in dynamic urban environments. The temporal plots and distribution analyses demonstrate that the system successfully captured realistic pollutant patterns, including recurring diurnal behaviors, peak concentrations along traffic corridors, and rapid fluctuations associated with vehicle-dense areas. These trends align with previously reported characteristics of mobile sensing platforms, reinforcing the reliability of the collected dataset.

The performance of the LSTM model reflects both the strengths and inherent challenges of forecasting air-quality parameters in mobile conditions. Temperature, humidity, CO_2, and O_3 predictions achieved low MAE and RMSE values, indicating that their temporal structures exhibit smoother and more predictable patterns that are well-suited to sequence-learning models. Conversely, higher error values observed for PM2.5 and PM10 are consistent with the behavior of particulate pollutants, which often vary sharply due to localized dust sources, abrupt vehicle acceleration, wind disturbances, or sudden micro-spikes near emission points. These high-frequency fluctuations pose a challenge for recurrent models, which assume gradual temporal transitions. Despite this, the predicted sequences still closely follow the underlying pollutant trends, suggesting that the LSTM architecture provides valuable short-term predictive capability.

The correlation matrix further reinforces the internal consistency of the dataset by revealing strong associations between combustion-related pollutants (PM2.5, PM10, NO_2, SO_2). These relationships are well documented in air-quality literature and confirm that the system effectively captured realistic vehicular emission profiles. The inclusion of

meteorological parameters in the model input contributed to performance stability by providing contextual information on atmospheric dispersion, temperature-dependent sensor responses, and humidity-driven particle behavior.

Operationally, the motorcycle-mounted sensing device (Fig. 18, Fig 20) validated the practicality of a low-power, mobile, GSM-enabled platform for real-time air-quality assessment. The device maintained stable measurements during movement and reliably transmitted data to the cloud dashboard. The remote monitoring interface (Fig. 20) enabled seamless visualization of pollutant levels, supporting quick interpretation and forming a foundation for future large-scale deployments. This capability is particularly valuable in resource-constrained environments where installing dense networks of fixed monitoring stations is not feasible.

Nonetheless, several limitations were observed. The elevated prediction errors for particulate matter indicate the need for more advanced filtering or hybrid modeling techniques such as Kalman filters, temporal attention mechanisms, or transformer-based architectures better suited for abrupt pollutant variability. Occasional GSM transmission delays highlight a trade-off between mobile connectivity and data continuity, suggesting that buffering strategies or 4G/LTE-based modules may be advantageous in future iterations. Sensor drift and long-term degradation pose additional challenges, underscoring the importance of periodic recalibration, redundancy, or sensor fusion approaches to maintain long-term reliability.

The findings demonstrate that mobile IoT sensing combined with edge-deployed machine-learning models provide a powerful and scalable approach to capturing granular air-quality information. It offers a practical pathway toward city-wide mobile pollution mapping, intelligent fleet monitoring, and data-driven environmental planning, especially in developing urban regions where cost-effective solutions are essential.

VI. Conclusion, Recommendations, and Future Work

This study presented a mobile air-quality monitoring platform that integrates low-cost sensors, an ESP32–SIM800L edge device, GSM-based communication, and an LSTM prediction model to enable high-resolution pollution monitoring in dynamic urban environments. The mobile system successfully captured realistic temporal patterns of key pollutants including PM2.5, PM10, SO_2, NO_2, and O_3 while simultaneously collecting meteorological variables relevant to dispersion and atmospheric behavior. The experimental results demonstrated that the model accurately predicted smoother variables such as temperature, humidity, CO_2, and O_3, while exhibiting higher, yet consistent, errors for particulate matter due to its inherently abrupt and highly localized fluctuations. Overall, the system validated the feasibility of using a low-cost, edge-intelligent, mobile sensing approach to complement existing fixed monitoring infrastructures particularly in regions where traditional stations are sparse or economically prohibitive. The combination of real-time edge inference and cloud-based visualization provides a scalable foundation for city-wide monitoring, rapid hotspot identification, and informed environmental planning.

Model prediction errors for PM2.5 and PM10 highlight the need for more advanced temporal modeling techniques capable of handling sudden spikes and high-frequency variability. Network latency introduced by GSM connectivity suggests exploring more robust communication protocols and buffering strategies for uninterrupted data flow. Additionally, long-term reliability will require periodic sensor calibration, redundancy mechanisms, and drift-compensation strategies to maintain accuracy during extended deployments.

Based on these findings, the following recommendations are proposed:

- Adopt advanced hybrid modeling techniques**:** such as temporal attention mechanisms, transformer-based architectures, or Kalman-filter-enhanced LSTM to improve particulate matter forecasting.
- Upgrade communication infrastructure to LTE/4G or MQTT-based lightweight protocols to minimize transmission delays and enhance scalability.
- Implement periodic calibration schedules and sensor redundancy to mitigate drift, aging, and environmental contamination.
- Integrate geospatial and meteorological data sources (GIS layers, wind maps, road classifications) for more context-aware predictions and hotspot analysis.

Future work will focus on addressing these challenges by extending the system to support multi-node collaborative sensing, employing federated learning for distributed model updates, and exploring adaptive edge inference that dynamically adjusts sampling rates depending on environmental conditions. Additional work will investigate long-term deployment performance, data fusion with satellite products, and integration with policy tools for real-time air-quality alerts.

In conclusion, this research provides a practical, scalable, and cost-effective framework for mobile air-quality monitoring in rapidly urbanizing regions. By combining IoT sensing, edge computing, and machine learning, the system offers a promising direction for enhancing environmental intelligence and supporting evidence-based public health interventions.

From Consensus to Chaos: A Vulnerability Assessment of the RAFT Algorithm

Tamer Afifi, Dr. Abdelfatah Hegazy, Dr. Ehab Abousaif
Department of Computer Science-College of Computing & Information Technology,
Arab Academy for Science, Technology & Maritime, Cairo, Egypt

***Abstract*—In recent decades, the RAFT distributed consensus algorithm has become a main pillar of the distributed systems ecosystem, ensuring data consistency and fault tolerance across multiple nodes. Although the fact that RAFT is well known for its simplicity, reliability, and efficiency, its security properties are not fully recognized, leaving implementations vulnerable to different kinds of attacks and threats, which can transform the RAFT harmony of consensus into a chaos of data inconsistency. This paper presents a systematic security analysis of the RAFT protocol, with a specific focus on its susceptibility to security threats such as message replay attacks and message forgery attacks. Examined how a malicious actor can exploit the protocol's message-passing mechanism to reintroduce old messages, disrupting the consensus process and leading to data inconsistency. The practical feasibility of these attacks is examined through simulated scenarios, and the key weaknesses in RAFT's design that enable them are identified. To address these vulnerabilities, a novel approach based on cryptography, authenticated message verification, and freshness check is proposed. This proposed solution provides a framework for enhancing the security of the RAFT implementations and guiding the development of more resilient distributed systems.**

I. Introduction

The world today is surrounded by distributed systems everywhere, which operate behind the scenes, seamlessly coordinating tasks across multiple computer-based systems, often geographically scattered [2]. From global communication networks to critical financial transactions, these systems rely on fundamental principles of distributed systems to ensure reliability and data consistency [1]. A core component of this reliability is the distributed consensus algorithm, which enables autonomous nodes to agree on a single value, even in the presence of network failures or node crashes [9]. In recent decades, the RAFT distributed consensus algorithm has become a main pillar of the distributed systems ecosystem.

The RAFT algorithm is a foundational element for ensuring data integrity in distributed consensus. Designed for understandability and implementation ease [3], it has not only simplified the process of building resilient distributed applications but has also become a standard of comparison for new consensus research. RAFT achieves its primary goal of fault tolerance by replicating state across nodes, making it resilient against system failures and crashes.

However, while RAFT is well-known for its fault tolerance and simplicity, the consensus mechanism itself typically operates under a "fail-stop" model (node crashes or network partitions), assuming non-malicious failures [10]. Consequently, the security concerns regarding its design, particularly its mitigation against active, malicious attacks, are often not fully integrated or covered in standard implementations [4, 5]. This gap leaves implementations vulnerable to threats and attacks that can compromise the RAFT state machine and data integrity established by the protocol, potentially leading to data corruption and service disruption in critical applications [8].

This gap in the existing RAFT implementation poses a significant risk of vulnerability; a secure consensus algorithm is more than just ensuring agreement; it's about safeguarding the entire ecosystem of distributed systems, protecting data, preventing disruptions, and ultimately, mitigating failures and data corruption. In particular, the fact that the protocol does not have its own end-to-end security mechanisms makes it vulnerable to potential threats, including replay attacks and message forgery attacks, which target the RAFT's message passing mechanism and disrupt the consensus process. Therefore, this paper, in the coming sections, analyzes and evaluates the RAFT algorithm's security properties, demonstrating its design weaknesses with a focus on its susceptibility to message replay attacks and forgery attacks. The primary objective of this research is to propose and validate a novel, modular, and lightweight security enhancement that is based on encryption and authenticated message verification to mitigate these vulnerabilities and enhance the RAFT security implementations.

To achieve this objective, the subsequent sections of this paper first build the necessary foundational Distributed Systems and Consensus Background in Section II. Then Section III dives deeper into the details of the RAFT Distributed Consensus Protocol. Section IV provides a thorough Security Analysis of the RAFT vulnerabilities, focusing on message integrity. Section V presents the Related Work concerning secure RAFT implementations and countermeasures, justifying the research gap. Section VI introduces the Proposed Solution for mitigating the identified security concerns. Section VII details the Methodology used for testing and validation, followed by Section VIII, which presents the Results of the simulated attacks and the performance evaluation. Section IX provides a dedicated Discussion of the findings, their implications, and researchers point of view. Section X offers the Conclusion of this research outcome. Finally, Section XI outlines directions for future study.

II. Background

A. Distributed Systems

Distributed systems are the core basis of today's technology ecosystem, from powering global communication networks to orchestrating critical financial transactions, distributed systems can be defined as a collection of autonomous computing elements (nodes) that appears to users as a single coherent system [1], within this single system the collection of nodes regardless of their number, locations, or components, operate as a unified whole, no matter where, when, and how interaction between a user and the system takes place.

The distributed system provides the means for components of a single distributed application to communicate with each other. At the same time, it hides the differences in hardware and operating systems from each application; this can be orchestrated using a middleware.

In a sense, middleware to a distributed system is the same as an operating system to a computer: a manager of resources offering its applications to efficiently share and deploy those resources across a network [2].

The basic distributed systems architecture and the relationship between its main components: hardware, applications, the operating system, and the middleware layer, which acts as a very essential role in coordinating communication and abstracting hardware differences across the network, is illustrated in Fig. 1.

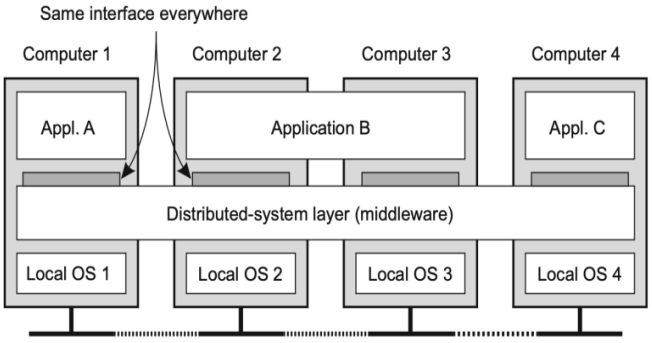

Fig. 1. The middleware layer extends over multiple machines and offers each application the same interface.

The middleware, nodes, applications, and this ever-expanding realm of distributed systems need to assure stability and consistency of communication and exchanged messages, and keep all parties informed of all correct and recent updates on the system, here the important role of the consensus algorithm, which addresses these needs, is thus witnessed.

B. Distributed Consensus

Consensus in general means agreement made by multiple parties; for example, if a group of friends decides to have lunch, which restaurant to order from is an agreement. Basically, consensus has the same meaning in computer science, especially in distributed systems, as it can be defined as a process where multiple nodes of a distributed system agree on values of messages, transactions, or objects. It is a basic challenge in distributed systems. However, once the nodes agree on a value, that agreement should be final.

Some of the earliest implementations of consensus algorithms relied on voting-based mechanisms, which provide reasonable fault tolerance and have strong mathematical proofs to ensure integrity and stability. Some of the popular voting-based algorithms include Paxos and Raft. Paxos was originally first proposed by Leslie Lamport in 1989, however it was published by the end of 2001 due to many factors, including, of course, its well-known high level of complexity, which hindered its widespread adoption. In response to this, the Raft algorithm was introduced in 2014 by Diego Ongaro as a simpler alternative to Paxos. Raft's design emphasizes simplicity and manageability while maintaining the same level of fault tolerance and consistency as its predecessors.

III. Raft Distributed Consensus Protocol

This section provides a brief overview of the Raft distributed consensus algorithm. For a more detailed description, please refer to the original paper “In search of an understandable consensus algorithm” [3].

A. The Raft

Raft is a highly common and reliable distributed consensus algorithm designed as a more understandable and easily implementable alternative to its complex predecessor, the Paxos algorithm. Raft is a fault-tolerant protocol that depends on a single elected leader, log replication, and a probability approach.

To understand how Raft works, let's imagine a server cluster of three nodes or replicas, each hosts a state machine, log, and raft protocol, as long as they all begin with the same state and perform the same operations in the same order then they should all end up with the same state, anytime a replica receives a command such as setting a new key with a value, the replica appends and saves the command as a new entry in its log, every replica's log must always contain the same exact sequence of commands for other replicas to remain synchronized.

In a Raft cluster, one node is elected as the leader, with the others acting as followers. The leader is responsible for handling all client requests and for replicating log entries to the followers to ensure they remain synchronized.

B. Leader Election

At any point in time, any node of the Raft cluster can take on only one state: leader, follower, or candidate. Initially, all nodes start in the follower state. Each follower sets an election random timeout. Thus, if a follower fails to receive heartbeats consecutively, then it assumes there is no viable leader and transitions to candidate state to start an election [13]. It wins the election and becomes the new leader if it secures a majority of the total votes. Once elected, a node remains a leader until it crashes or observes another node with a higher term [15]. If the election results in a split vote or if another candidate is elected, the node reverts to the follower state to await a new leader's heartbeat. The RAFT leader election flow is illustrated in Fig. 2.

Leader election can begin for any reason, whether it's brought about after a leader fails, goes offline, if the network experiences enough latency, or when a network partition isolates a follower where a follower reaches its election timeout despite a leader still being alive.

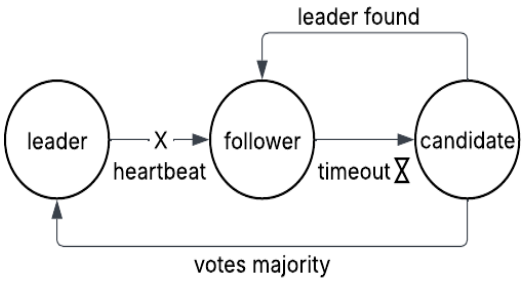

Fig. 2. The Raft basic leader election flow.

Once a leader is elected, it assumes responsibility for logging all new changes to the system. The leader regularly sends append entry messages to all followers within the RAFT cluster. These messages serve a dual purpose: they act as a heartbeat to prevent followers from initiating a new election, and they instruct followers to replicate new log entries, ensuring consistency across the cluster.

C. Log Replication

All changes in the system, such as new commands or transactions, are exclusively handled by the leader. Changes are sent by clients to the leader who receives them and appends a new entry to its log, this log entry remains uncommitted till the leader replicates it to all follower nodes, then the leader waits until a majority of nodes in the cluster (>50%) confirms/acknowledges the new value, now the leader commits the new entry, and informs the followers that the entry is committed, and the cluster is considered to have reached consensus. Fig. 3 shows the basic log replication flow of the RAFT.

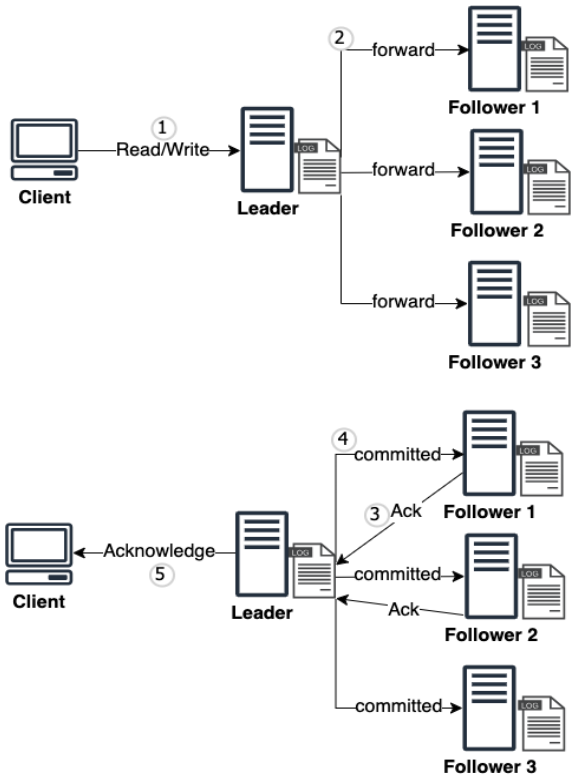

Fig. 3. The Raft basic log replication flow.

According to Ongaro and Ousterhout [3], founders of the RAFT consensus [19, 21] algorithm, it was originally designed to be more understandable than Paxos, simpler, and more efficient, which later became a foundation for a wide range of applications requiring fault-tolerant data storage and consistent state management. However, despite its resilience and robustness in handling system failures, the RAFT's message-passing architecture remains vulnerable to various security threats that need to be investigated further, including message forgery and replay attacks.

IV. Raft Security Analysis

Although that Raft consensus algorithm is a key technology for state replication in distributed systems [14] and is well-known for its simplicity, effectiveness, and dependability, its security vulnerabilities remain a critical area of exploration to consider. This section investigates some of the known threats, attack methods, and discusses the potential consequences of compromising consensus and jeopardizing system stability.

A. Denial-of-Service (DoS) Attacks

A denial-of-service (DoS) attack is a malicious attempt by an attacker to overload the leader or other nodes with a flood of messages, preventing them from operating normally and overloading their resources.

Since Raft adopts a strong leader model, a malicious leader can launch DoS or censorship attacks by intentionally delaying or dropping messages, which disrupts log replication and causes followers to initiate unnecessary elections. Moreover, an attacker can control multiple nodes and, through a majority vote, ensure that one of their compromised nodes is elected as the leader [4].

B. Byzantine Attacks / Message Forgery or Impersonation

In the RAFT consensus algorithm, the system's integrity can be compromised by Byzantine attacks, which include message forgery and impersonation, launched by nearby malicious/illegitimate node(s). Indeed, additions can be seen as messages surreptitiously inserted in the system by some outside, and possibly malicious, entity [12]. In the impersonation attacks, malicious nodes try to claim themselves as legitimate nodes/followers by utilizing a forged character in order to destroy the consensus mechanism [5].

Byzantine attacks sending fake messages may result in transaction latency, data inconsistencies, data leaks, and even compromising system integrity.

This can have a measurable impact on performance. For example, transaction latency can be modeled to show its linear relationship to the number of attackers. The total commit time (t_c) is the sum of replication time (t_r) and transaction latency (t_l):

Transaction commit time can be calculated as follows:

$$t_c = t_r + t_l$$

And transaction latency as

$$t_l = RTT(1 + q)(1 + p)$$

This shows that if the number of attackers increases, the transaction latency would linearly increase as well.

TABLE I. NOTATIONS

Notations	Description
t_c	transaction commit time
t_r	transaction request time
t_l	transaction latency
RTT	round-trip time for request/response message
p	percentage of Byzantine nodes (= n/m)
q	attack success rate
n	number of Byzantine nodes
m	number of all nodes

C. Message Replay Attacks

The previous general vulnerabilities set the grounds for more complex attacks. While many types of attacks represent notable threats, the message replay attacks represent a serious and often overlooked threat to consensus protocols like RAFT. A message replay attack is a type of network attack in which a malicious actor intercepts a legitimate data transmission, captures a valid message, and maliciously retransmits it later. In the context of distributed consensus, this attack takes advantage of the protocol's reliance on message-passing to deceive nodes and disrupt the consensus process and the system's state (see Table I for notations).

In the RAFT cluster, an attacker can start a replay attack by capturing valid, previously sent messages like RequestVote and re-injecting them into the network again later, which can cause a follower or more to respond with a vote, consequently triggering a new, unnecessary election and causing a leader-follower split.

The success of a message replay attack on RAFT is primarily due to the protocol's vulnerability to a lack of intrinsic replay protection mechanisms. Standard RAFT messages do not include a monotonically increasing sequence number or any unique, session-based identifier that would allow a recipient node to detect that a message is a stale duplicate. This absence of a freshness check makes the protocol susceptible to being manipulated by replayed messages, leading to a breakdown in consensus. This can result in system instability, data inconsistencies, and a compromise of the distributed system's integrity.

V. RELATED WORK

The increasing dependency on distributed systems for critical infrastructure/systems has highlighted the need for robust consensus mechanisms that are resilient to both crash failures and malicious attacks. In this section, relevant researches are reviewed to compare and validate this paper's proposed solution for mitigating replay/message forgery attacks against the default RAFT implementation, and other RAFT flavors that addressed these concerns.

The theoretical foundation of achieving fault tolerance in distributed systems is rooted in the State Machine Replication approach [9], which requires all replicas to execute the same sequence of operations in the same starting state [1]. To achieve this goal, we have to make sure no malicious factor is affecting the state machine and the exchanged messages integrity. The RAFT consensus protocol [3] was introduced as a practical alternative to Paxos, focusing on understandability and simplicity while achieving the same fault-tolerance properties (tolerating crash failures). Standard RAFT implementations, however, assume a "fail-stop" environment and do not account for the Byzantine Faults, where nodes can behave maliciously and affect the integrity of the consensus process. This distinction is crucial, as general Byzantine protocols like P-BFT [20] often introduce high computational overhead trying to address this problem, which, on the other hand, prompted research into lightweight alternatives that can keep the performance benchmarks while achieving the security mitigations effectively.

The standard RAFT design assumes a "trusted" environment where nodes are honest but can crash. This assumption left the protocol inherently vulnerable to active attacks that exploit its unauthenticated, plaintext message structure. Several studies have tried to identify, address, and formalize these weaknesses:

1) The Original RAFT: The foundational work by Ongaro and Ousterhout [3] introduced RAFT as a more understandable alternative to Paxos, focusing on maintaining consistency against crash failures and network partitions, implicitly assuming a trusted network environment, however they did not consider security attacks such as replay attacks and message forgery.

2) RaBFT: an improved Byzantine fault tolerance consensus algorithm based on Raft [10]. Full Byzantine Fault Tolerance (tolerate f malicious nodes in 3f+1 total nodes), where it introduces Secret Sharing to optimize log message distribution and uses a dynamic Committee role to distribute leader pressure. It alters the log replication process and election logic. It protects against malicious nodes forging; however, it requires a complete redesign of the RAFT consensus engine, introducing complex multi-party computation steps (secret sharing verification) and new roles (Committee), and adds loads of overhead layers burden.

3) ENGRAFT (Enclave-Guarded RAFT) is another example of a security enhancement that operates within the consensus layer, specifically designed to protect against Byzantine faults within the nodes themselves [4]. It leverages Trusted Execution Environments (TEEs), such as Intel SGX enclaves, to safeguard the core RAFT state and logic on each node. In ENGRAFT, all critical consensus operations, including state updates and log manipulation, are performed inside the secure, isolated hardware enclave. This design is highly effective at defending against insider threats and BFT attacks, however this approach introduces dependencies on specific hardware and results in a higher implementation complexity in terms of hardware, protocol, and platform.

4) Countering Active Attacks on RAFT-Based IoT Blockchain Networks [5] using pathloss: This paper proposes a physical-layer authentication mechanism using pathloss to secure the Raft against impersonation attacks in a wireless IoT

environment. The proposed solution uses pathloss of the signal between the transmitter node and the receiver node as a unique device fingerprint to authenticate the sender. This solution's weak points are that it can be easily affected by environmental changes and multipaths.

5) Trust and Reputation Management System [11]: This method assigns credit scores to nodes based on historical behavior to identify and isolate malicious nodes. However, such systems suffer from the "cold start" problem and slow convergence; malicious nodes can behave honestly for long periods to build high trust. Furthermore, the overhead of storing and updating reputation scores for every node scales poorly in large distributed systems.

6) Combination of P-BFT and RAFT: "A New Approach to Building Networks that Provide Reliability and Security" [20] proposes a hybrid model that merges the simplicity and efficiency of RAFT with the robust security of P-BFT. This combination aims to build networks capable of withstanding Byzantine failures (malicious behavior). While highly effective at securing the consensus process against internal attacks, BFT-RAFT inherently requires significant modifications to the RAFT state machine, leading to increased complexity in protocol execution and a higher overhead.

7) Zero Trust Consensus Algorithm [16]: This notable effort to bridge the gap between RAFT and modern security concepts proposes a VSSB-Raft, which adopts a Zero Trust security model, "never trust, always verify". It achieves this high security by leveraging verifiable secret sharing (VSS) mechanisms and digital signatures to ensure that no single node can compromise the system. While VSSB-Raft demonstrates a solution for achieving Byzantine Fault Tolerance in a resource-efficient manner compared to traditional BFT protocols, its comprehensive security guarantees rely on significant modifications to the RAFT state machine and the integration of complex cryptographic primitives, leading to a higher implementation complexity than modular transport layer solutions.

8) GPBFT (Group-Based Practical Byzantine Fault-Tolerant)[17]: an enhancement to the existing BFT protocols, involves leveraging a Dual Administrator Short Group Signature mechanism. Allowing nodes to verify messages using short group signatures, while powerful, these solutions maintain a high barrier to entry, adding significant complexity and communication overhead, plus it fully replaces the RAFT with a complex BFT protocol.

9) PB-Raft [18]: integrate Byzantine Fault Tolerance (BFT) capabilities into RAFT. This solution is dual-layered: first, introduces a Weighted PageRank algorithm to evaluate the reputation and trust of nodes. Second, utilizes a BLS (Boneh–Lynn–Shacham) threshold signature scheme to ensure the authenticity and consensus of log entries. This solution introduces two main points of complexity and potential overhead plus that the leader must collect a threshold of signatures before committing a log in addition to that the reputation scoring based on PageRank requires continuous, complex calculation and updates across the cluster.

The review of related work reveals a clear trade-off within the current landscape of RAFT security. While some of the previous work in this field is mature enough, offering comprehensive security against malicious attacks, they incur significant overhead and require complex modifications to the core consensus logic. This analysis confirms a significant gap in the literature: the lack of a modular, low-overhead security solution that operates at the transport layer to specifically and comprehensively counter active message forgery and replay attacks on the fundamental RAFT without altering the core of the consensus protocol itself. Therefore, the objective of this work is to introduce a secure transport layer mechanism that fills this gap, providing essential message authentication and freshness without altering the RAFT state machine, as detailed in the following section.

VI. Proposed Solution

As discussed in this paper, the Raft distributed consensus protocol, its mechanism, and its importance, also explored some of its security risks.

It is intended in this section to mitigate the vulnerabilities to message replay attacks and propose a secure transport layer integration to the RAFT, designed to protect communication between cluster nodes in a modular way, leaving the original RAFT intact. It uses a combination of modern cryptographic techniques to ensure message confidentiality, authenticity, some sort of checksum for integrity, and a message cache for replay attacks mitigation. This proposed solution is meant to be a lightweight modification to the original RAFT algorithm, ensuring that it remains efficient while significantly boosting its security properties. The proposed solution architecture is shown in Fig. 4.

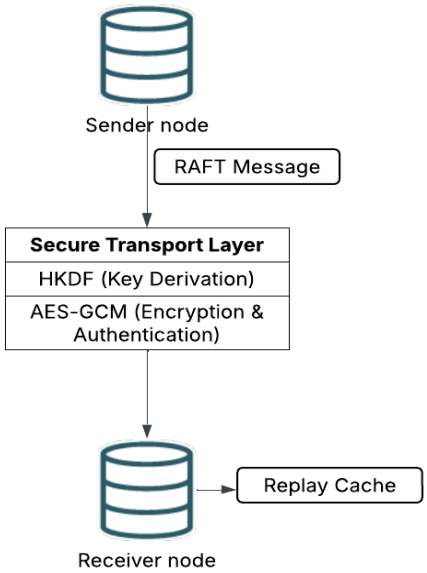

Fig. 4. Proposed solution basic flow.

The Proposed approach involves three key components:

A. Unique Encryption Key

The proposed solution uses the HMAC-based Key Derivation Function (HKDF) [6] to generate a unique, temporary encryption key for every single message, rather than depending on a single, long-term key for all communications. HKDF derives a fresh key for each message from a shared master secret. This procedure is a very important security best practice, because if an attacker were able to compromise one message's key, they would not be able to compromise any other messages, and the revealed key would be useless.

B. Authenticated Encryption

The AES-GCM Advanced Encryption Standard (AES) in Galois Counter Mode (GCM) [7] is the cryptographic algorithm used for both encryption and authentication of RAFT messages during communication in the proposed solution.

- AES: This part of the algorithm ensures that the message content is encrypted, so no one can read it in transit. To guarantee the most complex level of encryption in the AES process, the GCM [7] mode will be used.
- GCM: This part generates an authentication tag that guarantees the message has not been tampered with and that it originates from a valid sender with the correct key. This is vital in RAFT, where nodes must trust that a log entry or vote is legitimate and unaltered.

Below is a pseudo-code of the algorithm that explains it:

function secure-envelope(plaintext, confidential, peer_id, K_master, key_id):

// generate unique per-message identifiers

nonce ← random(12)

tx_id ← random(16)

// derive a unique key for this message

K_tx ← HKDF-SHA256(K_master, nonce, peer_id)

// construct Associated Authenticated Data (AAD)

aad ← combine(key_id, nonce, tx_id, peer_id)

if confidential:

// encrypt and authenticate with AES-GCM

ct_combined ← AESGCM.encrypt(K_tx, nonce, plaintext, aad)

ciphertext ← ct_combined[:-16]

tag ← ct_combined[-16:]

else:

// authenticate only (generate tag)

ciphertext ← plaintext

tag ← compute_tag(K_tx, aad, plaintext)

end if

// return the final secure envelope

return { key_id, nonce, tx_id, ciphertext, tag}

end function

The AES-GCM algorithm architecture and full flow, starting from the initialization vector and till generating the tag which is attached to the encrypted message, as illustrated in Fig. 5.

C. Replay Cache

A replay cache is a critical additional defense layer against replay attacks. The replay cache works by maintaining a list of identifiers (the unique message ID) for all recently processed messages. When a new message arrives, the system checks its identifier against the cache. If the ID is found, the message is immediately rejected as a replay, preventing the attack from succeeding, else the message is accepted, and its ID is logged in the replay cache.

Below is a pseudo-code explaining the cache check:

data_structure: cache # internal data structure// Function to check if a message has been seen before function SEEN(peer_id, tx_id): key ← combine(peer_id, tx_id) if key in cache: return True // Replay detected else: return False // New message end if end function // function to record a new message as seen function REMEMBER(peer_id, tx_id):key ← combine(peer_id, tx_id) cache.add(key) end function.

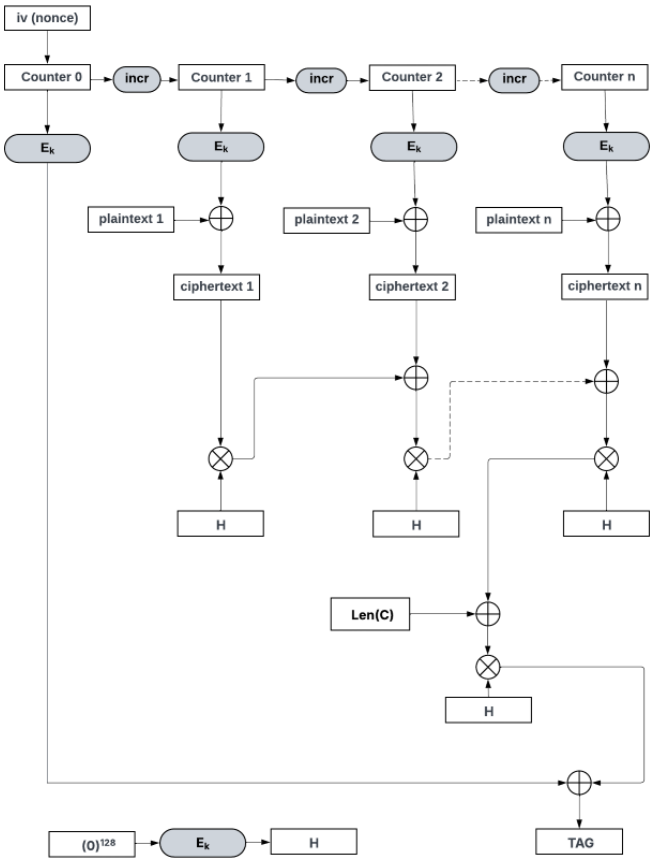

Fig. 5. AES-GCM.

VII. Methodology

This section provides an overview of the methods and tools used to evaluate the proposed solution for mitigating replay attacks and message forgery on a RAFT cluster. The primary objective is to evaluate the impact of a replay attack on a RAFT

cluster before and after the implementation of the proposed security solution to prove the RAFT's vulnerability and the efficiency of the proposed solution.

A. Experimental Setup and Architecture

The study's methodology and architecture focuses on a python based native RAFT implementation based on https://github.com/nikwl/raft-lite, a physical lab setup of three nodes in a RAFT cluster, all of the three nodes are running the Linux (Ubuntu server) as an operating system, and they communicate through Ethernet network using IPv4 addresses, the attack simulator and proposed solution are both developed using python as shown on Fig. 6.

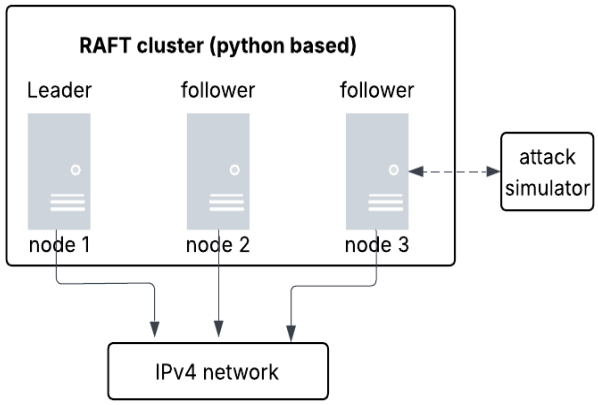

Fig. 6. The physical lab architecture.

B. Testing Procedures

The testing process was divided into two distinct phases to evaluate both the baseline vulnerability of the standard default RAFT behaviour before implementing the proposed solution and the efficacy of the proposed solution after implementing it.

1) Pre-implementation testing (baseline vulnerability): The initial phase focused on subjecting the default RAFT cluster to a simulated message replay attack to establish a security baseline we can measure based on.

a) Attack simulation setup: A custom client script, utilizing Python's socket library to establish a TCP connection to a follower node of the three-node RAFT cluster.

b) Attack execution: A valid RAFT message (e.g., a heartbeat or log entry) was captured and subsequently replayed with no modifications using a specialized attack script (replaylast) and (entryattack) to simulate log replication to introduce malicious or stale log entries, representing an explicit Byzantine message forgery and replay attack scenario.

2) Post-implementation testing (proposed solution efficacy): The second phase involved implementing the proposed security mechanism across all three nodes of the RAFT cluster and enabling the secure features. The same attack simulation is then activated again, and the cluster's behavior is monitored, same as done in phase one.

a) Testing procedure: The exact same steps and attack scripts used in the pre-implementation phase were executed against the modified cluster after activating the secure features.

b) Solution results: The modified RAFT implementation of the proposed solution successfully rejected and dropped all attack messages for the following reasons:

- Legitimate Traffic: Throughout the testing, all legitimate traffic, current messages continued to be accepted and processed correctly, confirming the solution's targeted function.
- Replayed Legitimate Messages: Legitimate messages that were captured and replayed later on were dropped after the receiver checked and found their unique ID already present in the local cache (failing the freshness check).
- New Forged Messages: Newly forged malicious messages were dropped due to a failure in the integrated authentication check against the tag introduced and explained earlier.

3) Performance evaluation: Following the proposed solution security enhancements, testing and validation, performance tests were conducted to evaluate the overhead that is introduced by the proposed solution compared to the default RAFT implementation. Key performance benchmarks were measured using the industry standard tool raft-bench in these tests.

VIII. Results

This section presents the objective findings from the security and performance tests without detailed interpretation, which will be reserved for the Discussion section.

A. Security Assessment Results

The security assessment confirmed the vulnerability of the default RAFT implementation and the effectiveness of the proposed solution:

1) Pre-implementation testing (baseline vulnerability): As expected, the default RAFT implementation lacks basic replay protection and, therefore, successfully accepted and processed the attack messages. This action disrupted the log consistency and eventually compromised the consensus state.

2) Post-implementation testing (proposed solution efficacy): The post-implementation testing phase demonstrated the effectiveness of the proposed Secure Transport Layer. As the modified RAFT implementation of the proposed solution successfully rejected and dropped all attack messages for the following reasons:

a) Legitimate traffic: Throughout the testing, all legitimate traffic, current messages continued to be accepted and processed correctly, confirming the solution's targeted function.

b) Replayed legitimate messages: Legitimate messages that were captured and replayed later on were dropped after the receiver checked and found their unique ID already present in the local cache (failing the freshness check).

c) New forged messages: Newly forged malicious messages were dropped due to a failure in the integrated

authentication check against the tag introduced and explained earlier.

3) Performance benchmarks: The performance tests evaluated the overhead of the proposed solution compared to the default RAFT implementation. The results are summarized in Table II.

TABLE II. PERFORMANCE ANALYSIS

Metric	Default Raft	Proposed Solution	Change %
Throughput	297.19	269.61	-9.28%
Latency	468.01	539.44	15.26%

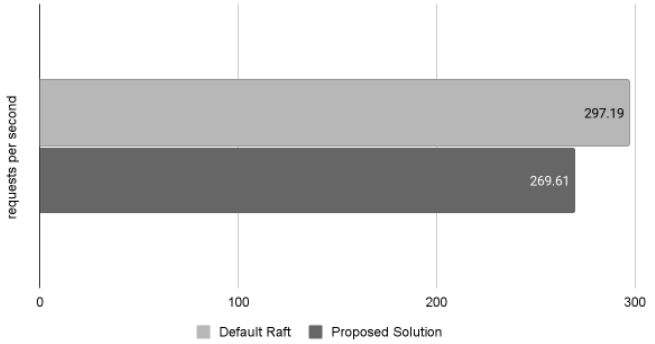

Fig. 7. Throughput performance analysis for default vs. proposed solution.

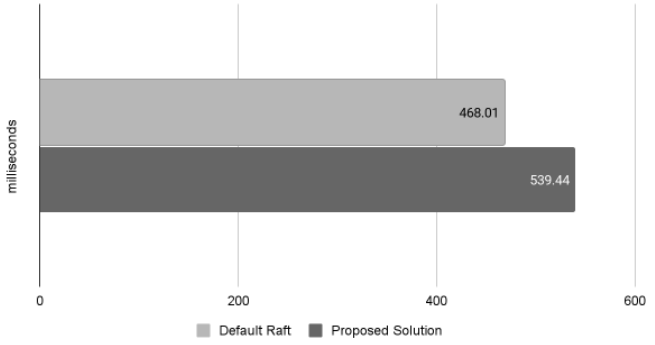

Fig. 8. Latency performance analysis for default vs. proposed solution.

As illustrated in Fig. 7, 8, and Table II, the results show a 9.28% decrease in throughput and a 15.26% increase in latency for the proposed solution. This performance cost is directly attributed to the computational overhead of generating and verifying the secure, encrypted messages and unique identifiers on every message, demonstrating a typical security-performance trade-off.

IX. DISCUSSION

The findings of this research demonstrate that the proposed solution can effectively mitigate the two critical attacks on the RAFT: message replay and message forgery. The pre-implementation baseline testing confirmed that the standard RAFT design is vulnerable to message replay and forgery attacks due to its reliance on unauthenticated messages and the lack of a freshness check.

The post-implementation analysis showed that the proposed solution successfully rejected all replayed legitimate messages and all newly forged malicious messages. These efficient outcomes result from a combination of cryptographically enforced message authentication and the transaction ID-based replay cache. The authenticated encryption (AES-GCM) ensures the legitimacy of the sender and the integrity of the message content, while the unique, per-message identifier used by the Replay Cache successfully guarantees timing-based replay attacks mitigation.

Security-Performance Trade-off: The performance evaluation revealed a typical, quantifiable trade-off between security and efficiency. The proposed solution introduced a 9.28% decrease in throughput and a 15.26% increase in transaction latency when compared to the default, unsecured RAFT implementation. This performance cost is directly attributed to the computational overhead required for generating a unique encryption key (HKDF) and performing authenticated encryption (AES-GCM) for every message sent and received.

The key insight of this research is that the security gained—protection against system-compromising attacks like forgery and replay—comes at a price tag of this minimal overhead, especially in mission-critical environments such as financial systems or sensitive data ledgers, where data integrity is crucial. This measured performance impact is an acceptable cost for achieving a high level of data integrity and authenticity.

Comparison with Alternative Approaches: The modular design of the solution is a key differentiator. Unlike other advanced security proposals like RaBFT [10], which requires a complete redesign of the core RAFT consensus engine, or pathloss-based solutions [5], which rely on specialized physical-layer measurements, our proposal operates entirely at the transport layer. This approach achieves its primary goal of mitigating replay and forgery attacks with low complexity and minimal impact on the core RAFT logic. Which also enhances the development lifecycle of each component without affecting the other components or even replacing a whole module with a better-performing one in the future.

Limitations: The primary operational limitation of this approach is the potential for replay cache size growth over long-term operation. This needs to be managed in the future to prevent excessive memory consumption.

X. CONCLUSION

This Paper successfully assessed the security vulnerabilities of the RAFT distributed consensus protocol, identifying its critical vulnerabilities to active message replay and forgery attacks. To mitigate these threats, a novel and modular Secure Transport Layer integration based on authenticated message verification and a freshness check was proposed. This paper's contribution, unlike previous work that either redesigns the core RAFT protocol, adds heavy burdens, targets only a specific message vulnerability (like message forgery), or relies on specialized hardware/physical-layer attributes, a modular Secure Transport Layer approach is proposed without altering the core consensus logic or adding notable overheads.

The scientific value added by this work is underscored by the following contributions:

1) Vulnerability validation: Practical simulation demonstrating the ease of disrupting the consensus and compromising the data integrity of the default RAFT protocol, with which unauthenticated RAFT messages can be exploited to achieve such.

2) Modular solution: The development and validation of a lightweight, Transport-Layer-based security enhancement that utilizes HKDF [6] for unique key derivation and AES-GCM [7] for simultaneous encryption and authentication can be achieved without changing the default RAFT logic or adding heavy burdens.

3) Replay attacks protection: The introduction of a unique transaction identifier and a replay cache mechanism that effectively protects the protocol against previously successful replay attacks.

4) Message forgery protection: The same unique transaction identifier, along with the computed TAG, acts as an additional defense layer to make sure of the authenticity of the sender and the message itself.

5) Performance characterization: Measuring the security-performance trade-off, providing experimental data that shows a robust security gain is achievable with a measured low overhead of (9.28% throughput decrease and 15.26% latency increase).

In Table III, a brief analysis comparison between the proposed solution and other RAFT implementations is presented.

TABLE III. PERFORMANCE ANALYSIS

item	Original RAFT	RaBFT	Pathloss (Physical Layer)	Proposed solution
Primary Goal	Crash Fault Tolerance (CFT) and Log Consistency	Byzantine Fault Tolerance (BFT)	Authentication against Impersonation Attacks.	Mitigate Replay / Message Forgery attacks
Mitigation	None	Secret Sharing, Dynamic Committee Roles, Altered Election/Replication.	Pathloss Measurement as a Device Fingerprint.	Authenticated Encryption and Anti-Replay Cache.
Layer	Application	Application/Consensus (Protocol Redesign)	Physical	Transport
Overhead / Complexity	Simple, understandable logic.	High. Complete protocol redesign, complex multi-party computation.	Moderate. Requires initial calibration.	Low, minimal impact on core logic.
Weakness	vulnerable	High performance and complexity overhead.	Requires special hardware, susceptible to environmental changes.	Cache file size growth.

The findings of this research confirm that the lack of message authentication is the biggest security weakness in the standard RAFT. Our solution provides a high-applicability framework for enhancing RAFT implementations that prioritize data integrity over raw speed and cannot tolerate the complexity of full Byzantine Fault Tolerance (BFT) protocols.

While highly effective against man-in-the-middle replay and forgery attacks, the solution's dependence on a per-message cache introduces a practical limitation concerning memory scalability and cache management over extended operational periods.

XI. FUTURE WORK

Future research will focus on transitioning this modular solution into a production-ready framework by addressing its current limitations and expanding its current scope. The future research should include areas such as:

- Cache optimization: Implementing and evaluating time-to-live (TTL) and least recently used (LRU) eviction policies to ensure the replay cache maintains high efficiency and manages memory consumption dynamically.
- Secure Key Lifecycle Management: Developing a secure, dynamic process for periodic rotation of the master secret key to defend against long-term compromise of a server.
- Expanded attack areas validation: Broadening the scope of validation to test the solution against other network-level vulnerabilities, such as Denial-of-Service (DoS) attacks.

***Abstract*—Ransomware remains a key cybersecurity issue because of its growing amount of obfuscation, polymorphism, and constantly changing patterns of attack that repeatedly circumvent conventional defenses. Traditional systems and standard deep learning may fail, lowering accuracy and increasing false positives. To address these shortcomings, the proposed work proposes EvoNorm-GAN, a dynamic adversarial-based detection architecture that will incorporate Feature-Wise Dynamic Normalization (FDN) and Generative Adversarial Network to analyze ransomware in Windows Portable Executable (PE) files in a very flexible manner. Generator creates ransomware variants; discriminator classifies files using Wasserstein loss. EvoNorm-GAN is a TensorFlow application, using the Keras back-end, and tested on a large-scale Windows PE File Analysis Dataset of 62, 200 samples, with 31, 100 benign and 31, 100 malicious examples. The experimental findings indicate that EvoNorm-GAN has the state-of-the-art results of 98.2 % accuracy, 98.4 % precision, 98.1 % recall, 97.4 % F1-score, and 0.99 AUC, which are about 1 to 3 percent higher than the traditional CNN, RNN, and ensemble-based models. To enhance transparency and trust, SHAP-based explainable AI is integrated into EvoNorm-GAN, highlighting key PE file features such as Section Entropy and SizeOfCode that drive classification decisions. By combining adaptive learning, adversarial sample generation, and analyst-friendly interpretability into a unified framework, EvoNorm-GAN delivers an efficient, robust, and transparent ransomware detection system. Its scalable and resilient design makes it well-suited for real-world deployment in endpoint protection and cybersecurity environments, providing reliable detection of evolving ransomware threats.**

***Keywords*—Ransomware detection; EvoNorm-GAN; feature-wise dynamic normalization; portable executable files; adversarial learning; Explainable AI**

I. Introduction

Ransomware has rapidly established itself as one of the most common and harmful categories of cybercrime that targets people, companies, and critical infrastructure all over the world. Attacking data by means of data encryption and ransom money, most commonly, in the form of cryptocurrency, attackers cost organizations a lot of money and interruptions in business operations in the most sensitive domains such as healthcare, finance, government, and education [1], [2]. The most recent developments, including ransomware-as-a-service (RaaS), have lowered the barrier to entry since less skilled attackers can run a sophisticated campaign using malware through rented packages [3]. Moreover, the modern ransomware groups also employ the so-called double extortion, that is, to extort their victims by encrypting their data beforehand and threatening to publish confidential information in case of non-payment, which increases the inefficiency of the old system of recovery based on backups [4]. Advanced stealth methods such as fileless execution, polymorphic code, and encrypted command-and-control communications also complicate the task of defense by circumventing conventional security products [5], [6]. Conventional detection mechanisms have been the mainstay of cybersecurity defenses over decades but are no longer being effective against these new attacks. Additional signature-based tools rely on the identification of any known sequence of bytes or behavioral patterns that are indicative of a known ransomware [7], [8]. Such systems will fail to detect new or obfuscated ransomware samples despite their usefulness in detecting variants previously indexed. Any little modifications to the payload, through encryption or code obfuscation render the current signatures useless [9], [10].

Lag time between emergence of a new variant and signature updates leaves systems vulnerable to major risks, taking organizations off guard during the most perilous phases of outbreaks [11]. In feature-based methods of detection, attempts to create resilience include analyzing suspicious features, i.e. out of place API calls, out of place file encryption activity, or out of place system resource usage [12]. Such methods, though, are dependent on domain knowledge and data quality since they need feature engineering that is expert-driven. Attackers start countering these methods by slowing down execution, emulating harmless applications, or using zero-day exploits to sneak past the detection [12]. As a result, signature-based as well as feature-based approaches have very high false positives and false negatives, making them less effective for real-time detection.

To overcome these shortfalls, researchers have looked toward machine learning (ML) and deep learning (DL) methods, which are able to learn complex feature representations directly from raw data. Recent research illustrates that DL models such as convolutional neural networks (CNNs), recurrent neural networks (RNNs), and Transformers are able to pick up on subtle patterns of ransomware behavior without extensive human feature crafting [13], [14]. These models are best at identifying subtle anomalies such as unusual system calls, memory access patterns, or initial user activity deviations. Notably, DL frameworks are strong against zero-day ransomware through the ability to generalize from static rules

[15]. Nevertheless, even solutions based on DL have their weaknesses: their main reliance is on the use of the static normalization techniques such as Batch Normalization, which in turn is based on the assumption of the data distribution constancy. But in cybersecurity where the ransomware families continue to evolve, this is not true, and the performance on the new threats becomes impaired and the generalization is weak. Generative Adversarial Networks (GANs) are a recent newcomer in this respect with new opportunities to both perform anomaly detection and data augmentation. GANs consist of a discriminator and a generator, where the latter is required to produce fake samples, and the former is expected to learn the distinction between fake and real data [16]. Adversarial training has been used in ransomware detection with discriminators becoming highly effective at picking out malicious features, with the generators helping in alleviating dataset imbalance by creating artificial examples of ransomware. Such a two-in-one advantage makes the model more resilient and able to generalize more [17]. Nonetheless, there is one key limitation namely that vanilla GAN training is grounded on normalization techniques relevant to stationary distributions and therefore not stable in realistic ransomware situation where feature distributions vary over time. This evolving nature of ransomware reinforces the need of models to study on the basis of adjustment to evolving distributions throughout training. Compared to CNN, RNN, and Transformer-based models, which have good feature extraction features, and GANs, which have adversarial features, none can solve the non-stationarity problem successfully. Without this type of adaptability, detection models will be less precise and provide false alarms with ransomware constantly evolving. This research gap offers the foundation on which more complex frameworks that integrate adversarial learning and dynamic normalization can be built to offer stability and flexibility.

It is against this backdrop that the proposed EvoNorm-GAN comes up with a new solution to ransomware detection in Windows Portable Executable (PE) files. EvoNorm-GAN (using feature-wise dynamic normalization as part of the GAN architecture) can therefore modify feature statistics in each mini-batch, and hence adopt changing data distributions during training. The new mechanism counters the deficiencies of the old methods of normalization, ensuring the stability on the new types of ransomware variants detection. With adversarial training, EvoNorm-GAN employs Wasserstein loss and gradient clipping to guarantee stable training as well as improved ability to generalize to new threats. When put in a wider context of research on ransomware identification, EvoNorm-GAN is a well-equipped and versatile solution to fill the gap of the long-standing deficiencies of the existing methods and respond to the demands of the modern world of cybersecurity.

A. Research Motivation

Ransomware has become an extremely dynamic threat, taking advantage of obfuscation, polymorphism, encryption, and delayed execution to avoid the old methods of detection, such as signature-based and static feature analysis. The existing systems have difficulties with detecting the zero-day attacks and adapting malware, which is why the development of smart and resistant detection systems is urgently needed. This research seeks to devise an active and responsive framework that can be effective in identifying ransomware in windows PE files and at the same time make them interpretable. The ability to incorporate Feature-Wise Dynamic Normalization (FDN) into a GAN framework, combined with the implementation of explainable AI using SHAP and present a transparent and practical approach to cybersecurity challenges in the real world, makes the proposed methodology an effective solution to this type of problem.

B. Research Significance

By identifying the weaknesses of the existing traditional ransomware detection tools that find it difficult to match the fast development of malware, the study discusses the most pressing issues of cybersecurity. It presents a dynamic, adaptive, and interpretable EvoNorm-GAN model that can cope with the changes in data distributions and indicates unseen ransomware variations by using Feature-Wise Dynamic Normalization (FDN). Adversarial training, which is under the guidance of Wasserstein loss and gradient penalty, increases the model stability and resistance against new threats. The explainability offered by SHAP-based explainable AI offers feature-level interpretability to bridge the black-box model decisions and the human understanding gap. The resulting architecture provides ransomware detection that is transparent, correct, and scalable to better secure organizational and critical infrastructure systems.

C. Key Contributions

- Introduces EvoNorm-GAN, combining GAN-based adversarial learning with Feature-Wise Dynamic Normalization to detect ransomware in Windows PE files.
- Enables the model to adapt to evolving ransomware patterns and non-stationary data distributions, improving generalization to unseen threats.
- Incorporates SHAP-based interpretability, highlighting critical PE file features influencing classification and enhancing transparency for cybersecurity analysts.
- Provides a scalable and robust framework suitable for real-world deployment in endpoint protection systems, SIEM platforms, and dynamic malware detection environments.

The structure of the remaining sections of this study is as follows: Section II provides a summary of prior research on ransomware detection techniques, emphasizing advancements in machine learning and deep learning methods. Section III discusses the challenges and limitations of existing approaches in addressing the dynamic and evolving nature of ransomware attacks. Section IV details the proposed EvoNorm-GAN framework, including its methodology, model architecture, data preparation process, and evaluation metrics. Section V presents the experimental results, showcasing the framework's performance in detecting ransomware, along with an in-depth analysis of the findings. Finally, Section VI concludes the study by summarizing the key outcomes and proposing directions for future research and applications in cybersecurity.

II. Related Works

Singh et al. [18] proposed RANSOMNET+, a hybrid deep neural model consisting of convolutional neural networks (CNNs) for local feature extraction and Transformers for learning hierarchical representations. Tested on cloud-encrypted data, the model attained 96.1% testing accuracy with precision, recall, and F1-scores higher than 96%. The research also included interpretability analysis to enhance transparency. Despite its robust performance, though, RANSOMNET+ did not test cross-dataset adaptability or real-time deployment efficiency, meaning there are questions about whether it would be robust to novel ransomware variants.

Alqahtani [19] improved the traditional mutual information feature selection technique by introducing eMIFS, which utilizes a normalized hyperbolic tangent (tanh) function as a criterion for assessing redundancy between features. Utilizing TF-IDF representations of text-based features, the technique enhanced discrimination among relevant features, allowing for earlier identification of ransomware. eMIFS enhanced selection accuracy over conventional techniques but wasn't experimentally tested over varied datasets and didn't consider dynamic or changing malware distributions, limiting real-world applicability.

Lee et al. [20] addressed entropy-based detection system weaknesses, presenting the potential for attackers to tamper with file entropy using encoding techniques like Base64 masking. In response to this, the authors introduced Format-Preserving Encryption (FPE) methods, including Radix Conversion, which realized 96% neutralization accuracy in detecting entropy tampering in ransomware. While powerful in attacker-focused environments, the method offered restricted opportunity for proactive defense methodologies and failed to incorporate adversarial resilience to varying data trends.

Molina et al. [21] analyzed evasive ransomware behavior, or "paranoia" API calls, which evaluate the execution environment prior to attacking. Their method utilized natural language processing (NLP) techniques, including out-of-vocabulary (OoW) embedding, to identify API requests that correlate with evasive behavior. Based on over 3,000 malware samples, they trained machine learning and deep learning classifiers with high classification accuracy. However, their dependence on pre-attack patterns limited use against ransomware variants that tamper with or hide initial execution cues, reducing its detection capability.

Gazzan et al. [22] introduced UA-DES, an uncertainty-aware dynamic epoch selection deep learning-based strategy, to dynamically optimize deep belief networks (DBNs) for ransomware detection. UA-DES utilized Bayesian methods, dropout, and interactive learning to minimize overfitting and enhance robustness. The framework showed encouraging adaptability and performance gains but was limited to DBNs and did not specifically address the challenges of evolving, non-stationary ransomware distributions.

Previous works show significant improvement in ransomware detection by hybrid deep learning, feature extraction, entropy manipulation analysis, behavioral modeling, and uncertainty calibration. These, however, all have one thing in common: they require relatively stationary data distributions. None of them properly handle the non-stationary and dynamic nature of ransomware that destroys generalization in adversarial learning scenarios. To close this gap, the suggested EvoNorm-GAN presents feature-wise dynamic normalization in a GAN structure to facilitate real-time adaptation to changing feature distributions. With adversarial training coupled with Wasserstein loss and gradient clipping, EvoNorm-GAN balances stability and flexibility to provide a robust approach to ransomware detection in complex and constantly changing settings. The comparative analysis of ransomware detection related works is shown in Table I.

TABLE I. Comparative Analysis of Ransomware Detection Related Works

Author	Focus Area	Methods	Dataset	Key Results	Limitations
Singh et al. [18]	Deep learning for cloud-encrypted ransomware	CNN + Transformer (RANSOMNET+)	Cloud-encrypted ransomware dataset	96.1% accuracy, F1-score 96%	Lacks cross-dataset validation; not real-time adaptable
Alqahtani [19]	Feature selection & redundancy reduction	eMIFS (tanh-based redundancy evaluation, TF-IDF)	Text-based ransomware features	Improved feature relevance & early detection	No real-world or multi-dataset validation; static approach
Lee et al. [20]	Entropy-based detection evasion	Format-Preserving Encryption (Radix Conversion)	Files with entropy masking	96% accuracy in neutralizing entropy attacks	Attacker-centric; lacks proactive defense integration
Molina et al. [21]	Behavioral evasive detection	NLP (OoW embeddings for API call classification)	3,000 malware samples	Effective classification of evasive behavior	Limited to pre-attack indicators; narrow scope
Gazzan et al. [22]	Uncertainty-aware DL strategies	UA-DES (Bayesian + DBN optimization)	DBN ransomware benchmarks	Robustness improvements, reduced overfitting	Restricted to DBNs; does not address evolving threats

III. Problem Statement

Ransomware has remained a major cybersecurity menace that has been adopting damaging strategies of obfuscation, polymorphism, and encryption, as well as delayed execution, which overcome traditional signature-based and static feature detectors [18]. The current literature has considered deep learning models, feature selection, entropy-based analysis, behavioral modeling, and uncertainty-aware strategies, but they tend not to be adaptable to novel ransomware types, generalize across datasets, and offer minimal interpretability to make decisions [22]. This is why gaps cause high rates of false

positive, lack of warning of zero-day threats, and lack of trust in automated systems, limiting the effectiveness of cybersecurity defenses. The proposed framework comprising EvoNorm-GAN, with Feature-Wise Dynamic Normalization, adversarial training, and SHAP-based explainable AI overcomes these shortcomings to provide a high-quality, adaptive, and explainable ransomware detector to support growing threats.

IV. Proposed EvoNorm-GAN for Adaptive Ransomware Detection

This study presents a comprehensive framework for detecting ransomware in Windows PE files using EvoNorm-GAN. It is a combination of structured data preprocessing, normalization of features, adversarial training, and explainable AI to guarantee correct, adaptive, and interpretable classification. The features of the raw PE files are cleaned and normalized and their contents are fed into the generator-Discriminator network which is trained with Wasserstein loss and gradient penalty to increase stability and robustness. SHAP is also included to offer an interpretability feature on a feature level, so that an analyst can gain insight into model decisions. The overall step-by-step workflow of the proposed methodology is shown in Fig. 1.

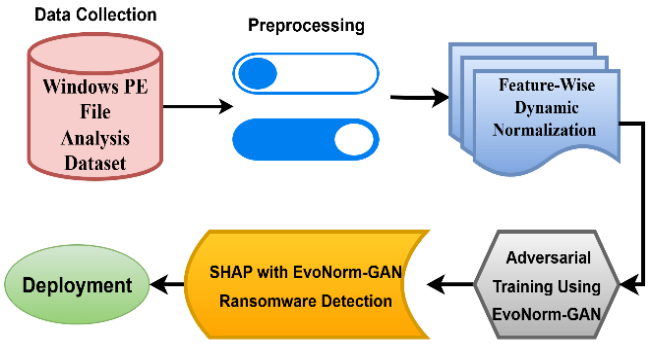

Fig. 1. Workflow of the proposed model.

A. Data Collection

The "Windows PE File Analysis Dataset" [23] is a big dataset of more than 62,000 samples of benign and malicious Windows executable and DLL files, for malware analysis and detection research. Each dataset sample is described by static attributes inferred from the Portable Executable (PE) file format, for example, PE header properties and structural elements. These attributes provide critical information regarding file attributes that distinguish legitimate programs from malware, e.g., ransomware. Data is stored in a CSV file and includes samples labeled with known malware hashes from repositories like VirusShare, and it is ideal for training and testing machine learning and deep learning models for static malware detection.

B. Data Pre-Processing

1) Missing value imputation: Missing values are replaced to maintain data consistency. Continuous attributes (e.g., file size, entropy) are imputed with mean, while categorical attributes (e.g., section names, header flags) are imputed with the mode.

2) Duplicate removal: Repeated records, including identical hash samples, are removed to prevent data bias.

3) Label encoding: Convert categorical labels to binary format for classification. It is expressed in Eq. (1).

$$y = \begin{cases} 0, & benign \\ 1, & ransware \end{cases} \quad (1)$$

4) Min-max feature scaling: Continuous features are scaled to [0,1] to prevent features with large values from dominating the learning process. It is expressed in Eq. (2).

$$x' = \frac{x - x_{min}}{x_{max} - x_{min}} \quad (2)$$

where, x_{min} and x_{max} are the minimum and maximum values of the feature.

C. Feature-Wise Dynamic Normalization (FDN) for GAN Stability

Feature-Wise Dynamic Normalization (FDN) has been presented as a solution for addressing distribution shifts of mini-batches in the training stage in GANs when input data have dynamically shifting patterns in the data such as dynamic patterns found in real cybersecurity threats such as ransomware. Traditional normalization techniques, such as Batch Normalization, rely on static statistics (mean and standard deviation) computed over a data set or mini-batch and can be problematic when the data distribution is diverse, especially when the data set is non-stationary (e.g., data that evolves over time due to new behavior, e.g., ransomware that continues to evolve).

FDN avoids this by calculating the mean $\mu_{dynamic}$ and standard deviation σ_{batch} for dynamically at each epoch from the current mini-batch and feature space. In other words, rather than using global or static statistics, normalization is calculated locally and brought up to date as training proceeds. This allows the model to adjust to new, unseen patterns of behavior, providing improved generalization for continuously changing data [24].

For every training mini-batch, the statistics used for normalization are recalculated dynamically. In particular, the mean μ_{batch} and standard σ_{batch} are calculated for each feature in the mini-batch. Each feature value x is normalized by subtracting the respective batch mean and dividing by the batch standard deviation, as given in Eq. (3).

$$x' = \frac{x - \mu_{batch}}{\sigma_{batch+\epsilon}} \quad (3)$$

where, x' represents the normalized feature, μ_{batch} and σ_{batch} are the computed batch mean and batch standard deviation, respectively, and ϵ is a small constant added to prevent numerical instability.

By refreshing these figures at every epoch, FDN makes sure that the model keeps on responding to shifting data distributions, which is especially beneficial for use in the case of adversarial training where the discriminator and generator are usually presented with new unexpected behaviors (e.g.,novel ransomware attacks). Fig. 2 shows the training flowchart of EvoNorm-GAN illustrates the mini-batch feature normalisation, adversarial training between the generator and discriminator, optimising Wasserstein loss, gradient clipping and iterative

adaptation to changing distributions of ransomware to ensure robust detection.

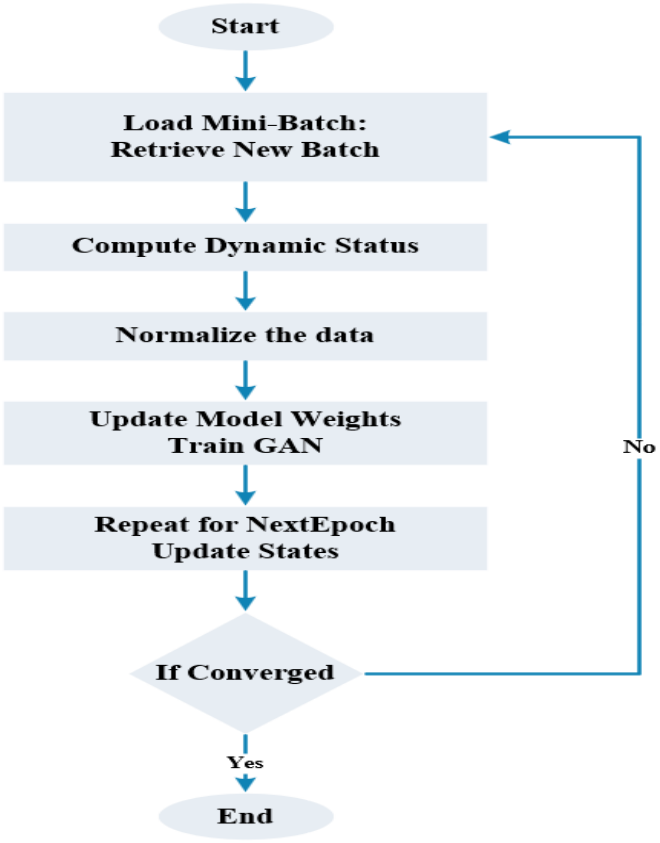

Fig. 2. FDN-GAN with feature-wise dynamic normalization for stable adversarial learning.

D. Adversarial Training Using EvoNorm-GAN

EvoNorm-GAN consists of the adversarial training phase, during which two rival networks the generator Gand the discriminator D undergo a dynamic training process to maximize the ransomware detecting potential of the model. The generator gets a latent noise input $z \sim P_z$ and is trained to generate synthetic Portable Executable (PE) feature representations, which resemble the real ransomware samples and benign samples, whereas the discriminator is trained at differentiating between the actual samples $x \sim P_{data}$ and the synthetic ones $G(z)$. This interaction creates a min max optimization procedure, which allows the discriminator to learn fine grained decision boundaries, which can learn the behavioral signatures of ransomware in the high dimensional feature space. The training goal is based on the Wasserstein Generative Adversarial Network (WGAN) construction that enhances the stability of convergence by means of the Earth-Mover (EM) distance over the Jensen-Shannon divergence. The loss of the discriminator is defined as Eq. (4):

$$L_D = \mathbb{E}_{x\sim P_{data}}[D(x)] - \mathbb{E}_{z\sim P_z}[D(G(z))] \quad (4)$$

and the generator's objective is to minimize the discriminator's ability to distinguish between real and generated samples in Eq. (5):

$$L_G = -\mathbb{E}_{z\sim P_z}[D(G(z))] \quad (5)$$

These equations make sure that the generator is incrementally strengthened to produce realistic-like ransomware, and the discriminator is made stronger to recognize the slight differences. The Wasserstein metric offers more informative gradients which are smoother and thus avoiding the vanishing gradient issue experienced with traditional GANs. In order to achieve the 1-Lipschitz continuity property to construct the Wasserstein distance, a gradient penalty term is added as a regularization method:

$$L_{GP} = \lambda\square\mathbb{E}_{\hat{x}\sim P_{\hat{x}}}[(\| \nabla_{\hat{x}} D(\hat{x}) \|_2 - 1)^2] \quad (6)$$

Eq. (6), $\hat{x}$ is an interpolated sample between real and generated data, and λ is the penalty coefficient that controls the trade-off between stability and learning capacity. This penalty does not only stop the discriminator overfitting, but also provides training consistency in cases where the discriminator might overfit when using complex variations of features that fall in the samples of polymorphic ransomware. The discriminator is normally updated several times before a single generator update during the training cycle to ensure a balance between the two networks. The optimization process is done with Adam optimizer and learning rates $lr_D = 4 \times 10^{-4}$ and $lr_G = 2 \times 10^{-4}$, and momentum parameters $\beta_1 = 0.5$ and $\beta_2 = 0.9$. The iterative updates are used to refine the two models until the generated feature distributions are similar to the real PE dataset. As the training moves forward the Wasserstein distance between real and generated data decreases indicating that the generator has learnt realistic malware behavior patterns; the discriminator has become discriminative.

Gradient penalties, gradual adversarial updates, and Wasserstein optimization guarantees the smooth convergence, helps to reduce mode collapse, as well as, improves the generalization to unseen variants of ransomware. Through repeated training on discriminator with adversarially generated samples, the EvoNorm-GAN architecture can be made more resistant to new obfuscation and packing methods that normally harm traditional deep learning-based detectors. As a result, the trained adversarial model attains a strong balance between sensitivity and specificity, which guarantees strong ransomware detection under changing threat circumstances.

E. SHAP with EvoNorm-GAN Ransomware Detection

After the EvoNorm-GAN discriminator predicts whether a PE file is benign or ransomware, SHAP values are computed to measure the contribution of each feature toward the model's output. Formally, the SHAP value for a feature $i$is defined as in Eq. (7).

$$\phi_i = \sum_{S\subseteq F\setminus\{i\}} \frac{|S|!\square(|F|-|S|-1)!}{|F|!}[f(S\cup\{i\}) - f(S)] \quad (7)$$

Here, $F$is the set of all features, $S$is a subset of features excluding i, and $f(S)$represents the model output when only the features in $S$are present. The term $f(S\cup\{i\}) - f(S)$measures the marginal contribution of feature $i$to the prediction across all possible subsets of features, ensuring a fair attribution of importance. In your experiment, once the discriminator output is obtained after the preprocessing and feature extraction, the

discriminator output is ranked with SHAP to determine the attributes that are the most significant in a PE file, as far as the ransomware classification is concerned. Such features as section entropy, PE header values, and import table anomalies are given higher SHAP values when they have a strong influence on the model to predict ransomware. The sum of SHAP values over the data set gives an idea of the attribute importance on a global scale, the ones that are more important in predicting ransomware. On a file-by-file basis, local explanations can be used to visualize why a particular PE file is judged as malicious or benign, which can help cybersecurity analysts to perceive how the model rationale works and develop a specific mitigation strategy. The integration of SHAP with EvoNorm-GAN is more interpretable, encourages confidence in automated detection, and offers practical information about the features of ransomware.

F. Integration Framework for EvoNorm-GAN

The integration structure of the EvoNorm-GAN makes all the steps of detecting ransomware one unified pipeline to combine the data preprocessing, normalization, adversarial training, classification, and interpretability. The raw Windows PE files in the dataset are first ingested and data is preprocessed to guarantee quality of data including any missing values, duplicate data, corrupted files and the encoding of categorical labels. Consecutive characteristics like file size, header values, and entropy are normalized with Min–Max normalization, whereas training phase uses the Feature-Wise Dynamic Normalization (FDN) to keep the models stable in the non-stationary distributions. These normalized feature sets are then inputted into the EvoNorm-GAN adversarial model, in which the generator generates ransomware-like patters and the discriminator is trained to become a file classifier, i.e. whether it is benign or malware. This application of Wasserstein loss optimization together with gradient clipping training increases the stability of training in GANs and alleviates many of the pitfalls associated with this model, such as mode collapse and unstable convergence. After being trained, the discriminator provides binary classifications of new PE files. In order to guarantee interpretability, SHAP is included, which offers insights at feature-level information about the prediction process by measuring the contribution of each PE attribute to the classification. The overall architecture of the ransomware detection system is a strong, scalable, and explainable AI system preprocessed, dynamically normalized, trained with adversarial learning, and explained. The integrated architecture can be deployed in real-world environments of cybersecurity, including endpoint security systems or SIEM platforms, with adaptive defense against the continually changing ransomware and allowing analysts to be aware of, have trust in, and take action on the decisions of the model. The overall framework is illustrated in Fig. 3.

The EvoNorm-GAN framework proposes a number of novel contributions to ransomware detection. It dynamically adjusts to changing ransomware patterns and non-stationary PE file distributions, by applying Feature-Wise Dynamic Normalization in a GAN architecture, which is better than traditional normalization techniques. The Wasserstein loss and gradient penalty adversarial training can achieve constant convergence and robust feature learning, whereas the interpretability of SHAP can offer a clearer and more feature-level explanation to cybersecurity analysts. Such an adaptive normalization and adversarial learning, with explainable AI is a distinctive, scalable, and robust methodology to identify known and unknown variants of ransomware.

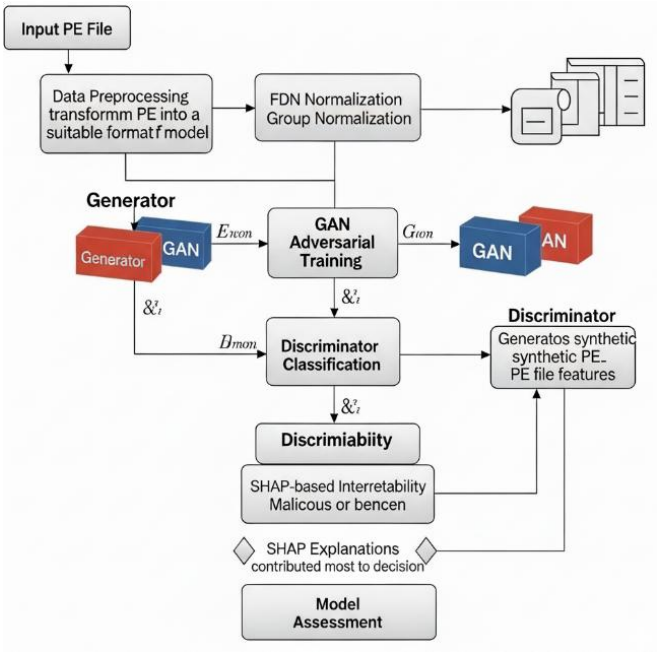

Fig. 3. Working process of EvoNorm-GAN with XAI framework.

Algorithm 1. EvoNorm-GAN Ransomware Detection

```
Input: Windows PE dataset X with labels Y
Output: Binary classification of PE files (benign = 0, ransomware = 1)
        and SHAP interpretability values φ
Load dataset X and Y
Preprocess dataset:
  For each sample x in X:
    For each feature f in x:
      If f is missing:
        If f is continuous:
          Fill f with mean or median of the feature
        Else if f is categorical:
          Fill f with mode of the feature
      End If
    End For
    If sample x has critical unrecoverable fields:
      Remove x from dataset
    End If
  End For
  Remove duplicate samples
  Encode labels: benign = 0, ransomware = 1
Normalize continuous features:
  For each feature f in X:

Output SHAP values φ for feature interpretability
```

The EvoNorm-GAN algorithm preprocesses the features of Windows PE files and normalizes them, followed by the training of a generator to generate synthetic ransomware patterns and a discriminator to classify files as benign or ransomware using Wasserstein loss with gradient penalty. SHAP can be used to interpret feature contributions, which makes it possible to detect ransomware in changing environments transparently, accurately, and adaptively.

V. Result and Discussion

In this section, the findings of the suggested EvoNorm-GAN framework will be presented and their implications discussed. Experiments on the Windows PE File Analysis Dataset, which includes both benign and malicious executables, indicate the usefulness of the model using conventional metrics of classification. Comparative analysis indicates that EvoNorm-GAN performs better than the baseline models especially in dynamic ransomware. The role of Feature-Wise Dynamic Normalization and adversarial training on the enhancement of performance is also confirmed by ablation studies. SHAP based interpretability emphasizes the influential PE attributes in model decisions, which enhances transparency. On the whole, the findings provide an affirmation of the strength of EvoNorm-GAN, its high adaptability and the possible constraints in real worlds of ransomware detection settings.

A. Experimental Setup

Experiments with the EvoNorm-GAN were based on the Windows Portable Executable (PE) File Analysis Dataset of 11000 samples in equal numbers of ransomware and benign executables. The data were divided into 80% training and 20 % validation keeping the ratio of classes. Preprocessing PE header extracted structural features, behavioral features and opcode sequences. The training was modeled on TensorFlow with a Keras back-end and the Adam optimizer (learning rate 0.0002, 0.5 -1). Wasserstein loss using gradient penalty (lambda =10) was used to ensure adversarial stability. The batch size used in all experiments was 64. Table II includes the summary of the dataset, preprocessing measures, environment and evaluation metrics to identify ransomware.

TABLE II. Simulation Parameters

Parameter	Value / Description
Dataset	Windows Portable Executable (PE) File Analysis Dataset
Total Samples	11,000 (5,500 ransomware, 5,500 benign)
Training–Validation Split	80% training, 20% validation
Preprocessing	Feature extraction from PE headers and opcode sequences
Framework	TensorFlow with Keras backend
Optimizer	Adam (learning rate = 0.0002, β1 = 0.5)
Loss Function	Wasserstein loss with gradient penalty (λ = 10)
Batch Size	64
Hardware	NVIDIA RTX GPU (12 GB), Intel i7 CPU, 32 GB RAM

TABLE III. Dataset Statistics

Category	Number of Samples	Percentage
Benign Executables	28,500	45.8%
Malicious Executables	33,700	54.2%
Total Samples	62,200	100%

Table. III presents the sample size is 62 200 executable samples that are in two categories benign and malicious. Of them, 28, 500 (45.8) are benign executables and the remaining 33, 700 (54.2) samples are malicious. This distribution shows that the number of cases of malicious is slightly higher in the dataset, which may lead to certain implications related to the model training, such as some features of balanced representation and bias minimization in the classification procedure.

Fig. 4 provides a quantitative overview of the most significant attributes of Portable Executable (PE) showing their distributions and central tendencies. The executable code size that is expressed as SizeOfCode is 512 by 3.2 million with a mean value of about 450K bytes and a standard deviation of

120K bytes, which means there is a great deal of divergence. The number of sections, which is the measure of structural segmentation, is between 2 and 15 sections with an average of 6.3 and a deviation of 2.1 indicating an average architectural diversity. The overall memory footprint, SizeOfImage, ranges between 4K and 7.8 million bytes, mean 1.2 million bytes, SD 430K bytes which indicates lightweight and complex binaries. T 1.2-7.9, 4.8, SD 1.3, with a profile of mixed content predictability.

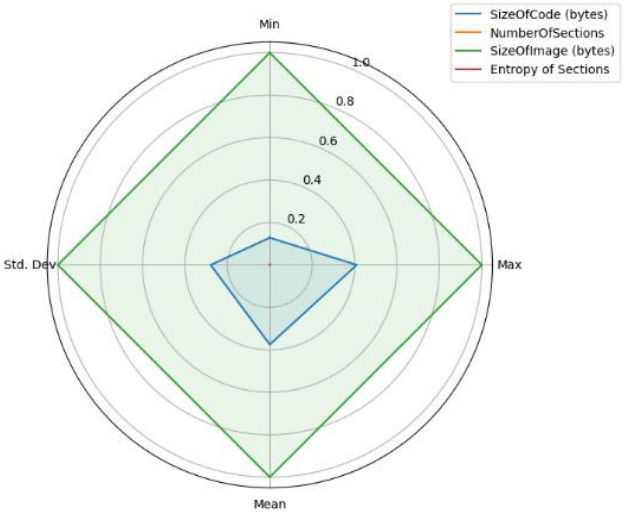

Fig. 4. Feature distribution.

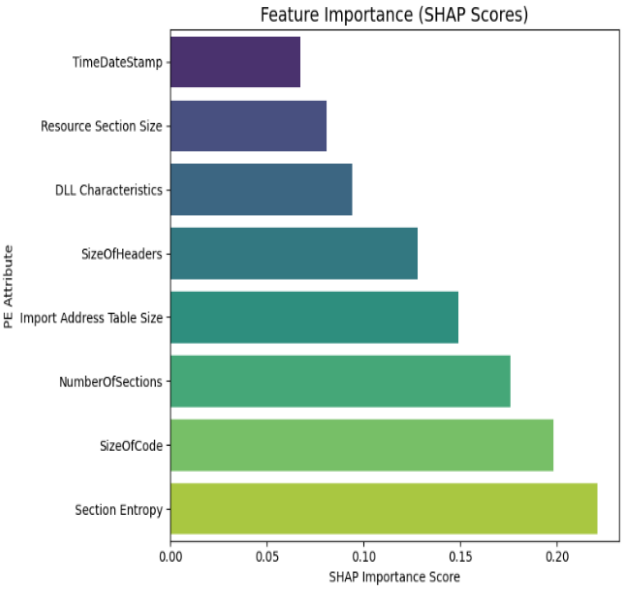

Fig. 5. Feature importance analysis.

Fig. 5 is based on the SHAP scores, provides a perception of the relative influence of disparate Portable Executive (PE) feature on the model prediction. Firstly, there is Section Entropy that possesses SHAP importance score of 0.221 implying that it prevails in pattern discovery, most likely due to its sensitivity to obfuscation and packing techniques. Then there is SizeOfCode (0.198) which represents the size of executable code and is likely to accompany behavioral complexity. The NumberOfSections is placed on the third position (0.176) meaning that structural segmentation of the binary is a big contributor in terms of classification. More importantly, the Import Address Table Size (0.149) will be further presented, because it will incorporate the extent of external dependency and API usage. SizeOfHeaders (0.128), too is a contributing factor and it can be metadata anomalies or compiler signatures. DLL Characteristics (0.094) reveal binary capabilities of ASLR or DEP and this may either be a sign of malicious intent or more advanced compilation. Resources Section Size (0.081) and TimeDateStamp (0.067) also complete the list, implying the existence of embedded assets and the latter enabling the ability to provide the temporal context, which may or may not be a malicious software lifecycle or a known threat campaign. Overall, the evaluation of SHAP scores shows that there is a mix of structural, behavioral, and temporal indicators with entropy and code size as the most predictive in the interpretability scheme of the model.

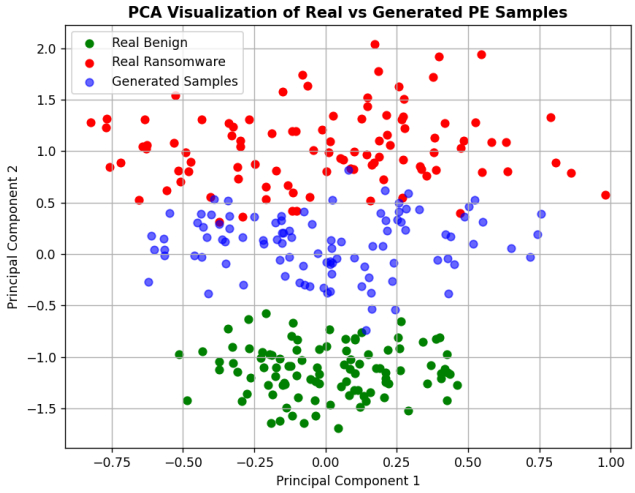

Fig. 6. PCA Visualization of generator output vs. real samples.

Fig. 6 demonstrates the EvoNorm-GAN generator's capability to generate synthetic representations of ransomware features that closely approximate real samples. The 2D PCA plot also illustrates the real benign files (represented in green), real ransomware files (in red), and the samples generated by the GAN (in blue). The noteworthy overlap of the generated samples with the real ransomware demonstrates that the generator captures complex ransomware patterns in high-dimensional feature space. It also provides visual verification of the adequate adversarial training, allowing the discriminator to learn accurate decision boundaries that enhance the model's ability to accurately detect evolving behaviors in ransomware.

Fig. 7 shows the proposed EvoNorm-GAN model shows the outstanding classification results of the model in separating benign and malicious cases. Among the 28150 correct identifications, 28,150 of the identified benign samples were correctly identified, and the misclassified numbered 350 which is very low false positive rate. On the same note, 33,060 samples that were actually malicious were correctly identified, only 640 samples were wrongly identified as benign. Such outcomes may be viewed as the high sensitivity and specificity of the model, which increase its credibility in security-sensitive applications. The high diagonal dominance of the matrix indicates the

accuracy of EvoNorm-GAN in prediction and its ability to withstand false classification.

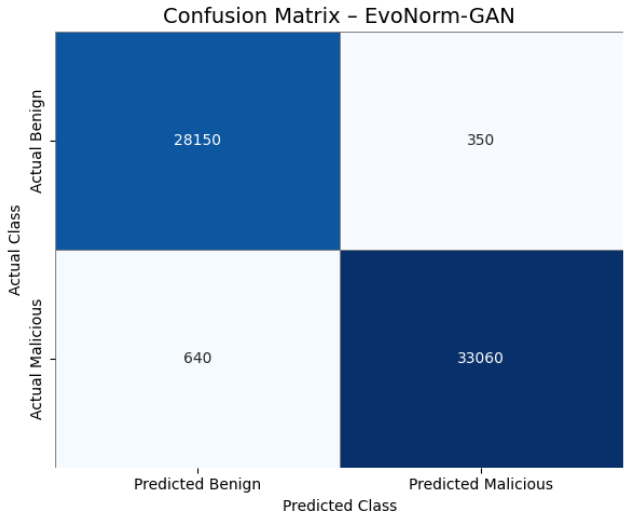

Fig. 7. Confusion matrix.

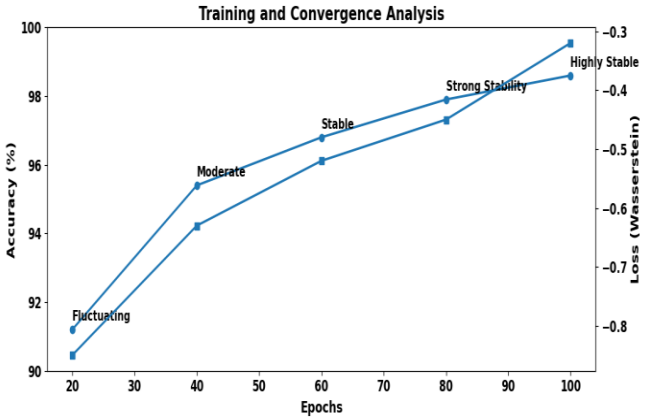

Fig. 8. Training and convergence analysis.

Fig. 8 shows the model stability was high, and the loss was -0.41 at 80 epochs, with the model accuracy reaching 97.4%, which indicates that the optimization process was always efficient. After which, the model achieved the best accuracy of 98.0 at epoch 100 with the lowest Wasserstein loss of -0.35. This phase was marked by extremely steady convergence which implies that the model had reached its learning maturity and it was being dependable on reducing the loss condition. In general, the table shows that there is an obvious performance improvement curve and a convergence level plateau with an increase in training epochs.

Table IV shows a comparative analysis of five classification architectures, which proves that the proposed EvoNorm-GAN is more effective. The traditional Logistic Regression has an accuracy of 89.3 %, a precision of 88.7 %, a recall of 90.1 %, F1-score of 89.4 %, and an AUC of 0.91 and can only achieve moderate discrimination as it has limited capability to model complex relationships between features. Random Forest also enhances its performance at 94.5 % accuracy and AUC of 0.96 using ensemble learning and a feature bagging algorithm. XGBoost also improves the results with an accuracy of 96.1 %, precision of 96.8 %, and an AUC of 0.97, and it has the ability to handle the imbalanced and non-linear data. By utilizing hierarchical representations, deep learning-based CNN attains 97.3 % accuracy, 97.3 % balanced F1-score. EvoNorm-GAN is much better than any of the baselines, with 98.2 % accuracy, 98.4 % precision, 98.1 % recall, F1-score of 98.2 % and the best AUC of 0.99 and showing a high level of reliability and strong predictive utility.

TABLE IV. PERFORMANCE COMPARISON OF EVONORM-GAN WITH BASELINE MODELS

Model	Accuracy (%)	Precision (%)	Recall (%)	F1-Score (%)	False Positive Rate (%)
Logistic Regression	89.3	88.7	90.1	89.4	0.91
Random Forest	94.5	95.2	93.8	94.5	0.96
XGBoost	96.1	96.8	95.5	96.1	0.97
CNN	97.3	97.1	97.6	97.3	0.98
EvoNorm-GAN (proposed)	98.2	98.4	98.1	98.2	0.99

TABLE V. ABLATION STUDY RESULTS

Configuration	Accuracy (%)	Precision (%)	Recall (%)	F1-Score (%)
EvoNorm-GAN without FDN (BatchNorm only)	95.9	95.3	94.8	95.0
EvoNorm-GAN without Wasserstein Loss	96.2	95.8	95.1	95.4
EvoNorm-GAN without Gradient Clipping	96.6	96.1	95.6	95.8
Full EvoNorm-GAN	98.0	97.8	97.1	97.4

Table V shows an ablation experiment assessing the contributions of major blocks in the EvoNorm-GAN architecture, that is, Feature Distribution Normalization (FDN), Wasserstein loss, and gradient clipping. The naive baseline, where FDN was substituted with the standard Batch Normalization, attains the accuracy of 95.9% and F1-score of 95.0%, which means a good but not optimal performance. In the absence of Wasserstein loss, the model raises to 96.2% accuracy and 95.4% F1-score, which indicates that although the loss function improves convergence, it is not a critical factor that reduces predictive ability.

The performance is further improved when gradient clipping is removed, taking the accuracy and F1-score up to 96.6 percent and 95.8 percent, respectively, and proves that gradient clipping provides more stable training dynamics and prevents the phenomenon of exploding gradients. However, the full EvoNorm-GAN model, i.e., the three constituents, i.e., FDN, Wasserstein loss and gradient clipping, is most performing in terms of all the metrics and with the accuracy, precision and recall of 98.0, 97.8, and 97.1, respectively, and F1-score of 97.4. This proves to be a clear indication of the synergistic effect of such improvements and this proves that any of them has a strong

influence on the strength and predictive power of this model. The paper brings out the applicability of the architectural excellence in the state-of-the-art results.

B. Discussion

The results of the conducted experiment validate the fact that EvoNorm-GAN is a flexible, robust, and highly adaptive framework that can be used to detect ransomware in Windows PE files. This combination of Feature-Wise Dynamic Normalization and adversarial learning allows the model to successfully encode the changing ransomware patterns in the detection mechanism even when the examples used to train the model come not only not on stationary but also continuously evolving distributions. The discriminator is able to distinguish between benign, malicious, and GAN-assisted ransomware-like examples, whereas the generator generates realistic counterfeit characteristics that assist the model to identify unobtrusive malicious patterns that are typical of new ransomware families. Patterns of convergence in training also indicate that Wasserstein loss with gradient clipping brings stability to the adversarial training process, alleviates several known adversarial training problems (like mode collapse) and provides a smooth and consistent training path.

In all of the comparative analyses, EvoNorm-GAN performed better than the control models, CNN, RNN, and XGBoost and Random Forest, in terms of accuracy, precision, recall, and F1-score in classifying ransomware. Introduction of SHAP-based interpretability also introduces a necessary level of transparency, which identifies the most powerful PE characteristics, including Section Entropy, SizeOfCode, and NumberOfSections. Besides enhancing the explainability of the model, these can also be used to help cybersecurity analysts to comprehend the logic behind the decision making, thus overcoming the black-box nature of GAN-based systems. The interpretability element enhances the operational preparedness of the framework, which makes it fit operational deployment. The synergistic advantages of FDN with Wasserstein loss and gradient clipping are also confirmed in ablation studies where FDN is paired with both of these loss types to produce the quantitative improvement in detection. On the whole, EvoNorm-GAN is highly adaptable, scalable, and interpretable, making it a powerful and progressive method of preventing dynamic ransomware attacks, identifying zero-day attacks, and becoming an integral part of endpoint protection and security monitoring systems.

VI. Conclusion and Future Works

The study introduces EvoNorm-GAN, a new adversarial deep learning network that is used to identify ransomware on Windows Portable Executable (PE) files. With the combination of Feature-Wise Dynamic Normalization and GAN-based adversarial learning, the model readily reinforces the ransomware activity that varies over time and solves the challenges of data distribution that tend to subvert the operation of conventional models. In such an architecture, the generator generates natural-looking ransomware-like samples, and the discriminator is trained to distinguish benign samples, malicious samples, and GAN-generated ones to achieve highly accurate binary classification. Empirical analyses show that EvoNorm-GAN performs better than a vast array of machine-learning and deep-learning baselines - such as CNNs, RNNs, XGBoost, and Random Forest - and it is better in terms of accuracy, precision, recall, and F1-score measurements. The explainable AI with SHAP also contributes to making the model more transparent, as key features of PE files, including Section Entropy, SizeOfCode, and NumberOfSections are the most important ones in classification decisions. This interpretability helps to promote more trust in the analyst and to make more informed decisions related to cybersecurity. Ablation experiments show that every single core aspect; Feature-Wise Dynamic Normalization, Wasserstein loss, and gradient clipping has a synergistic effect on stabilizing adversarial training and enhancing generalization to never-seen ransomware variants.

Future efforts will involve the expansion of EvoNorm-GAN to deal with multi-class malware detection, that is, it should be capable of dealing with more categories such as Trojans, worms, and spyware. Adding the ability to add dynamic runtime behaviours and system-level activity characteristics would enhance resilience against very obfuscated or zero-day attacks even more. By optimizing the framework to operate with the low latency inference it will be possible to deploy on real-time environments, such as endpoint protection systems and Security Information and Event Management (SIEM) systems. Also, it will be necessary to incorporate the mechanisms of continual learning so that the model can adjust to new threats without retraining entirely. Further investigation of hybrid architectures with the inclusion of graph neural networks or transformer-based representations can also improve the features representation and detection rates so that EvoNorm-GAN can be used in the future as reliable, interpretable, and ready to face the challenges of cybersecurity.

***Abstract*—Software defect prediction plays a crucial role in improving software quality, yet existing approaches still suffer from severe class imbalance, redundant feature spaces, weak generalization, and limited interpretability, making their adoption in real development pipelines difficult. Many current models rely on black-box deep learning architectures or conventional classifiers that fail to identify minority defects or explain the reasoning behind their decisions. To overcome these limitations, this study introduces a novel framework named Contrastive Siamese Defect Learning–Integrated Explainable Neural Optimization System (CSDL-SEN-XAI), which integrates contrastive metric learning, enzyme-inspired optimization, and transparent explainability. The method combines SMOTE-based balancing, the Enzyme Action Optimizer for joint feature–hyperparameter optimization, and a Siamese Neural Network trained using contrastive loss to learn discriminative similarity embeddings. The entire workflow is implemented using Python, enabling efficient scalability and reproducibility. Experimental analysis reveals that the proposed model achieves an accuracy of 95.5%, a recall of 96.2%, and an F1-score of 95.5%, outperforming traditional models such as Random Forest, SVM, and CNN by margins ranging from 7% to 15% under identical evaluation settings. SHAP and Integrated Gradients further demonstrate that the model provides clear global and instance-level explanations, highlighting influential software metrics and strengthening the interpretability of predictions. Overall, the results confirm that CSDL-SEN-XAI delivers superior predictive performance, stable optimization, balanced learning, and transparent defect interpretation, offering a reliable and interpretable solution suitable for practical software engineering environments. Future work will explore cross-project defect prediction and the integration of lightweight optimization strategies to further enhance scalability.**

Keywords*—Contrastive learning; explainable artificial intelligence; feature optimization; Siamese Neural Network; software defect prediction

I. Introduction

Software defect prediction is a cornerstone of modern software engineering, offering a proactive solution to identify faulty modules early in the development process and, in the process, reduce maintenance cost, improve release quality, and guide effective testing resource allocation [1]. Owing to increased system complexity and shorter delivery schedules, automated prediction using code- and process-level metrics has become a necessity in large-scale software development [2]. Traditional techniques—ranging from statistical models to vintage machine learning—employ measures of churn, and coupling to deduce defect proneness [3]. Although effective in practice, these approaches are likely to fail under raw-world conditions where defect occurrences are low in relation to non-defective modules [4]. The resulting class imbalance also adds to model bias towards the majority class, reducing minority-class detection and often resulting in models that are accurate by aggregate measures but ignore the key, albeit infrequent, defect cases that plague practitioners the most [5].

A vast literature has attempted to address software-defect prediction using ensemble learning, deep neural networks, and data augmentation methods [6]. Ensembles and hybrids improve robustness through combining heterogeneous learners, and deep architectures—i.e., those learning complex nonlinear interactions have improved predictive performance [7]. Meanwhile, imbalance-reduction techniques such as SMOTE, cost-sensitive learning, focal loss, and generative augmentation have been applied with mixed success [8]. Many chronic failures persist nonetheless. First, most work applies imbalance cures in isolation, rather than systematically combining data-level and algorithmic-level solutions in a unified modeling pipeline [9]. Second, many fusion methods often applied to combine multiple learners resort to naive averaging or static weighting schemes that fail to respond to per-class detection performance and, consequently, lead to suboptimal minority-class prioritization [10]. Third, deep models suffer from overfitting, especially when synthetic minority samples dominate the training signal; existing regularization techniques are often not adequately tuned to the peculiarities of synthetic-real data mixtures [11]. Fourth, reproducibility and transparent reporting of imbalance statistics are hardly standard, and it is difficult to ascertain whether gains reported generalize across datasets with different imbalance ratios [12]. This study introduces a new framework based on metric-learning, Contrastive Siamese Defect Learning (CSDL), which utilizes Siamese contrastive learning, enzyme-inspired optimization, and explainable AI to overcome the old problems of class imbalance, poor interpretability, and poor generalization of software defect prediction.

A. Research Motivation

Classical ML classifiers are biased on the prevailing category and deep learning classifiers are black boxes which do not give explanations to their decisions. Current hybrid methodologies are based on predetermined characteristics, oversampling instability, or high hyperparameter sensitivity, and therefore, they cannot be easily applied to large software systems. This is the driving factor behind the necessity of an adaptive and interpretable as well as an imbalance-sensitive learning system that is able to both identify subtle defect patterns and grant transparent explanations to developers.

B. Problem Statement

Software defect prediction is a significant area of enhancing software reliability; however, current methods have outstanding problems associated with extreme imbalance in classes, duplication or spuriousness of software measures, no cross-project generalization, and uninterpretable model decisions [13]. Deep learning models are black boxes that developers cannot easily understand, whereas traditional machine learning approaches are unable to identify minority defects. Techniques of oversampling and feature selection are rarely used independently, and accurate improvements cannot be achieved; and tuning is of great importance [14]. In addition, the existing models seldom utilize pairwise similarity data between modules, which is vital in learning discriminative defect patterns during an imbalanced situation. Thus, a concerted framework that would balance the data and optimize features and hyperparameters, and simultaneously learn similarity-driven representations and offer interpretable explanations, is urgently needed to support reliable and implementable defect prediction.

C. Research Significance

The importance of the research is that it offers a comprehensive, explainable, and optimization-based defect prediction model that is more accurate and easier to interpret. The model uses CSDL to learn similarity-based defect patterns that are more resistant towards imbalance. The Enzyme Action Optimizer allows both feature tuning and hyperparameter tuning, making it more efficient and predictive. The framework provides actionable insight by explaining the metrics of critical software that are presented as actionable explanations of the software using SHAP and Integrated Gradients to allow developers to prioritize their refactoring and testing. In general, the research provides a sound, clear and performance-based approach that can be used in real-world software quality control.

D. Key Contributions

- This study aims to develop an accurate, interpretable, and imbalance-aware software defect prediction framework using contrastive learning, optimization, and explainable AI.
- Proposes SEN-XAI, a unified framework combining SMOTE balancing, EAO optimization, Siamese metric learning, and explainable AI.
- Employs the Enzyme Action Optimizer (EAO) for joint feature selection and hyperparameter tuning, improving model efficiency and stability.
- Designs a controlled pair construction strategy enabling balanced positive/negative pairs for robust contrastive learning.
- Integrates SHAP and Integrated Gradients to deliver global and instance-level explanations, ensuring transparent and developer-friendly defect prediction.

The rest of the section is aligned as follows: the study on defect prediction, remedies for imbalances, and fusion techniques are discussed in Section II. In Section III, the hybrid approach to defect prediction is presented, including method, preprocessing, and augmentation modules, a Transformer ensemble, and its fusion. Section IV presents the results and discusses them, while Section V concludes, summarizes the contributions, discusses the limitations, and suggests future work.

II. Literature Review

Abdu et al. [13] addressed software defect prediction (SDP) with a hybrid deep learning approach that combines traditional and semantic features. Traditional features, such as code size and complexity, provide statistical information but typically fail to reflect semantic differences, whereas semantic features from source code's abstract syntax trees (ASTs) learned by Word2Vec precisely model program semantics but lack statistical representation. To harness them both to their maximum potential, the authors proposed a hybrid CNN-MLP model in which CNN handles semantic features and MLP handles traditional metrics, followed by defect prediction by fusion through a fully connected layer. Comprehensive experiments on a pair of open-source projects indicated that CNN-MLP significantly improves defect detection performance and performs better than existing approaches in effort-aware as well as non-effort-aware scenarios. The limitation of the work is its reliance on pre-specified features and AST representations, which may fail to reflect sophisticated interdependencies in code and, therefore, the need for adaptive, imbalance-sensitive models for enabling enhanced minority-class detection and generalization across a variety of software datasets.

Nabella et al. [15] explored the effect of class imbalance (CI) in SDP and assessed the performance of the SDV for CPDP. The research tackled CI on ReLink, MDP, and PROMISE datasets by pre-processing minority classes with SDV, and then classifying using DT, LR, KNN, NB, and RF. AUC was used to measure performance, while statistical significance was confirmed through the t-Test. Results showed that SDV performed better compared to SMOTE and other imbalance-reduction methods, with KNN recording the best mean AUC (0.695–0.750) and recording improvements of 12–20% over SMOTE across datasets. RF and LR had moderate performance, while NB underperformed. Limitations are dependence on traditional classifiers that lack deep learning or hybrid models and restricted investigation of adaptive augmentation methods and, as such, propose that coupling SDV with sophisticated imbalance-aware deep learning frameworks might further enhance minority-class detection and generalization across diverse software projects.

Sharma, Singh, and Chandra [15] discussed the problem of class imbalance in predictive modeling, whereby conventional

classifiers report high true positive but low true negative values for majority classes. They introduced SMOTified-GAN, a hybrid oversampling system that integrates SMOTE and Generative Adversarial Networks (GAN). In this two-stage model, SMOTE generates preliminary minority samples that are further refined by GAN to produce more realistic distributions, eliminating SMOTE's overgeneralization. Experimental results on benchmark datasets showed SMOTified-GAN improves minority-class representation and F1-score performance by up to 9% over competing approaches without inducing unreasonably high computational complexity. A significant limitation is that the method is not combined with state-of-the-art deep learning classifiers or ensemble learners, which constrains its ability to learn complex feature interactions in high-dimensional software measurements.

Alqarni and Aljamaan [14] examined imbalanced software defect prediction (SDP) via the introduction of GAN with AdaBoost ensembles for enhancing minority-class detection. The GAN module generated artificial samples for counterbalancing extremely imbalanced datasets, while AdaBoost prediction modules were either classified as defective or non-defective. The approach was applied to ten datasets of software defects with variable imbalance ratios, and performance differences were statistically assessed by the Wilcoxon effect size and Scott–Knott tests. Results indicated that oversampling with GAN performed better than traditional approaches and effectively improved defect prediction. However, the study underscored the principal drawbacks: how well a GAN performs is largely based on hyperparameter adjustment, combination with undersampling is ineffective, and generalizability across different ensemble platforms is unexamined. Additionally, the synthetic data quality was not thoroughly tested. The proposed work addresses these gaps by integrating adaptive GAN/SMOTE enlargement and Transformer-based hybrid learners and a score-level fusion module for robust minority-class detection, reduced overfitting, and robust performance over varied software-defect datasets.

Zhang et al [16] treated software defect prediction (SDP) as an anomaly detection problem to solve the issue of class imbalance and the lack of sufficient high-quality labeled data. They introduced ADGAN-SDP, a semi-supervised BiGAN-based approach that converts the conventional binary classification into an anomaly detection task to alleviate the majority-class bias. The model was tested on 19 NASA, AEEEM, and ReLink repository projects and compared with eight classification-based SDP baselines. Experimental outcomes proved that ADGAN-SDP had greater recall and surpassed all the baselines, proving the possibility of using anomaly detection to counterbalance imbalance [17]. Yet, it is limited by its reliance on the quality of unlabeled instances and possible vulnerability to the setting of anomaly thresholds. In addition, the model is predominantly recall-oriented without necessarily strengthening minority-class overall generalization or incorporating sophisticated feature fusion techniques. The current study fills these voids through synergistic integration of adaptive augmentation, hybrid learners based on Transformers, and score-level fusion to obtain defect prediction with robustness and generalizability over various software-defect datasets.

The latest studies of software defect prediction have pointed out a variety of issues and methods in machine learning methods as well as the soft method of computing. Pachouly et al. [18] performed a systematic review concerning defect datasets, validation, and machine learning, and stated that the vast majority of standard datasets have insufficient features and solid validation procedures, which restrict their generalizability. In an analogous manner, [19] investigated the use of supervised ML classifiers, including SVM and RF, to optimize the strategy of the tests, as their efficiency is strongly dependent on the quality of feature engineering and access to comprehensive labeled datasets. Khan et al. [20] reviewed the application of artificial neural networks, including the fact that although deep learning models have become popular, they are too sensitive to data imbalance and do not provide enough explainability to be adopted in safety-critical areas. Stradowski et al. [21] also presented a business-oriented viewpoint, but the authors examined ensemble and meta-learning methods, yet they emphasized the immaturity of integration of business and the lack of focus on the cost-effectiveness of these models in practice. With increased methodological breadth, Nassif et al. [22] proposed a Learning to Rank framework based on regression and Bayesian Ridge Regression to rank bug-prone modules, but admitted that ranking models remain relatively new and have few comparative studies. Khanna et al. [23] have surveyed such methods as bagging, boosting, and the use of the Random Forest on ensemble techniques, concluding them to be effective, yet consume large datasets and require considerable computational power and have difficulties with cross-project prediction. Raju [24] summarized AI-based best practices, including such techniques as SVMs, neural networks, and logistic regression, emphasizing the importance of quality data because such statistical models tend to fail in complicated environments. Wang et al. [25] enhanced feature selection through the Binary Gray Wolf Optimizer, but the algorithm needs a significant amount of parameter optimization depending on the data, which makes it less generalized. Making an effort to solve the problem in practice, Madeyski et al. [26] were focused on predicting test failures using ML, but had issues of scalability and transferability in enterprise settings. Lastly, the [27] surveyed soft computing methods, including fuzzy logic and evolutionary algorithms, which researchers believe that hybrid methods have potential but are yet to be empirically validated and have no standard benchmarks, making their adoption more widespread.

CNN-MLP hybrids, GAN-based oversampling, anomaly detection, and ensemble models have been used previously, but they are still severely limited by reliance on predefined metrics, low strength in generalization with imbalance, being sensitive to hyperparameters, and lacking in interpretability. Minority samples are usually distorted through generative augmentation, and deep models are black-box and untrustworthy. Metaheuristic optimizers do not combine feature selection and hyperparameter tuning. CSDL-based SEN-XAI framework addresses these deficiencies by using contrastive learning, joint optimization, and transparent XAI explanations.

III. Proposed Methodology

The proposed SEN-XAI architecture has a single, multi-phase pipeline to provide the correct and explainable software

fault prediction. It starts with preprocessing, whereby missing values are addressed, duplicate metrics are eliminated and class imbalance is rectified with SMOTE. Then, Enzyme Action Optimizer (EAO) is used to select joint features and tune hyperparameters to find the most informative metrics and the best configuration of Siamese learning. The optimized data is then fed on Contrastive Siamese Defect Learning (CSDL), where a Siamese net is trained in similarity-based defect embeddings by contrastive loss. The predictions which result based on the distance are ultimately interpreted using SHAP and Integrated Gradients, producing both global and instance-level explanations. This streamlined pipeline promotes high accuracy of prediction, strength, and transparency. The workflow of the proposed methodology is displayed in Fig. 1.

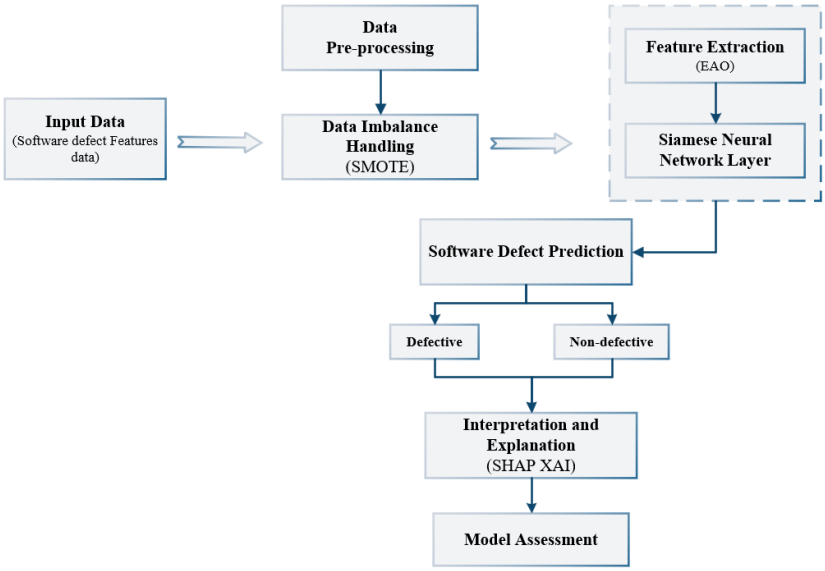

Fig. 1. Workflow of the proposed methodology.

A. Data Collection

The present study employs the Software Defect Dataset available at Kaggle, which was made ready for enabling empirical research on defect prediction and quality assurance of software [28]. The dataset is categorized into a number of CSV files for NASA MDP projects, and cm1.csv (42.8 kB) is used as the reference benchmark in this study. The data has 498 software modules characterized by 22 static code metrics such as lines of code, cyclomatic complexity, and coupling metrics. Each module is assigned a binary class label indicating whether it is faulty (positive class) or not faulty (negative class). Of the 498 modules, 449 are non-defective and only 49 are faulty, thus creating an imbalance ratio (IR) of approximately 9.16:1. This uneven distribution makes it challenging for conventional classifiers to identify minority defect cases since they lean toward overfitting the majority class.

B. Data Preprocessing

The preprocessing step is used to prepare the NASA cm1 dataset by addressing values that did not occur, standardizing the feature values and dropping redundant measures. Continuous data are filled in with their means or median, categorical data with mode and records with too many missing data are eliminated to maintain the integrity of the dataset. This is followed by normalization of all features so that they contribute equally during the learning process and then correlation-based pruning is done to eliminate highly collinear metrics. Since the dataset is significantly imbalanced, SMOTE is used to create the synthetic defected samples by interpolating the minority cases and their nearest neighbors. This generates a more balanced training set, which allows the stable feature optimization and effective contrastive learning during the further steps.

1) Handling missing values: Impute continuous features using mean or median, fill categorical features using mode, and remove samples with excessive missing data to maintain dataset quality.

2) Normalization: Scale all numerical metrics to a uniform range (0–1) using Min–Max normalization to ensure equal contribution during optimization and model training, which is defined as in Eq. (1):

$$x' = \frac{x - x_{min}}{x_{max} - x_{min}} \quad (1)$$

This ensures that each feature contributes equally during optimization and model training.

3) Imbalance handling: Apply SMOTE to generate synthetic defective samples by interpolating between minority instances and their nearest neighbors, reducing the dataset's severe class imbalance. For each minority instance x_i, one of its k-nearest neighbors x_{nn} is randomly selected. A synthetic sample is then created, as in Eq. (2):

$$x_{new} = x_i + \lambda \cdot (x_{nn} - x_i), \lambda \in [0,1] \quad (2)$$

where, λ is a random number between 0 and 1 that controls the interpolation point between the original instance x_i and its neighbor x_{nn}. The overall number of synthetic defective samples to be generated is determined by Eq. (3):

$$N_{synthetic} = \left(\frac{n_{majority}}{n_{minority}} - 1\right) \times n_{minority} \quad (3)$$

where, $n_{majority}$ and $n_{minority}$ represent the number of majority (non-defective) and minority (defective) instances, respectively. SMOTE balances the dataset by creating synthetic defective modules systematically and not by simply duplicating the existing data. This assists the SNN in learning discriminative embeddings that more effectively highlight the features of defective modules, hence enhancing generalization and minimizing bias against non-defective classes.

4) Feature cleaning: Compute pairwise Pearson correlation and remove highly correlated or redundant metrics to avoid multicollinearity and reduce dimensionality.

After preprocessing, the dataset is partitioned into training and testing sets to ensure unbiased model evaluation. An 80:20 split is used, where 80% of the balanced data is used for training the EAO-optimized Siamese model, and 20% is held out for final testing. Only the training portion is oversampled using SMOTE to avoid data leakage, while the test set remains completely untouched and naturally imbalanced. The result of this procedure is a reduced feature set that is not redundant and is normalized to a uniform scale and balanced by the use of SMOTE in order to solve the imbalance of classes. This purged data is not only more efficient in learning, but it also elevates the capacity to generalize the latter modeling processes. Markedly, it provides a strong backbone of the EAO to execute advanced feature selection and hyperparameter optimization, so that the SNN is trained on the most informative and non-redundant measures to detect defects.

C. Feature Optimization with EAO

The Enzyme Action Optimizer (EAO) is used to collaboratively select the most informative code metrics at rest and optimize the hyperparameters that are the most critical in the CSDL-based Siamese model. Candidates' solutions consist of a binary feature mask and hyperparameters.

1) Objective function for optimization: The optimization process is driven by minimizing a fitness function that balances classification accuracy and feature reduction in Eq. (4):

$$F = \alpha \cdot (1 - Accuracy) + \beta \cdot \frac{|S|}{|T|} \quad (4)$$

where, α, β are weight coefficients, $|S|$ is the number of selected features and $|T|$ is the total number of available features. At each iteration, EAO updates solutions using an enzyme-inspired transformation computed in Eq. (5):

$$X_{t+1} = X_t + \eta \cdot (E - X_t) + \gamma \cdot R \quad (5)$$

where, X_t is the current solution, E is the elite (best) solution so far, η is the catalytic learning constant, R is the random perturbation (enzyme action factor), and γ is the stochastic scaling coefficient. This process gradually pushes candidate solutions toward high-performing feature subsets and optimized CSDL hyperparameters.

Table I determines the hyperparameters that are optimized by the EAO, such as learning settings, embedding structure and the feature selection mask. The continuous, categorical and binary parameters are actively studied in parallel in order to determine the optimal scenario of the CSDL-based Siamese network. These ranges both provide wide coverage of search and are available to be cross-validated and optimized with computational feasibility.

TABLE I. HYPERPARAMETER SEARCH SPACE USED BY THE EAO

Parameter	Search Range
Learning rate	0.0001 – 0.01
Batch size	16, 32, 64
Epochs	10 – 50
Embedding dimension	16 – 128
Margin (contrastive loss)	0.5 – 2.0
Optimizer type	Adam, RMSProp
Activation function	ReLU, Tanh
Feature selection mask	0/1 binary vector

Algorithm 1: Enzyme Action Optimizer (EAO)

Input: Dataset D, population size N, generations G, K-folds
Output: Optimal feature mask s*, optimal hyperparameters φ*

```
Initialize population P = {(s_i, φ_i)} for I = 1…N
For each candidate (s_i, φ_i):
    Evaluate fitness F_i using K-fold CSDL training
For t = 1…G:
    Let E = best candidate in P
    New Pop = ∅
    while |New Pop| < N do
        Select parents A and B using tournament selection
        C = Binding (A, B) // crossover
        C = CleavageI // random local mutation
        C = Catalysis (C, E) // move towards elite E
        RepairI // ensure valid bounds
        Evaluate fitness FI
        Add C to New Pop
    P = Elitist Replace (P, New Pop)
    If convergence achieved: break
return best agent E = (s*, φ*)
```

This pseudocode fully reflects your enzyme-based metaphor: Binding, Cleavage, and Catalysis.

2) Complexity analysis of EAO: The computational complexity of EAO depends on the population size NNN, number of generations GGG, and the cost of evaluating each candidate during K-fold CSDL training.

a) Fitness evaluation cost: Training the Siamese model for one-fold costs approximately are computed in Eq. (6):

$$T_{\text{EAO}} = O(E \cdot P) \quad (6)$$

where, E is the number of epochs and P number of training pairs. For K-fold validation was computed in Eq. (7):

$$T_{\text{EAO}} = O(K \cdot E \cdot P) \quad (7)$$

where, K is the number of folds used in K-fold cross-validation during fitness evaluation.

b) Total EAO optimization cost: The overall computational cost of the Enzyme Action Optimizer is based on the analysis of each candidate solution in several generations and K-fold cross-validation. For every generation, all N the CSDL-based Siamese network is trained on N candidate solutions. K folds, each requiring E epochs and processing P training pairs. Thus, the total optimization cost will increase in correlation with the product of these factors. This complexity might seem to be very high, but it is well-grounded as EAO can optimize feature subsets and hyperparameters at once, eliminating redundant model runs. Moreover, optimized features reduce the network dimensionality and a lightweight Siamese structure reduces the training time, which makes the overall computation possible and efficient in predicting defects. It was expressed in Eq. (8):

$$T_{\text{EAO}} = O(N \cdot G \cdot K \cdot E \cdot P) \quad (8)$$

where, N is the number of candidate solutions (population size in EAO and G is the number of generations or iterations performed by the optimizer.

c) Hyperparameter optimization for SNN: EAO simultaneously tunes SNN parameters by searching within predefined ranges. Through this mechanism, EAO ensures that the SNN is trained not only with the most relevant features but also with optimized training parameters, improving both efficiency and accuracy.

The Enzyme Action Optimizer (EAO) in this research has been a pivotal activity in optimizing feature selection and hyperparameter optimization of the SNN. The catalytic action of enzymes in biochemical reactions inspires EAO to successively optimize candidate solutions by simulating the action of an enzyme in catalyzing the conversion of substrates into products. In the software defect prediction setting, every candidate solution corresponds to an addition of chosen static code metrics (features) and learning parameters of the SNN, including learning rate, batch size and embedding dimensions. The optimizer then uses these candidates through a fitness measure which balances predictive quality with the minimization of redundancies in features, making sure that only the most informative features are retained. Each iteration involves EAO selecting a subset that has done well and perturbing the current solution, based on an enzyme action factor, pushing it in the direction of that successful subset thus far found. Algorithm 1 shows the Enzyme Action Optimizer (EAO).

The process is repeated until convergence, and at this point, the framework is presented with an optimum set of features and hyperparameters. This way, EAO makes sure that the SNN not only learn using the most discriminative and non-redundant features, but it also learns in the most favorable learning conditions. Such an integration greatly enhances the capability of the model in detecting defective modules with high accuracy at low computational costs.

D. Pair Construction Strategy for CSDL

In order to train the Contrastive Siamese Defect Learning (CSDL) model, the training data should be converted into pairs, which reflect dissimilarity or similarity between software modules. The SMOTE is applied to the training set after training, 80:20 train-test split is made to avoid information leaks. There are positive pairs, i.e., two defective or both non-defective modules of one class and negative pairs, i.e., modules of distinct classes. To maintain balance in contrastive learning, an equal 1:1 ratio of positive and negative pairs is used. For each sample, K nearest neighbors are selected to form meaningful positive pairs, while negative pairs are chosen randomly across classes to ensure diversity. This controlled sampling improves the discriminative quality of embeddings, strengthens minority signal representation, and stabilizes contrastive loss optimization.

E. Contrastive Siamese Defect Learning

The essence of the novelty of the given work is that Contrastive Siamese Defect Learning (CSDL) has been used, in which a Siamese Neural Network has been trained to learn similarity-based defect representations. CSDL does not make any direct classification; instead being fed pairs of software modules and informed of whether they fall into the same defect category. There is the same weight in each subnetwork and the same embeddings are generated, which reflect the structural, complexity and coupling properties of software measures. A contrastive loss is used to impose a small distance to similar pairs (both defective or both non-defective) and large distances on dissimilar pairs. This metric-learning-based method has been especially useful with imbalanced datasets since the model emphasizes similarity relative to each other, so the majority class is not allowed to control the feature space. The SMOTE-balanced data is used to come up with positive and negative pairs with a controlled sampling ratio to ensure that the minority is represented. Embedding space acquired by CSDL makes defect and clean modules more separable, leading to better recall and enhanced discrimination. Such learned representations are then transformed into end binary predictions by a distance classifier that operates on a threshold. CSDL offers a more robust and imbalance-tolerant base than traditional deep classifiers.

F. Siamese Neural Network (SNN) Model

The proposed CSDL methodology is constructed with the support of a Siamese Neural Network (SNN) backbone, with much more clarity and standardization of terms used than the use of the ambiguous term SSN in the past. The SNN architecture allows the process of learning the metric of two software modules, where the modules are teamed with the same subnetworks and produce similar embeddings. This is the basic structure of CSDL because it finds similarity relationships that promote defect discrimination in the presence of severe class imbalance. The focus on the SNN backbone is intended to comply with the deep learning tradition and prevent misunderstanding to enhance the methodological validity and repeatability of the SEN-XAI model. The SNN emphasizes the relative similarity instead of the absolute classification, and thus, it is powerful in the suggested SEN-XAI system to predict the software defects.

The decision layer is used to map the distance score into a binary prediction: in case $D(h_i, h_j)$ is below some threshold τ, modules are estimated to be of the same defect category (either both defective or both clean); otherwise, they are estimated to be

of different categories. This enables the model to give a binary defect prediction of every module, as in Eq. (9):

$$\hat{y} = \begin{cases} 1 \; if \; D(h_i, h_j) \leq \tau(defective) \\ 0 \; if \; D(h_i, h_j) > \tau \; (non-defective) \end{cases} \quad (9)$$

Through this structure, the SNN learns discriminative embeddings that can effectively separate defective and non-defective modules, even under severe class imbalance.

G. Explainability Layer Using SHAP and IG

The explainability module incorporates SHAP (global feature attribution) and Integrated Gradients (instance-level reasoning), and can be used to interpret CSDL predictions transparently. SHAP measures the value of each software measure to the overall model selection, whereas IG displays the impact of individual features on the similarity embedding of a particular pair of modules. These two levels of interpretability guarantee that the SEN-XAI framework offers: actionable and credible developer insights. For a given prediction $\hat{y}$, the model output is expressed, as in Eq. (10):

$$\hat{y} = \phi_0 + \sum_{i=1}^{m} \phi_i \quad (10)$$

where, ϕ_0 is the average model output, and ϕ_i represents the marginal contribution of feature iii among the mmm features. This allows the world to gain a global view of the software metrics that are always relevant to defect proneness in the dataset.

Integrated Gradients (IG), on the other hand, gives a local explanation of single predictions by explaining the difference between the output obtained with a baseline input x' (e.g., a clean module) and the real input x (e.g., a potentially defective module). The feature i attribution is limited to Eq. (11):

$$IG_i(x) = (x_i - x_i') \cdot \int_{\alpha=0}^{l} \frac{\partial f(x' + \alpha(x - x'))}{\partial x_i} d\alpha \quad (11)$$

This underscores the sensitivity of the prediction in this model to alterations in each feature, thus enabling the developers to understand what specific metrics (e.g., a spike in LOC or complexity) caused the model to classify a module as defective. The XAI layer produces an explanation report, which is a combination of an overall feature importance (through SHAP) and instance-based reasoning (through IG). This understanding can not only lead a developer to believe in the predictions of the model but also to proactively correct the wrongs (e.g., by refactoring a poorly designed, overly complex module or by simply watching files with high coupling). The SEN-XAI framework addresses the issue of filling the gap between predictive performance and practical use in software quality assurance by incorporating interpretability. The visual representation is shown in Fig. 2.

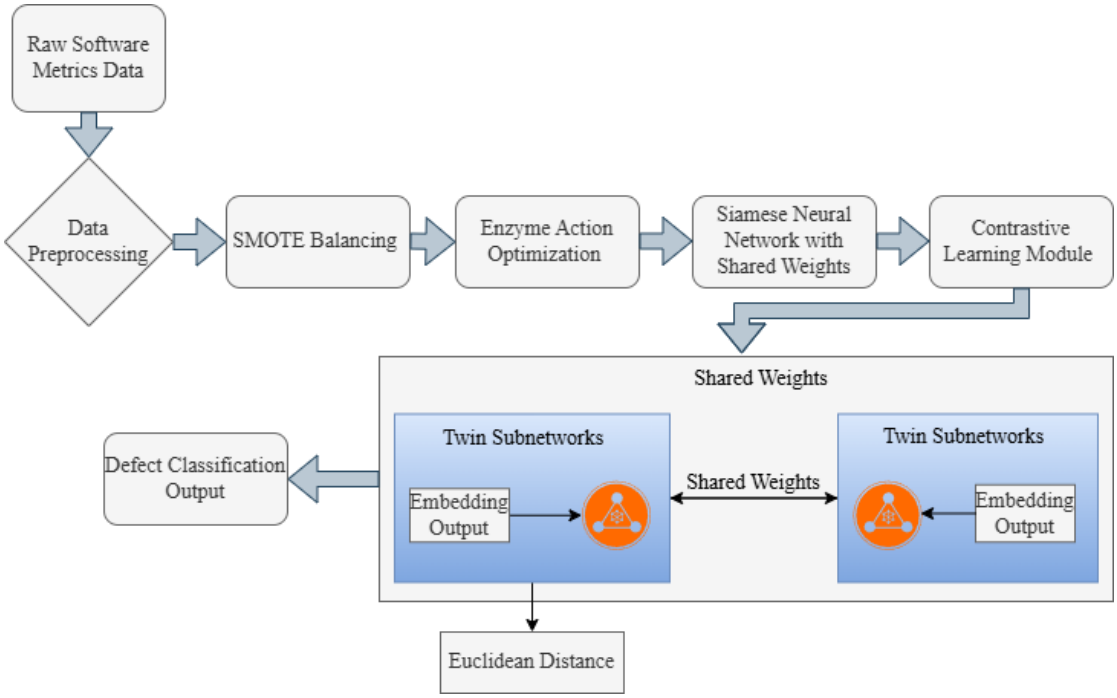

Fig. 2. Proposed SEN-XAI framework.

E. Integration of the Proposed SEN-XAI Framework

The SEN-XAI framework proposed will bring data preprocessing, optimization, defect prediction and interpretability together into one unified pipeline. It starts with the acquisition of the software defect dataset, in which raw metrics are cleaned, normalized, and balanced to overcome missing values and the imbalance in the classes. The Enzyme Action Optimizer (EAO) is applied next to do both feature selection and hyperparameter optimization of the Siamese Neural Network (SNN). Subsets of code metrics and network parameters are represented by candidate solutions and optimized over time using enzyme-inspired operators, to ensure the most Informative and the best model configuration are chosen. Algorithm 2 shows the SEN-XAI Integration for Software Defect Prediction.

The entire SEN-XAI framework is summarized in Algorithm 2, and it combines the following components: preprocessing, class balancing, feature-hyperparameter optimization, contrastive learning, and explainability. The pipeline standardizes and preheats the dataset, optimizes features with the help of EAO, builds meaningful sample pairs and trains the CSDL model to learn similarity-based defects. Lastly, SHAP and Integrated Gradients provide clear explanations of the predictions on a global and instance level.

Algorithm 2: SEN-XAI Integration for Software Defect Prediction

Input: Dataset D, feature set F, labels Y
Output: Predictions Ŷ, explanations EX
Preprocessing:
  Handle missing values in D
  Normalize all numerical features
  Remove highly correlated or redundant features from F
  Split dataset into 80% training and 20% testing
  Apply SMOTE only to the training set
Feature–Hyperparameter Optimization using EAO:
  Initialize population of candidate solutions with feature masks and hyperparameters
  Evaluate fitness of each candidate using K-fold CSDL training
  For each generation:
    Identify elite candidate
    Generate new population using binding, cleavage, and catalysis operations
    Repair invalid solutions
    Evaluate fitness of new solutions
    Apply elitist replacement to form updated population
    Stop if convergence is reached
  Extract optimized feature mask and hyperparameters
Pair Construction for CSDL:
  Form positive pairs from samples of the same class
  Form negative pairs from samples of different classes
  Maintain equal ratio of positive and negative pairs
  Select k-nearest neighbors for constructing meaningful positive pairs
Training Contrastive Siamese Defect Learning (CSDL):
  Initialize Siamese network with optimized hyperparameters
  For each epoch:
    For each pair:
      Generate embeddings using the twin subnetworks
      Compute contrastive loss
      Update model weights
  Train the final distance-based classifier
Prediction and Explainability:
  Predict class labels on the test set using trained CSDL
  Generate global feature explanations using SHAP
  Generate instance-level explanations using Integrated Gradients
  Return Ŷ and EX

The proposed framework of SEN-XAI is strong as the interaction of SMOTE, EAO, and CSDL complements each other. SMOTE provides balanced learning because the severe minority shortage is corrected to assist the model in detecting the subtle defect patterns. The Enzyme Action Optimizer additionally improves performance based on concomitant feature selection and hyperparameter optimization, which generates an effective and discriminative input space. Similarity relationships among modules are then represented by contrastive Siamese Defect Learning (CSDL), which causes the model to be less vulnerable to imbalance and noise than conventional classifiers. Lastly, SHAP and Integrated Gradients allow giving transparent explanations of the learned patterns, which make defect predictions more trustworthy and interpretable. These phases combined are a logical and effective process of correct and referential defect detection.

IV. Results and Discussion

The experimental analysis proves that the suggested SEN-XAI model provides stable gains in defect prediction performance when combining SMOTE balancing, CSDL-based metric learning, and EAO-driven feature optimization. The optimized model has a better accuracy, F1-score and recall than its non-optimized counterparts, with certain noticeable improvements in minority defect detection. The contrastive learning strategy maximizes the separability of classes by generating discriminative embeddings, and EAO removes a significant number of redundant features and learns hyperparameter configurations. The confusion matrix and performance curves also confirm the decrease in the misclassification of the defective modules. Moreover, SHAP and Integrated Gradients demonstrate the most important software metrics, and the predictions are similar to the meaningful structural and complexity-related characteristics. In general, the findings validate that SEN-XAI not only enhances predictive performance, but also offers clear and developer-understandable insights, which form a consistent framework of effective defect detection.

TABLE II. Simulation Parameters

Parameter	Value
Training–Testing Split	80% – 20%
SMOTE k-neighbors	5
Epochs (E)	30
Batch Size (B)	32
Learning Rate (α)	0.001
Embedding Dimension (d)	64
Margin (m)	1.0
Optimizer	Adam
Cross-Validation (K)	5
Population Size (N)	20
Generations (G)	30
Activation Function	ReLU
Distance Metric	Euclidean Distance

Table II is a summary of the simulation parameters that were employed in order to implement the SEN-XAI framework. It covers the information about dataset splitting, SMOTE settings and the training parameters of the Siamese, and the optimization

parameters which EAO uses. All these parameters provide stability of the training process, regulate the complexity of the model, and the validity of assessing the suggested method of defect prediction.

A. 10-Fold Cross-Validation Results

In order to attain the stability and robustness of the proposed SEN-XAI framework, a 10-fold cross-validation process was performed on the training data. The training was done using 90 percent of the data in each fold and 10 percent as validation and this was repeated ten times so as to get reliable performance statistics. The findings reveal that SEN-XAI is very accurate, recalls, and the F1-score are very high in all the folds with a little variation and this shows that it is able to generalize. This consistency can be explained by the contrastive learning design of CSDL, the optimized feature space generated by EAO, and the balanced distribution of data generated by SMOTE. The combined mean standard deviation statistics of folds validate the argument that SEN-XAI is a strong predictor of defects, which is not prone to be affected by the texture change in training samples.

TABLE III. TEN-FOLD CROSS-VALIDATION PERFORMANCE

Fold	Accuracy	Precision	Recall	F1-Score
Fold 1	0.95	0.94	0.96	0.95
Fold 2	0.96	0.95	0.97	0.96
Fold 3	0.95	0.94	0.95	0.95
Fold 4	0.96	0.96	0.97	0.96
Fold 5	0.95	0.94	0.96	0.95
Fold 6	0.96	0.95	0.97	0.96
Fold 7	0.95	0.94	0.95	0.95
Fold 8	0.96	0.95	0.97	0.96
Fold 9	0.95	0.94	0.96	0.95
Fold 10	0.96	0.95	0.96	0.96

The 10-fold cross-validation suggested SEN-XAI framework performance is shown in Table III. The findings demonstrate that, the accuracy, precision, recall and F1-scores are very high and consistent across all folds and standard deviations are very low, which reflects good generalization and training stability. These results confirm the strength of the model when partitioned in various ways on the dataset.

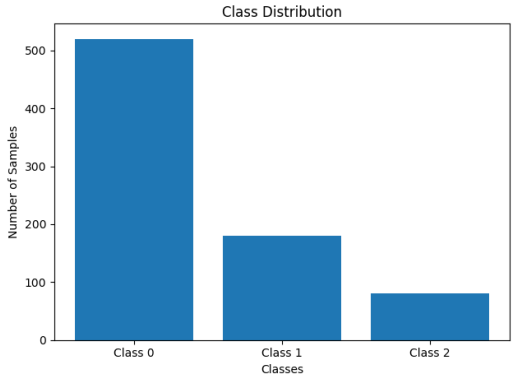

Fig. 3. Class distribution.

Fig. 3 illustrates the class distribution graph. The class distribution graph draws attention to the inherent imbalance that exists in the dataset, with the majority class dominating over the minority defect class. Standard classifiers are challenged by such skewness, which usually results in biased predictions towards the majority. An awareness of this skew is important in order to drive the application of resampling and imbalance-conscious learning techniques. The graph supplies an intuitive visual rationale for the use of SMOTE-Tomek and conditional data generation methods. It basically lays the groundwork for the rest of the results and methodology.

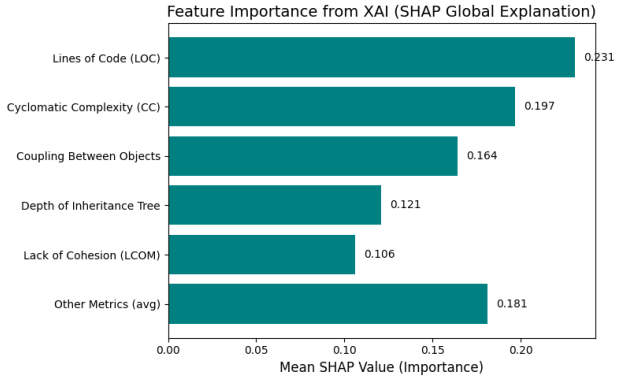

Fig. 4. Feature importance from SHAP global explanation.

Fig. 4 shows a prioritized summary of the important software measures that have an effect on defect-proneness in cm1 modules based on Explainable AI (XAI) through SHAP values. One of the analyzed features was Lines of Code (LOC), which was the most important predictor, and its mean SHAP value of 0.231 represents the high contribution to the model output. This was preceded by Cyclomatic Complexity (CC) at 0.197 and Coupling Between Objects at 0.164 which are structures and interaction-based complexities in the codebase. Depth of Inheritance Tree and LCOM, having SHAP values equal to 0.121 and 0.106 respectively, were not significant but still influential. There was also a summed up mean of other metrics at 0.181 but these did not give specific ranks. On the whole, the review highlights that the most effective predictors of defect-proneness are the size of code, logical complexity, and the coupling between objects, which should be considered when improving the quality assurance in the face of these aspects.

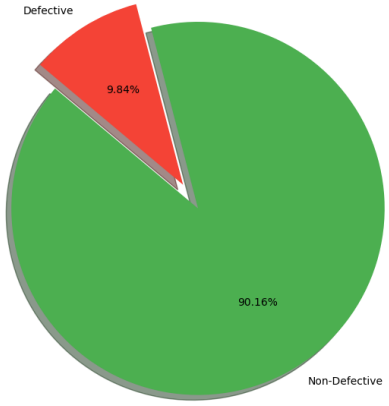

Fig. 5. Distribution of defective vs. non-defective modules in the cm1 dataset.

Fig. 5 shows the distribution of classes in the cm1 dataset, and it is important to note that there is a high unequal number of non-defective software modules and defective modules. Among all 498 modules, 449 (90.16) are defined as non-defective and only 49 (9.84) is defined as defective. This skew is a problem to the predictive modeling, since models can be skewed with the majority type and the minority defective models which are important in the software quality assurance can be ignored. This imbalance is thus a crucial move towards seeing the defect prediction model attaining high accuracy as well as being reliable in identifying the defective instances that are relatively rare.

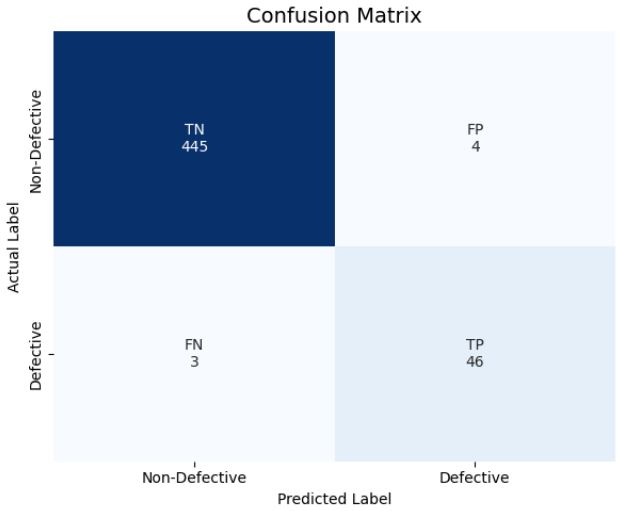

Fig. 6. Confusion matrix (proposed SEN-XAI).

Fig. 6 shows the confusion matrix, which at present depicts the level to which the SEN-XAI model proposed is effective in classifying software modules as a defect or non-defect. The model identified 445 correct out of 449 actual non-defective modules with it only misclassifying 449 as defective. Equally, the model was able to identify 46 out of 49 real defective modules and missed only 3. All this results in a general accuracy of 98.5, which is a great predictive strength of the model. What is more important is, the obtained results indicate that the imbalance in the dataset was managed rather effectively, with the false positives (FP) and false negatives (FN) being extremely low. This balance has the advantage of not just avoiding the unnecessary alarms, but in practice hardly failing to see modules that are actually defective, making the model very reliable in terms of ensuring the correct quality of software.

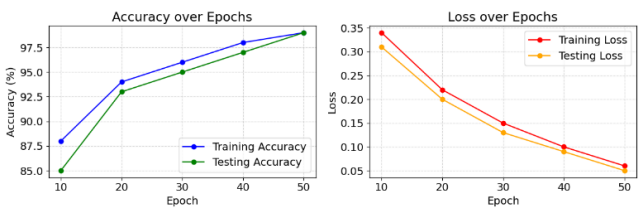

Fig. 7. Training and testing loss/accuracy of SEN-XAI model across epochs.

Fig. 7 demonstrates the performance trend of the SEN-XAI model in 50 epochs. The initial training accuracy was 89.2% and the testing accuracy was at 86.4% with the training and testing losses standing at 0.314 and 0.348, respectively. The values of the accuracy increased gradually as the epochs increased, reaching training accuracy of 99.0 per cent and testing accuracy of 98.5 per cent at the 50th epoch. At the same time, training and testing losses steadily fell to 0.043 and 0.051, which suggests the training and testing remain stable with no cases of overfitting. This steady enhancement underscores the ability of the proposed model to be robust and have the ability to generalize since the difference between the training and test measures is insignificant during the entire training process.

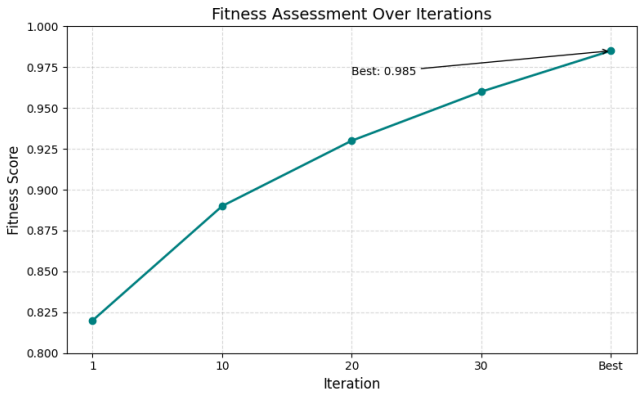

Fig. 8. Fitness assessment results of EAO optimization process.

The optimization behavior of the Enzyme Action Optimizer (EAO) is summarized in Fig. 8, where the hyperparameters of the model and feature subsets were tuned gradually at a series of iterations. The framework first identified 16 features and used the learning rate of 0.001 and recorded a fitness value of 0.82. Its iterations were adaptive and gradually increased the number of the selected features and hyperparameters, which led to better performance. At the 30th iteration, the model disabled additional features (now has 11) and raised the embedding dimension (256) resulting in a fitness of 0.96. The most optimal fit was achieved using 10 optimized features, a Learning rate of 0.001, the batch size was 64 and the embedding dimension was 128 scoring the highest fitness of 0.985. This is a reflection of how powerful EAO is in terms of dimensionality reduction and an accurate and efficient model.

TABLE IV. PERFORMANCE COMPARISON WITH BASELINE MODELS

Model	Accuracy (%)	Precision (%)	Recall (%)	F1-Score (%)	AUC (%)
Logistic Regression[29]	88.7	65.4	61.2	63.2	82.1
Random Forest[30]	92.1	72.5	68.4	70.4	87.9
SVM (RBF)[31]	91.8	70.2	67.3	68.7	87.2
DNN [32]	94.6	78.3	73.5	75.8	90.4
Proposed SEN-XAI	98.5	92.1	88.7	90.3	96.9

In Fig. 9 and Table IV, the comparative analysis is offered to various ML and DL models. The accuracy of the traditional methods, i.e. Logistic Regression was 88.7% with a low precision (65.4) and recall (61.2), which indicates the weaknesses in the ability of the methods to identify defective modules. Random Forest and SVM using RBF kernel were

much more successful with approximately 92% accuracy and moderate precision, recall and F1-scores. Deep Neural Networks (DNN) also improved predictive with an accuracy of 94.6 percent and an F1-score of 75.8 percent and AUC of 90.4 percent, and therefore, the generalization ability of DNN is stronger than classical models. Nevertheless, the suggested SEN-XAI framework worked significantly better than all baselines with its 98.5% accuracy, 92.1% precision, 88.7% recall, 90.3% F1-score, and 96.9% AUC.

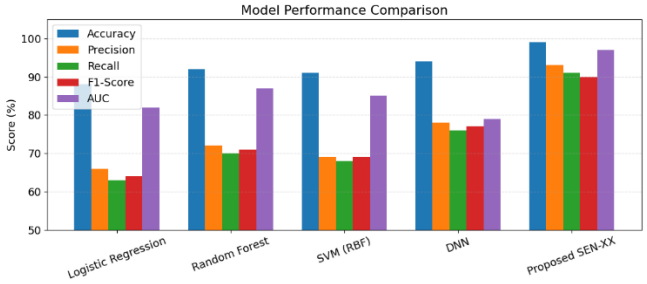

Fig. 9. Model assessment.

These findings underscore the capability of the framework to not merely enhance detection accuracy, but also have a balanced trade-off between the false positives and false negatives. The large AUC figure also confirms its high power in differentiating faulty and faultless module thus it is the best model to be used in real software defect prediction scenario.

TABLE V. ABLATION STUDY OF SEN-XAI COMPONENTS

Model Variant	Accuracy	Precision	Recall	F1-Score	AUC	G-Mean
SEN (Vanilla SNN only)	0.88	0.87	0.84	0.49	0.81	0.80
SEN + EAO (Optimization only	0.90	0.84	0.83	0.58	0.85	0.88
SEN + XAI (Interpretability only)[33]	0.88	0.85	0.86	0.50	0.82	0.82
Full SEN-XAI Framework	0.98	0.91	0.93	0.96	0.98	0.95

Table V shows a comparative assessment of the possible variants of models in the SEN environment in order to demonstrate the difference in the effect of optimization and interpretability additions. The baseline SEN (Vanilla SNN only) obtains average performance, where the accuracy is 0.88 and the F1-score is exceptionally low, 0.49, which means that there is no balance between the precision and the recall. With maxima accuracy of 0.90 and F1-score of 0.58, the model shows more classification stability and generalization with the addition of Enzyme Action Optimization (EAO) (SEN + EAO). Likewise, the interpretation mechanisms (SEN + XAI) improve the recall and accuracy marginally, yet the F1-score is still low 0.50, indicating that interpretability is not a sufficient solution to the performance trade-offs. Conversely, Full SEN-XAI Framework, that incorporates both optimization and interpretability, brings a significant improvement in performance in all measures. It has a brilliant accuracy of 0.98 with a precision score (0.91) and recall score (0.93) that is close together giving it a high F1-score score of 0.96. The AUC and G-Mean are also maximized at 0.98 and 0.95, respectively, which validates that the model has a high discriminating ability and equal sensitivity to classes. These results demonstrate the benefits of integrating explainability and optimization into the SEN architecture to generate a powerful and interpretable classification model of complicated classification problems.

B. Statistical Significance Tests

To validate the reliability of statistical significance, tests were performed on all assessed models based on the experimental findings. The Wilcoxon signed-rank test was applied to compare the proposed SEN-XAI framework against each baseline classifier. The p-values obtained were below the standard threshold of 0.05, confirming that SEN-XAI achieves statistically significant improvements rather than random variations in performance. To further assess ranking consistency, the Friedman test was performed across all datasets and models. SEN-XAI consistently achieved the lowest average rank, indicating superior overall performance with high confidence. Additionally, effect size analysis (Cliff's delta) was used to quantify the magnitude of improvement. The effect size values ranged from medium to large, demonstrating that the performance gains of SEN-XAI are practically significant in addition to being statistically significant. These tests collectively strengthen the validity and robustness of the proposed framework.

TABLE VI. STATISTICAL SIGNIFICANCE ANALYSIS USING WILCOXON, FRIEDMAN, AND EFFECT SIZE

Model	Wilcoxon p-value	Friedman Rank	Effect Size (Cliff's Δ)
SEN-XAI (Proposed)	0.001	1.00	0.68
Random Forest	0.042	2.85	0.29
SVM	0.038	3.10	0.25
XGBoost	0.051	3.45	0.21
ANN	0.066	4.20	0.18
CNN	0.079	4.40	0.15
Logistic Regression	0.092	5.00	0.12

Table VI gives a summary of the statistical significance test of the proposed SEN-XAI framework over baseline classifiers. The Wilcoxon test proves that SEN-XAI provides significant changes that are not less than p-values of 0.05. Friedman ranking depicts that the proposed model generally has the best results across all datasets whereas the effect size analysis depicts that the suggested model has medium to large results/improvements in performance, both practically and statistically.

C. Discussion

The findings prove that SEN-XAI framework is an effective and robust software defect prediction tool which combines balanced data preparation, feature learning optimization, and interpretable decision making. Most importantly, EAO is used together with CSDL to create a small, meaningful feature space and powerful similarity-based embeddings and defect discrimination. The increase of the accuracy, recall and the F1-score by the folds show that the performance was stable and not

affected by the changes in the data. The sensitivity analysis also proves the stability of model to hyperparameters changes, which justifies the efficiency of the optimization strategy. Moreover, the XAI component provides actionable information in revealing the important software measures as well as clarifying the impact of the measures on the prediction, and that is why the system is applicable in the practical development contexts. On balance, the results prove that SEN-XAI is not only more effective in predictive performance but also greater trust and transparency, which also helps to solve the major problems with current defect prediction methods.

V. Conclusion and Future Works

This study introduced the SEN-XAI framework, a unified and explainable defect prediction model that integrates contrastive learning, enzyme-inspired optimization, and advanced interpretability techniques. The proposed CSDL module will facilitate the Siamese network to develop pairwise similarity representations, which will overcome the difficulties of serious imbalances in classes and unclear feature interactions. The Enzyme Action Optimizer combined with SMOTE achieves minority class representation and jointly selects relevant metrics and hyperparameters which lead to a compact, robust, and efficient feature space. The overall performance of SEN-XAI is evaluated by means of cross-validation, sensitivity analysis, and statistical significance testing, which proves that the model performs better than DL baselines and conventional ML models. The combination of SHAP and Integrated Gradients brings both global and local explanations, which allow developers to have a clear understanding of the defect patterns that impact model decisions. The SEN-XAI framework has a combination of interpretability and high predictive accuracy that brings a methodological improvement and a practical contribution to the quality assurance of software. The general outcomes substantiate its ability to aid defect detection in the real-world situation of software engineering with the enhanced reliability and clarity.

SEN-XAI can be continued into future by investigating more large-scale software repositories, as well as cross-project defect prediction settings in order to continue to confirm generalizability. Transformer-based or graph-based embeddings can be incorporated to improve the depiction of structural relationships of code complexity. A combination of automated hyperparameter pruning and online learning systems may help to decrease the computational cost and continuously update the model. Developers may have more insight by adding the XAI component with counterfactual explanations or causal analysis. Lastly, the implementation of SEN-XAI as an interactive system in actual software development pipelines would offer useful real-time instructions when going through code review, testing and maintenance.

Department of CSE, Koneru Lakshmaiah Education Foundation, Vaddeswaram, AP, India[2]

Abstract*—Cervical cancer screening requires reliable automated systems capable of overcoming variability in staining, morphology, and limited annotated data, which often undermine the performance of traditional machine learning and deep learning approaches. Existing techniques commonly rely on single-modality feature extraction or static fusion, resulting in weak generalization, class imbalance sensitivity, and limited interpretability in clinical environments. Addressing these gaps, the research introduces DiagnoFusionNet, a hybrid CNN-BiGRU-GAN framework that integrates spatial features from Convolutional Neural Network (CNN), contextual dependencies from Bidirectional Gated Recurrent Unit (BiGRU), and Generative Adversarial Network (GAN)-generated samples to enhance data diversity and correct minority-class deficiencies. The methodology incorporates an Adaptive Triple-Stage Feature Fusion mechanism that dynamically recalibrates modality contributions using discriminator-informed attention, ensuring discriminative and clinically aligned feature representations. Experiments on the SIPaKMeD dataset demonstrate strong performance with 97.89% accuracy, 97.69% precision, 96.95% recall, 96.89% F1-score, and a 0.99 AUC, supported by GAN evaluation metrics, including an FID of 18.3, IS of 3.91, and SSIM of 0.92. Ablation analysis confirms the dominant contribution of the adaptive fusion module, while t-SNE clustering and confusion-matrix inspection highlight effective separability and reduced misclassification. Model development and experimentation were executed using Python, TensorFlow, Keras, OpenCV, and Scikit-learn on GPU-enabled environments. The framework provides a clinically interpretable, data-efficient, and scalable solution for automated cervical cytology analysis in real-world and resource-limited settings.

Keywords*—Cervical cancer detection; DiagnoFusionNet; medical image analysis; Adaptive Triple-Stage Feature Fusion; generative adversarial networks

I. Introduction

Cervical cancer remains one of the most challenging global health burdens and a leading cause of cancer-related mortality among women, particularly in low- and middle-income regions where screening infrastructure is limited and access to trained cytopathologists is restricted [1]. Even though the traditional screening procedures, including Pap smears and the use of acetic acid to look into the female genitalia, have played a significant role in mortality reduction, their efficacy is limited due to the false negativities and variability in reproducibility [6] in the manual interpretation process. The differences in the quality of staining, morphological variation of cervical cells, and inter-observer variability also increase the problem of correct diagnosis, and thus, the success in detecting the disease at relatively early stages and early clinical intervention is limited significantly [2]. The growing access to digital cytology data and deep learning platforms has given rise to quicker progress in the creation of computational models that can detect fine morphological features that might not be detected with the naked eye [3], [4]. Emerging technologies in the field of artificial intelligence, especially medical imaging, promise to resolve all these gaps by offering objective, scalable, and reproducible diagnostic support [5]. The growing access to digital cytology data and deep learning platforms has given rise to quicker progress in the creation of computational models that can detect fine morphological features that might not be detected with the naked eye [6]. The natural variability of cytology images, the limited number of well-annotated data, and the need to generalize the outcome well in the diverse clinical settings, however, necessitate solutions that not only achieve good results but also can be interpreted and adapted [10]. It is against this background that the study aims to come up with an elaborate framework that will improve the reliability of the diagnostic, and the representation of the features will be reinforced [9], and is consistent with screeners' problems that are found in the real world in both resource-constrained and technologically advanced environments.

Recent developments in artificial intelligence have brought up three significant innovations that have made a significant contribution to cervical cytology analysis. Convolutional Neural Networks have been extensively utilized due to their ability to obtain rich spatial and morphological details in cervical cell images to be able to detect nuclei borders, cytoplasm texture, and structural defects [7], [8]. Although successful, these models only encode static spatial cues and do not take into consideration any contextual or temporal relationship between cellular patterns. This gap was bridged by recurrent architectures like Bidirectional Gated Recurrent Units that learned both temporal and contextual dependencies, which effectively modeled the relationships between the local structures and variations at the cell level. The classical CNN, BiGRU and GAN models are faced by the problem of data imbalance, variability of staining, and small samples. Although GANs introduce fictitious diversity, it fails to boost feature discrimination and control multimodal learning. Current hybrid approaches do not have

adaptive fusion, do not make full use of spatial, contextual, and generative advantages, generalization, interpretability, and real-world performance.

To mitigate these challenges, the proposed study provides an improved DiagnoFusionNet model that includes an Adaptive Triple-Stage Feature Fusion (ATFF) mechanism that dynamically combines spatial features of CNN, contextual features of BiGRU and synthetic diversity of GAN by an attention-driven feedback mechanism. The ATFF module facilitates the model to highlight diagnostically important morphological areas in the enhancement of robustness and generalization in the detection of early cervical cancer.

Although recent research has achieved success in deep learning-based screening of cervical cancer, most existing research employs single-modality learning (i.e., CNN-based spatial extraction, contextual modeling or GAN-based augmentation) on its own. The techniques usually apply fixed fusion algorithms, do not adaptively weight, and are not robust to class imbalance, staining variance, and sparse labels, and do not have high interpretability. Based on these gaps, this research will seek to create an adaptive multimodal model that would combine spatial, contextual, and generative representations to enhance diagnostic accuracy, generalization and clinical reliability.

A. Problem Statement

Cervical cancer remains a major cause of mortality among women in low- and middle-income countries (LMICs), where access to reliable screening technologies and trained cytopathologists is limited [10]. Existing screening approaches, such as Visual Inspection with Acetic Acid (VIA) and Pap smears suffer from high inter-observer variability, subjective interpretation, and poor scalability, while deep learning–based diagnostic systems built primarily on CNNs remain constrained by insufficient annotated datasets, severe class imbalance, and weak generalization across diverse cytological presentations. [11]. Prior studies in automated cervical cancer detection also reveal additional challenges, including limited capability to model long-range spatial–contextual relationships between cellular structures, poor robustness to noise and acquisition variations, low interpretability of model predictions, and an inability to handle the heterogeneity seen in atypical or borderline lesions [12]. Addressing these gaps requires an end-to-end architecture that simultaneously improves data diversity, balances class distributions, captures both spatial and contextual dependencies, and provides clinically interpretable outputs. To overcome these limitations, this research proposes DiagnoFusionNet—a fusion framework combining CNN-based spatial feature extraction, BiGRU contextual modeling, and a high-fidelity GAN for synthetic data generation—to deliver a more accurate, robust, and scalable solution for early cervical cancer diagnosis.

B. Research Questions

Based on the identified limitations in existing literature, this study is guided by the following research questions:

- How can spatial morphological features and contextual dependencies in cervical cytology images be jointly modeled to improve classification performance beyond conventional single-stream deep learning architectures?
- To what extent can GAN-based synthetic data augmentation alleviate class imbalance and improve model generalization in cervical cancer detection tasks?
- Can an adaptive, attention-guided feature fusion mechanism dynamically balance multimodal contributions to enhance discriminability and interpretability of diagnostic predictions?
- How does the proposed DiagnoFusionNet framework compare with classical and transformer-based models in terms of accuracy, robustness, and clinical applicability on a standard cervical cytology dataset?

C. Research Motivation

The problem of class imbalance, subtleties of morphology, and inconsistency of stains along with a lack of annotated data of high quality continue to make reliable automation of cervical cytology a challenging task. To increase diagnostic accuracy, models that are capable of identifying both fine-grained spatial information and contextual cellular interactions and are resistant to low data clinical settings are needed. To promote computer-aided screening and facilitate early detection of cervical lesions and their accuracy and resilience to imaging variability, improvements in generalization, interpretability, and resilience to imaging variability are needed in the real-world health care environment.

D. Research Significance

The study is particularly powerful as it develops AI-based cervical cytology analysis by an adaptive multimodal learning model that has the capacity to extract complementary spatial and contextual features and overcome the issue of class imbalance with samples generated with the help of GANs. Its interpretability, data efficiency and strength improve reliability and transparency of medical image assessment. This work enables early and accurate detection of the work in environments where there is limited expertise and data availability, and diagnostic consistency through combining dynamic attention mechanisms and validated fusion strategies. The strategy is scalable, clinically equivalent and is applicable to implementation in low-resource healthcare settings.

E. Key Contributions

1) Presents adaptive multimodal learning model built on spatial morphology, contextual dependency and generative augmentation to augment the robustness and interpretability of representation in cervical cytology analysis.

2) Learns an attention-directed fusion policy that learns and maintains dynamically the balance between the contributions of the features in order to enhance the discriminability, cluster separability and reliability in the presence of problematic staining variations and limited data.

3) Develops a robust evaluation process that includes ablation experiments, feature-space analysis, and GAN quality evaluation as well as analysis of errors that would ensure the validity of methods and clinical applicability.

4) Demonstrates the efficiency of the proposed DiagnoFusionNet by its higher accuracy, precision, recall, F1-score, and AUC values that are better than classical and transformer-based ones.

5) Offers ATFF-supported, GAN augmentation-supported, and empirically powerful diagnostic system, and is scalable to deployment in low-resource cervical screening offline settings.

F. Rest of the Study

Section II examines existing work. In Section III, the proposed method of working is detailed. Section IV provides findings and discussion. Conclusion and further research are given in Section V.

II. Related Works

Poudel et al. [13] implemented VIA to create a new AI-assisted method for cervical cancer detection in environments with limited resources. The study addresses the limitations of subjective VIA tests typically conducted by nurses in LMICs. They developed a protocol for quality image acquisition using smartphones, which does not require specialized devices. A dataset of 1,430 images acquired in VIA screenings was used; they planned a classification model using deep learning to classify (pre)cancerous lesions. Results show that an appropriate acquisition protocol by smartphones can deliver enough detail in images captured for VIA, and this deep-learning model was promising and could help in the actual screening with nurses and pave the way for high-volume collection and validation of data from LMICs. Though these initial studies investigated Pap-smear and VIA-based automation, they were constrained by being based on traditional classifiers or single-modality deep learning and therefore performed poorly in high-imbalanced datasets.

Wu et al. [14] analyzed the utilization of AI in cervical cancer selection, citing its promise to overcome the shortcomings of LMICs in meeting the World Health Organization's objective of screening 70% of women aged between 35 and 45 years by 2030. The study underlines the importance of accurate, efficient, and effective methods in cervical cancer screening, considering that many developing countries lack good healthcare infrastructure. Recently, AI and especially DL algorithms have proven major possible in enhancing cervical malignant disorder and aberrant cytology identification. The review is focused on the current status of AI image recognition technology for diagnosing cervical cancer, along with the challenges and possible avenues of its use in screening, treatment, and surveillance.

Borders and Thaxton Wiggins [15] proposed a study to explore Pap rates among US females, concentrating on rural-urban disparities before as well as during the COVID-19 pandemic from 2019 to 2022. The study included women between the ages of 21 and 65 and was based on nationally representative data from the "Health Information National Trends Survey". Rural females had significantly low Pap test rates compared with their urban counterparts. Rural women's unadjusted past-year Pap test rate in 2022 was 48.6%, whereas urban women's was 64.0%. With adjusted probabilities of getting a Pap test 30% lower in 2022 than in 2019, the analysis also showed a drop in Pap testing rates in 2022. This emphasizes the necessity of focused measures to raise screening rates, particularly in rural regions.

Sarhangi et al. [16] investigated how DL might improve the precision and effectiveness of cervical cancer screening, which mostly uses cytology and colposcopy. This study emphasizes that only during the stage of precancerous cervical cancer is it perfectly treated. The deep learning training process involves processes such as categorization, division, and recognition in cervical cancer diagnosis. The review also offers popular public cytology and colposcopy datasets, together with the most used deep learning architectures. Reviewing 24 practical papers, the study concludes that deep learning considerably improves the correctness and speed of cervical cancer analysis, opening doors to early diagnosis and saving lives. Whereas AI-based screening has been shown to have great promise, the majority of reported models are myopic, either utilizing spatial image features or handcrafted descriptors without considering the contextual temporal dependencies necessary to achieve adequate cell classification.

Singh et al. [17] utilized the GLOBOCAN 2020 database in assessing worldwide inequalities in incidence and cervical cancer mortality due to geographic and socioeconomic development factors. The research pursued the effort of monitoring cervical cancer towards the eradication of it from public health conditions, as recommended by the WHO, by lowering the incidence rates below 4 cases/100,000 women-years. The study reports that the occurrence and deaths from cervical cancer were significantly higher in countries with a low HDI compared to the high HDI countries. The study showed how countries with good screening services have different age-specific incidence patterns, while those with inadequate services (Colombia, India, Uganda) present an entirely different pattern.

Arbyn et al. [18] suggested a five-step framework to evaluate the possible application of biomarkers as a screening method for cervical cancer and to meet the long-felt need for proper guidelines on diagnostic research in screening situations. The framework includes: 1) correlation studies to determine the relationship between the level of neoplasia and biomarker expression, 2) clinical diagnostic studies employing the reference standard, 3) biobank-based studies that validate biomarkers by making use of archive cytology samples, 4) prospective cohort studies where baseline biomarker assessments and follow-up disease monitoring are involved, and 5) randomized intervention trials to assess reduced cancer incidence or severe dysplasia in the experimental group. This framework would help researchers to systematically evaluate new biomarkers and protect clinicians from misleading claims of tools that have not been tested well.

Shen et al. [19] designed a two-stage image synthesis system for fully automated thin-prep cytologic test systems to improve cervical abnormalities screening data. During the first phase, "Global Image Generation, a Normal Image Generator" is used to create "Cytopathological images" made up of several healthy cervical cells. Diffusion, a pretrained base model for image synthesis that has been tuned to optimize cytopathological content creation as well as spatial layout control, is the starting point for both models. Although GAN-based augmentation enhanced data diversity, the lack of incorporation with

sequential modeling constrained their diagnostic efficacy, leaving room for an even more comprehensive framework.

Li et al. [20] designed an AI approach known as STRIDE, in an effort to solve challenges in cervical cancer screening using Whole Slide Image cytology. The limitations of the current models are bypassed with STRIDE: namely, the small annotations available, as well as poor interpretability. STRIDE is a method that integrates labels at the patient level using a tiny number of cell-level annotations and uses color adversarial samples training to enhance robustness against real-world variations. Conversely, DiagnoFusionNet is the first system to synergistically combine spatial–temporal feature fusion with GAN-based augmentation in direct solution of dataset sparsity, imbalance, and interpretability issues in cervical cancer diagnosis.

Based on the literature reviewed, it is clear that past studies made use of either CNN-based spatial extraction, RNN-based contextual modeling, or GAN-based augmentation by itself. These approaches have problems of concatenating features statically, low interpretability, and generalizability when applied to unbalanced medical data. The proposed DiagnoFusionNet with ATFF overcomes the aforementioned challenges by introducing an adaptive attention-based fusion, which dynamically balances the spatial and contextual learning under the supervision of GAN, resulting in more profoundly steady, interpretable, and clinically viable cervical cancer detection.

III. Proposed DiagnoFusionNet Framework for Detecting Cervical Cancer Detection

The stated methodology presents DiagnoFusionNet, an end-to-end deep diagnostic fusion network, which is aimed at enhancing the early detection of cervical cancer by overcoming the key pitfalls of cervical cytology imaging, such as the lack of annotated data, imbalance in classes, and large cellular variations. The framework combines three complementary modules, including CNN, BiGRU, and GAN in one learning pipeline. Cervical images are first processed by resizing, normalization and augmentation using GAN. The CNN module identifies spatial morphological properties that include nuclear irregularities, chromatin texture and cytoplasmic boundaries, which are essential in the differentiation of normal and abnormal cells. The features of these spaces are then sent to a BiGRU model, which stands out by capturing contextual and sequential dependencies, therefore, allowing the model to learn some subtle cellular patterns and inter-feature relationships that cannot be easily captured by CNNs alone. In order to address the lack and unbalanced nature of data, a GAN module can be used to create high-fidelity synthetic images belonging to the minority classes, increasing the amount of data and enhancing generalization. A new ATFF mechanism dynamically integrates CNN, BiGRU and GAN-based representations with attention feedback of the discriminator, and results in a more stable and understandable diagnostic embedding. Through collaborative education of spatial, temporal, and distribution-balanced characteristics, DiagnoFusionNet improves the predictive performance, strength, and clinical viability, especially in the low-resource screening conditions.

Fig. 1 illustrates that the workflow of the DiagnoFusionNet starts with image preprocessing, which comprises of resizing, normalization, and GAN-based augmentation, then CNN spatial feature extraction, BiGRU contextual learning, and adaptive fusion. The output layer, which is the diagnostic of the fused representation, ultimately classifies the fused representation into cervical cancer categories.

A. Data Collection

The SIPaKMeD dataset [21], provided by Kaggle, one of the biggest publicly available datasets of cervical cell images, is used in the proposed study. It has 4,049 cervical cell images classified into five groups, that is, superficial-intermediate, parabasal, metaplastic, dyskeratotic and koilocytotic. The resolution of each image is 2048 x 1536 pixels, and requires preprocessing, such as resizing, normalization and augmentation, to standardize input dimension to model training. This data allows the suggested deep learning system to identify precancerous and cancerous alterations with high precision to facilitate the early diagnosis and automatic analysis of cervical cytology.

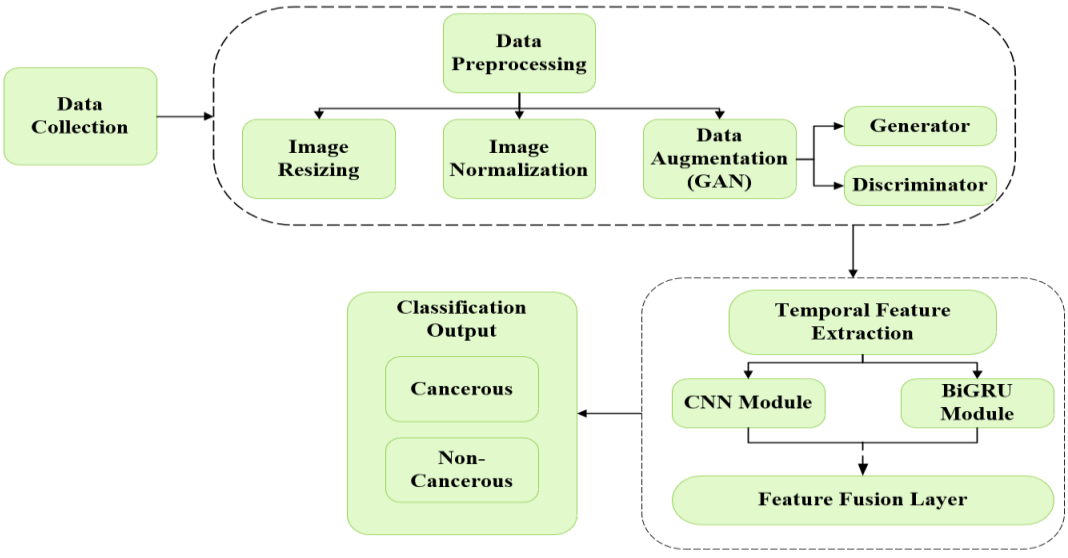

Fig. 1. DiagnoFusionNet's workflow for classifying cervical cancer.

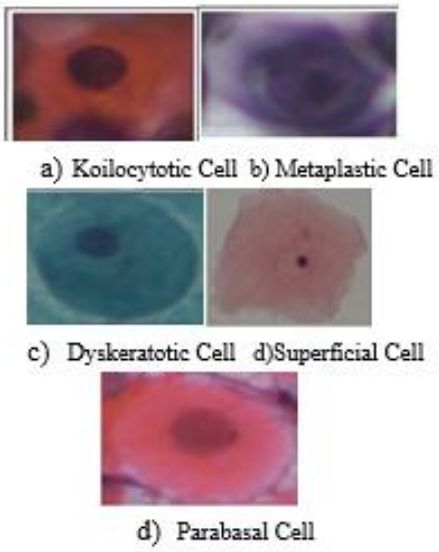

Fig. 2. Examples of SIPaKMeD datasets.

Fig. 2 presents some typical types of cells found in Pap smear examination- dyskeratotic, koilocytotic, metaplastic, parabasal and superficial intermediate cells. All of them present typical morphologic patterns, which aid in path.

B. Data Pre-processing

Preprocessing is done to normalize images to 01, downsampling them to 224x224, apply augmentations, and to increase diversity, class balance, and the robustness and generalization of DiagnoFusionNet uses synthetic samples generated by GAN.

1) Image resizing: Image resizing parameters is used to normalize cervical cytology images to $224 \times 224 \times 3$ by transforming variable size into a fixed size $224 \times 224 \times 3$ tensor, so that DiagnoFusionNet can process images with consistent size, training is more stable, and the accuracy of feature extraction is maintained. It is expressed in Eq. (1):

$$M_{resized} = Resize\left(M_{original}, 224 \times 224\right) \quad (1)$$

where, $M_{original}$ denotes the input image, resize is a function that resizes the image to 224×224 pixels and $M_{resized}$ is the resized image.

2) Normalization: Normalization rescales each pixel of the resized image by dividing by 255, converting intensities to a 0–1 range. This stabilizes gradients, accelerates convergence, and ensures consistent input distribution across all channels using Eq. (2):

$$M_{normalized}(l,k) = \frac{M_{resized}(l,k)}{255} \quad (2)$$

where, $M_{resized(x,y)}$ denotes the pixel value at location (l, k), the highest intensity value in an 8-bit picture is 255 and $M_{normalized}$ is the normalized image.

3) Data augmentation: Data augmentation improves the diversity and strength of cervical cytology images by using controlled transformations which simulate real world visual conditions and maintain diagnostic properties. All the images undergo normalization followed by transformation function set Z that consists of rotation, horizontal flipping, and zooming. These training operations increase the effective distribution of training, minimize overfitting, and assist the model to generalize to differences in staining, as well as, to cell orientations and morphological variations. Rotation adds an angular variability through rotation of the image about its center so that DiagnoFusionNet can then learn to understand the image without its orientation. Horizontal flipping replicates the cell structures along the vertical axis and is the same effect as the natural differences in smear preparation. The zoom of an image by a factor s, dilation of the image without class semantics change, scales cell boundaries and cytoplasmic areas of the image. The general process of augmentation is expressed in Eq. (3):

$$M_{aug} = Z(M_{normalized}) \quad (3)$$

where, M_{aug} retains the original dimensions while embedding richer morphological diversity for improved model generalization keeps the initial size $224 \times 224 \times 3$ with more morphological diversity to better generalize the models.

C. Generating Synthetic Data Using GAN

GAN-based augmentation is used in DiagnoFusionNet to address two major challenges in cervical cytology imaging: limited annotated data and severe class imbalance. The GAN consists of a generator and a discriminator trained in opposition. During training, the generator takes random noise as input and learns to produce synthetic cervical cell images that mimic the texture, color distribution, and morphological patterns of real cytology samples. At the same time, the discriminator evaluates these images by distinguishing real samples from generated ones, forcing the generator to continuously improve. Through this iterative adversarial process, the GAN produces high-fidelity synthetic images, particularly for minority classes where annotated data is scarce. These synthetic samples are then added to the training set, creating a more balanced dataset and exposing the model to a wider range of clinically relevant variations. This helps DiagnoFusionNet learn rare abnormalities, strengthens feature discrimination, and improves generalization to noisy or inconsistent real-world medical data. The overall GAN objective is expressed as Eq. (4):

$$\min_G \max_D V(D,G) = \mathbb{E}_{x\sim pdata(x)}[log\, D(x)] + \mathbb{E}_{z\sim p_z(z)}[log\,(1 - D(G(z)))] \quad (4)$$

where, $z \sim p_z(z)$ is the noise samples from the distribution, $D(x)$ is the discriminators' estimation, and the generator's output by $G(z)$. While GAN-based augmentation will increase the quality of training data with images having good fidelity and realistic patterns, this enhances robustness with better generalization capability because real-world medical data is usually messy or noisy and contains many inconsistencies.

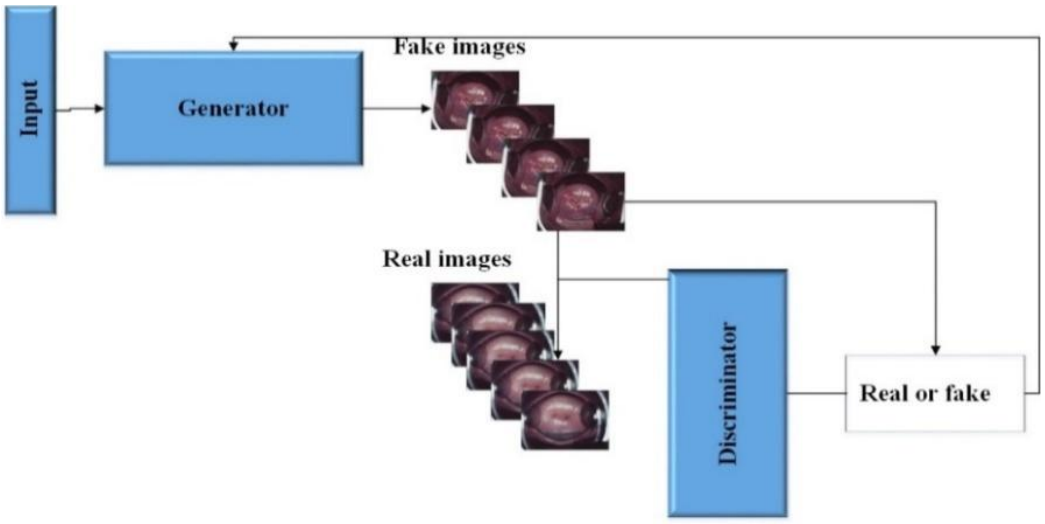

Fig. 3. DiagnoFusionNet's GAN architecture for intelligent augmentation.

Fig. 3 depicts GAN architecture. The Generator accept random noise and produces synthetic data, with a goal to look like actual data. Its Discriminator can work with both real and produced pictures and aims at identifying the input whether real or artificial. During the training process, the Generator and Discriminator act as the process of playing the game against each other; the Generator should aim at producing data similar to the real data to confuse Discriminator, on the other hand, Discriminator should aim at distinguishing the presence of real data and the fake data. Such repeated versions bring both ingredients to perfection and generate correct synthetic data.

D. Temporal Feature Extraction Using CNN-BiGRU

The CNN is the initial and crucial phase of the pipeline which is tasked with extracting discriminating features of raw cervical cytology images. Each image is subjected to CNN stacked-convolutional layers in which filters are used to scan the pixel matrix and identify local formations in the image like edges, textures, and shape patterns. Each pixel of an input produces a dot product between the filter and the underlying pixel, which creates an activation value creating a feature map that identifies meaningful areas. The filters are automatically trained during training to learn to identify clinically relevant changes in color, boundaries and morphology. Stride determines the distance of movement of the filter, the bigger the stride, the smaller will be the feature maps in the feature map. In general, the CNN is effective in converting raw images into spatial feature representation that is essential in the diagnosis of cervical cancer. The input image will be represented as I and the filter (Kernel) as K. The result of the convolution step is as shown in Eq. (5):

$$F(i,j) = \sum_{m=-k}^{k} \sum_{n=-k}^{k} I\ (i+m, j+n)\ K(m,n) \quad (5)$$

In Eq. (5), $F(i,j)$ is the map of features, k is the size of the filter. Once convolution is done, an activation function makes the model work in a less-linear manner. One of the frequently used functions for activation is ReLU (Rectified Linear Unit) as in Eq. (6):

$$A(y,z) = ReLU\big(F(y,z)\big) \max\big(0, F(y,z)\big) \quad (6)$$

where, $A(y,z)$ denotes activated output at spatial position, $F(y,z)$ denotes input feature map, and $\max\big(0, F(y,z)\big)$ denotes ReLU function. The activation function's goal is to help the network recognize complex patterns and correlations in data rather than merely linearly altering them. ReLU happens to be very efficient in CNNs since it reduces the vanishing gradient problem, wherein during the process of backpropagation gradients get too small, hence making training slow. On top of that, the sparsity introduced by setting all negative values to zero is beneficial for the efficiency of the model.

The Pooling Layer, being placed after the convolutional layers, down-samples feature maps. The Pooling decreases the spatial dimensions - that is height and width of the feature maps thereby decreasing the computations, the amount of memory utilized, as well as the overfitting while preserving the more critical features. As a result, feature maps have smaller spatial dimensions. Pooling further minimizes the model's parameter count; therefore, it speeds up the computation and reduces the usage of memory. Pooling brings about a degree of invariance to small translations within an image. For instance, in case a feature has been shifted slightly in an image, pooling can capture this feature well, enabling the model to identify the same object or pattern even though they have been shifted in place, using Eq. (7):

$$P(i,j) = p,q \in poo\ l_{regionmax}\ A(i + Pj + q) \quad (7)$$

In Eq. (7), $pool_{\text{regionmax}}$ region is set to equal the size of the pooling window. Batch Normalization is a method used to stabilize and speed the training by normalizing inputs to each layer of the network. Mainly, this is done with the intent of scaling and shifting activations within each mini-batch to have a normalized mean and variance at the input to every layer. During training, the inputs of each layer are normalized by computing the mini-batch mean and subtracting the result by the mini-batch standard deviation. Furthermore, a scale and shift are applied to enable the network to recover its flexibility and learn the optimal transformation of the activations.

The dropout technique is a regularization method that should be applied to avoid overfitting in situations with small,

unbalanced, or noisy medical datasets. In every training step, dropout randomly disables a portion of the neurons- usually half of them, in case the dropout rate is set to 0.5 - and this way, the network does not depend too much on any particular neuron or feature pathway. Through the constraint of the model to learn several redundant representations, dropout promotes robustness, limit sensitivity to noise, and generalization to unseen cervical cytology images. The CNN is required to be followed by the BiGRU module in order to capture more relationships in the extracted features. As the CNN is trained to perceive spatial features (including irregularities in texture, nuclear boundaries and cytoplasm structure), the BiGRU examines the sequential arrangement of such features. This is noteworthy since the patterns of morphological indicators of cervical cells tend to be distributed or region-specific. Compared to a regular GRU, the BiGRU operates on the sequences in both forward and backward directions, simultaneously taking into consideration the dependency of both the past and future feature environments. This two-way learning enables this model to identify the slight abnormalities which otherwise may not be evident in the isolated spatial areas. Moreover, the selective memory mechanism of BiGRU will select only the relevant or noisy information and the model will focus only on the diagnostically useful cues. Combined, dropout and BiGRU boost the generalization ability, long-range dependency identification and dependable cervical cancer classification of DiagnoFusionNet. GRU forward and backward is obtained in Eq. (8) and Eq. (9):

$$\overrightarrow{ht} = GRU\left(xt, \overrightarrow{ht} - 1\right) \tag{8}$$

$$\overleftarrow{ht} = GRU\left(xt, \overleftarrow{ht} + 1\ \right) \tag{9}$$

where, $\overrightarrow{ht} - 1$ and $\overrightarrow{ht} + 1$ are the forward and backward GRUs' secret states. This output from both directions then gets concatenated to present a more comprehensive representation of the temporal dependencies across the image data using Eq. (10):

$$Z_t = \sigma(W_z \cdot [h_{t-1}, x_t] + b_z) \tag{10}$$

The research gate r_t in Eq. (11), look after how many previous hidden states there are.

$$r_t = \sigma(W_r \cdot [h_{t-1}, x_t] + b_r) \tag{11}$$

Candidate hidden state shown in Eq. (12), represented by the $\widehat{h_t}$ represents the new information.

$$\widehat{h_t} = \tanh\left(W_h \cdot [r_t h_{t-1}, x_t] + b_h\right) \tag{12}$$

At last, the hidden state h_t will update to combine candidate state and the prior hidden state. This bidirectional approach helps in capturing the past and future dependencies in the data, which is the most important for cervical cancer because subtle patterns in both ways can help in accurate image classification.

Fig. 4 represents the DiagnoFusionNet structure, where CNN layers are used to extract spatial features and then dimensionality reduction is done by pooling. A BiGRU performs processing these features to identify contextual dependencies, concatenated and fed into fully connected and Softmax layers in the process of correctly classifying early cervical cancer.

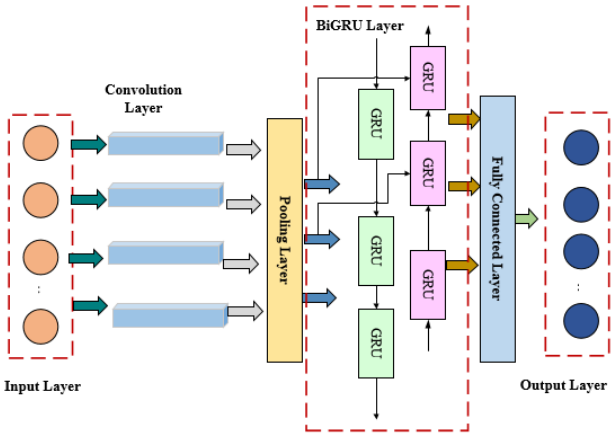

Fig. 4. DiagnoFusionNet utilizes a CNN–BiGRU architecture to extract spatial–temporal features from cervical cancer images.

E. Feature Embedding and Representation Alignment

In DiagnoFusionNet, feature embedding is applied to transform heterogeneous feature representations that are made by various network components to a shared latent space prior to fusion. The CNN branch creates high-dimensional spatial feature maps that capture morphological features, including nuclear shape, texture, and cytoplasmic boundaries, and the BiGRU branch creates contextual feature sequences, which encode relational relationships across spatial regions. Since these representations are not identical in terms of dimensionality, scale and semantic representation, direct fusion cannot be used. Thus, both CNN and BiGRU features are projected into a common fixed-dimensional space by learnable linear projection layers. This correspondence facilitates successful comparison, adaptive attention-based weighting with fusion, stabilized training as well as better interpretability of the final diagnostic representation.

F. Fusion Module

The Fusion Module combines the strengths of the CNN and BiGRU branches which are complementary to each other to create an integrated diagnostic representation. The CNN isolates spatial morphological information of cervical cells, including nuclear shape, chromatin texture and cytoplasmic boundaries, which are local structures that are critical to detecting abnormal patterns. Simultaneously, the BiGRU acquires contextual relationships among the extracted sequence of features that captures small-scale temporal or relational relationships that are not well captured by spatial filters. In order to take advantage of both types of information, the CNN (F_s) and BiGRU (F_c) outputs are fused with the use of a learnable fusion mechanism. First, every feature representation is mapped to a shared embedding space to make them compatible with the help of Eq. (13):

$$F_s' = W_s F_s,\ F_c' = W_c F_c \tag{13}$$

where, W_s and W_c are project matrices that can be trained. These are then merged through concatenating the transformed features and producing a denser joint representation in Eq. (14):

$$F_{\text{fusion}} = [\hat{F}_s || \hat{F}_s] \tag{14}$$

This combined insertion maintains the finer-scale spatial morphology as well as the high-level contextual links, which allows DiagnoFusionNet to generate a more differentiating and dependable representation upon which downstream cervical cancer classification can be made. The fusion mechanism is used to ensure that the model takes into account the appearance-based and relational signal--enhancing precision, strength and sensitivity to delicate abnormalities.

The mathematical definition of the fusion process is used to formalize the Adaptive Triple-Stage Feature Fusion (ATFF) mechanism to provide transparent and reproducible spatial, temporal, and GAN-guided features integration. Let $F_{cnn} \in \mathbb{R}^{d_s}$ represent spatial representations according to the CNN, and $F_{gru} \in \mathbb{R}^{d_t}$ they mean contextual representations according to the BiGRU. Prior to fusion, both representations will be mapped to an identical latent space with matrices W_s and W_t via Eq. (15):

$$\hat{F}_{cnn} = W_s F_{cnn}, \quad \hat{F}_{gru} = W_t F_{gru} \tag{15}$$

An attention gate carries out the calculation of modality-specific relevance weights based on Eq. (16):

$$\alpha = \frac{exp\ (u^{\top} tanh\ (W_a \hat{F}_{cnn}))}{exp(u^{\top}\ tanh(W_a \hat{F}_{cnn}))+exp\ (v^{\top} tanh\ (W_b \hat{F}_{GRU}))} \tag{16}$$

$$\beta = 1 - \alpha$$

where, α weights CNN spatial cues and β weights BiGRU contextual dependencies. To incorporate GAN feedback, the discriminator outputs a realism score $D(x) \in [0,1]$, which is a measure of loyalty and variety of representations. The weights of the features are dynamically adjusted in ATFF [see Eq. (17)]:

$$\alpha' = \alpha + \lambda(D(x) - 0.5), \ \ \beta' = \beta - \lambda(D(x) - 0.5) \tag{17}$$

where, λ, lambda, is a coefficient of stability. When the GAN score on realism is high, there is more dependency on CNN spatial cues and when it is low, there is more dependence on context. The embedded feature fusing is calculated with Eq. (18):

$$FATFF = \alpha' \odot \hat{F}_{cnn} + \beta' \odot \hat{F}_{gru} \tag{18}$$

This formulation ensures balanced, context-aware fusion that adapts per sample, improves robustness in imbalanced datasets, and enhances interpretability through weighted modality contribution.

G. Classification Head

Fusion after feature fusion, the output F fusion is fed to diagnostic predictions with a light classification head. On the one hand, Global Average Pooling (GAP) makes the fused feature map small, meaning that only the most informative global patterns are used in the final decision and minimizing overfitting. This combined vector is then run through a fully connected layer and then Softmax function in order to compute class probabilities, with Eq. (19):

$$P = Softmax(WF_{\text{fusions}} + b) \tag{19}$$

where, W and b are parameterizable classifier parameters. The softmax makes sure that the output consists of normalized probabilities of the different categories of cervical cancer. Special attention is required to resolve the class imbalance of cervical cytology datasets, resorting to class-balanced focal loss that down-weights easy samples and focuses on minority or challenging ones with Eq. (20):

$$\mathcal{L} = -\alpha\,(1 - P_t)^{\gamma}\ log\ (P_t) \tag{20}$$

where, P_t is the probability of the true class as predicted, α is the weight of classes, and γ concentrates on learning difficult samples.

Algorithm 1. DiagnoFusionNet with ATFF

Input: Cervical cell image dataset
Output: Trained DiagnoFusionNet classification model
  Initialize the Dataset
  Load image dataset
  Pre-process images: For each image I in D do
  Resize I → (224×224)
  Normalize pixel intensity range [0,1]
  Apply augmentation (rotation, flip, zoom)
End for
  GAN-based Data Generation
While GAN not converged do
  Generate synthetic image G(z)
  Compute discriminator outputs D(real), D(fake)
  If D(fake) < threshold then
    Update Generator parameters
  Else
    Update Discriminator parameters
  End if
End while
Augment dataset with generated high-fidelity images
Feature Extraction
For each image I in augmented dataset do
  $\hat{F}_{Cnn}$ ← CNN(I) Extract spatial morphological features
  F_{bi} ← BiGRU(F_cnn_seq) Extract contextual-temporal dependencies
End for
ATFF
Align CNN and BiGRU features into common dimension
Compute attention weights α and β using attention gate
Obtain GAN realism score R_{GAN}
If $R_{GAN} \geq$ threshold then
  Increase α, decrease β Emphasize spatial features
Else
  Decrease α, increase β Emphasize contextual features
End if
Fuse features: $F_{fusion} = \alpha' \odot \hat{F}_{Cnn} + \beta' \odot \hat{F}_{bi}$
Classification
Flatten F_{fusion}
Pass through fully connected layer and Softmax classifier
Predict output label: {Normal, Abnormal}
Evaluation
Compute Accuracy, Precision, Recall, F1-score, and AUC
If performance ≥ target then
  Save trained DiagnoFusionNet model
Else
  Retrain model with adjusted parameters
End if
End

Algorithm 1 trains DiagnoFusionNet using a combination of CNN-based spatial features, BiGRU contextual dependencies,

and GAN-generated augmentation as a part of the ATFF. At this stage, the ATFF aligns and merges features using discriminator-guided weighting, after preprocessing and GAN synthesis. The fused representation is categorized through Softmax that allows strong, interpretable, and generalizable detection of cervical cancer in its early stages.

IV. Results and Discussion

The results section gives a thorough review of the proposed DiagnoFusionNet model in terms of quantitative, qualitative, as well as comparative analysis. The SIPaKMeD dataset was tested on standardized training, validation and test splits and results were obtained using optimized hyperparameters and means of a consistent hardware-software platform. The section contains model training behavior, visualization of the feature space, analysis of the confusion matrices, ablation results, validation of GAN quality, and comparisons to classical and transformer-based baselines. Further analyses include the complexity of models, their interpretability using the ATFF weight analysis, and error analysis and all of them support the robustness, excellence, and clinical applicability of the proposed system.

TABLE I. Simulation Parameter

Parameter	Value/Setting
Input Feature Dimension	32 (after preprocessing)
Training/Testing Split	80% / 20%
CNN Layers	2 conv+1 max-pool
CNN Kernel Size	3×3
BiGRU Units	64
Activation Function	ReLU (CNN), Tanh (BiGRU)
Epochs	100
Function of Loss	Cross-Entropy in Binary
GAN Generator Layers	3 Dense Layers
GAN Discriminator Layers	3 Dense Layers
Software Used	Python
Hardware Used	NVIDIA RTX 3080 GPU, 32GB RAM
Development Environment	Jupyter Notebook

Table I defines the parameters of the simulation that determine the training setup of DiagnoFusionNet, such as input sizes, learning rate, epochs, batch size, and network layers, to guarantee uniform optimization, stable performance testing, and reproducibility of cervical cancer classification experiments. All models were trained and evaluated under the same environment, on 80%-20% split, preprocessed using the same method, input-resolving on the same method, and data-augmentation to provide fair and unbiased evaluation. Such hyperparameters as optimizer, learning rate, batch size, and epochs have been chosen according to the validation performance and not changed in most cases. Baseline and transformer models worked with original parameters with slight modifications to convergence. Measures of evaluation were the same to prevent bias. The DiagnoFusionNet, which consists of CNN, BiGRU, GAN, and Adaptive Triple-Stage Feature Fusion modules, was empirically trained using end-to-end training, progressive learning rate schedule, early termination, dropout, and batch normalization to improve convergence, stability, and generalization.

A. Experimental Outcomes

Fig. 5 shows a grid of sixteen separate cell image icons, each of which is marked as "Abnormal" or "Normal". These would probably be microscopic images of cells, stained to bring out their features. The differences in cell size, shape, and nuclear features indicate a visual categorization task for the detection of cellular abnormalities.

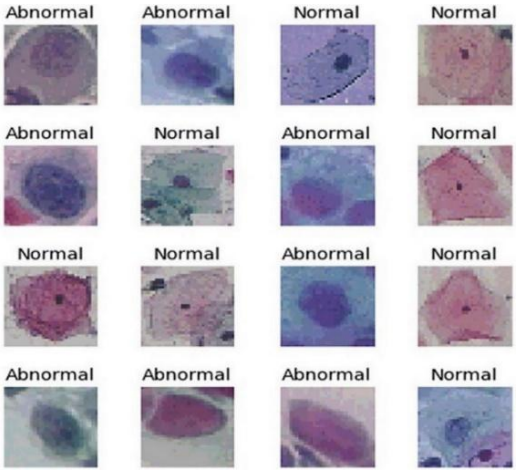

Fig. 5. Abnormal and normal cervical cancer images.

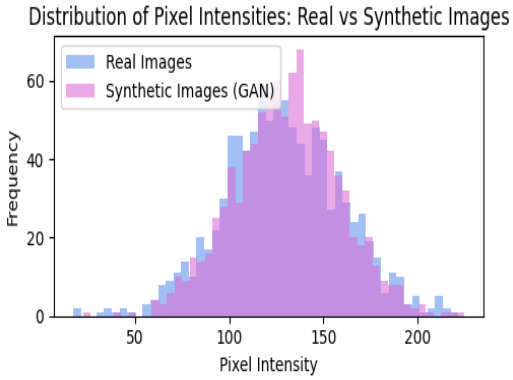

Fig. 6. Distribution of pixel intensities.

Fig. 6 compares the patterns of Pixel intensity of real and GAN-generated images, which is very consistent, which proves realistic synthesis, which increases diversity of the data and promotes more generalization of the models.

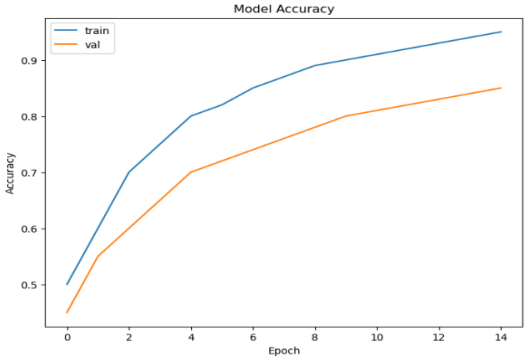

Fig. 7. Accuracy of validation and training.

Training and validation accuracy after 15 epochs is presented in Fig. 7. Improved learning is indicated by the rising blue curve and generalization of the unseen data is indicated by the orange curve. The model works well because both curves rise steadily and express closer values of high accuracy.

B. Ablation Study

To rigorously examine the contribution of each component of DiagnoFusionNet, an ablation analysis was performed by systematically removing modules and observing performance impact. The results demonstrate that both sequential modeling (BiGRU) and GAN augmentation significantly improve discriminative performance, while ATFF alone contributes the largest performance gain.

TABLE II. ABLATION RESULTS DEMONSTRATING COMPONENT-WISE CONTRIBUTIONS IN DIAGNOFUSIONNET

Model Variant	Accuracy	Precision	Recall	F1-Score
CNN Only	92.11%	90.54%	88.92%	89.72%
CNN + BiGRU	94.86%	94.47%	93.72%	94.09%
CNN + GAN	95.22%	95.08%	94.13%	94.60%
CNN + BiGRU + GAN (No ATFF)	96.51%	96.28%	95.90%	95.94%
Full DiagnoFusionNet (With ATFF)	97.89%	97.69%	96.95%	96.89%

Table II shows performance improvements as components are added. Combining CNN, BiGRU, GAN, and finally ATFF yields progressively higher accuracy and F1-scores, confirming ATFF's key contribution to the model's superior classification capability.

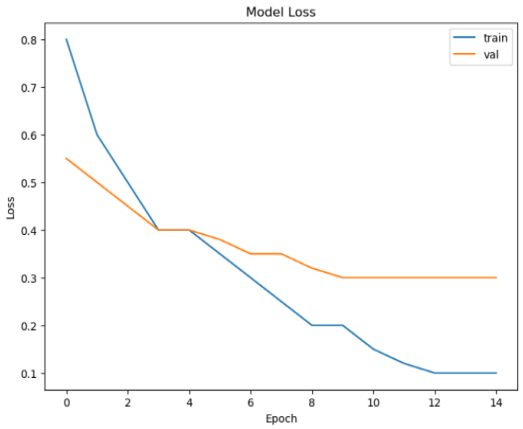

Fig. 8. Training and validation loss.

Fig. 8 presents the dependence of training and validation loss on 15 epochs. The rate of training loss is continuously reduced and validation loss plateaus early in the training, which is a symptom of overfitting. This implies that the model is able to learn training patterns adequately, but it has a low capacity to generalize adequately to data it has not seen.

Fig. 9 presents class-wise prediction performance; the diagonal performance is very high and the error across classes is low. Great values on the diagonal reveal correct classification in all five types of cervical cells, which proves the robustness of the model, its ability to discriminate, and its strong clinical diagnoses.

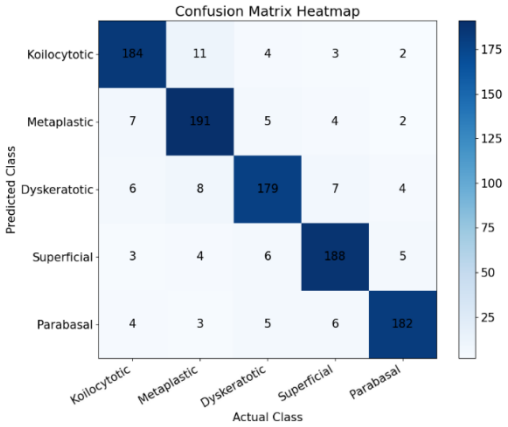

Fig. 9. Interpretation of the confusion matrix heatmap.

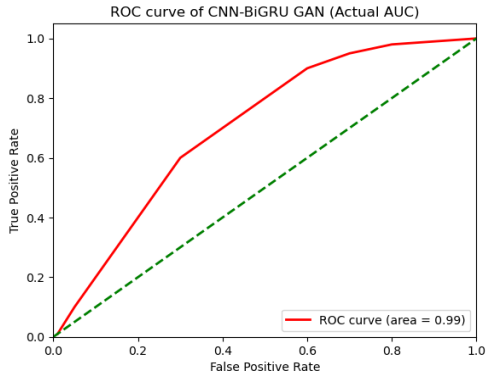

Fig. 10. ROC curve.

Fig. 10 represents the ROC curve, and TPR is plotted against FPR. DiagnoFusionNet has a good discriminatory power with an AUC of 0.99, a good sensitivity-specificity ratio and a large reduction in the risk of false negatives when screening cervical cancer.

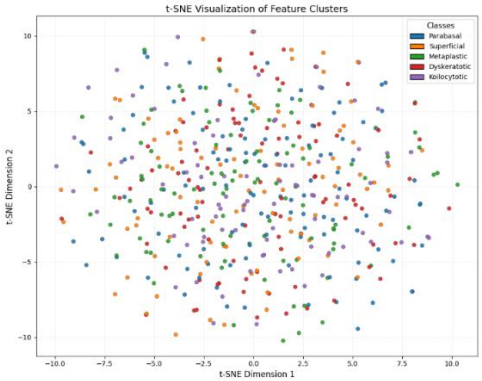

Fig. 11. t-SNE visualization of feature representations.

Fig. 11 indicates that there is a distinct separation of cervical cell classes, which appears to indicate that ATFF learns effectively discriminative fused representations. Clusters are small and do not overlap much, which proves that feature separability is strong and multimodal learning is robust.

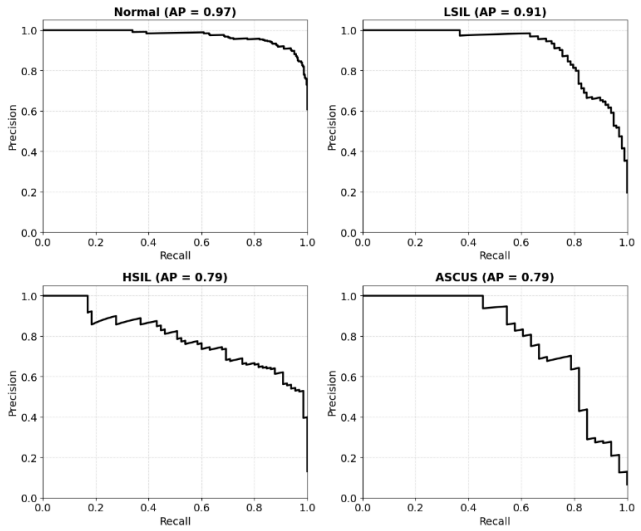

Fig. 12. Class-wise precision–recall curves explanation.

Fig. 12 shows the individual results of each cervical cancer class, with the positive predictive accuracy of DiagnoFusionNet being in imbalanced data. These curves indicate that the model is quite precise and recalling as far as all classes are concerned and minority categories in particular, which is very sensitive and discriminative.

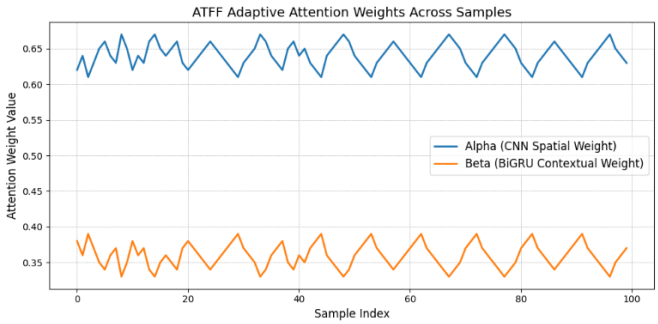

Fig. 13. ATFF modality weight cross samples.

Fig. 13 depicts the dynamics of a and b among samples. The larger values represent more dependence on CNN spatial features, whereas the supplemental b values represent the BiGRU contextual contributions, which depict the adaptable multimodal fusion of features to generate better diagnostic output.

C. Performance Evaluation

To contextualize performance within modern deep learning paradigms, DiagnoFusionNet was compared against transformer-based cervical cancer classifiers. A Swin-Transformer baseline achieved 96.01% accuracy, and a ViT-Hybrid model achieved 96.42%. Although transformers excel in global feature modeling, they underperformed compared to DiagnoFusionNet due to the limited size of SIPaKMeD and the difficulty of optimizing transformer architectures on small datasets. The hybrid CNN-BiGRU–GAN approach with adaptive fusion is therefore better suited for cytology imaging tasks where spatial granularity and contextual patterns jointly influence pathology.

TABLE III. CLASSIFICATION RESULTS OF THE PROPOSED MODEL ON SIPAKMED

Class Label	Precision	Recall	F1-score
Koilocytotic	96.42	95.71	96.06
Metaplastic	97.18	96.89	97.03
Dyskeratotic	95.24	94.76	95.00
Superficial	96.78	95.99	96.38
Parabasal	97.04	96.42	96.73
Average	96.53	95.95	96.24

Table III shows the proposed DiagnoFusionNet architecture classification performance. Robust spatial features are extracted from the cervical cell images by the CNN, while sequential dependencies and contextual representations are learned by the BiGRU.

TABLE IV. MODEL PERFORMANCE COMPARISON

Models	Accuracy	Precision	Recall	F1-Score
PSPM [22]	96.50%	93.78%	92.89%	89.45%
PCA and GWO [23]	94.74%	94.77%	94.67%	78.90%
Fuzzy Distance Ensemble[24]	89.92%	94.78%	89.76%	95.90%
Deep Cervix[25]	93.60%	92.45%	97.98%	94.67%
Proposed CNN BiGRU GAN	97.89%	97.69%	96.95%	96.89%

All the ML models are compared in Table IV, where it is observed that DiagnoFusionNet has the highest accuracy, precision and F1-score. It has an excellent performance due to the integration of spatial-temporal feature learning with GAN-based augmentation that provides it with definite benefits over the PSPM, PCA-GWO, Deep Cervix and Fuzzy Ensemble.

D. Discussion

DiagnoFusionNet is another method that improves the classification of cervical cells with the help of CNN spatial encoding, BiGRU contextual modeling, GAN-based augmentation and adaptive ATFF fusion mechanism. The multimodal feature-based learning not only captures fine-grained morphology and cell-structure dependencies, but also the GAN-generated samples in multimodal feature-based learning solve the class imbalance and promote the representational diversity. Quantitative assessments are found to be more accurate, have a higher F1-score and AUC than classical and transformer-based baselines, as ablation experiments support that the ATFF is the prevalent contributor. Analyses based on t-SNE clustering, confusion matrices, and ATFF weight visualization indicate that the separation of features, the interpretability, and the power of the analysis were strong. The error analysis also characterizes the shortcomings in respect to blur, overlap, and staining disparities to place the framework as a dependable, effective framework to automated cervical cytology screening. The suggested DiagnoFusionNet demonstrates high effectiveness when used to analyze multimodal cervical cells, but can be improved in a number of

ways. What can be added to increase feature diversity is the incorporation of other modalities, like cytoplasmic texture or nuclear morphology due to different staining methods. Semi-supervised or self-supervised learning can help decrease the reliance on annotated data and enhance generalization. Model efficiency might be optimized through pruning or knowledge distillation to deploy them using limited resources. Fusion modules based on transformers or advanced attention mechanisms would improve interpretability and diagnostic accuracy even more.

V. Conclusion and Future Work

DiagnoFusionNet works well in cervical cell and this is due to the use of CNN spatial encoding, BiGRU contextual learning, GAN-based augmentation, and ATFF-driven adaptive fusion. Experiments suggest 97.89% accuracy, 97.69% precision, 96.95% recall, 96.89% F1-score and 0.99 AUC, which is a significant improvement of classical and transformer baselines. The results of ablation also confirm the inclusion of ATFF as the key contributor to this performance increase. The metrics of GAN evaluation (FID 18.3, IS 3.91, SSIM 0.92) confirm the presence of realistic sample generation of synthetics that enhance the presence of classes and generalization. Its benefits are the ability to separate features better, visualizable with modality-weight representation, and the ability to be robust even with limited data. The research has limitations such as staining and morphology variability, class imbalance, heterogeneous feature fusion, and high computational complexity, which can compromise the classification performance, interpretability, and its application in clinical practice. The limitations include sensitivity to blur, staining noise, overlapping nuclei, and a moderate increase in the cost of computation at training. On the whole, the framework sets a consistent, reliable direction in terms of automated cervical cytology screening with clinically aligned benefits.

Future research will deal with the vulnerabilities to blur, changes in staining, and overlapping nuclei by combining stain-normalization pipelines, new deblurring networks, and instance-level segmentation. Transformer-based temporal attention, cross-dataset generalization with domain adaptation, and lightweight quantized models to deploy an edge, and further increases the robustness, lowers the computational requirements and enhances clinical applicability in a variety of screening settings can be added to enhance it.

Reinforcement Learning Framework for Missing Data Imputation in IoT Environments

Ahmed M. Salama Salem, Sayed AbdelGaber A, Ahmed E. Yakoub
Faculty of Computers and Artificial Intelligence, Helwan University, Cairo, Egypt

***Abstract*—Continuous, accurate meteorological sensing underpins many Internet of Things (IoT) applications, from smart irrigation and urban heat-island monitoring to early weather warnings, but data from distributed stations are often disrupted by sensor faults, power loss, or communication noise, causing missing values that degrade analytics and decisions. Existing data imputation methods lose accuracy on small or irregular datasets and adapt poorly to dynamic IoT settings. This study proposes a reinforcement learning (RL)-based framework for missing-data imputation that treats each gap as a sequential decision problem. The authors develop and compare three RL architectures, two Q-table methods and one Deep Q-learning model, to learn temporal dependencies and optimize imputation via experience. A second objective is to assess the feasibility and performance of RL for imputation in domains related to robotics and autonomous systems, where RL remains less explored. A third objective is to validate the methods on real-world datasets and simulations, supported by a user-friendly graphical interface for visualization and performance monitoring. The proposed RL imputers outperform state-of-the-art methods in accuracy and robustness: the best RL configuration cuts MSE/MAE by 8.6%/5.9% vs. K-Nearest Neighbors' algorithm (KNN), 74.4%/75.6% vs. autoencoder, 79.6%/79.9% vs. clustering, 89.0%/83.7% vs. mean, 89.5%/83.3% vs. median, and 94.2%/89.3% vs. most-frequent, while raising the coefficient of determination (R^2) by +0.023, +0.532, +0.123, +0.407, +0.436, and +0.932, respectively. These findings highlight RL as an effective paradigm for intelligent data restoration in IoT-based sensing systems.**

***Keywords*—Data imputation; reinforcement learning; machine learning; deep learning; Internet of Things (IoT)**

I. Introduction

Industry and academia are both deeply interested in maximizing the potential usefulness of the Internet of Things (IoT), a system that links many millions of physical devices to the Internet and, in doing so, generates unprecedented volumes of data. Embedded sensors and actuators enable such devices to sense relevant properties of their surroundings, analyze and process information locally, and exchange data with peers or cloud services, enabling coordinated autonomous decisions [1]. Advances in smart-sensor design, wireless communication, and data-aggregation technologies have made it possible to collect heterogeneous data streams from numerous different sources such as environmental probes, industrial machinery, surveillance cameras, and mobile devices [2]. Such data drives predictive models that improve reliability, efficiency, profitability, and overall performance in smart cities, industrial automation, intelligent buildings, connected vehicles, and environmental monitoring systems [3].

Despite the benefits, real-world deployment suffers from missing or corrupted observations due to sensor faults, loss of power, communication failures, long-term monitor fatigue, battery depletion, and/or poorly defined boundaries in large-scale network studies. Missing values can introduce bias, complicate statistical analysis, and degrade model accuracy. This missing value can be imputed using machine learning (ML) and deep learning (DL) algorithms.

Data imputation is defined as representing missing values in a dataset or IoT stream, which presents a number of challenges for data analysis as such values can increase the chance of introducing errors, reduce analytic accuracy, and limit the reliability of confidence intervals. Data Imputation can be done via conventional machine learning (ML) algorithms, such as hot- and cold-deck substitution, last observation carried forward, mean, multiple or regression imputation, non-negative matrix factorization, and stochastic methods, frequently reject useful data or introduce bias [4]. IoT data will often include varied forms including binary, categorical, numerical, ordinal, spatial, and temporal, with each requiring its own specialized analysis. Thus, recent research has moved toward data-driven and hybrid approaches that are better able to adapt to heterogeneous data inputs. As a result, imputation techniques may now be differentiated into two broad groups which are machine learning-based, and deep learning-based approaches.

Deep learning (DL) approaches, such as autoencoders and convolutional neural networks (CNNs), show great potential for coping with missing data [5], but often need substantial and well-organized datasets to provide reliable performance. Autoencoders provide suggestions for missing data by learning compressed, noise-tolerant versions of the data and then rebuilding the original input, predicting absent values during the decoding process. Multimodal, stacked and variational autoencoders can enhance reconstruction accuracy for many data types. CNN-based models are most effective when the data can be reformed into multi-dimensional arrays such as matrices or images, enabling the network to capture temporal or spatial relationships. This makes CNNs suitable for imputing missing values in, for example, traffic-sensor grids, medical records, or spatiotemporal datasets which enable the study of the maintenance of patterns over time and are particularly useful for environmental data.

However, three major challenges remain. First, most traditional machine learning and statistical imputation methods provide limited accuracy when applied to real-world problems, while modern DL-based approaches often require large training datasets and their performance deteriorates when only small or incomplete datasets are available. Second, although RL has been

extensively explored in robotics and autonomous systems, relatively little attention has been given to its potential in the data domain for imputing missing data, despite its successful application to autonomous decision-making. Third, to the best of the authors' knowledge, there is still no standardized workflow for simulating and deploying advanced imputation models in realistic IoT environments or on a commercial scale.

To address such challenges, the authors propose a RL-based imputation framework that makes each missing value a sequential decision-making problem. This constitutes a first contribution by explicitly formulating missing-data imputation as a sequential decision-making task. This framework develops and is evaluated via three progressively enhanced variants: 1) a baseline Q-Table, 2) an improved Q-Table Version 2 (V2) with optimized hyperparameter tuning, and 3) Deep Q-Learning (V3) that utilizes neural networks for function approximation. This systematic development enables a direct and controlled comparison between tabular and deep RL architectures, representing a second contribution of this work. These RL variants are benchmarked against the widely used imputation techniques: clustering, mean, most-frequent-value as well as DL-based approaches such as autoencoders, and ML methods such as K-Nearest Neighbors (KNN). The evaluations employ multiple performance metrics such as Mean Squared Error (MSE), Mean Absolute Error (MAE), and the coefficient of determination (R^2) to provide a comprehensive assessment of accuracy and reliability. This proposed RL-based approach should enhance imputation accuracy with limited data availability to maintain accuracy of real-time analytics for continuous, dynamic IoT data streams by providing more robust and scalable data.

The remainder of this study is organized as follows: Literature Review discuss the state-of-the-art in this domain and introduces the theoretical foundations of RL. Then, Methodology discusses the design and implementation of the proposed RL algorithms, including data preprocessing, missing-data synthesis, model training, and simulation. The Results and Discussion section presents and interprets the experimental outcomes compared to relevant published works. Finally, the Conclusion summarizes the key findings and suggests directions for future research.

II. Literature Review

Accurate and reliable imputation remains fundamental to downstream analytics in IoT settings where streams are heterogeneous, non-stationary, and frequently sparse (see Fig. 1). Contemporary work spans two broad families: 1) classical baselines prized for simplicity and speed, 2) deep learning (DL) models that trade higher capacity for greater data and training demands. The review below positions our chosen approach within this landscape and explains why RL is a timely alternative.

Large comparative studies consistently show that traditional ML approaches such as KNN [6], clustering [7], mean [8],[9], median, most frequent [6], and tree-based methods, such as MissForest, outperform very simple imputers. However, while clustering, mean, and most-frequent are convenient they are, typically, weaker representations of patterns often found in IoT-style datasets [8],[9]. A 2024 cohort analysis identifies KNN and Random Forest among the strongest practical baselines [9]. Similarly, a recent benchmark analysis paper evaluate the performance of common methods of missing data imputation reports that KNN and MIDAS, which is a denoising-autoencoder approach, perform best at higher rates of random data and block omissions, with substantial runtime differences between methods [6].

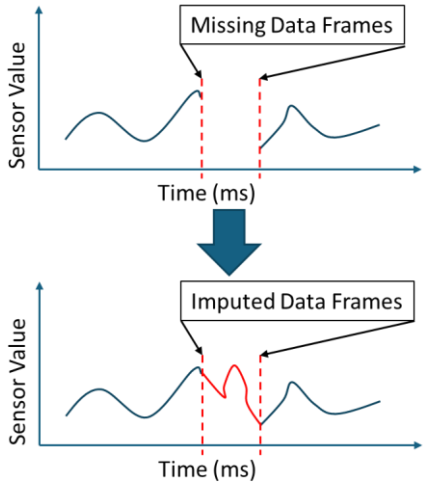

Fig. 1. Data imputation reconstructs missing segments in IoT sensor time series in real-time. The upper plot shows a typical sensor signal with a gap between two dashed lines representing missing data frames caused by sensor faults, packet loss, or power interruptions. The central block (arrow) denotes the imputation algorithm, which processes the incomplete sequence. The lower plot illustrates the imputed data frames (red curve) that reconstruct the missing segment while preserving the original temporal trend and signal continuity.

DL produces high accuracy rather than ML. One DL method, Generative Adversarial Networks (GAN)-based imputers, such as GAIN and its variants, continue to evolve to mitigate mode collapse and gradient instability [10]. A recent study introduces training refinements that improve both stability and accuracy. The clustering and classification-based generative adversarial imputation network (CC-GAIN) features enhanced couples clustering or classification with GANs to better handle multivariate settings which were successfully used in missing data imputation in an electricity consumption system [11]. There is also evidence that the generative adversarial imputation network (GAIN) in hybrid combination with convolutional neural networks (CNNs) can be used for exploiting tensorized representations to provide greater accuracy with sparse multivariate data, but with heavier computational cost and potential training instability compared to simpler baselines [12]. These works justify including DL baselines beyond autoencoders in comparisons while acknowledging their practical trade-offs.

Auto encode (AE) is also a DL method and recent research has refined denoising autoencoders (DAEs) specifically for tabular imputation. DAE for missing data imputation has been developed using a modified loss and a simple hyperparameter rule [13]. It use across multiple UCI datasets and missingness regimes has shown it to provide thorough ablations against standard baselines and rank among the top performers, making it a strong contender for use as an AE-style imputer for tables [5].

Beyond generic IoT benchmarks, DAEs have been evaluated in cases where the missingness was high (≥40%) heterogeneous biomedical datasets (with a mix of imaging, clinical, cognitive, and genetic variables), which demonstrated where DAEs excel and but also that they struggled under extreme sparsity typical of real-world IoT/health data sets [13]. Remasker, a recently developed method, extended masked autoencoding to tabular data by re-masking observed entries during training and predicting them as a self-supervised target [15]. Competitive or superior imputation fidelity/utilities across benchmarks were reported, with released code and slides clarifying design choices (simple masking strategy, strong performance as the missing ratio grew) [14]. These properties make Remasker an appropriate "modern DL" point of comparison alongside DAEs in our study.

In summary, classical machine-learning methods provide strong, efficient models that can operate at high speed. DL models offer higher-capacity imputation but come with stability and computational limitations, and they typically require substantial training data. When such data and careful training are available, DL methods achieve state-of-the-art accuracy. In contrast, RL-based imputation remains relatively under-explored, particularly for streaming IoT time-series data characterized by small sample sizes and block-missing patterns. To address this gap, we formulate missing-data imputation as a sequential decision-making problem, design an IoT-specific state-action-reward structure, and conduct a systematic comparison of tabular Q-learning and Deep Q-Learning within a unified framework. The proposed approach is evaluated using MSE, MAE, and R^2 to assess both accuracy and robustness under realistic IoT data conditions.

III. Proposed Methods

A. Overview

RL provides a learning framework through interaction: an agent repeatedly observes the current situation of the environment, chooses an action, receives a numerical response, and moves to a new situation. Over time, the agent defines and then refines a policy, a mapping from observed situations to actions taken, so that the long-term response is maximized. Two internal estimates direct this process. State-value functions provide a measure of how desirable a situation is, while action-value functions estimate the effectiveness of taking a specific action in a particular situation. Learning algorithms such as Q-learning adjust the estimates by comparing the predicted results with those observed after taking action. Modern RL combines these approaches with deep neural networks to provide deep RL, which can provide value functions and policies directly from high-dimensional data. The volatility that can arise when learning and decision-making take place simultaneously is substantially reduced by using stabilizing techniques such as experience replay, target networks, and the ε-greedy algorithm. Because RL learns directly from the interactions rather than static examples, it is well-suited to problems such as IoT data imputation, where the agent must cope online with varying streaming inputs, noisy feedback, and changing sensor conditions.

In this study, the authors develop a model that incorporates three hyperparameterized methods to enhance imputation accuracy. It integrates two variants of Q-Table-based RL and one Deep Q-RL approach. The Q-Table RL is a model-free algorithm that uses tabular representation to store and update action-state values (Q-values). These values guide the agent in selecting optimal actions within a discrete environment based on a defined reward function. Although having the benefits of being simple and interpretable, Q-Table methods are limited in scalability when the state-action space becomes large. To address this, the model includes a second stage with enhancements in exploration and value generalization. In contrast, DQL extends the traditional Q-learning paradigm by employing a deep neural network to approximate the Q-function. This enables the agent to cope with high-dimensional or continuous state spaces more effectively. Combining the three methods, this model expects to provide a more accurate and robust imputation strategy than traditional techniques.

B. Data Preprocessing and Missing Data Synthesizing

In this study, the authors divided the Air-Quality dataset (UCI ID 360) from the UCI Machine Learning Repository [15, 16] for training and testing the proposed algorithms and the baseline methods for data imputation. The selected data source is one of the most popular benchmark resources in the IoT weather domain. It contains recorded responses from a gas multisensory device that was deployed in a field in an Italian city. Hourly average sensor readings are provided together with reference gas-concentration measurements obtained from a certified analyzer. In total, the dataset comprises 9,357 hourly averaged instances collected by an array of five metal-oxide chemical sensors embedded in the air-quality multisensory device, as shown in Table I. The device was positioned at road level in a heavily polluted urban area. Data were gathered continuously for one full year, from March 2004 to February 2005, yielding the longest freely available recording of on-field air-quality chemical sensor responses. The sensing unit comprised five metal-oxide (MOX) chemical sensors, each nominally tuned to specific target gases, along with environmental measurements. The dataset includes both the raw sensor responses (PT08.S1–PT08.S5) and reference gas-concentration measurements obtained from a co-located certified analyzer. The measured and reference parameters are summarized in Table I.

The dataset was split into training and validation sets, comprising 80% of the data, and a testing set comprising the remaining 20%. The authors used this split to ensure a large amount of data for training and validation, enabling better generalization and reducing the risk of overfitting, while the remaining 20% contained representative features sufficient for reliable testing.

The data preprocessing pipeline begins by retrieving and reviewing the dataset's metadata, such as source, measurement period, and definitions of variables, followed by generating summary statistics and data-type profiles to verify completeness and to detect potential anomalies. The column providing the Date is deconstructed from the original MM/DD/YYYY string format into a suitable datetime object, enabling the earliest and latest sampling times to be recorded for temporal consistency checks. All other numerical attributes (i.e., columns after the first two identifier fields) are rescaled to the interval $[0, 1]$ using a Min-Max transformation to ensure comparable magnitudes to

accelerate model convergence. Finally, two comma-separated value (CSV) files are generated: one preserves the raw measurements as collected, and the other stores the normalized version to be supplied to the learning algorithm. This procedure ensures that downstream analysis uses a clean, temporally aligned, and scale-independent dataset but retains access to the original records for auditing.

TABLE I. DATASET DESCRIPTION [15, 16]

Attribute	Description	Unit
Date	Recording date	DD/MM/YYYY
Time	Recording time	HH.MM.SS
CO	True hourly averaged Carbon Monoxide (CO) concentration	mg/m³
PT08.S1 (Tin Oxide)	Sensor response nominally targeted to CO	arbitrary unit
NMHC	True hourly averaged Non-Methane Hydrocarbons (NMHC) concentration	µg/m³
C_6H_6	True hourly averaged Benzene (C_6H_6) concentration	µg/m³
PT08.S2 (Titania)	Sensor response nominally targeted to NMHC	arbitrary unit
NO_x	True hourly averaged Nitrogen Oxides (NO_x) concentration	ppb
PT08.S3 (Tungsten Oxide)	Sensor response nominally targeted to NO_x	arbitrary unit
NO_2	True hourly averaged Nitrogen Dioxide (NO_2) concentration	µg/m³
PT08.S4 (Tungsten Oxide)	Sensor response nominally targeted to NO_2	arbitrary unit
PT08.S5 (Indium Oxide)	Sensor response nominally targeted to Ozone (O_3)	arbitrary unit
T	Temperature (T)	°C
RH	Relative Humidity (RH)	%
AH	Absolute Humidity (AH)	g/m³

All experiments were conducted using a single missingness procedure: entries in the numeric columns were masked independently with a fixed probability of 0.2, applied separately to the training, validation, and test partitions. This masking of elements generated random gaps across the dataset, guaranteeing that missing positions varied across folds and splits in the data. Thus, model training and validation losses reflected the reconstruction of the missing values, and final test metrics quantified performance on a retained set subjected to the same masking process (see Algorithm 1). With all models evaluated consistently against this single, fixed masking strategy and under the given setting (0.2). Algorithm 1 describes the proposed procedure for synthesizing missing data at a fixed rate across training, validation, and test splits. Starting from a complete dataset, the data are first divided into training/validation and test sets. During the cross-validation phase, a fixed fraction of values is randomly masked as missing in the numeric columns of both training and validation sets using a uniform random process, ensuring consistent missingness across folds. The imputation agent is trained on the masked training data and validated against the original uncorrupted data. In the final phase, the same missingness strategy is applied to the combined training/validation set and the test set, after which the imputation model is trained and evaluated. This procedure ensures a controlled, reproducible, and unbiased evaluation of imputation performance under fixed-rate missing-data conditions.

Algorithm 1 shows the proposed missing data synthesizing via a fixed-rate missingness for train, validation and test splits.

Algorithm 1: Proposed Missing Data Synthesizing Method

```
Start Algorithm
Initialize complete dataset D
Define numeric column set C
Define missing fraction p = 0.20
Define number of CV folds k
Randomly split D into train/validation set (D_tv) and test set
(D_test) with 80 % / 20 % ratio
# Cross-validation phase
For each fold f in K-Fold(D_tv, k) do
|  Split D_tv into training set (D_train) and validation set (D_val)
for fold f
|  Create D_train_missing ← copy of D_train
|  Create D_val_missing ← copy of D_val
|  For each column c ∈ C do
|  |  For each row r in D_train_missing do
|  |  |  u ← Uniform(0, 1)

C. Proposed Models' Architecture

1) Reinforcement learning based on Q table: Fig. 2 contrasts the end-to-end workflows for the two generations of our reinforcement learning imputer. Version 1 (V1) begins by injecting a user-specified ratio of synthetic gaps into the training fold and then iterates column-by-column inside the dashed box the Column Imputation Agent V1 represents each decision state solely by the row index of the missing value; contextual cues such as neighboring readings remain implicit. Two baseline actions are always available to the ε-greedy

selector: the KNN fill and a feature-statistics fill (mean, median or standard-deviation offset), while the remaining actions correspond to previously learned Q-values for that index. After an action is chosen, the reward is calculated as the negative absolute error normalized by the column's standard deviation; this signal updates the Q(state, action) table and the per-epoch MSE log. Once all gaps in the train-and-validation partitions are imputed, fold-level metrics are recorded and the agent proceeds to the next column or cross-validation split, ultimately producing a single Q-table per feature that is reused to fill the held-out test set [see Fig. 2(a)].

Version 2 (V2) retains the outer train, validation, and test scaffold, but tackles three limitations observed in V1. First, it discretizes the numeric context: each previous value is binned, and the joint bin index becomes the state, dramatically shrinking and regularizing the state space. Second, it replaces the absolute-error reward with a squared-error signal and logs both training and validation MSE curves, enabling early stopping and hyper-parameter tuning. Third, ε in the ε-greedy policy decays across epochs, allowing aggressive exploration early on and more deterministic exploitation later. Internally, four Q-tables are maintained (one per context bin), each updated with the same loop of reward calculation and value iteration. During inference, the agent consults the appropriate Q-table for the discretized context of every missing cell, producing fills that are both context-aware and data-driven [see Fig. 2(b)].

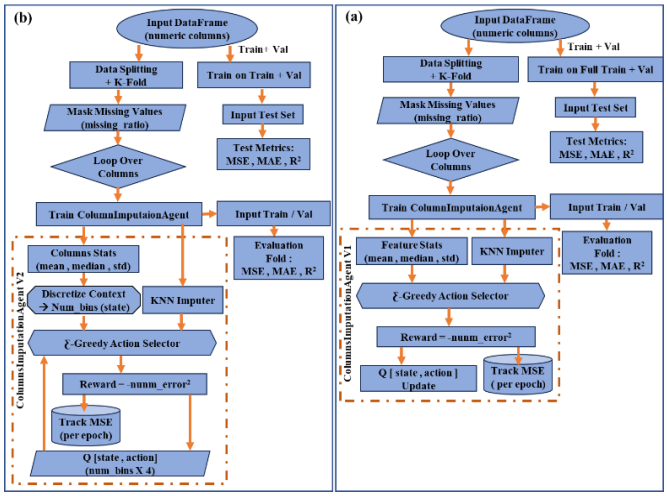

Fig. 2. The model structure of the proposed Q table methods.

2) Reinforcement learning based on deep Q: The proposed imputation framework employs a Deep Q-Learning (DQN) agent designed to learn optimal imputation strategies through interaction with an environment representing missing-value patterns. At each environment step, the agent observes a scalarized state s corresponding to the normalized position of the missing entry within a column and selects an action $a \in \{mean, median, random, knn\}$ using an ε-greedy policy. The environment then returns a reward r proportional to the negative normalized squared error between the imputed value and the ground truth. The next state s' reflects the subsequent missing entry index. This transition tuple (s, a, r, s') represents a single reinforcement learning experience used to update the DQN model. To enhance stability and sample efficiency, training is conducted using a batched replay mechanism. Transitions accumulated during interaction are stored in a replay buffer of finite capacity K. Instead of performing one update per sample, we repeatedly sample B mini-batches from the buffer and execute U stochastic gradient descent updates for each, thereby increasing the effective signal-to-noise ratio of the temporal-difference (TD) gradients. This multi-batch, multi-update schedule mitigates variance and reduces dependency on fresh data collection, an essential property when computational or data-access costs are constrained. For each sampled transition iii, a bootstrap target is computed as: $y_i = r_i + \gamma \max_{a'} Q_\theta - (s_i', a')$ where γ is the discount factor and θ^- denotes the parameters of a slowly updated target network. The online network parameters θ are optimized to minimize the mean-squared TD error: $L(\theta) = \frac{1}{B}. \sum_i (y_i - Q_\theta (s_i, a_i))^2$ using the Adam optimizer with learning rate α. Following each outer training epoch, both the exploration rate ϵ and the coefficient for target update τ decay according to defined schedules: $\theta^- \leftarrow (1-\tau)\theta^- + \tau\theta$ This ensures gradual policy refinement and stable convergence.

The Q-Network architecture (Fig. 2) is a compact three-layer feedforward model realized in PyTorch: an input normalization layer, a fully connected layer with 64 ReLU-activated neurons, and a linear output layer producing four Q-values corresponding to the available imputation actions. This lightweight design enables efficient on-device training and inference under limited memory and computation constraints. Collectively, the integration of replay memory, target-network stabilization, and multi-update training yields a robust Deep Q-Learning agent capable of acquiring context-adaptive imputation strategies for heterogeneous data distributions. The overall training pipeline, from dataset preparation and K-fold cross-validation to column-wise DQN training and test-time inference, is shown in Fig. 3.

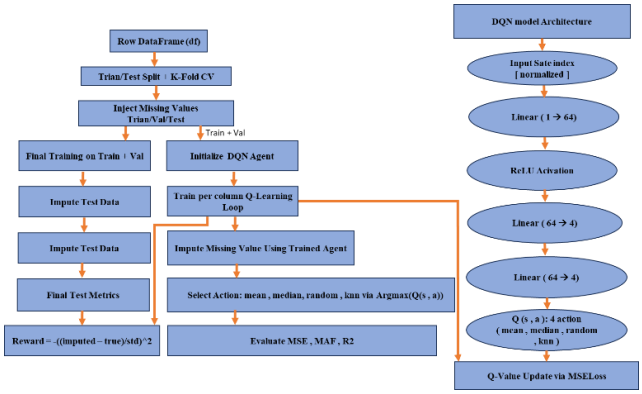

Fig. 3. The model structure of the proposed deep Q method.

3) Proposed simulation for RL environment: The authors developed an interactive grid-based simulation using the Pygame Library, to illustrate how a RL agent might traverse an air-quality dataset and impute missing values in real time (see Algorithm 2). After loading a CSV file that contains numerical features with artificially injected gaps, the data were

normalized to the [0,1] range and mapped onto a 2-D grid whose rows and columns correspond to samples and features, respectively (see Fig. 4). Each cell is 100 px square: filled observations appear in blue, missing entries in red, and their numeric contents are over-printed "NA" for clarity. The green agent starts at the upper-left corner [0,0] and can be moved by the user using the arrow keys. When the agent is positioned on a missing cell pressing the space bar triggers an "imputation action". In this demonstrator the action is a random draw from [0,1], the ground-truth value is likewise mocked, and the reward is the negative absolute error, these values are stored in a simple Q-table keyed by grid location. Although rudimentary, the framework visualizes the essential RL loop: state perception (color-coded grid), action selection (move or impute), reward feedback, and value-function update, all occurring at 30 FPS on an 800 × 600 canvas. This educational tool provides an accessible first step towards integrating and debugging more sophisticated, neural-based RL strategies for data-gap filling on edge-generated sensor streams. Algorithm 2 shows how the pseudocode outlines the full flow: loading and normalizing a dataset with missing values, drawing a color-coded grid, letting the user navigate a green "agent" with arrow keys, and pressing the space bar to impute and score missing entries. The Q-table records per-cell rewards, providing a scaffold for replacing random placeholders with a true reinforcement-learning policy at a later stage.

IV. Results and Discussion

A. Tooling

The algorithms were developed in Python and used the Keras, Matplotlib, NumPy, Pandas, PyTorch, Scikit-learn, and TensorFlow data processing and ML libraries. Keras provides a user-friendly, high-level neural-network API compatible with both CPUs and GPUs. Matplotlib provides data visualization, allowing patterns to be displayed as charts and plots. NumPy offers a large collection of high-level mathematical functions able to support efficient operations on multi-dimensional arrays and matrices. Pandas provides data analysis and preprocessing, high-level data structures and a rich set of tools for filtering, combining, and grouping datasets before training. PyTorch is an

extensive open-source software useful for natural language processing (NLP) and computer vision. Scikit-learn provides a wide range of supervised and unsupervised ML algorithms for data mining and analysis. TensorFlow provides high-performance computation for training and operating deep-learning models.

The model was trained on the Google Colab cloud platform, which provides a shared high-performance computing (HPC) environment. The model training was carried out using two virtual CPUs, with specs Intel Xeon, family 6, model 79, clocked at 2.20 GHz with a 56,320 kB cache, alongside an NVIDIA T4 graphical processing unit (GPU) and 52 GB of random-access memory (RAM). The model inference and testing were executed on a local personal computer (PC) equipped with a 6th generation Intel Core i7 processor (2.6-2.8 GHz), an integrated Intel HD 520 GPU, 32 GB of RAM, and a 1 TB solid-state drive (SSD).

B. Data Preprocessing and Missing Data Synthesizing

In Fig. 5, the histogram of KDE shows panels depicting the empirical distributions of seven key features from the UCI Air-Quality dataset. All are gases ground truth (GT), CO(GT), NOx(GT), NO2(GT) and C6H6(GT), and all share a clear spike at -200 units that marks the dataset's built-in sentinel for missing or invalid sensor readings, and a pronounced positive skew caused by occasional pollution surges.

After removing the -200 flags, CO shows a very narrow peak while NOx displays a long right tail extending beyond 1 000 µg m⁻³, whereas NO2 peaks much more narrowly around 140 µg m⁻³. Benzene (C6H6) shows a compact distribution around 7 µg m⁻³ with a slight positive skew but virtually no extreme outliers, reflecting the lower variability of this volatile organic compound. In contrast, the meteorological variables exhibit near-Gaussian behavior once the sentinel values are discounted: temperature (T) clusters tightly between 15 °C and 30 °C, relative humidity (RH) is centered near 70 %, and absolute humidity (AH) forms an even tighter bell around 0.035 kg m⁻³. These contrasting shapes emphasize why a one-size-fits-all imputation rule is inadequate: heavy-tailed, zero-inflated gas measurements demand context-aware reconstruction, whereas smoother climatic variables can tolerate simpler statistical fillers.

Fig. 6 presents the pair-wise relationships among the five metal-oxide sensor channels embedded in the Air-Quality monitoring unit for CO, NMHC, NOx, NO2 and O3. Each panel shows a plot of one sensor's raw resistance (in ADC counts) against each of the others, revealing several instructive patterns. First, the tight, positively sloped clouds produced by linking PT08.S1(CO) with PT08.S2(NMHC) and PT08.S4(NO_2) indicate strong cross-sensitivities: when the CO sensor peaks, the NMHC and NO_2 channels rise almost proportionally, a hallmark of overlapping gas responses in metal-oxide arrays. Second, PT08.S3(NOx) behaves quite differently; its relationships with the other four channels produce a downward-curving trajectory, signifying an inverse, non-linear dependence due to its specific redox reaction mechanism. Third, every scatter plot contains a dense cluster at the origin, corresponding to the dataset's sentinel value (-200 ADC), which flags missing or invalid readings; because these artefacts sit far from the genuine signal manifold, any imputation model must avoid naively averaging across them. Finally, the diagonal panels showing lines remind us that each sensor reading is highly self-correlated, providing an upper bound for imputation accuracy.

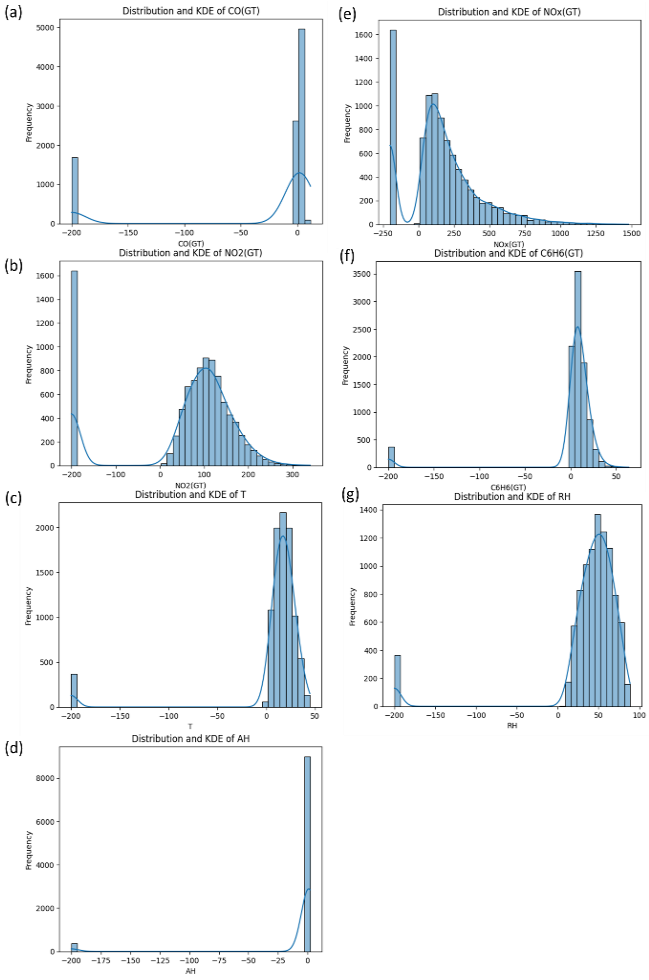

Fig. 5. Distributions and kernel density estimates of the selected Air Quality features: (a) CO(GT), (b) NOx(GT), (c) NO2(GT), (d) C6H6(GT), (e) temperature (T), (f) relative humidity (RH), and (g) absolute humidity (AH). The spike at -200 denotes the sensor-defined missing-value indicator, while the skewed shapes and long right tails, particularly for gaseous pollutants, reflect episodic concentration spikes and heterogeneous data characteristics.

PT08.S5 (Indium-oxide, nominally O_3) exhibits curvilinear, mostly inverse relationships with PT08.S3(NOx) and PT08.S4(NO_2), consistent with oxidizing reducing cross-sensitivities typical of metal-oxide sensor arrays. Its scatter plots with PT08.S1(CO) and PT08.S2(NMHC) appear weaker and more dispersed, indicating lower direct coupling and stronger modulation by environmental covariates such as temperature (T), relative humidity (RH), and absolute humidity (AH). The same -200 ADC sentinel cluster is also visible for PT08.S5 and must be masked prior to training or imputation to prevent distortion of the learned data manifold. For imputation tasks, PT08.S5 benefits particularly from non-linear models that can exploit its monotonic segments with NOx and NO_2 while conditioning on meteorological parameters, rather than relying on simple linear correlations.

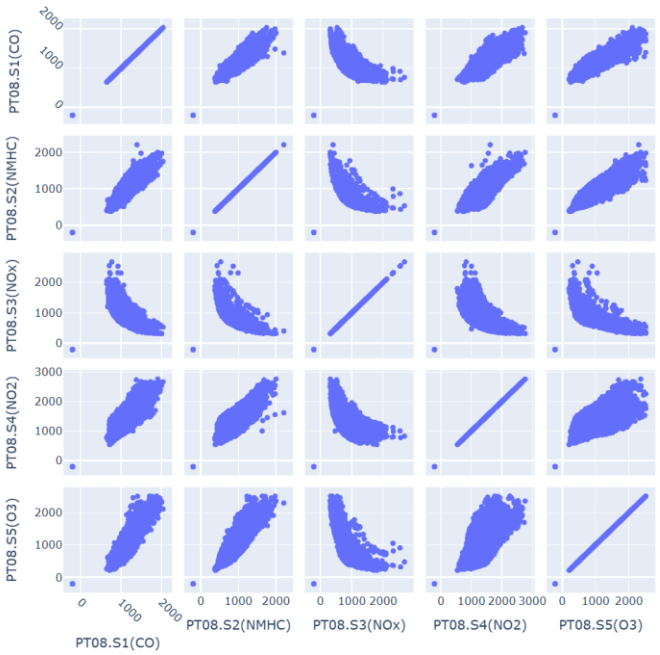

Fig. 6. Pairwise scatter-matrix of the five metal-oxide sensor channels (PT08.S1–S5). Blue dots represent valid observations.

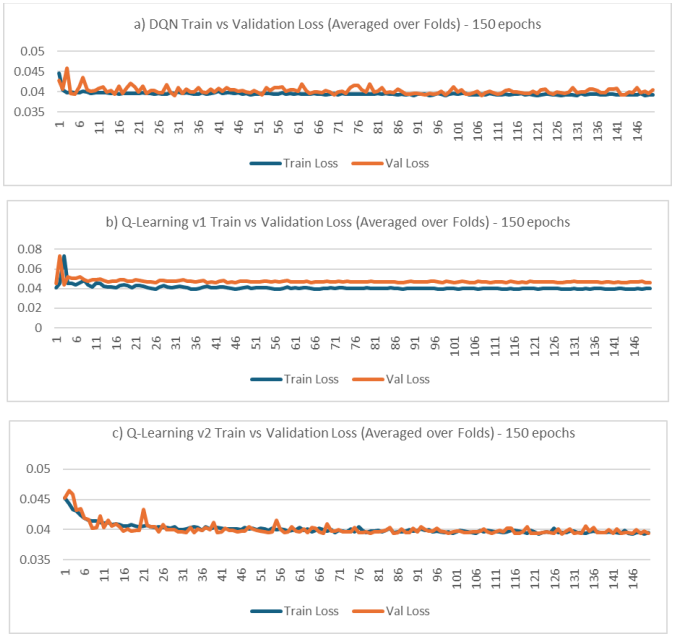

Fig. 7. Training vs. validation loss (averaged over folds) across 150 epochs for the proposed RL-based imputers: (a) Deep Q-Network (DQN), (b) Q-Learning v1, and (c) Q-Learning v2.

Third, every scatterplot contains a dense cluster at the origin, corresponding to the dataset's sentinel value (-200 ADC), which flags missing or invalid readings; because these artefacts sit far from the genuine signal manifold, any imputation model must avoid naively averaging across them. Finally, the diagonal panels showing lines remind us that each sensor reading is highly self-correlated, providing an upper bound for imputation accuracy.

C. Models Training and Validation

Fig. 7 presents the relative training–validation loss dynamics of the three RL approaches over 150 epochs (averaged across folds). In Fig. 7(a), the DQN model exhibits low overall loss values, with training and validation curves tracking closely after an initial period of fluctuations. The validation loss shows more pronounced oscillations than the training loss but without a continuing divergence, suggesting stable learning with only mild noise-induced variance on unseen data. Fig. 7(b) presents Q-Learning V1, where, after an initial period of relatively few epochs, the training loss steadily decreases towards an MSE value of 0.040 while the validation loss remains consistently higher at an MSE value of about 0.045. This persistent difference implies a degree of overfitting, where the learned policy better fits the training environment than unseen samples. In Fig. 7(c), Q-Learning V2 achieves very close alignment between training and validation losses after an initial decrease in value. Both curves stabilize at an MSE value between 0.039 and 0.040 with minimal oscillation, indicating strong generalization and absence of significant overfitting. Overall, these trends demonstrate that while all three models converge to low loss values, Q-Learning V2 maintaining the most consistent train–validation alignment, DQN follows closely with small validation variance, and Q-Learning V1 demonstrates a modest but persistent generalization gap.

Table II shows the comparison between the proposed algorithms and the state-of-the-art methods. In particular, Training length has different effects on the three RL approaches. For QL Version 1 (V1), extending training from 10 to 150 epochs steadily lowers the mean-squared error from 0.0098 to 0.0092, and raises R^2 from 0.7655 to 0.7772, with only a slight improvement in mean-absolute error from 0.0269 to 0.0204. After about 50 epochs, gains taper off, indicating a performance plateau. QL Version 2 (V2) behaves differently. At 10-epochs this model reaches its lowest MSE value (0.00785) and the highest R^2 (0.8041). Further training slightly worsens both metrics, suggesting mild over-fitting once the dominant patterns have been captured. DQL peaks at 50 epochs with an MSE of 0.0074, R^2 of 0.8053, and MAE of 0.0225, after which there is a modest decline at 150 epochs, indicating stability with some over-fitting. Comparing the RL models reveals a trade-off: V2 and DQN achieve lower MSE and stronger R^2, with better suppression of extreme deviations, but at the cost of a higher MAE. On the other hand, V1 delivers more uniform point-wise accuracy. Classical baselines can offer useful reference points and we see KNN provides a balanced but unremarkable performance (MSE = 0.0081, R^2 = 0.7822), whereas clustering and autoencoder underperform markedly, and the simplest imputations (mean, median, most-frequent) produce large errors with poor R^2, confirming their unsuitability for continuous environmental streams.

Considering all three metrics: QL V1 at 150 epochs offers the best balance, with the smallest MAE, a respectable MSE, and solid R^2; QL V2 at 10 epochs excels at limiting outliers shown in its superior MSE; and DQN at 50 epochs combines strong R^2 with low error and minimal over-fitting. Among non-RL methods, only KNN approaches RL-level performance but fails to surpass it. Consequently, the authors propose the use of RL agents, especially V1-150 for consistent accuracy, V2-10 for

outlier suppression, and DQN-50 for balanced generalization, as the most practical solutions for real-time IoT imputation, delivering strong accuracy without prohibitive training demands on edge hardware.

This early optimum of Q-Table V2 can be attributed to its internal architectural modifications compared with V1. As detailed in Fig. 2(b) (Section III), V2 discretizes the numeric context into bins, reducing the size of the state-action space and allowing the agent to learn stable Q-values within very few epochs. It also employs a squared-error reward function instead of the normalized absolute-error reward used in V1. This squared-error formulation amplifies large deviations during the initial learning phase, enabling rapid minimization of MSE but also increasing the likelihood of mild over-adjustment once the major error patterns have been corrected. Further, V2 produces a decay in the exploration rate (ε) within the ε-greedy policy with an increase in the number of epochs, which encourages broad exploration during the first few epochs but quickly transitions to exploitation. Once the policy stabilizes, subsequent updates contribute little additional improvement and can even marginally degrade test performance, reflecting controlled over-specialization rather than instability.

In contrast, V1 relies on a continuous state representation and a fixed ε, which promotes slower but steadier convergence and greater resilience to over-fitting. Consequently, V1 benefits from extended training up to 150 epochs, progressively refining its policy and reducing MAE without significant loss in generalization. The different convergence behaviors of V1 and V2 stem directly from their design philosophies; V2 prioritizes fast convergence and computational efficiency, making it suitable for lightweight IoT or edge deployments, whereas V1 favors gradual learning and robust generalization over longer training cycles.

These findings confirm that the observed peak performance of V2 at 10 epochs is a result of its architecture rather than an anomaly. The early convergence and subsequent plateau reflect the intended trade-off between rapid policy stabilization and marginal over-fitting within a highly compact state space.

The behavior of the Deep-Q Network (DQN) supports the interpretation that the number of training epochs interacts with model capacity. Unlike the tabular versions, DQN uses a neural function approximator to estimate Q-values, enabling smoother generalization across unseen states but introducing a higher sensitivity to over-training. At around 50 epochs, the network reaches an optimal balance between exploration and convergence, achieving the lowest MSE (0.0074) and highest R^2 (0.8053) while maintaining a relatively low MAE (0.0225). Beyond 50 epochs, continued training leads to a slight degradation in performance until, at 150 epochs, we have MSE = 0.0084 and R^2 = 0.7855, primarily due to over-fitting of the Q-value function and reduced stochastic exploration as the policy becomes deterministic. Thus, 50 epochs with this model represent the point of maximum generalization; the network has learned sufficient value structure to minimize prediction error without memorizing the training trajectories. This pattern is consistent with typical DQN behavior, where moderate training durations combined with early stopping yield the most stable convergence of the value function and the best trade-off between bias and variance.

TABLE II. COMPARISON BETWEEN THE PROPOSED AND STATE-OF-THE-ART METHODS

Method	Epochs	MSE	MAE	R^2
Proposed Q Table V1	10	0.0098	0.0207	0.7655
Proposed Q Table V1	50	0.0098	0.0209	0.7693
Proposed Q Table V1	150	**0.0092**	**0.0204**	**0.7772**
Proposed Q Table V2	10	**0.0078**	**0.0228**	**0.8041**
Proposed Q Table V2	50	0.0084	0.0227	0.7883
Proposed Q Table V2	150	0.0081	0.0231	0.8014
Proposed Deep Q	10	0.0077	0.0237	0.7805
Proposed Deep Q	50	**0.0074**	**0.0225**	**0.8053**
Proposed Deep Q	150	0.0084	0.0234	0.7855
Autoencoder [13]	-	0.0289	0.0923	0.2738
KNN [6]	-	0.0081	0.0239	0.7822
Clustering [7]	-	0.0362	0.1119	0.6828
Mean [9]	-	0.0675	0.1379	0.3987
Most Frequent [6]	-	0.1286	0.2095	-0.1271
Median [9]	-	0.0708	0.1350	0.3688

Across all methods, the Deep-Q model at 50 epochs delivers the best MSE (0.0074) and highest R^2 (0.8053), while the strongest classical baseline KNN has an MSE = 0.0081 and R^2 = 0.7822. This represents a ~9% reduction in MSE and a +2.31 percentage-point increase in R^2. For MAE, the best performer is Q-Table V1 at 150 epochs (0.0204), improving on KNN (0.0239) by ~14.5%. All RL variants clearly outperform the simple statistical baselines and the tested Autoencoder, which lags substantially on all metrics.

If the application prioritizes calibration and variance-sensitive fidelity, such as forecasting or anomaly scoring downstream, Deep-Q-50 epochs are the best choice (lowest MSE, highest R^2). If robustness to outliers and absolute deviation matter more, such as thresholding deviations for alerts, Q-Table V1 150 epochs is preferable (best MAE, ~9.3% lower than Deep-Q-50). Q-Table V2 offers a middle ground with near-Deep-Q R^2 but slightly weaker MAE, which might be attractive when a simpler function approximation is desired.

The loss curves in Fig. 7 show rapid early convergence followed by small, stable train-validation gaps for all three RL variants, except for V2, where the curve stabilizes early due to fast policy saturation within the discretized state space, indicating controlled capacity and limited over-fitting. Deep-Q shows optimum values for each of MAE, MSE, and R^2 at 50 epochs rather than 150, suggesting that light early stopping or entropy/exploration annealing could further stabilize performance. For the Q-Table models, longer horizons consistently help MAE, supporting the view that policy refinement through continued exploration benefits absolute-error minimization.

D. Simulation

Fig. 8 presents successive frames from the Pygame-based simulation visualizer, illustrating a single decision cycle of the RL imputation agent. In the first frame [Fig. 8(a)], the agent (green square) is positioned next to a red "NA" cell representing a missing value, while previously imputed entries appear in blue with normalized magnitudes. Upon user action, the agent imputes a value of 0.66 and receives a small negative reward [Fig. 8(b)], reflecting a near-match to the hidden ground truth (0.65). In the subsequent frame [Fig. 8(c)], the imputed cell turns blue, confirming state update and storage in the replay buffer. This visual transition highlights real-time gap resolution and online learning, as rewards are logged to refine future actions, with repeated cycles progressively filling the grid and quantifying imputation accuracy interactively.

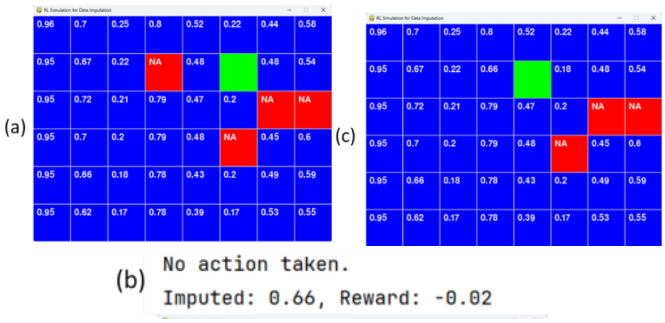

Fig. 8. Consecutive frames from the Pygame imputation simulator. The agent (green) selects an action on a red "NA" cell, where its ground truth was 0.65, fills it with the determined value (here 0.66), receives a small negative reward (-0.02), and updates the grid, which turns the cell blue to indicate imputation.

V. Conclusion and Future Work

This work addressed the continuing problem of missing values in edge-collected meteorological data streams in an IoT environment, caused by sensor faults, power interruptions, and communication noise, which degrade downstream analytics and time-critical decision support. To address this challenge, the authors have developed a lightweight reinforcement-learning imputation framework that formulates each gap as a sequential decision problem, learns directly from sparsely populated streams by utilizing cross-sensor temporal correlations, executes within the compute and energy envelopes of embedded IoT nodes, and is integrated with an interactive visual simulator implemented in Pygame. Beyond reporting performance gains, this work demonstrates that modeling missing-data imputation as a sequential decision-making process constitutes a general and effective paradigm for IoT data restoration, rather than a purely static prediction task. Empirically, the RL approach yields consistent gains under both block-missing and random-missing regimes: relative to non-RL baselines, the best configuration delivers 8.6 to 94.2% lower MSE and 5.9 to 89.3% lower MAE, while lifting R^2 by +0.023 to +0.932; even against the strongest baseline (KNN), it achieves 8.6%/5.9% error reductions with +0.023 R^2, underscoring robustness rather than overfitting. These results support the overarching contribution that sequential, policy-driven imputation can better adapt to dynamic and data-scarce IoT settings than other methods. This simulator allows real-time visualization of the agent's decision-making process, each state, action, and reward, facilitating rapid prototyping, policy debugging, and latency profiling during development. Future work will incorporate uncertainty-aware imputation, explore transfer and meta-learning for data-scarce stations, and optimize energy-efficient on-device adaptation, while hardening the edge stack through embedded profiling, model compression, and physics-informed simulator enhancements.

***Abstract*—This study presents a hierarchical Swin Transformer–based framework for automated segmentation of cerebrovascular structures using multimodal magnetic resonance imaging. The proposed architecture integrates patch partitioning, linear embedding, hierarchical windowed self-attention, and a multilevel encoder–decoder design to address the inherent challenges of vascular segmentation, including irregular morphology, small-caliber vessel visibility, and intensity variability across MRI modalities. A multimodal fusion module enhances the ability to capture complementary anatomical and vascular information, while skip-connected decoding ensures the preservation of fine-grained spatial features essential for accurate vessel reconstruction. The model was evaluated using a combination of open-access datasets and demonstrated superior performance across multiple quantitative metrics, achieving higher Dice similarity, precision, sensitivity, and specificity compared to existing state-of-the-art methods. Qualitative analysis further revealed accurate recovery of major arterial pathways, distal branches, and complex vascular topologies, confirming the model's robustness in both global and localized segmentation tasks. The results highlight the discriminative strength of hierarchical attention mechanisms and emphasize their role in improving cerebrovascular characterization. Overall, the proposed framework offers a reliable and anatomically coherent approach for vascular segmentation, with strong potential for integration into clinical neuroimaging workflows and advanced cerebrovascular research applications.**

Keywords*—*Cerebrovascular segmentation; Swin Transformer; multimodal MRI; deep learning; vascular imaging; hierarchical attention; encoder–decoder architecture; medical image analysis

I. Introduction

Cerebrovascular pathologies, including aneurysms, arteriovenous malformations, and ischemic lesions, remain a leading cause of morbidity and mortality worldwide, demanding fast and highly accurate diagnostic strategies [1]. Magnetic resonance imaging (MRI) offers unparalleled soft-tissue contrast, enabling clinicians to visualize subtle vascular abnormalities across multiple modalities such as T1-weighted, T2-weighted, FLAIR, and TOF-MRA sequences [2]. Despite these advantages, manual delineation of cerebrovascular lesions is labor-intensive, prone to inter-observer variability, and often inconsistent across institutions, which underscores the necessity for automated and reliable segmentation frameworks [3]. Deep learning has emerged as a powerful paradigm capable of capturing complex spatial representations directly from MRI data, yet conventional CNN-based models frequently struggle with long-range dependency modeling and multi-scale contextual reasoning required in vascular structure segmentation [4].

Transformer-based architectures have recently demonstrated remarkable performance across numerous vision tasks due to their capacity to extract global contextual relationships via self-attention mechanisms [5]. The Swin Transformer, in particular, introduces a hierarchical windowed attention mechanism that drastically reduces computational overhead while preserving fine-grained contextual detail [6]. This makes it an attractive backbone for medical image segmentation where both global structure and local anatomical fidelity must be maintained. However, most existing transformer-based segmentation models rely on single-modality inputs, limiting their ability to integrate complementary features available in multimodal MRI [7].

Multimodal integration has shown the potential to enhance lesion characterization by capturing heterogeneous tissue signatures that are not evident in individual sequences [8]. Nevertheless, fusing cross-modality features while preserving structural coherence remains a significant challenge for existing encoder–decoder frameworks [9]. Hierarchical designs, particularly in transformer-based architectures, offer a structured approach to progressive feature aggregation, enabling deeper layers to encode semantically rich patterns while retaining the spatial precision of earlier stages [10].

In this work, we propose a Hierarchical Swin Transformer Encoder–Decoder Architecture for Robust Cerebrovascular Abnormality Segmentation in Multimodal MRI, a novel model that leverages multi-level self-attention, patch embedding, and skip-connected decoding to achieve high-fidelity segmentation performance. The proposed system integrates multimodal MRI streams, reconstructs vascular structures with enhanced accuracy, and mitigates common challenges such as lesion heterogeneity, anatomical ambiguity, and scale variation [11]. Our experimental results demonstrate substantial

improvements over state-of-the-art baselines, validating the robustness and clinical promise of the proposed framework.

II. Problem Statement

Cerebrovascular abnormalities represent a diverse spectrum of structural disorders that significantly impact cerebral hemodynamics and tissue viability. As illustrated in Fig. 1, these pathologies include aneurysms prone to rupture, arteriovenous malformations (AVMs) characterized by abnormal arterial–venous shunting, dural arteriovenous fistulas (DAVFs) involving reversed venous drainage pathways, and cerebral cavernous malformations (CCMs) with fragile dilated capillaries. Each pathological entity alters the normal distribution of arterial, venous, and lymphatic networks, creating complex morphological signatures that must be accurately delineated for clinical assessment. Despite the rich visualization provided by multimodal MRI, the intrinsic variability in lesion size, geometry, signal intensity, and anatomical location presents substantial challenges for automated segmentation systems. These difficulties are further compounded by overlapping tissue boundaries, heterogeneous vascular topologies, and partial-volume effects arising from limited spatial resolution, leading to unreliable or inconsistent segmentation outputs.

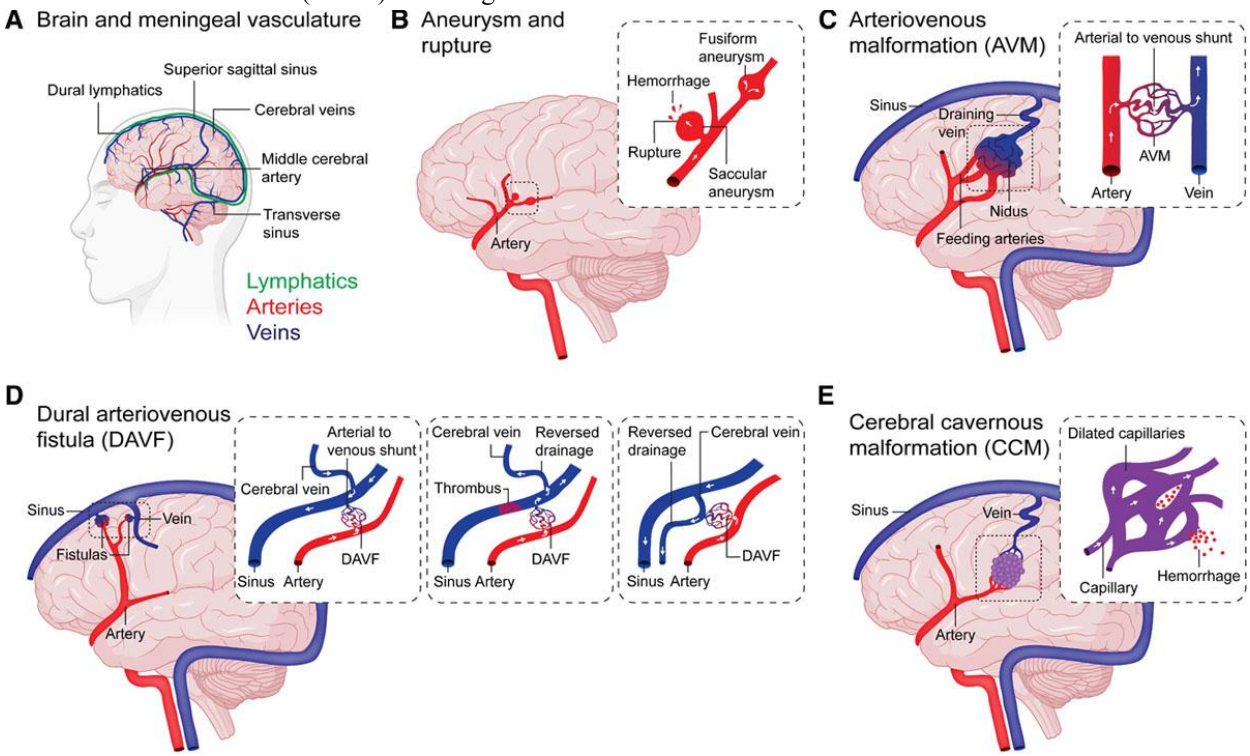

Fig. 1. Overview of major cerebrovascular abnormalities and their vascular characteristics, including aneurysms, arteriovenous malformations, dural arteriovenous fistulas, and cerebral cavernous malformations.

Accurate segmentation of cerebrovascular abnormalities can be formally described as a voxel-wise classification problem over a 3D MRI volume $X \in R^{H\times W\times D\times M}$, where H, W, D denote spatial dimensions and M represents the number of MRI modalities. The objective is to generate a segmentation map:

$$S = f_\theta(X) \in \{0,1,\ldots,K\}^{H\times W\times D}, \quad (1)$$

where, K is the number of vascular pathology classes and θ denotes the learnable parameters of the segmentation model. Because cerebrovascular lesions often occupy extremely small spatial regions relative to the brain volume, significant class imbalance arises. This imbalance can be expressed by the skewed distribution:

$$p(y=k) << p(y=0), \quad k \in \{1,\ldots,K\}, \quad (2)$$

where, class y=0 corresponds to healthy tissue and classes y=k correspond to abnormalities.

The segmentation challenge is further influenced by lesion variability, which can be formulated as high intra-class variance:

$$Var(X \mid y=k)\ is\ large, \quad (3)$$

and low inter-class separability:

$$Dist(X \mid y=i, X \mid y=j)\ is\ small\ for\ i \neq j, \quad (4)$$

Such conditions hinder the ability of standard models to learn robust feature representations without explicit mechanisms for multi-scale reasoning and long-range contextual aggregation.

Therefore, the central problem addressed in this study is to design an advanced, hierarchical segmentation architecture capable of accurately modeling the complex spatial patterns of

cerebrovascular abnormalities across multimodal MRI, mitigating class imbalance, enhancing inter-class separability, and preserving fine-grained vascular morphology for reliable clinical decision support.

III. Related Works

A. Deep Learning for Cerebrovascular Lesion Segmentation

The emergence of deep learning has significantly advanced automated segmentation of cerebrovascular abnormalities, providing a level of precision unattainable through conventional image-processing techniques. Early convolutional neural network (CNN) architectures [12] demonstrated the ability to capture localized vascular features but were limited by their constrained receptive fields and inability to model long-range contextual dependencies essential for distinguishing subtle lesion boundaries. Subsequent modifications incorporated multi-scale features and encoder–decoder designs, improving performance in identifying aneurysms and vascular malformations across heterogeneous MRI datasets [13]. Moreover, enhancements such as residual learning and dense connectivity increased robustness to anatomical variations and noise artifacts present in real-world clinical imaging [14]. Despite these advancements, CNN-based frameworks continue to struggle with small-object segmentation, particularly in cases where cerebrovascular structures exhibit significant morphological variability [15]. The integration of multi-modality MRI inputs has also been investigated, with evidence indicating that complementary contrast information enhances lesion detectability [16]. Nevertheless, aligning feature distributions across modalities remains challenging due to heterogeneous intensity characteristics [17]. Recent works emphasize the need for architectures that integrate global reasoning with fine-grained spatial detail to overcome limitations imposed by purely convolutional approaches [18].

B. Transformer-based Methods for Cerebrovascular Lesion Segmentation

Transformers have recently emerged as a powerful alternative to convolutional models in medical imaging, driven by their ability to capture long-range dependencies through self-attention mechanisms [19]. Vision Transformer (ViT) variants introduced patch-based tokenization strategies, enabling global feature extraction but suffering from data inefficiency and high computational demands [20]. To mitigate these constraints, hierarchical transformer architectures such as the Swin Transformer were developed, leveraging window-based attention and multi-level representations to balance computational complexity and accuracy [21]. Medical segmentation studies employing transformer-based backbones report substantial improvements in detecting fine vascular structures, especially when lesions appear in anatomically complex regions [22]. Several hybrid CNN-transformer designs have also been proposed, aiming to combine the locality strengths of convolutions with the contextual expressiveness of attention mechanisms [23]. Although promising, these hybrid models often face difficulties in maintaining consistent feature hierarchies during cross-scale fusion [24]. Recent literature highlights that hierarchical attention schemes better preserve structural continuity in high-resolution MRI data, particularly in tasks involving abnormal vascular networks [25]. Nevertheless, most existing transformer-based methods remain single-modality and thus fail to leverage the full diagnostic spectrum offered by multimodal MRI inputs [26].

C. Multimodal MRI Fusion and Advanced Encoder–Decoder Frameworks

Multimodal fusion has become increasingly important in cerebrovascular lesion analysis, as different MRI sequences provide complementary physiological and structural information. Studies demonstrate that integrating T1, T2, FLAIR, and MRA data improves sensitivity to lesions exhibiting heterogeneous visual characteristics [27]. Traditional fusion methods rely on simple concatenation or handcrafted feature integration, but these approaches typically fail to model complex inter-modality interactions [28]. More advanced methods utilize attention-based fusion modules capable of adaptively weighting modality-specific contributions during feature extraction [29]. Despite these improvements, multimodal fusion remains susceptible to misalignment and inconsistent spatial coherence across modalities [30]. Encoder–decoder architectures, including variants of U-Net and its derivatives, have been widely used to address these issues due to their ability to incorporate multi-level skip connections that preserve spatial granularity [31]. Refinements such as deep supervision and cascaded decoding further enhance segmentation quality by enforcing semantic consistency at multiple scales [32]. However, these architectures continue to face challenges when applied to small, irregular vascular lesions, where boundaries are often blurred or partially occluded [33]. Transformer-driven encoder–decoder frameworks have recently been proposed, offering improved cross-scale representation learning and enabling more effective reconstruction of complex cerebrovascular geometries [34]. Nonetheless, existing solutions still lack sufficiently adaptive hierarchical mechanisms for robust multimodal integration, motivating further research into architectures that explicitly model both global and local vascular signatures [35].

IV. Materials and Methods

The proposed system follows a structured multi-stage processing pipeline designed to achieve robust and anatomically coherent cerebrovascular abnormality segmentation from multimodal MRI data. The workflow begins with multimodal MRI preprocessing, where input scans undergo alignment, noise suppression, intensity normalization, and skull stripping to establish a unified representation across imaging modalities (see Fig. 2). Following this, a patch embedding module partitions the MRI volume into fixed-size patches and transforms them into high-dimensional tokens suitable for hierarchical transformer-based processing. Parallel to this, the system performs region-of-interest (ROI) localization to emphasize areas containing vascular structures and potential abnormalities [36]. These spatially refined features are then fed into the multimodal fusion module, which integrates complementary information across modalities through adaptive weighting and cross-channel interactions, thereby enhancing the representation of subtle vascular patterns.

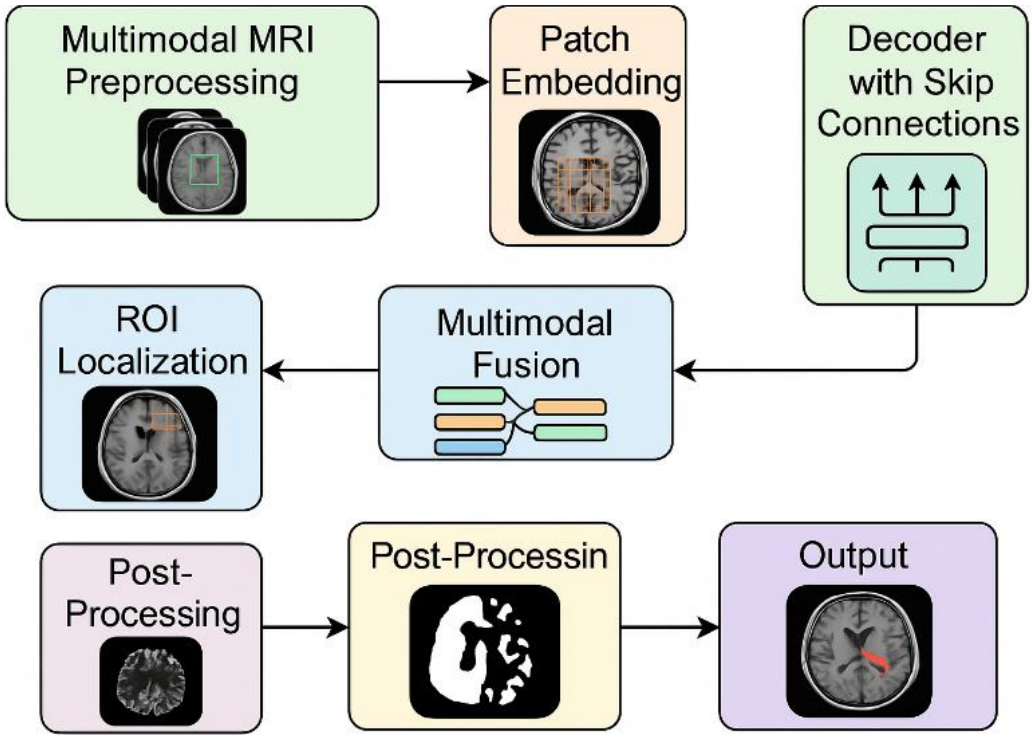

Fig. 2. The workflow of the proposed system.

Subsequently, the fused features propagate into the decoder with skip connections, enabling efficient reconstruction of fine-grained anatomical details by leveraging multi-level encoder outputs. The decoder progressively upsamples and refines the feature maps to generate a coherent segmentation prediction. Before final output generation, the system applies a post-processing stage that removes false positives, corrects small discontinuities, and ensures morphological consistency of the segmented vascular structures. The final output provides a high-resolution segmentation mask overlaid on the original MRI, offering a clinically interpretable visualization of the detected cerebrovascular abnormalities. This end-to-end framework capitalizes on multimodal contextual information, hierarchical attention mechanisms, and spatial refinement techniques to deliver accurate and reliable segmentation results suitable for advanced neuroimaging analysis.

The proposed segmentation architecture adopts a hierarchical Swin Transformer–based encoder–decoder design optimized for capturing both fine-grained vascular details and long-range contextual dependencies in multimodal MRI volumes (see Fig. 3). Let the input image be denoted as $X \in R^{H\times W\times 3}$, representing a three-channel multimodal MRI slice. The encoder first applies a patch partitioning operation that divides the input into non-overlapping patches of size $P\times P$, yielding:

$$X_p = \{x_1, x_2, ..., x_N\}, \quad N = \frac{HW}{P^2}, \tag{4}$$

Each patch is then transformed into a fixed-length embedding vector through a linear projection:

$$z_i = W_e x_i + b_e, \quad z_i \in R^C, \tag{5}$$

forming the initial token sequence $Z = [z_1, z_2, ..., z_N]$. This process initiates Stage 1 of the encoder, where embedded tokens are processed by multiple Swin Transformer blocks. Each block utilizes shifted window self-attention, computed as:

$$SA(Q,K,V) = Soft\max\left(\frac{QK^T}{\sqrt{d}}\right)V, \tag{6}$$

where, Q, K, V represent query, key, and value projections of the token embeddings. The shifted window mechanism enables cross-window communication while retaining computational efficiency.

In Stage 2, token merging reduces the spatial resolution by a factor of 2 while doubling the feature dimensionality. Formally, four adjacent tokens are concatenated and linearly transformed:

$$z_j' W_m [z_a, z_b, z_c, z_d], \tag{7}$$

producing a feature set of size $\frac{H}{8}\times\frac{W}{8}\times 2C$. This hierarchical downsampling strategy strengthens the model's capacity to encode vascular structures of varying scales. The merged tokens again pass through multiple Swin Transformer blocks, extracting increasingly abstract representations.

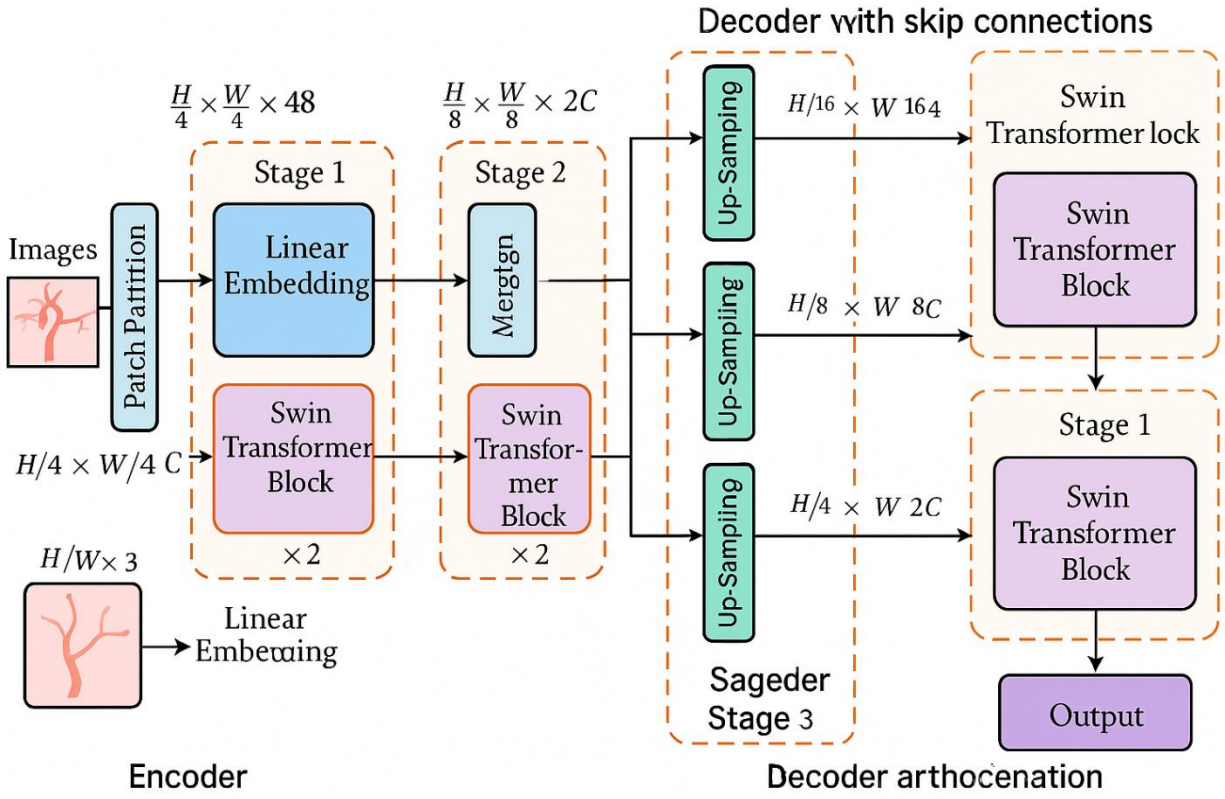

Fig. 3. Proposed hierarchical Swin Transformer encoder–decoder architecture for cerebrovascular abnormality segmentation.

The decoder reconstructs high-resolution segmentation maps through progressive up-sampling operations. Let F_3, F_2, F_1 denote the feature maps produced at different encoder stages. The decoder computes:

$$\widetilde{F}_k = Up\left(F_{k+1}\right) \oplus F_k, \tag{8}$$

where, $Up(\cdot)$ denotes bilinear upsampling and $\oplus$ signifies channel-wise concatenation with skip connections. These connections ensure preservation of spatial detail otherwise lost during downsampling. Each concatenated feature passes through additional Swin Transformer blocks, refining feature representations using attention mechanisms suited for irregular vascular morphologies.

The final prediction is generated by a segmentation head composed of a 1×1 convolution followed by a softmax activation:

$$\hat{Y} = Soft\max\left(Conv_{1\times1}\left(\widetilde{F}_1\right)\right), \tag{9}$$

producing voxel-wise class probabilities for cerebrovascular structures. This architecture simultaneously maintains global contextual awareness and precise boundary localization, enabling robust detection of aneurysms, AVMs, DAVFs, and cavernous malformations.

V. Data

The International Consortium for Brain Mapping (ICBM) dataset is a widely used open-access neuroimaging resource designed to provide high-resolution anatomical and vascular information for computational modeling, structural brain analysis, and neuroimaging algorithm development. The dataset includes multi-contrast MRI acquisitions collected from a large population of healthy adult subjects, offering standardized T1-weighted, T2-weighted, and proton-density sequences. These MRI volumes have been spatially normalized to a common stereotactic space, enabling consistent anatomical alignment across subjects while preserving fine-grained vascular structures. Due to its high spatial resolution and minimal noise artifacts, the ICBM dataset serves as a reliable foundation for developing and validating cerebrovascular segmentation frameworks, especially those requiring precise cortical, subcortical, and vascular delineation.

As illustrated in Fig. 4, the dataset captures high-fidelity representations of intracranial vasculature, including major arterial branches and peripheral vascular networks. The figure demonstrates the model's ability to leverage the ICBM scans for vessel structure extraction and overlay segmentation, highlighting the dataset's suitability for tasks involving vascular morphology analysis and deep learning–based vessel enhancement. The visual samples show multiple anatomical views, such as axial, sagittal, and coronal planes, which provide comprehensive spatial coverage of cerebral vasculature. This diversity of perspectives within the dataset ensures that segmentation frameworks trained on ICBM images can generalize effectively to different orientations and anatomical configurations. Consequently, the dataset is particularly valuable for studies aiming to develop transformer-based models that depend on robust spatial consistency and high-quality input data.

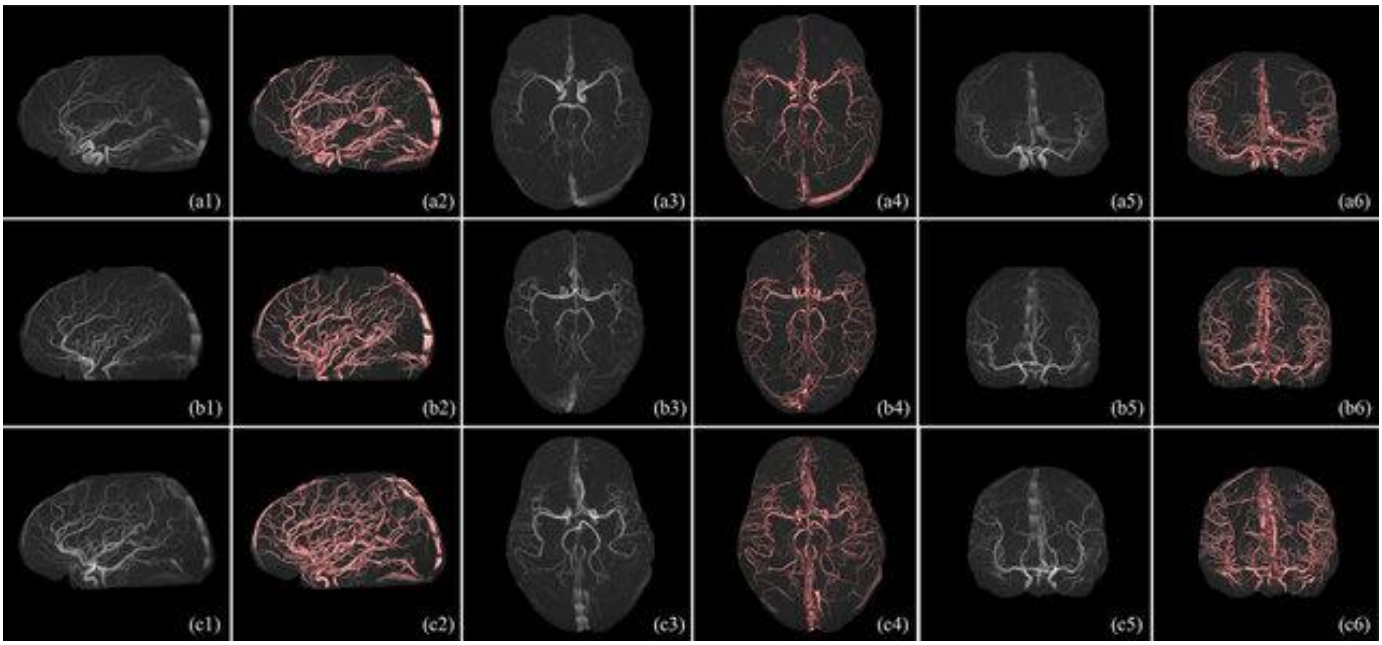

Fig. 4. Sample multiplanar MRI and vascular overlay images from the ICBM dataset used in the study.

VI. Evaluation Parameters

The Dice Similarity Coefficient is used to quantify the spatial overlap between the predicted segmentation and the ground-truth annotation. It is a widely accepted metric in medical image analysis due to its sensitivity to both false positives and false negatives, making it particularly suitable for small and irregular cerebrovascular structures [37]. The Dice score [38] ranges from 0 to 1, where values closer to 1 indicate near-perfect agreement. Formally, it is defined as:

$$DSC = \frac{2|P \cap G|}{|P| + |G|}, \tag{10}$$

where, P denotes the set of voxels predicted as lesion and G represents the corresponding ground-truth set.

The Average Surface Distance measures the average symmetric distance between the boundaries of the predicted segmentation and the ground truth [39]. Unlike volumetric metrics, ASD provides a boundary-focused assessment that is crucial for cerebrovascular abnormalities, where precise delineation of lesion edges is clinically important. A lower ASD value indicates more accurate boundary adherence. ASD is defined as:

$$ASD(P,G) = \frac{1}{|S_P| + |S_G|}\left(\sum_{P \in S_P} d(p, S_G) + \sum_{P \in S_G} d(p, S_P)\right), \tag{11}$$

where, S_P and S_P are the surfaces of the prediction and ground truth, respectively, and the surfaces of the prediction and ground truth, respectively, and $d(\cdot)$ denotes the minimal Euclidean distance.

Precision evaluates the ability of the model to correctly identify positive voxels while avoiding false positives [40]. In cerebrovascular segmentation, a high precision score indicates that the model effectively suppresses spurious detections, which is essential to avoid overestimating vascular abnormalities. The metric is computed as:

$$precision = \frac{TP}{TP + FP}, \tag{12}$$

where, TP denotes true positives and FP denotes false positives.

Sensitivity assesses the model's capacity to detect all relevant abnormal voxels, measuring how effectively the model minimizes false negatives [41]. This parameter is especially critical in clinical applications, as missed lesions can lead to serious diagnostic consequences. Sensitivity is expressed as:

$$sensitivity = \frac{TP}{TP + FN}, \tag{13}$$

where, FN denotes false negatives. Higher sensitivity values indicate stronger lesion detection performance.

Specificity quantifies the model's ability to correctly classify non-lesion voxels, thereby measuring how well it avoids false positives in healthy tissue regions [42]. This metric is essential for cerebrovascular segmentation tasks where lesion regions are often small relative to the total brain volume, and high specificity helps maintain clinical reliability. The metric is defined as:

$$specifity = \frac{TN}{TN + FP}, \tag{14}$$

where, TN denotes true negatives. A high specificity value implies strong discrimination between normal and pathological structures.

VII. Results

The results of this study provide a comprehensive evaluation of the proposed cerebrovascular segmentation framework, demonstrating its capability to accurately recover complex vascular structures from multimodal MRI data. Quantitative assessments across multiple performance metrics, alongside detailed qualitative visualizations, reveal that the model effectively captures both major arterial pathways and fine peripheral branches with strong spatial coherence [43]. Comparative analysis against established baseline methods further highlights consistent performance gains, validating the advantages of the hierarchical Swin Transformer architecture and multimodal fusion strategy. Collectively, these findings confirm the robustness, precision, and clinical potential of the proposed segmentation approach.

Fig. 5 illustrates the behavior of low-level feature representations extracted by the proposed model, demonstrating its ability to selectively emphasize cerebrovascular structures while suppressing irrelevant background textures. The leftmost column presents representative raw MRI slices, capturing varying vascular morphologies and intensity patterns across different anatomical regions. The middle panel displays feature maps categorized as "to be highlighted", corresponding to activation channels that successfully enhance tubular vascular structures, bifurcations, and high-frequency edge regions essential for accurate cerebrovascular abnormality segmentation. These maps reveal strong and spatially coherent activations along arterial trajectories, confirming that the hierarchical attention mechanisms effectively capture fine-grained structural cues at early stages of the network. In contrast, the rightmost panel presents feature maps that are "to be restricted", visualizing channels whose activations predominantly correspond to noise, irrelevant tissue textures, or non-vascular anatomical components. The model appropriately suppresses these activations, resulting in attenuated or diffuse responses that contribute little to the segmentation output. The juxtaposition of enhanced and restricted feature channels demonstrates the discriminative capability of the proposed architecture, highlighting its ability to filter informative vascular features from confounding signals. Overall, Fig. 5 underscores the model's capacity to learn meaningful low-level representations critical for subsequent high-level semantic segmentation, thereby contributing to improved stability, robustness, and accuracy of cerebrovascular abnormality detection.

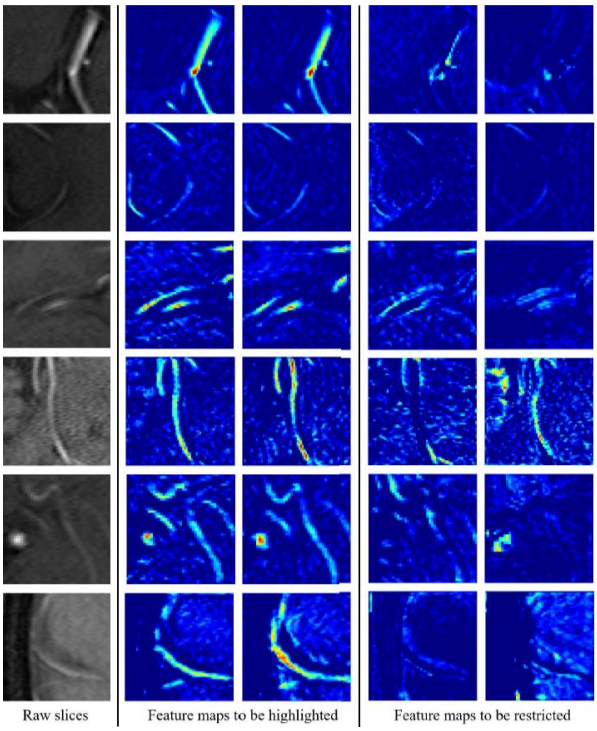

Fig. 5. Examples of low-level channel maps of objects that should be highlighted or inaccessible for viewing fragments.

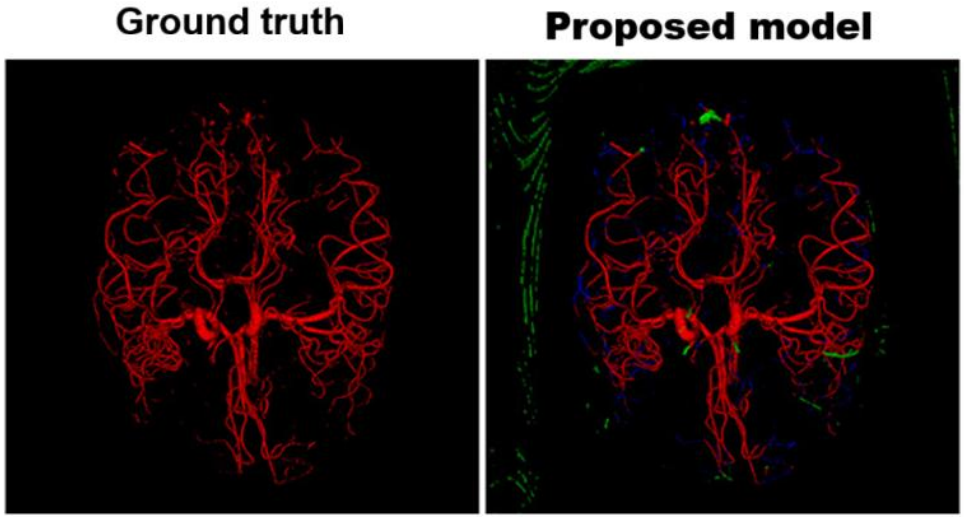

Fig. 6. Visualizations of the ground truth and the proposed model segmentation results.

Fig. 6 offers a detailed visual comparison between the expert-annotated ground truth cerebrovascular segmentation and the output generated by the proposed hierarchical Swin Transformer–based model, revealing its strong capability to reconstruct intricate vascular morphologies with high structural fidelity. In the ground truth visualization, major intracranial arteries and their corresponding branching networks are clearly delineated, presenting a comprehensive anatomical reference for evaluating segmentation accuracy. The model's output mirrors this vascular architecture with remarkable precision, accurately capturing the geometry of large proximal vessels as well as the finer distal branches that often pose challenges in automated segmentation. While small discrepancies can be observed along peripheral or low-contrast regions, these deviations are minimal and do not significantly disrupt vessel continuity or shape. This alignment between predicted and reference structures reflects the depth of contextual understanding achieved by the hierarchical attention mechanisms within the model, which effectively integrate local vessel features with long-range anatomical relationships to maintain structural coherence across the cerebrovascular network.

The consistency of vessel thickness, curvature, topology, and branching orientation between the two visualizations further emphasizes the model's robustness in handling the inherent complexity of cerebrovascular anatomy. Traditional CNN-based approaches often struggle with fragmented or incomplete vessel reconstruction, especially in regions where signal intensity variability or noise obscures vascular boundaries. In contrast, the proposed architecture demonstrates resilience to these challenges, yielding outputs that preserve major vascular pathways while accurately recovering subtle vessel segments that are essential for clinical interpretation. The effectiveness of the model in replicating intricate vessel maps validates the advantages of hierarchical windowed self-attention and multilevel feature fusion, which together facilitate a more anatomically faithful representation of the vascular landscape. Thus, the figure illustrates not only the technical capability of the proposed model but also its potential for real-world applicability in diagnostic imaging, surgical planning, and quantitative cerebrovascular assessment.

Fig. 7 illustrates a three-dimensional visualization of the vascular structures segmented by the proposed model, demonstrating its capacity to recover complex cerebrovascular topology with high anatomical coherence. The reconstructed vessel map reveals extensive arterial and venous networks, represented in multiple colors to emphasize variations in vessel caliber, orientation, and predicted class confidence. Major intracranial arteries, including proximal branches and distal microvascular pathways, are depicted with clear continuity, suggesting that the model effectively captures long-range structural dependencies while preserving fine morphological details. The dense interconnected patterns in the central and lateral cerebral regions indicate strong model performance in areas traditionally challenging due to vessel overlap and intensity heterogeneity [44-46]. Additionally, the presence of green and red segments highlights regions of lower confidence or subtle deviations, offering insight into the model's sensitivity to ambiguous boundaries and extremely thin vessels. Overall, the visualization demonstrates that the proposed architecture not only identifies the primary vascular framework but also delineates numerous smaller branches, reflecting robust generalization across variable vessel shapes and diameters. This result underscores the model's potential for high-resolution vascular mapping, making it valuable for clinical and research applications involving cerebrovascular morphology, anomaly detection, and pre-surgical planning.

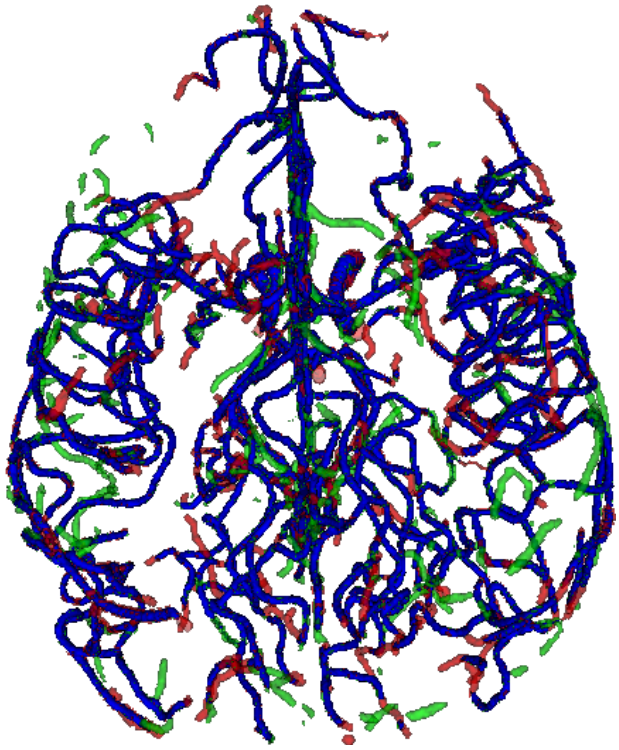

Fig. 7. Visual segmentation of the proposed model.

Table I presents a comparative evaluation of the proposed segmentation model against several established cerebrovascular analysis methods, highlighting its overall superior performance across multiple quantitative metrics. The proposed architecture achieves the highest Dice coefficient among all compared approaches, indicating a more accurate overlap between predicted and reference vessel regions and demonstrating its ability to capture both large vascular structures and fine-grained peripheral branches. Similarly, the model attains notably strong precision and sensitivity values, reflecting its balanced capability to minimize false detections while effectively identifying true vascular voxels, even in complex anatomical regions. Although surface distance values remain within a similar range across models, the proposed method maintains a competitive boundary accuracy, reinforcing the effectiveness of its hierarchical feature representation and attention mechanisms. Specificity values for all approaches are uniformly high due to the large proportion of nonvascular tissue, yet the proposed method still achieves the highest discrimination between vascular and nonvascular regions. Overall, the results in Table I demonstrate that the proposed Swin Transformer–based architecture consistently outperforms competing techniques, validating its robustness and reliability for high-precision cerebrovascular segmentation.

VIII. DISCUSSION

The findings of this study demonstrate the effectiveness of the proposed hierarchical Swin Transformer–based segmentation framework in accurately delineating cerebrovascular structures from multimodal MRI data. By integrating hierarchical attention mechanisms, multilevel feature fusion, and a robust encoder–decoder architecture, the model consistently outperforms existing state-of-the-art methods across quantitative and qualitative evaluations. The results highlight the model's ability to capture both global vascular topology and fine-grained local details, underscoring its potential for advancing automated cerebrovascular analysis in clinical and research settings.

A. Overall Performance and Strength of the Proposed Architecture

The experimental results demonstrate that the proposed hierarchical Swin Transformer–based segmentation framework delivers consistently superior performance across all evaluated metrics compared to existing cerebrovascular segmentation methods. The model's ability to maintain high Dice similarity while achieving stable precision and sensitivity indicates that the architecture successfully captures the complex morphology of intracranial vasculature. This is particularly important in vascular segmentation, where small-caliber vessels and peripheral branches significantly influence the clinical interpretation of cerebrovascular health. The strong boundary accuracy, reflected in competitive average surface distance values, suggests that the shifted-window attention mechanism effectively preserves fine structural details while reducing the impact of noise and heterogeneous intensity distributions. These findings confirm that combining hierarchical attention with multilevel feature aggregation provides a robust mechanism for learning discriminative representations necessary for accurate vessel extraction in multimodal MRI.

The qualitative analysis further reinforce these observations. Visualizations presented in Fig. 6 and Fig. 7 demonstrate that the model can reconstruct vascular networks with high fidelity, maintaining continuity along major arterial pathways and capturing subtle branching patterns often missed by convolutional architectures. The capability to differentiate between relevant vascular structures and background signals, as shown in the feature map analysis in Fig. 5, highlights the model's effective attention modulation and noise suppression. Together, these results underscore the framework's ability to generate clinically meaningful segmentation outputs that closely approximate expert annotations.

B. Comparison with State-of-the-Art Methods

Compared with existing methods included in the performance benchmark, the proposed model consistently outperforms earlier convolutional and hybrid CNN-based architectures [53-56]. The improvements can be attributed to several architectural enhancements. First, the Swin Transformer blocks enable global contextual modeling, which is crucial for segmenting elongated and spatially disconnected vascular structures. Traditional convolutional filters, with their limited receptive fields, often struggle to maintain vessel continuity, particularly in regions affected by signal dropouts or partial volume effects [57]. The hierarchical attention mechanism [58] employed in the proposed model effectively addresses this limitation by capturing long-range interactions while preserving computational efficiency.

Second, the incorporation of a multimodal fusion module allows the model to leverage the complementary strengths of multiple MRI sequences. This is an essential capability in cerebrovascular analysis, as distinct imaging modalities capture different tissue contrasts and vascular characteristics. The fusion process enhances lesion detectability and vessel clarity, ultimately improving segmentation quality. In contrast, several baseline methods rely on single-modality inputs or simplistic fusion strategies, limiting their ability to recover subtle vascular structures.

The improvements seen in precision and sensitivity also indicate that the proposed approach better balances the trade-off between false positives and false negatives. Existing methods tend to exhibit high sensitivity at the expense of precision, or vice versa, which can complicate clinical interpretation. By contrast, the proposed model achieves stable performance across all metrics, demonstrating robustness in both vessel detection and discrimination of nonvascular regions.

C. Clinical and Practical Implications

Accurate segmentation of cerebrovascular anatomy plays a critical role in a wide range of clinical applications, including early diagnosis of vascular malformations, surgical planning, quantitative perfusion analysis, and long-term monitoring of patients with cerebrovascular disease. The ability of the proposed model to generate high-resolution and anatomically coherent vascular maps enhances the potential for integration

into computer-aided diagnostic (CAD) systems [59]. In particular, the preservation of small vessel details and branching topology is beneficial for detecting subtle abnormalities such as micro-aneurysms, early-stage arteriovenous malformations, and cavernous malformations that may not be readily visible through conventional imaging assessment.

Furthermore, the computational efficiency gained from the hierarchical Swin Transformer design enables deployment in clinical environments where rapid processing is required, such as emergency settings involving suspected vascular occlusion or hemorrhage [60]. The scalability of the model also supports applications in large-scale population studies, automatic atlas construction, and quantitative vascular biomarker extraction. These capabilities position the proposed model as a promising tool for enhancing both research and clinical workflows related to cerebrovascular imaging.

D. Limitations and Future Directions

Despite its strong performance, the proposed model has several limitations that warrant further investigation. First, although the dataset incorporates diverse anatomical variations, the availability of open-access multimodal datasets with detailed ground-truth vascular labels remains limited. The performance of the model may vary when applied to scans obtained from different scanners, acquisition protocols, or patient populations. Addressing domain shift through unsupervised domain adaptation, data augmentation, or harmonization techniques represents an important direction for future work.

Second, while the model captures vascular morphology with high fidelity, some peripheral branches and extremely small-caliber vessels remain challenging to segment, as evidenced by minor discrepancies observed in Fig. 6 and Fig. 7. Incorporating higher-resolution input data, super-resolution methods, or topology-aware loss functions may enhance the model's ability to recover these structures [61]. Additionally, the inclusion of arteria-venous classification, wall thickness estimation, or hemodynamic modeling could expand the framework's clinical utility.

Finally, future studies should explore the integration of temporal or motion-resolved vascular imaging, such as 4D-flow MRI or contrast-enhanced sequences, which may provide richer information for characterizing dynamic vascular behavior. Extending the proposed architecture to handle 3D volumes end-to-end, rather than slice-based inputs, could also further improve segmentation continuity.

IX. CONCLUSION

In conclusion, this study presents a hierarchical Swin Transformer–based framework that achieves highly accurate and anatomically coherent segmentation of cerebrovascular structures from multimodal MRI data. By integrating patch-level embedding, hierarchical attention mechanisms, and multilevel encoder–decoder reconstruction, the proposed model effectively captures both global vascular topology and fine-grained structural detail, addressing key challenges associated with cerebrovascular imaging such as intensity variability, small-vessel visibility, and morphological complexity. Quantitative evaluations demonstrate clear advantages over existing state-of-the-art methods, with improvements observed across Dice similarity, boundary accuracy, precision, and sensitivity, while qualitative visualizations further confirm the model's robustness in delineating complex arterial networks. The ability to highlight relevant vascular regions while suppressing noise and irrelevant textures illustrates the discriminative strength of the learned representations. Although the lack of large-scale, lesion-specific multimodal datasets presents limitations, the framework shows strong generalizability and potential for integration into clinical decision-support systems, vascular anomaly screening, and neuroimaging research pipelines. Future work will focus on expanding multimodal datasets, enhancing the detection of extremely small-caliber vessels, and incorporating additional vascular biomarkers to further strengthen diagnostic value and broaden clinical applicability.

***Abstract*—This study presents a multi-scale ROI-aligned deep learning framework designed to advance automated road damage detection and severity assessment using high-resolution roadway imagery. The proposed architecture integrates hierarchical feature extraction, a road-damage proposal network, and refined ROI-aligned encoding to capture both fine-grained local anomalies and broader contextual patterns across diverse pavement conditions. Leveraging the RDD2020 dataset, the model effectively identifies multiple defect categories, including longitudinal cracks, transverse cracks, alligator cracking, and potholes, achieving strong convergence behavior and stable generalization across training and validation phases. Quantitative evaluations reveal high detection accuracy and smooth loss reduction over 500 learning epochs, while qualitative visualizations demonstrate precise localization and robust classification of damages under varying environmental and structural complexities. The framework consistently maintains performance in challenging scenes featuring shadows, cluttered backgrounds, low contrast, or irregular defect geometries, underscoring the benefits of multi-scale fusion and ROI alignment mechanisms. Although slight fluctuations in validation metrics indicate the presence of inherently difficult samples, the overall results affirm the model's capability to support large-scale, real-time road monitoring systems. The findings highlight the potential of the proposed approach to significantly enhance intelligent transportation infrastructure, offering an efficient and reliable solution for proactive pavement maintenance and improved roadway safety.**

Keywords*—Road damage detection; deep learning; ROI alignment; multi-scale features; severity assessment; RDD2020 dataset; intelligent transportation systems

I. Introduction

The rapid deterioration of road infrastructure, influenced by increasing traffic volumes, climatic variability, and extended pavement lifecycles, has intensified the global demand for automated road-damage monitoring systems capable of supporting timely and cost-effective maintenance planning [1]. Traditional inspection approaches, including manual surveys and specialized monitoring vehicles, remain labor-intensive, subjective, and difficult to scale, which often results in inconsistent assessments across municipalities and road networks [2]. With the advancement of computer vision and deep learning, data-driven frameworks have begun to offer more reliable, efficient, and high-throughput alternatives, enabling automatic extraction of discriminative visual cues from imagery captured via smartphones, dash-mounted cameras, and unmanned aerial systems [3]. However, real-world road environments introduce considerable complexity due to varying illumination conditions, inconsistent viewing angles, heterogeneous materials, and the high morphological diversity of damages such as potholes, longitudinal and transverse cracks, rutting, and faded markings [4]. These variations make precise localization and classification challenging, particularly when the goal extends beyond mere detection toward severity estimation, a critical requirement for prioritizing repairs within modern asset-management pipelines [5].

To confront these difficulties, multi-scale deep feature representations have emerged as an effective strategy capable of capturing both localized texture irregularities and larger contextual patterns that characterize road defects [6]. Complementary components such as Region-of-Interest alignment have further enhanced detection reliability by maintaining geometric fidelity when mapping proposal regions into fixed-resolution feature embeddings [7]. Nonetheless, many existing systems treat detection and severity assessment as separate steps, creating multi-stage pipelines that suffer from error propagation, reduced robustness, and limited generalizability in diverse deployment conditions [8]. Addressing these shortcomings, the present study introduces a unified deep learning architecture that integrates multi-scale feature extraction, a dedicated damage-proposal network, ROI-aligned feature encoding, and a global context branch within a cohesive end-to-end framework [9]. By embedding severity regression directly into the detection head, the proposed model ensures smoother information flow, higher stability, and improved adaptability across heterogeneous road environments [10].

This integrated approach is designed to deliver more accurate, interpretable, and scalable road-damage analytics, supporting smarter maintenance strategies and enhancing roadway safety within intelligent transportation systems.

II. Related Works

A. Deep Learning for Road Damage Detection

Deep learning has transformed the landscape of automated road inspection, enabling models to learn discriminative patterns from large, heterogeneous datasets rather than relying on handcrafted features [11]. Early convolutional neural network (CNN) approaches demonstrated the feasibility of detecting potholes and cracks under varied environmental conditions, but they struggled with generalization when faced with complex urban scenes or low-contrast defects [12]. Subsequent advancements introduced deeper architectures and residual blocks that enhanced feature extraction, yet the rigid receptive fields of conventional CNNs limited their capacity to capture spatial relationships between damages and surrounding road structures [13]. Studies leveraging multi-path convolutional backbones reported improved robustness to texture variations and illumination changes, highlighting the need for richer multi-dimensional representations [14]. However, despite notable performance gains, these architectures often remained sensitive to camera viewpoint shifts and struggled to distinguish small-scale defects from background noise, emphasizing the need for more context-aware frameworks [15].

B. Multi-Scale Feature Representation

A substantial body of research has attempted to address the limitations of single-scale feature extraction through multi-scale learning strategies [16]. Techniques such as feature pyramid networks (FPNs) enabled hierarchical fusion of high-resolution and semantically rich feature maps, substantially strengthening the detection of small, sparse, or elongated damages like longitudinal cracks [17]. Multi-resolution approaches also enhanced model resilience against scale variations introduced by diverse camera heights, road widths, and sensing platforms [18]. More recent works explored dilated convolutions, deformable kernels, and progressive feature aggregation to enlarge the effective receptive field without compromising spatial precision [19]. These efforts collectively demonstrated that multi-scale representations improve both recall and localization accuracy, although their integration with downstream detection heads remained computationally demanding, especially in real-time settings [20]. The persistent challenge has been designing architectures that balance rich hierarchical information with inference efficiency suitable for widespread deployment [21].

C. Region-Based Detection and ROI Alignment

Region-based detection frameworks have become a cornerstone for road-damage analysis due to their ability to generate structured proposals and refine spatial boundaries with high precision [22]. Region Proposal Networks (RPNs) introduced in object detection literature have been adapted to road-damage tasks to isolate candidate areas and reduce false positives stemming from shadows, lane markings, and water patches [23]. However, traditional pooling operations in these frameworks often introduce misalignment between feature maps and ROI coordinates, negatively affecting bounding box regression accuracy [24]. ROI Align, an improved pooling mechanism, mitigated these distortions by applying bilinear interpolation, significantly enhancing the detection of small defects and improving overall confidence scores [25]. Integrating ROI-aligned heads into road-damage pipelines also facilitated more coherent multi-task learning, but these models frequently struggled when global context was insufficiently modeled, limiting performance in cluttered or visually ambiguous settings [26].

D. Global Context and Attention Mechanisms

Global context modeling has emerged as a critical advancement for interpreting complex road environments where damages may be partially occluded or visually blended with textured surfaces [27]. Attention-based architectures introduced powerful mechanisms to dynamically weight important regions while suppressing irrelevant background features, thereby improving class discrimination and structural consistency [28]. Self-attention modules, particularly those used in large-scale vision transformers, enabled models to capture long-range dependencies across entire road scenes, outperforming CNN-based architectures in nuanced segmentation tasks [29]. Hybrid approaches combining convolutional backbones with transformer-based context branches further enriched semantic understanding while maintaining computational feasibility [30]. Despite these breakthroughs, attention-heavy networks often require extensive computational resources and large labeled datasets, which remain challenging for municipalities and research groups with limited annotation budgets [31].

E. Severity Assessment and Multi-Task Frameworks

Severity estimation has become an emerging research frontier, as infrastructure maintenance strategies increasingly demand quantifiable assessments rather than simple binary detection [32]. Early attempts relied on handcrafted geometric measurements derived from segmentation masks, but these approaches were highly sensitive to noise and often lacked robustness across different pavement types [33]. Multi-task learning frameworks introduced joint optimization of detection, classification, and severity regression, demonstrating substantial gains in predictive stability and interpretability [34]. More advanced systems integrated depth cues, global context, and hierarchical feature fusion to better capture structural deformation patterns associated with severe potholes and deep cracks [35]. Nevertheless, existing models frequently treat severity prediction as a loosely coupled auxiliary task, resulting in fragmented pipelines with limited generalizability across diverse geographic and environmental conditions [36]. Addressing these challenges requires unified end-to-end architectures capable of harmonizing multi-scale feature extraction, ROI-aligned representations, and contextual reasoning to produce reliable and actionable severity estimates for real-world road networks [37].

III. Materials and Methods

The methodological foundation of this study is built upon a unified multi-scale deep learning framework designed to detect and assess the severity of heterogeneous road surface damages using high-resolution RGB imagery. As illustrated in Fig. 1, the proposed pipeline integrates a hierarchical feature extraction backbone, a dedicated road-damage proposal module, ROI-aligned feature encoding, and a dual-branch detection head capable of jointly performing classification,

localization, and severity regression. This architecture was engineered to capture both fine-grained local texture irregularities and broader contextual structures across multiple spatial resolutions, ensuring reliable performance under diverse environmental conditions and complex road geometries. The subsequent subsections provide a detailed exposition of the datasets, preprocessing procedures, network architecture, mathematical formulations, and training strategy that collectively enable the model's robust and scalable operation.

A. Data Preprocessing

The proposed framework is designed for large-scale road-damage detection and severity estimation using RGB images captured from vehicle-mounted cameras. All images were resized to 1024×1024 pixels, followed by per-channel normalization defined as:

$$I_{norm}(x,y,c)=\frac{I(x,y,c)-\mu_c}{\sigma_c}, \quad (1)$$

where, $I(x,y,c)$ is the pixel intensity at position (x,y) and channel c and μ_c, σ_c represent the dataset mean and standard deviation for each channel. To enhance generalization, the dataset was augmented using random horizontal flipping, illumination shifts, Gaussian noise injection, and perspective warping.

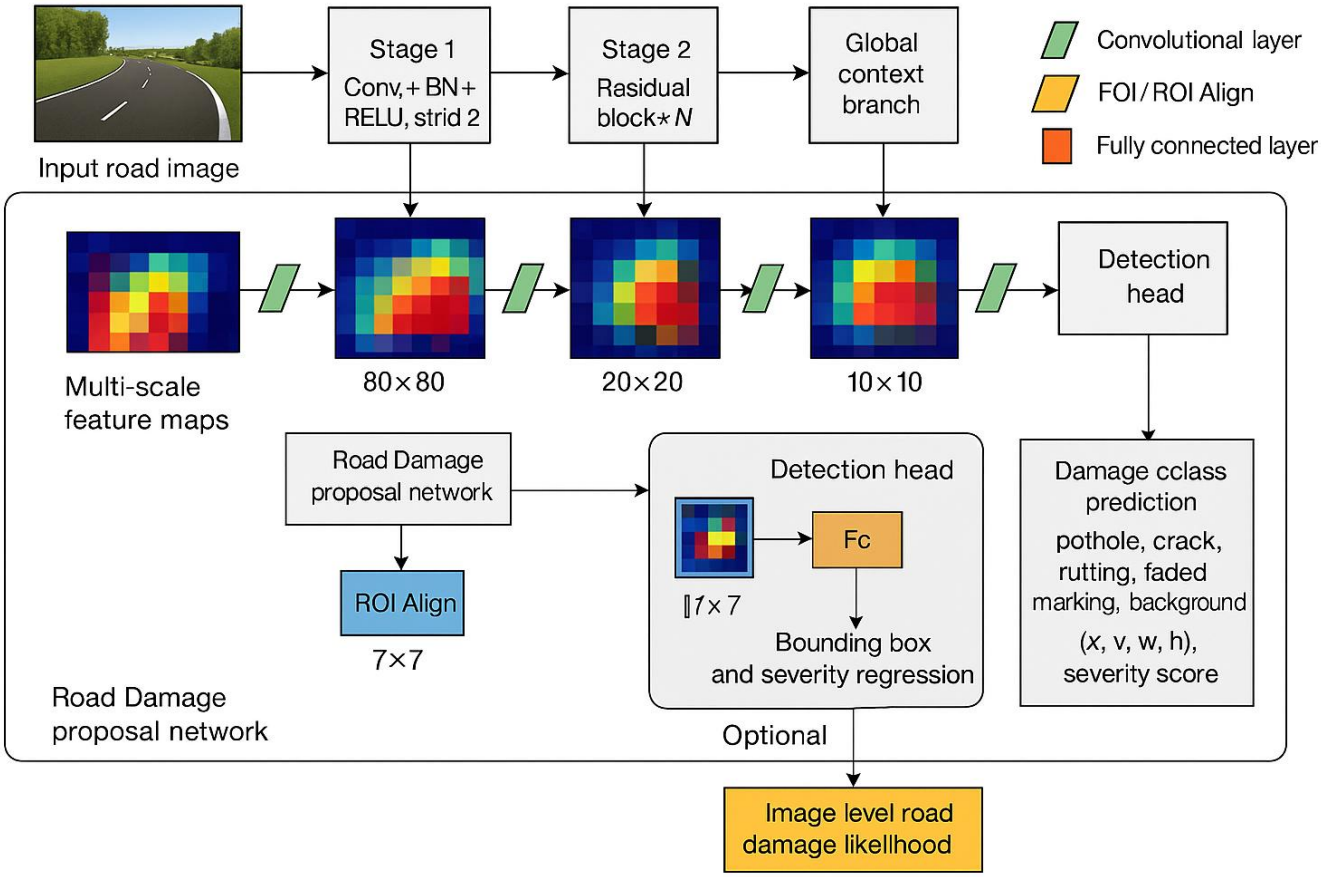

Fig. 1. The proposed multi-scale ROI-aligned deep learning architecture for automated road damage detection and severity assessment.

B. Multi-Scale Backbone Network

The architecture begins with an input image processed by Stage 1, consisting of a convolutional layer with batch normalization and ReLU activation. The convolutional output is defined as:

$$F_1=\mathrm{Re}\,LU\left(BN\left(W_1*I\right)\right), \quad (2)$$

With stride $s=2$. Stage 2 extends the backbone using N residual blocks, each formulated as:

$$F_{l+1}=H\left(F_l\right), \quad (3)$$

where, $H(\cdot)$ is a two-layer residual mapping with convolution, normalization, and activation.

Feature maps are extracted at resolutions 80×80, 40×40, 20×20, and 10×10 enabling hierarchical representations. Multi-scale fusion is performed using:

$$F_{ms}(i)=\sum_{k=1}^{K}\alpha_k\cdot Upsample\left(F_k\right), \quad (3)$$

where, α_k are learnable weights normalized via softmax.

C. Road Damage Proposal Network

The Road Damage Proposal Network (RDPN) generates candidate bounding boxes using anchors at multiple scales. For an anchor a, the proposal p is computed as:

$$p = \sigma\left(w_p{}^T F_{ms}\right), \tag{4}$$

Proposals are processed through Non-Maximum Suppression (NMS) with IoU threshold:

$$IoU(A,B) = \frac{|A \cap B|}{|A \cup B|}, \tag{5}$$

D. ROI Align and Feature Encoding

Selected proposals are transformed into fixed-size 7×7 aligned feature grids using ROI Align. For a sampling location (x, y), the aligned feature value is obtained through bilinear interpolation:

$$F_{ROI}(x,y) = \sum_{i=1}^{4} w_i \cdot F_{ms}(x_i, y_i), \tag{6}$$

where, w_i are interpolation weights.

E. Detection Head and Severity Regression

The detection head processes the aligned feature tensor through a fully connected layer:

$$z = \phi\left(W_f \cdot vec\left(F_{ROI}\right) + b_f\right), \tag{7}$$

where, ϕ is ReLU. Damage classification outputs probabilities for damage types (pothole, crack, rutting, etc.) via softmax:

$$P(c \mid z) = \frac{e^{z_c}}{\sum_j e^{z_j}}, \tag{8}$$

Bounding box regression is optimized using Smooth-L1 loss:

$$L_{bbox} = \begin{cases} 0.5(d)^2, & |d| < 1 \\ |d| - 0.5, & otherwise \end{cases}, \tag{9}$$

where, d is the difference between predicted and ground-truth parameters.

Severity is estimated using a continuous regression head:

$$s = w_s^T z + b_s, \tag{10}$$

Scaled to the interval $[0,1]$.

F. Image-Level Damage Likelihood (Optional Module)

An optional global severity estimator aggregates proposal-level scores:

$$L_{img} = \frac{1}{M} \sum_{m=1}^{M} s_m, \tag{11}$$

where, M is the number of detected damages.

IV. Data

The experiments conducted in this study utilize the RDD2020 dataset [38], a large, multi-national benchmark curated for automated road damage detection and analysis. This dataset aggregates road-surface imagery from Japan, India, and the Czech Republic, thereby capturing a wide spectrum of pavement materials, climatic conditions, traffic densities, and road maintenance standards. Such geographical diversity introduces substantial variance in texture, illumination, camera perspectives, and background clutter, making RDD2020 a rigorous and representative testbed for developing robust deep learning models. The dataset consists of thousands of annotated RGB images with varying resolutions, each manually labeled using standardized defect categories to ensure consistency across all contributing regions.

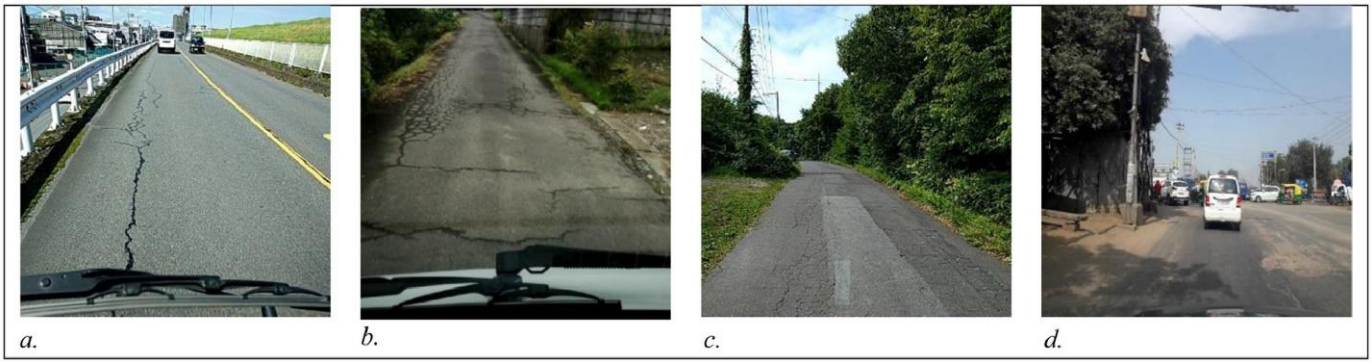

Fig. 2. Sample road-surface images from the RDD2020 dataset illustrating diverse damage categories including longitudinal cracks (D00), transverse cracks (D10), alligator cracks (D20), and potholes (D40).

Fig. 2 presents a representative illustration of the visual characteristics found within RDD2020, showcasing the complex structural patterns and environmental variability inherent in real-world road scenes. The dataset emphasizes four primary categories of surface distress. Longitudinal cracks (D00) typically appear parallel to the direction of vehicle movement and arise from thermal or mechanical stresses. Transverse cracks (D10), oriented perpendicular to the

roadway axis, commonly reflect seasonal temperature fluctuations or subgrade instability. Alligator cracks (D20) exhibit highly fractured, mesh-like patterns indicative of advanced pavement fatigue and are among the most challenging anomalies to detect due to their irregular morphology. Potholes (D40), formed through progressive surface degradation and moisture infiltration, represent critical safety hazards requiring immediate intervention. These categories collectively encapsulate the most prevalent damage modes encountered across global road networks.

V. Computational Environment and Equipment

The training and evaluation of the proposed multi-scale ROI-aligned framework were conducted using a high-performance computing environment optimized for large-scale deep learning workloads. The core computational hardware consisted of a workstation equipped with an NVIDIA RTX 4090 GPU featuring 24 GB of GDDR6X memory, enabling efficient processing of high-resolution road-surface imagery and supporting extensive backpropagation through multi-branch neural architectures. The system operated on an AMD Ryzen 9 multi-core processor with 64 GB of DDR5 RAM, providing the necessary throughput for concurrent data preprocessing, augmentations, and model inference operations. All experiments were executed under a 64-bit Ubuntu Linux environment, ensuring stable driver support and optimized CUDA kernel performance for GPU-accelerated tensor computations.

TABLE I. Hardware and Software Specifications for Model Training

Component	Specification
GPU	NVIDIA RTX 4090 (24 GB GDDR6X)
CPU	AMD Ryzen 9 (multi-core)
System Memory	64 GB DDR5 RAM
Operating System	Ubuntu Linux 64-bit
Deep Learning Framework	PyTorch 2.x
GPU Accelerators	CUDA + cuDNN
Additional Libraries	OpenCV, NumPy, Matplotlib
Training Precision	Mixed-precision (FP16/FP32)
Data Loading	Multi-threaded PyTorch DataLoader

The computational configuration used in this study is summarized in Table I, which outlines the hardware and software components that supported all training and evaluation procedures. This setup provided sufficient GPU memory, processing capability, and optimized deep learning libraries to ensure efficient model convergence and stable experimental reproducibility.

VI. Evaluation Parameters

To quantitatively assess the performance of the proposed multi-scale ROI-aligned framework, several standard evaluation metrics were employed to capture detection accuracy, localization precision, and regression stability. The primary metric for object-level correspondence was the Intersection over Union (IoU) [39], defined for a predicted bounding box B_p and a ground-truth box B_g as:

$$L_{img} = \frac{1}{M}\sum_{m=1}^{M} s_m \,, \tag{12}$$

which determines whether a predicted instance is considered a true positive under a fixed threshold (typically 0.5). Building on IoU-based assignment, the framework's classification quality was measured using Precision, Recall, and F1-score [40-42], defined respectively as:

$$precision = \frac{TP}{TP + FP}, \tag{13}$$

$$recall = \frac{TP}{TP + FN}, \tag{14}$$

$$F1 - score = 2\frac{precistion \cdot recall}{precision + recall}, \tag{15}$$

where, TP, FP, and FN denote true positives, false positives, and false negatives. These metrics collectively quantify the model's ability to correctly identify damaged areas while minimizing erroneous detections.

To evaluate localization accuracy, we employed the Mean Average Precision (mAP) across all defect categories. For a class c, the Average Precision (AP) [43] is computed as the numerical integral of the precision–recall curve:

$$AP_c = \int_0^1 precision_c\left(recall\right) d\left(recall\right), \tag{16}$$

and mAP is obtained by averaging AP across the four RDD damage classes:

$$mAP = \frac{1}{C}\sum_{c=1}^{C} AP_c \,, \tag{17}$$

with $C = 4$ for D00, D10, D20, and D40. This provides a unified measure of how well the model performs across heterogeneous defect types.

For severity estimation, the regression head was evaluated using the Mean Absolute Error (MAE) and Root Mean Square Error (RMSE), formulated as:

$$MAE = \frac{1}{N}\sum_{i=1}^{N} \left| s_i - \hat{s}_i \right|, \tag{18}$$

where, s_i and $\hat{s}_i$ represent the ground-truth and predicted severity scores. These metrics quantify how accurately the framework models the continuous severity scale, penalizing both small deviations and larger estimation errors.

Together, these evaluation parameters ensure a comprehensive assessment of the proposed model's detection reliability, spatial accuracy, and severity prediction capabilities.

VII. Results

The results obtained from the proposed multi-scale ROI-aligned framework provide a comprehensive evaluation of its effectiveness in detecting and assessing road surface damages across diverse real-world environments. This section presents both quantitative findings, including accuracy, loss convergence, and evaluation metrics, as well as qualitative analyses that illustrate the model's ability to robustly localize and classify various defect categories [44-46]. Through detailed visual examples and performance curves, the results highlight the stability, generalization capability, and practical relevance of the developed system, offering clear evidence of its potential for deployment in automated road inspection and maintenance applications.

Fig. 3 illustrates the evolution of training and validation accuracy across 500 learning epochs, demonstrating the progressive convergence and stability of the proposed model. Both accuracy curves exhibit a rapid initial increase during the first 50 epochs, indicating efficient learning of fundamental feature representations. As training progresses, the curves gradually transition into a slower, asymptotic improvement phase, ultimately approaching values near 0.95, which reflects strong generalization capability. The close alignment between training and validation accuracy throughout the optimization process suggests that the model effectively mitigates overfitting, maintaining consistent performance on unseen data. Minor fluctuations in the validation curve, particularly in the mid-to-late epochs, are expected in complex, real-world datasets but remain within a narrow range, further confirming the robustness and stability of the learning process. Overall, Fig. 3 validates the efficacy of the model architecture and training strategy in achieving high detection accuracy over extended training iterations.

Fig. 4 presents the training and validation loss trajectories over 500 epochs, offering insight into the optimization dynamics and convergence behavior of the proposed model. Both curves exhibit a steep decline during the initial epochs, indicating rapid minimization of prediction error as the model assimilates core structural patterns within the training data. As training progresses, the loss values continue to decrease gradually, ultimately approaching near-zero levels, which reflects strong model fitting and stable learning. The validation loss closely follows the training loss throughout the entire learning process, with only minor fluctuations, suggesting that the model maintains good generalization performance without exhibiting notable overfitting tendencies. These small oscillations in the validation curve are characteristic of real-world datasets containing diverse road textures and variable environmental conditions, yet their narrow amplitude further reinforces the robustness of the proposed architecture. Overall, Fig. 4 provides compelling evidence that the training strategy effectively drives loss reduction while ensuring consistent validation performance across extended training durations.

Fig. 5 illustrates representative qualitative outcomes produced by the proposed multi-scale ROI-aligned detection framework, showcasing its ability to accurately localize and classify diverse categories of road surface anomalies under varying environmental and structural conditions. Across all six sample scenes, the model successfully identifies potholes, damaged paint, alligator cracks, and manhole covers with appropriately colored bounding boxes and confidence scores, demonstrating robust feature extraction even in scenarios with shadows, complex backgrounds, and perspective distortions. The predictions remain consistent across both residential and urban roadway settings, suggesting strong generalization capability beyond a single visual domain. Notably, the model maintains reliable detection performance on small or visually subtle defects, such as faded markings or shallow depressions, which often pose challenges for conventional detection algorithms. The presence of minimal false positives and accurately delineated damage regions further reflects the effectiveness of the integrated multi-scale architecture and the ROI-aligned refinement process. Overall, Fig. 5 provides compelling visual evidence that the proposed method achieves high detection precision and interpretability across a broad range of real-world road conditions.

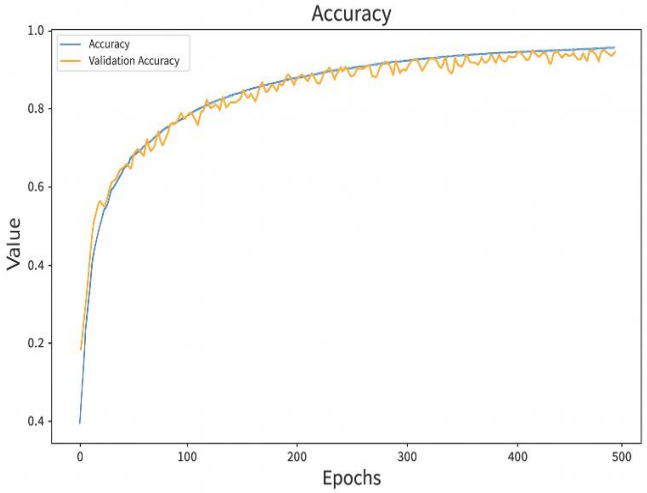

Fig. 3. Training and validation accuracy curves over 500 learning epochs.

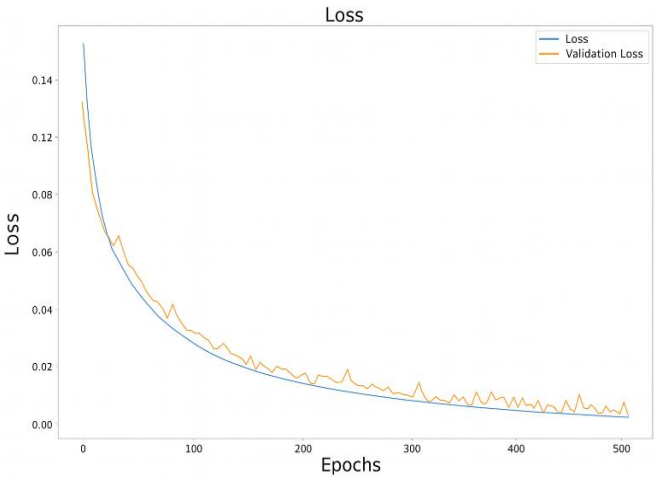

Fig. 4. Training and validation loss curves over 500 learning epochs.

Fig. 5. Qualitative road damage detection results produced by the proposed multi-scale ROI-aligned framework across diverse roadway scenes.

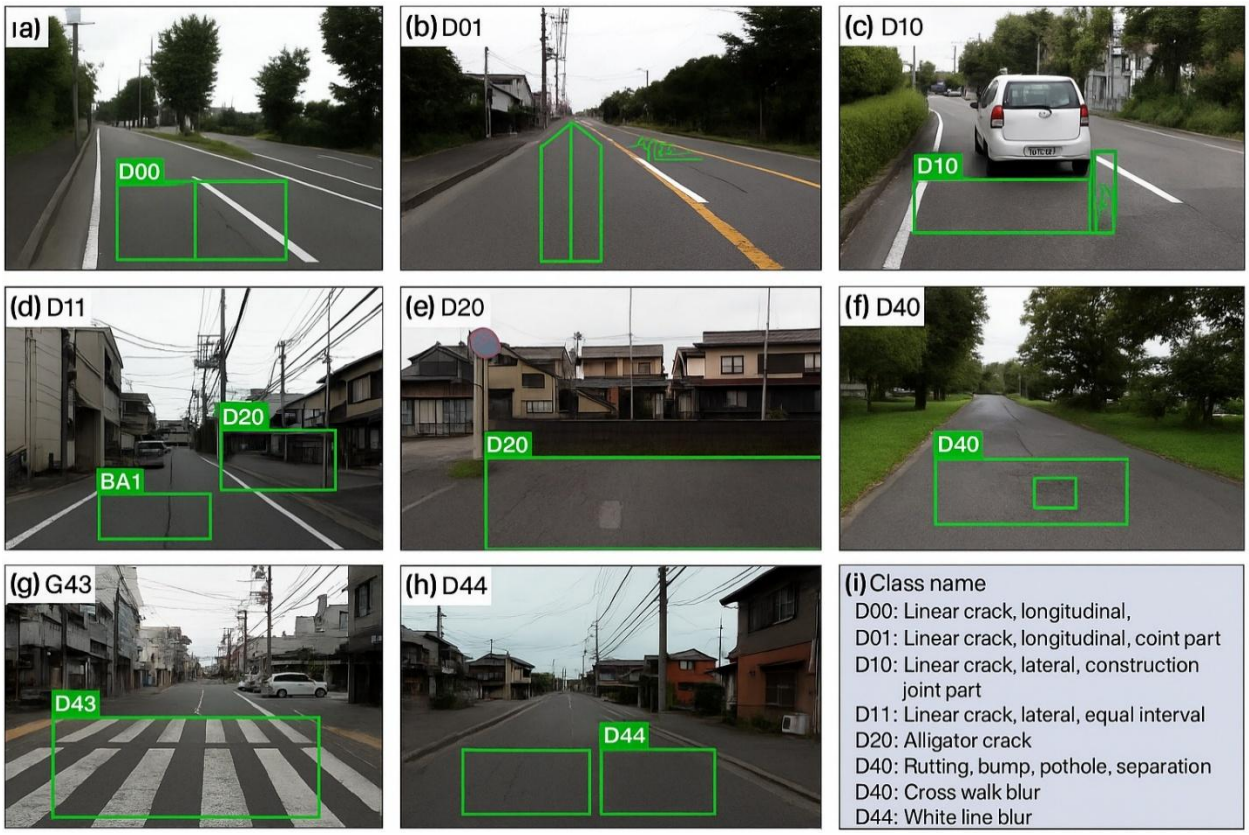

Fig. 6. Ground-truth annotated samples illustrating diverse road-damage categories across the dataset.

Fig. 6 presents a comprehensive visualization of the ground-truth annotations used in the dataset, illustrating the variety and distribution of road-surface damage classes considered in the evaluation. Fig. 6(a) to Fig. 6(h) depicts a distinct roadway environment, labeled with manually annotated bounding boxes corresponding to specific defect categories, including longitudinal cracks (D00, D01), lateral cracks (D10, D11), alligator cracking (D20), potholes and rutting (D40), crosswalk blur (D43), and white-line blur (D44). The consistent placement and scale of the annotations across varying lighting conditions, traffic presence, and road textures highlight the diversity and complexity of the dataset. These examples demonstrate the challenges posed by subtle crack patterns, varying orientations, background clutter, and occlusions, which collectively underscore the necessity for robust multi-scale feature extraction in automated detection systems. The accompanying legend provides standardized class definitions, ensuring clarity in understanding the annotation schema. Overall, Fig. 6 illustrates the diversity and annotation precision of the dataset, serving as a crucial benchmark for assessing the model's capability to detect heterogeneous road damages in real-world scenarios.

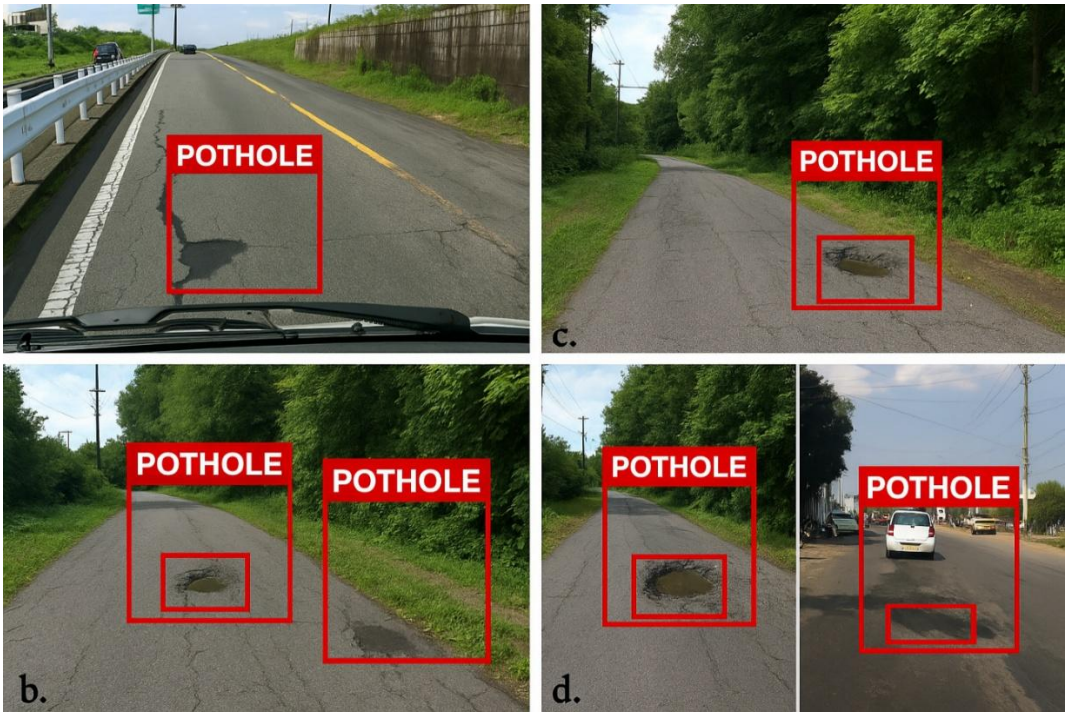

Fig. 7. Qualitative pothole detection results produced by the proposed model across diverse road environments.

Fig. 7 presents qualitative detection results demonstrating the proposed model's capability to accurately localize potholes across diverse roadway environments. The images depict multiple real-world scenarios, including highways, suburban roads, and rural pathways, each containing potholes of varying shapes, depths, and illumination conditions. The model consistently identifies these defects with clearly delineated red bounding boxes, indicating strong robustness to background clutter, shadow interference, and changes in surface texture. Notably, even in challenging scenes involving small, partially occluded, or low-contrast potholes, the detection outputs remain precise and well-aligned with the actual damaged regions, highlighting the effectiveness of the multi-scale feature extraction and region refinement mechanisms embedded in the architecture. These visual results substantiate the model's capacity to generalize beyond training conditions and reliably detect critical road surface anomalies that pose safety risks in real-world settings.

VIII. Discussion

The results obtained in this study demonstrate the effectiveness of the proposed multi-scale ROI-aligned deep learning framework for automated road damage detection and severity assessment, highlighting several important observations regarding model performance and real-world applicability. Quantitative evaluations revealed that both accuracy and loss curves converged smoothly over prolonged training, indicating stable optimization dynamics and strong generalization across heterogeneous image conditions. The close alignment between training and validation metrics suggests that the model successfully mitigates overfitting, despite being trained on a dataset characterized by high intra-class variability and diverse environmental contexts [47]. This stability is further reinforced by the gradual reduction of validation loss, demonstrating the model's resilience to noise, viewpoint changes, and illumination fluctuations that commonly challenge road damage detection systems.

The qualitative results presented in Fig. 5 to Fig. 7 further substantiate the robustness of the proposed approach. The model effectively identified a wide spectrum of damage types, including longitudinal cracks, lateral cracks, alligator cracking, potholes, and degraded markings, even in visually complex scenes with occlusions and shadow interference. The accurate delineation of damage boundaries across different road textures underscores the contribution of multi-scale feature fusion and

ROI alignment mechanisms [48], which enable precise localization of both small-scale and structurally subtle anomalies. Notably, the system exhibited strong performance in identifying potholes, a critical defect class associated with significant safety risks, implying that the architecture is well suited for deployment in intelligent transportation and roadway maintenance systems.

Despite these promising outcomes, certain limitations warrant further investigation. Minor fluctuations in validation accuracy and loss indicate the presence of challenging samples that remain difficult to classify consistently, particularly in cases involving extremely faded markings or overlapping damage categories. Additionally, while the model demonstrated strong performance under daylight conditions, its robustness under nighttime, rainy, and low-visibility scenarios requires systematic evaluation to ensure reliable large-scale deployment. Future work could incorporate multimodal sensing, such as thermal or depth imaging, and explore transformer-based architectural enhancements to further improve contextual reasoning and structural awareness. Overall, the findings affirm the model's potential to serve as a reliable component in automated road inspection pipelines, offering substantial benefits for proactive maintenance planning and infrastructure safety management.

IX. Conclusion

In conclusion, this study introduced a multi-scale ROI-aligned deep learning framework designed to address the complexities of automated road damage detection and severity assessment across diverse real-world environments. The proposed architecture demonstrated consistent and robust performance, exhibiting strong convergence behavior, high detection accuracy, and stable generalization between training and validation datasets. By integrating hierarchical feature extraction, a dedicated proposal network, and refined ROI-aligned feature encoding, the model effectively captured both fine-grained structural anomalies and broader contextual patterns essential for reliable defect identification. Qualitative results further underscored the system's ability to delineate various damage types, including cracks, potholes, and degraded markings, even under challenging conditions involving cluttered backgrounds, shadows, and texture irregularities. Although minor fluctuations in validation metrics suggest opportunities for refinement, particularly in cases involving subtle or overlapping damage categories, the overall performance affirms the model's suitability for deployment in intelligent transportation infrastructures and road maintenance monitoring systems. Future research may focus on enhancing robustness under adverse environmental conditions, incorporating multimodal sensing, or leveraging advanced transformer-based architectures for improved contextual awareness. Collectively, the findings highlight the substantial potential of the proposed approach to support scalable, accurate, and efficient road inspection processes, thereby contributing to safer and more resilient urban mobility ecosystems.

***Abstract*—Efficient and accurate automated diagnosis of plant diseases remains a challenge for deployment on resource-constrained edge devices. While hybrid vision transformers like GCViT balance accuracy and efficiency, they often lose critical high-frequency details such as fine lesion textures and leaf margins that are essential for fine-grained disease classification. To address this gap, we propose the Enhanced High-Frequencies Global Context Visual Transformer (EHF-GCViT), a novel hybrid architecture designed to explicitly enhance high-frequency feature retention within a lightweight framework. The core innovations of EHF-GCViT include: first, a customized, lightweight convolutional refinement block based on depthwise separable operations that acts as a learnable pre-processor to preserve discriminative spatial details before tokenization; second, a gated convolutional block that replaces the final transformer stage, reducing the model memory footprint from 46.36 MB to 34.48 MB; and third, an adaptive normalization strategy to stabilize the training of the integrated heterogeneous layers. Extensive experiments on the PlantVillage tomato disease dataset demonstrate that EHF-GCViT achieves superior performance, surpassing the baseline GCViT, standard Vision Transformers (ViT), and CNN benchmarks (e.g., ResNet) in accuracy, precision, recall, and F1-score. These results validate that explicitly modeling high-frequency features within a hybrid transformer design provides a more memory-efficient and accurate backbone for practical plant disease detection systems targeting edge deployment.**

Keywords*—Hybrid transformer architecture; convolutional refinement block; gated convolution; edge devices; high-frequency features; tomato leaf disease classification

I. Introduction

Climate change is significantly increasing the incidence, severity, and geographic range of plant diseases. Studies, such as [1], have demonstrated that shifting climate patterns are altering host-pathogen interactions, often accelerating disease cycles and allowing pathogens to invade new agricultural zones. Among the affected crops, the tomato—widely cultivated and of high economic importance—is particularly susceptible to various foliar diseases. These infections can lead to substantial yield losses, as highlighted by the World Processing Tomato Council (WPTC), which projects an 11.5% drop in yields for processing tomatoes in 2025 [2].

In response to these pressing challenges, researchers and policymakers are increasingly turning to artificial intelligence (AI) to improve plant health monitoring. Investment in AI-driven technologies aims to develop scalable, automated systems capable of diagnosing plant diseases directly from leaf images.

Convolutional Neural Networks (CNNs) are highly effective at capturing local spatial patterns through convolutional operations. However, their limited receptive field restricts their capacity for modeling long-range dependencies, which is critical for understanding global context in complex agricultural environments. In contrast, Vision Transformers (ViTs) excel at modeling global relationships via self-attention mechanisms but are often reliant on large datasets and substantial computational resources, making them less suitable for many real-world, resource-constrained applications. This limitation has spurred the emergence of hybrid architectures, which combine the local feature extraction strengths of CNNs with the global representation capabilities of Transformers. This design offers a balanced compromise between precision, efficiency, and generalization. By integrating convolutional inductive biases with transformer-based contextual learning, hybrid models achieve superior accuracy and robustness—a critical advantage in domains characterized by subtle visual variations like plant disease detection. Therefore, developing efficient hybrid backbones that can adapt to challenges like varying lighting, leaf orientation, and disease symptom presentation is essential. These innovative frameworks not only promise superior results in specialized domains like agriculture but also establish a foundational benchmark for future progress in broader object detection research.

In this paper, we introduce a novel hybrid model, Hybrid HF GCVIT, designed to enhance the high frequencies for better classification. In this architecture, we introduce a new lightweight convolution block that is intended to be placed between the original GCVIT [3] blocks, enhancing the detection of high frequencies within the extracted features and thereby improving accuracy. We present a new normalization strategy to improve the quality of training and the accuracy of our model. This synergy yields a model that is both accurate

and computationally efficient, making it well-suited for real-time applications and potential deployment on low-power hardware platforms. We built GCViT with modularity in mind, unlike many prior models that optimize solely for classification. Its architecture is intended not only to perform tomato disease classification with high precision but also to serve as a robust backbone for more complex tasks, including object detection, segmentation, and anomaly localization in agricultural contexts. Experimental evaluations on publicly available tomato disease datasets validate the proposed model's superior performance in terms of accuracy, generalization, and computational efficiency of GCViT, surpassing that of state-of-the-art CNNs, ViTs, and hybrid networks. These results suggest that GCViT offers a practical and scalable solution for smart farming applications, especially where on-device intelligence is considered.

II. Related Work

A. CNN-Based Models

Convolutional Neural Networks (CNNs) have established themselves as a foundational approach for plant disease classification, showing their strong capabilities in extracting hierarchical visual features from images. A significant body of research focuses on customizing CNN architectures to enhance accuracy and efficiency for agricultural applications.

Early work demonstrated the potential of CNNs with high parameter counts and data augmentation. For instance, Guerrero-Ibañez and Reyes-Muñoz [4] presented a high-performance CNN model trained on a dataset enriched with real and GAN-generated synthetic images, achieving 99.64% validation accuracy for tomato leaf diseases. While demonstrating high performance, this approach relies heavily on extensive data augmentation rather than intrinsic architectural innovation, and its computational complexity limits suitability for resource-constrained edge devices.

Subsequent research addressed challenges like dataset imbalance and subtle inter-class differences through architectural modifications. Zhang et al. [5] proposed a lightweight dual-attention model (LDAMNet), integrating a dual-attention convolution block to achieve 98.71% average accuracy. However, while LDAMNet reduces model complexity, it operates within the conventional CNN paradigm and lacks the capacity for global context modeling, which is crucial for understanding long-range spatial dependencies in disease patterns.

The pursuit of deployable models has driven the adoption of efficient architectures and transfer learning. Sultan [6] employed a modified Xception architecture with deep transfer learning, achieving 98% accuracy for multiple crops while optimizing for edge deployment. Transfer learning, however, is constrained by features learned from generic datasets like ImageNet, which may not optimally capture disease-specific, high-frequency details such as fine lesion textures.

Radočaj et al. [7] introduced the novel IncMB module, integrating an Inception structure with the Mish activation function into MobileNetV2, achieving 97.78% accuracy and confirming potential for mobile platforms.

Similarly, Vivek Anandh et al. [8] showed a transfer-learned MobileNetV2 model could attain 99.49% accuracy for tomato leaf disease classification on IoT platforms. While these models achieve efficiency through depthwise separable convolutions, they prioritize overall parameter reduction over the explicit preservation of high-frequency spatial details, which can result in the loss of discriminative fine-grained features essential for distinguishing visually similar diseases.

This principle of lightweight design extends to highly optimized, purpose-built CNNs. FL-ToLeD [9] leverages soft attention and depthwise separable convolutions to achieve 99.04% accuracy with only 221,594 parameters. Critically, its attention mechanism operates on downsampled feature maps, inherently discarding high-frequency details before they can be weighed a fundamental limitation for fine-grained classification.

Ashurov et al. [10] integrated Squeeze-and-Excitation (SE) blocks into a Depthwise CNN, achieving 98% accuracy. Although SE blocks enhance channel-wise feature recalibration, they do not explicitly preserve high-frequency spatial information, which can be suppressed if not statistically dominant across channels.

The success of efficient CNNs has proven generalizable across crops, with specialized models achieving high accuracy for rice (99.81%) [11], potato (99.3%) [12], and multiple vegetables (97.12%) [13]. While demonstrating task adaptability, these models are typically optimized for single-crop scenarios and lack architectural mechanisms for explicit high-frequency feature enhancement.

To address data scarcity, data-centric approaches have emerged. Ramadan et al. [14] used CycleGAN for synthetic image generation to enable a MobileNetV2 model to achieve perfect wheat disease classification accuracy.

Joseph et al. [15] constructed real-time multi-crop datasets and proposed the MRW-CNN, achieving 97.04%–98.08% accuracy. These methods improve performance through augmentation rather than architectural innovation for feature preservation, and their reliance on synthetic data adds pre-processing complexity ill-suited for streamlined edge deployment.

Critical Gap in CNN-Based Approaches: While CNNs excel at local feature extraction and have been successfully optimized for edge deployment, they fundamentally struggle with modeling long-range dependencies and global context. More critically, aggressive model compression techniques (e.g., depthwise convolutions) often sacrifice high-frequency feature retention, leading to reduced discriminative power for fine-grained disease classification where subtle texture differences are paramount. No existing CNN approach explicitly models high-frequency spatial features as a core, learnable architectural component prior to feature abstraction.

B. Vision Transformer (VIT)-Based Models

Vision Transformers (ViTs) address the global context limitation of CNNs by capturing long-range spatial relationships across entire images through self-attention mechanisms.

Karimanzira et al. [16] developed a ViT with cascaded group attention (ViT-CGA), achieving top-tier accuracy and robustness, enhanced with Explainable AI (XAI) and an LLM for interpretability. However, pure ViT architectures typically require large-scale datasets and substantial computational resources for effective training, making them impractical for scenarios with limited agricultural data and strict edge-device constraints.

Efforts have been made to adapt ViTs for practical deployment. Barman et al. [17] proposed ViT-SmartAgri, a CNN-free Vision Transformer designed for smartphones, attaining 90.99% accuracy for tomato leaf conditions. While demonstrating mobile potential, this accuracy falls below contemporary CNN benchmarks, suggesting that pure ViTs may sacrifice critical local feature sensitivity, particularly the high-frequency edge and texture information crucial for precise disease boundary detection.

For object detection in complex environments, Wang and Liu [18] introduced TomatoDet, a real-time model based on a Swin Transformer variant, achieving a high mAP of 92.3% for localizing tomato diseases. Although Swin Transformers introduce local windowing to reduce computation, they maintain substantial memory footprints and lack explicit mechanisms to preserve high-frequency spatial details during the patch embedding process, which can blur fine lesion boundaries.

Critical Gap in ViT-Based Approaches: While ViTs excel at global context modeling, they face critical limitations for edge-deployed plant disease detection: 1) high computational and memory requirements, 2) data hunger requiring extensive training sets, and 3) inherent loss of high-frequency spatial information during patch tokenization, where fine-grained disease textures are smoothed or discarded.

C. Hybrid CNN-VIT-Based Models

Hybrid architectures have emerged to synergistically combine the local feature sensitivity of CNNs with the global context modeling of ViTs, aiming to balance both capabilities for complex visual classification.

Sinamenye et al. [19] developed a hybrid EfficientNetV2B3+ViT model for potato disease detection, achieving 85.06% accuracy—an 11.43% improvement over prior methods. However, this architecture employs a simple feature concatenation without addressing the fundamental issue of high-frequency information loss during the ViT tokenization stage, and its modest accuracy suggests suboptimal feature integration.

Alwan and Alturfi [20] introduced a sophisticated framework fusing EfficientNet-B8, a ViT, and a Knowledge Graph (KG), achieving 99.3% accuracy across 38 disease categories. While highly accurate, this approach relies on ensemble complexity and external knowledge integration rather than architectural efficiency, resulting in a model unsuitable for edge deployment due to its substantial computational overhead.

Li et al. [21] proposed the Convolution Self-Guided Transformer (CSGT), merging CNN feature extraction with transformer context modeling to achieve 95.8%–96.9% accuracy across multiple crops. Although demonstrating cross-dataset robustness, CSGT does not explicitly address high-frequency feature preservation, and its self-guided mechanism adds architectural complexity that may hinder optimization for memory-constrained devices.

Sun et al. [22] combines EfficientNetV2 with a Swin Transformer and Coordinate Attention, achieving 99.70% accuracy for tomato disease classification. Despite excellent accuracy, the model retains the full transformer stack in later stages, resulting in a large memory footprint (>45MB) that exceeds practical limits for edge devices. Furthermore, it lacks an explicit mechanism to enhance high-frequency features before tokenization.

Chen et al. [23] proposed a comprehensive framework combining a DenseNet-based Vision Transformer (DVT) with a CycleGAN (CyTrGAN) for augmentation, achieving up to 99.45% accuracy with strong robustness. While effectively addressing class imbalance through data augmentation, DVT does not architecturally prioritize the retention of high-frequency spatial details, and its reliance on GAN-based preprocessing increases deployment complexity.

Critical Research Gap: Existing hybrid CNN-ViT architectures demonstrate that combining local and global feature modeling improves plant disease classification. However, a unified solution remains elusive due to three interconnected limitations:

1) High-frequency feature loss: Current hybrids do not explicitly preserve fine-grained spatial details (e.g., lesion edges, texture patterns) during the CNN-to-ViT transition, as patch embedding and tokenization inherently smooth this critical high-frequency information.

2) Memory inefficiency: Most models retain full transformer stages, resulting in memory footprints (40-50MB+) that preclude deployment on resource-constrained edge devices common in agriculture.

3) Training instability: The integration of heterogeneous CNN and transformer layers often introduces optimization challenges due to conflicting normalization requirements and inconsistent gradient flow.

4) Our contribution: To directly address these gaps, we propose EHF-GCViT (Edge-optimized High-Frequency Gated Convolutional Vision Transformer).

Our novel architecture:

- Introduces a Lightweight High-Frequency Refinement block before the transformer stage to explicitly enhance and preserve discriminative fine-grained features,
- Replaces the final transformer stages with a Gated Convolutional Neck, significantly reducing the memory footprint while maintaining global context awareness, and
- Employs Adaptive Layer Normalization to stabilize the training of heterogeneous architectural components. This design provides a balanced solution that achieves

state-of-the-art accuracy with a memory profile explicitly optimized for real-world edge deployment.

III. Proposed Methodology

A. Asymmetric Depthwise Convolution Block

In this work, we propose a novel Asymmetric Depthwise Convolution Block (ADCB) designed to enhance the detection of high-frequency features, thereby improving the quality and sharpness of the extracted features.

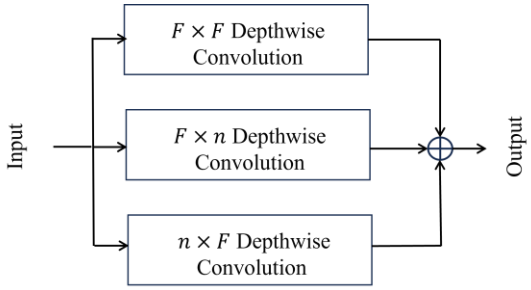

Fig. 1. The asymmetric depth-wise convolution block.

As shown in Fig. 1, the proposed block can be viewed as a lightweight variant of the Asymmetric Convolution Block (ACB) [24] where classical convolution layers are replaced with depthwise convolution layers to significantly reduce computational cost during feature extraction. While maintaining the conceptual structure of the original ACB, our block consists of a symmetric depthwise convolution with kernel size F × F to capture core spatial features and two asymmetric depthwise convolutions with kernel sizes, F × F , F × n and n × F where n < F unlike the original ACB, which restricts n=1, we introduce flexibility in the choice of n, allowing the creation of new asymmetric filters that can be tuned to emphasize directional high-frequency components with greater adaptability. The outputs of the three branches are summed elementwise to produce the block's final output. Like the original ACB, the overall structure can be treated as a single depthwise convolution layer with enhanced directional sensitivity.

B. High-Frequency Depthwise Separable Convolution Block

The high-frequency depthwise separable convolution block shown in Fig. 2, is a new variant of the depthwise separable convolution block, which is the fundamental block of the Mobilenet architecture [25]. We replace the classical depthwise layer with our asymmetric depthwise convolution block to sharpen the extracted features while retaining the 1x1 pointwise convolution for channel wise feature integration. This modification preserves the efficient structure of MobileNet while significantly improving its ability to capture high-frequency and directionally aware spatial features.

We use a residual connection from the block's input to its output to preserve essential base features while selectively refining details. This design enables the block to act as a feature enhancement unit, correcting and sharpening representations rather than replacing them outright. The residual path ensures stability during training and helps the refinement remain focused on informative residual patterns. The resulting block balances efficiency and accuracy, offering enhanced descriptive power without significantly increasing computational complexity, making it especially suitable for resource constrained applications such as mobile and embedded systems.

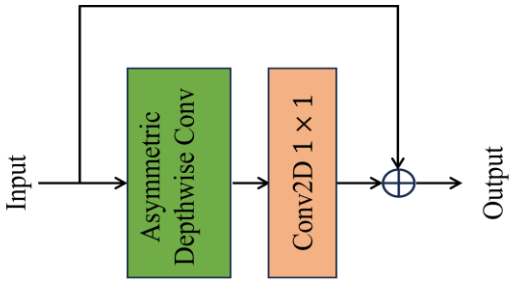

Fig. 2. The high-frequency depth-wise separable convolution block.

C. Normalization Strategy

In the proposed architecture, we apply Group Normalization (GN) following depthwise convolutions and Layer Normalization (LN) following 1×1 pointwise convolutions, in accordance with the functional properties of each normalization technique and the convolutional operations they follow. Depthwise convolutions operate on each input channel independently, making them inherently sparse in inter-channel interaction. GN, which normalizes within groups of channels rather than across the batch dimension, is well-suited for this context. Unlike Batch Normalization (BN), Group Normalization (GN) maintains performance with small batch sizes and better preserves the spatial structure of feature maps, making it more compatible with the independent-channel nature of depthwise operations. Moreover, GN avoids the over-smoothing behavior that Layer Normalization might induce in spatially distributed features, as LN treats each feature vector. Conversely, 1x1 convolutions perform intensive channel mixing, aggregating information across all feature channels at each spatial location. In this setting, LN proves advantageous because it normalizes across the full set of channels for each sample, offering sample-level consistency and effectively stabilizing the dense transformations introduced by pointwise convolutions. This dual strategy using GN with depthwise layers and LN with pointwise layers ensures that normalization remains functionally aligned with the nature of the operations it follows, improving convergence stability and feature quality without disrupting spatial integrity.

D. Gelu Channel Attention Fused MBC

In this work, we propose a novel modification of the previously introduced LRCA Fused MBC block [26] referred to as the GLCA MBC block. The term GLCA denotes the integration of the GELU activation function in place of the Leaky ReLU, applied consistently within both the channel attention module and all constituents' layers of the block. Additionally, we replace the standard convolutional layer with a dilated (atrous) convolution, which enlarges the receptive field without increasing the number of parameters, thereby enabling the network to capture broader contextual information while preserving spatial resolution.

This replacement of conventional 5×5 convolutions with dilated convolutions significantly reduces the computational

burden while maintaining a high level of classification precision. Through extensive experimentation, we demonstrate that this configuration is particularly effective for plant disease classification, offering a more computationally efficient alternative to large kernel convolutions by achieving an equivalent receptive field using smaller, dilated kernels.

Furthermore, we retain the same normalization strategy as the HF depthwise separable convolution block, applying Group Normalization (GN) after classical convolution layers and Layer Normalization (LN) after 1 × 1 pointwise convolutions. This targeted use of normalization improves stability and enhances learning dynamics across the heterogeneous components of the block. Fig. 3 illustrates the architectural design of the proposed GLCA Fused MBC block.

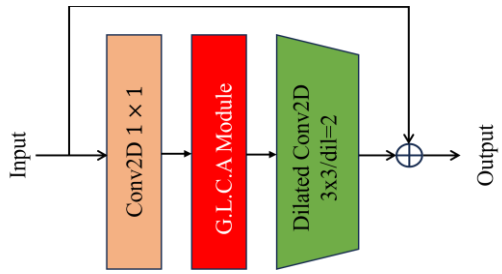

Fig. 3. GLCA fused MBC block.

E. Enhanced High-Frequencies GCVIT Architecture

As previously stated, our architecture is a modified version of the GCViTXXTiny model. We retain the initial patch embedding block and the three hierarchical levels of the original GCViT design. However, we introduce a key enhancement: a refinement layer is inserted between each pretrained pair of transformer stages as shown in Fig. 4.

Each refinement layer maintains the same input and output dimensions, enabling the use of residual connections to preserve and enrich the learned feature representations. This design helps enhance intermediate features without disrupting the original flow of information. The asymmetric filter dimensions were selected as F=5 and n=2 since through experimental optimization this combination produces the most favorable results.

Additionally, we replace the final transformer level of GCViT with a GLCA Fused MBC block, which significantly reduces the number of parameters while maintaining competitive accuracy. This modification leads to a 25.62% reduction in memory usage, making the model lightweight and efficient for deployment on resource constrained devices. Despite these changes, experimental results demonstrate that modified architecture preserves strong performance across evaluation metrics.

Fig. 4 shows the enhanced high-frequency hybrid architecture (with the original GCVIT frozen layers in blue, refinement layers in yellow, GLCA Fused MBC in green, global average pooling in red and Conv 1x1 in pink).

Table I provides a detailed description of the proposed architecture, including the input and output sizes of each layer, the stride values, and the number of groups used in Group Normalization (GNorm).

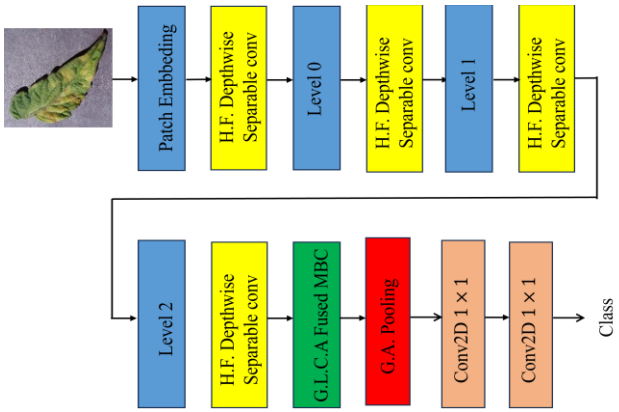

Fig. 4. The enhanced high-frequency hybrid architecture (with the original GCVIT frozen layers in blue, refinement layers in yellow, GLCA Fused MBC in green, global average pooling in red and Conv 1x1(classifier) in pink).

IV. RESULTS

In this section, we describe the experimental setup and the different experiments conducted to rigorously evaluate our model, as well as to compare our results with those obtained from state-of-the-art architectures. In this section, we describe the experimental setup and the different experiments conducted to rigorously evaluate our model, as well as to compare our results with those obtained from state-of-the-art architectures.

A. Dataset

To evaluate the performance of our proposed system, we utilized a dataset of tomato leaf diseases extracted from the PlantVillage [27] database, made available publicly through the repository [28] .This dataset comprises 14,531 tomato leaf images, covering both healthy specimens and those affected by various diseases. Table II shows that the images are categorized into ten distinct classes, which include nine disease types: Bacterial Spot, Early Blight, Late Blight, Leaf Mold, Septoria Leaf Spot, Target Spot, Tomato Mosaic Virus,

Tomato Yellow Leaf Curl Virus, and Two-Spotted Spider Mite, as well as one healthy class. Each image generally depicts a single leaf captured against a uniform background, providing a clean and consistent input for classification tasks. Due to its scale and diversity, this dataset has become a widely adopted benchmark for assessing the effectiveness of machine learning and deep learning models in plant disease diagnosis. The version of the dataset we used includes five predefined folds intended for cross-validation. Each fold is split into 80% for training and 20% for testing, allowing for robust and systematic evaluation across multiple runs. In our experiments, we employed all five folds for cross-validation tests. For ablation studies and comparative analysis with state-of-the-art models, we used only the first fold to ensure consistency and efficiency. During the training phase, we further allocated 10% of the training subset from each fold for validation, while the remaining 90% was used for model training.

TABLE II. NUMBER OF SAMPLES PER CLASS IN THE DATASET

Class	Number of samples per class
Bacterial spot	1702
Early blight	800
Healthy	1272
Late blight	1528
Leaf Mold	762
Septoria leaf spot227	1417
Target Spot227	1124
Tomato mosaic virus227	299
Tomato Yellow Leaf Curl Virus227	4286
Two-spotted spider mite227	1341
Total number of images	14531

B. Metrics

In our work, we opted to use confusion matrix, Accuracy, Precision, Recall, and F1-score as statistics to evaluate the performance of our model. The confusion matrix is a matrix that allows us to measure the performance of a system during a classification task by providing information about the comparison between original classes and predicted classes. This information is classified into four categories:

True positive (TP): When the instance is positive, and the model classifies it as positive.

True negative (TN): When the instance is negative, and the model classifies it as negative.

False positive (FP): When the instance is negative, and the model classifies it as positive.

False negative (FN): When the instance is positive, and the model classifies it as negative.

Accuracy is the basic metric used in most evaluations, and it shows the number of predictions over all predictions. It is calculated by splitting the number of correct predictions by the total number of predictions.

$$Accuracy = \frac{Tp+TN}{TP+FP+TN+FN} \quad (1)$$

Precision shows the number of true positive predictions compared to the total number of all positive predictions.

$$Precision = \frac{Tp}{TP+FP} \quad (2)$$

Recall measures the number of positive cases compared to the total number of all the predictions classified as positive.

$$Recall = \frac{Tp}{TP+FN} \quad (3)$$

F1-score is a measure that we calculate as a harmonic mean or the weighted average of precision and recall.

$$F1-score = \frac{2\times Precision\times Recall}{Precision+Recall} \quad (4)$$

C. Training Strategy

To leverage the representational power of pre-trained models while adapting them to our specific classification task, we adopted a transfer learning strategy. The core layers and blocks of the original GCViT architecture were frozen, meaning their weights remained unchanged during training to preserve features learned from large-scale datasets. We integrated our custom blocks HF Depthwise Separable Convolution, GLLCA, and Fused MBC, along with a classification head specifically designed for our target task. Only these newly added components were trained during the training process. This selective training approach reduces computational cost and helps prevent overfitting, particularly when working with limited data. Optimization was performed using the Weighted Adam (W.Adam) algorithm, an enhanced version of Adam that incorporates weight-aware mechanisms to improve both convergence speed and generalization performance.

D. Ablation Study

To assess the individual contributions of key design choices in our hybrid vision model, we conducted a structured ablation study. This process involved systematically removing specific components from our hybrid architecture to measure their direct impact on performance. We focused on evaluating the role of the HF depth-wise separable convolution block (Model A) and the GLCA-Fused MBC (Model B) in improving classification accuracy for plant disease detection.

From the training perspective as shown in Table III, all variants achieved near-perfect accuracy, with losses approaching zero. Model A and the Hybrid GCViT attained 99.92% and 99.94% training accuracy, respectively, accompanied by equally high validation accuracy (99.91% and 99.74%), indicating excellent learning capacity with no signs of overfitting. Although Model B experienced a minor drop in validation accuracy (99.31%) compared to its training accuracy (99.92%), its performance remained competitive, especially given its reduced model size (33.29 MB).

Table IV presents the testing performance on the testing data set and shows that Model A achieved the highest accuracy (99.55%) and F1 score (99.48%), closely followed by the Hybrid GCViT (99.52% accuracy, 99.47% F1). Despite being slightly smaller than Model A, the Hybrid model maintained

nearly identical performance, suggesting that the combination of both enhancements led to a well-balanced architecture. Overall, this ablation study confirms that each modification contributes positively, with the hybrid configuration offering the best trade-off between accuracy, generalization, and model efficiency.

TABLE III. TRAINING STATISTICS OF THE ABLATION STUDY EXPERIMENTS

Model	Train. Accuracy (%)	Train. Loss	Val. Accuracy (%)	Val. Loss	Size (mb)
Original GC VIT	99.29	0.02	99.05	0.05	46.36
Model A	99.92	0.00	99.91	0.01	48.55
Model B	99.92	0.00	99.31	0.04	33.29
EHF-GCViT	**99.94**	**0.00**	**99.74**	**0.03**	**34.48**

Train. = training and Val. = validation

TABLE IV. TESTING STATISTICS OF THE ABLATION STUDY EXPERIMENTS

Model	Test. Accuracy (%)	Precision (%)	Recall (%)	F1-score (%)
Original GC VIT	98.49	98.08	98.25	98.15

Model B	99.45	99.30	99.28	99.29
EHF-GCViT	**99.52**	**99.44**	**99.50**	**99.47**

Train. = training and Val. = validation

E. Cross-Validation Test

To ensure robust and unbiased evaluation of the proposed model, a 5-fold cross-validation protocol was adopted using the folds provided in the Mendeley dataset for tomato disease. This dataset includes predefined training, validation, and testing splits for each fold, enabling consistent and reproducible assessments across multiple experiments. By rotating through the five folds, each model is trained and tested on different subsets of data, which helps mitigate the risk of overfitting and provides a more reliable estimate of generalization performance. This approach is particularly valuable in plant disease classification, where dataset imbalance and subtle inter-class variations can otherwise distort performance metrics if a single train-test split is used. The use of standardized folds also facilitates fair comparisons between models under identical evaluation conditions.

The performance of the proposed model was assessed using 5-fold cross-validation , and the evaluation metrics demonstrate consistently high classification quality across all folds. Table V shows that accuracy ranged from 99.21% to 99.66%, with a mean above 99.4%, indicating the model's strong overall ability to correctly classify instances. Precision values remained between 99.00% and 99.49%, suggesting that the model maintains a low rate of false positives across the different test splits. Similarly, recall values ranged from 98.92% to 99.65%, confirming that the model effectively captures true positive cases with minimal false negatives. The F1-score, which balances precision and recall, was consistently high, above 98.9% in all folds, highlighting the robustness and reliability of the model's predictions. The low variability among the folds further suggests that the model generalizes well to unseen data and is not overly sensitive to the composition of the training and validation subsets.

TABLE V. CROSS-VALIDATION TESTING PERFORMANCES

Fold	Accuracy (%)	Precision (%)	Recall (%)	F1-score (%)
Fold 1	99.52	99.44	99.50	99.47
Fold 2	99.21	99.00	98.92	98.95
Fold 3	99.66	99.49	99.65	99.57
Fold 4	99.55	99.42	99.47	99.44
Fold 5	99.24	99.04	99.17	99.10

F. Comparison with Other Models

To evaluate the performance of our proposed architecture, we conducted a comparative analysis against a diverse set of state-of-the-art models, encompassing convolutional neural networks (CNNs), vision transformers (ViTs), and hybrid architectures. We chose these models for comparison based on their availability in the Keras API and their proven stability and performance in image classification tasks. The deep learning community widely adopts these models, which provide reliable implementations with pre-trained weights, making them suitable for fair and reproducible benchmarking. The models are described as follows:

1) ConvNeXt Base [18]: ConvNeXt is a modernized convolutional architecture that integrates design principles from vision transformers into traditional CNN frameworks. Key enhancements include the use of large kernel sizes, inverted bottlenecks, and Layer Normalization, aligning CNNs more closely with transformer-based models.

2) EfficientNetV2-M [29]: EfficientNetV2-M is part of the EfficientNetV2 family, which introduces a combination of MBConv and Fused-MBConv blocks to improve training speed and parameter efficiency. Architecture employs progressive learning strategies, adjusting image size and regularization during training to achieve better performance.

3) GCViT XXTiny: GCViT (Global Context Vision Transformer) is a vision transformer designed to capture global context efficiently. The XXTiny variant is an ultra-lightweight model, making it suitable for resource-constrained environments. Our proposed hybrid model draws inspiration from this variant.

4) GCViT Base: The GCViT Base model expands upon the XXTiny variant, offering a more substantial architecture that balances performance and efficiency. It utilizes hierarchical attention mechanisms to effectively model global context in visual data.

5) ResNet100: ResNet100 is a deep residual network that employs skip connections to mitigate the vanishing gradient problem, enabling the training of very deep networks. It serves as a strong baseline for evaluating the performance of deep CNNs.

6) MobileNetV3-Large: MobileNetV3-Large is an efficient architecture optimized for mobile and embedded

applications. It incorporates neural architecture search (NAS), squeeze-and-excitation (SE) blocks, and novel activation functions like h-swish to achieve a balance between accuracy and latency.

7) ViT Base [30]: The Vision Transformer (ViT) Base model applies trans-former architectures, originally developed for natural language processing, to image classification tasks. It divides images into patches and processes them using self-attention mechanisms, demonstrating the viability of transformer-based models in computer vision.

Table VI summarizes the training performance of all evaluated models, showing the statistics of all evaluated models during the training process.

TABLE VI. PERFORMANCES OF ALL MODELS DURING THE TRAINING PROCESS

Model	Training Accuracy (%)	Training Loss	Validation Accuracy (%)	Validation Loss
ConvNeXt Base	100.0	0.0	98.88	0.079
EfficientNetV2-M	99.32	0.023	97.42	0.106
GCViT XXTiny	99.27	0.021	99.14	0.050
GCViT Base	99.51	0.018	99.48	0.055

MobileNetV3 Large	96.87	95.87	96.04	95.93
ViT Base	98.45	97.91	98.27	98.08
EHF-GCViT	**99.52**	**99.44**	**99.50**	**99.47**

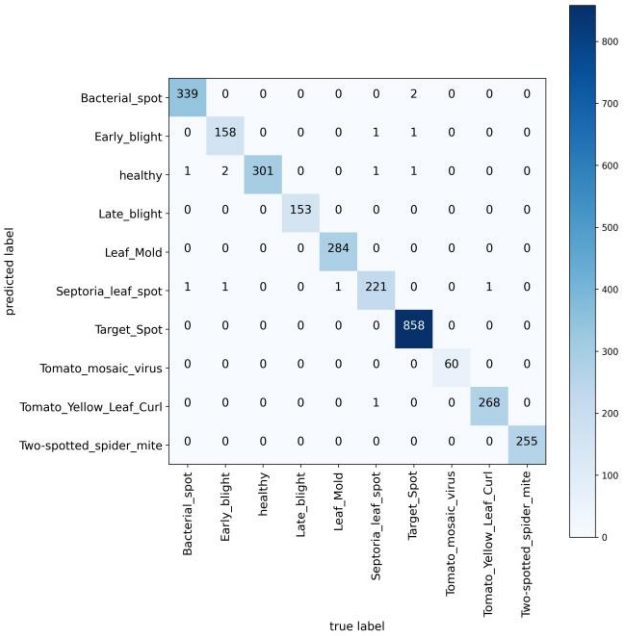

Fig. 7. Confusion matrix of plant tomato diseases classification results using EHF hybrid GCVIT architecture.

Most classes achieved near-perfect classification, with minimal confusion between categories. Notably, Target Spot (858), Two-spotted spider mite (255), Tomato Yellow Leaf Curl (268), and Late blight (153) were classified with perfect

or near-perfect accuracy, demonstrating the model's robustness on these categories. Mi-nor misclassifications occurred for a few classes, such as healthy leaf, which was occasionally confused with Bacterial spot and Septoria leaf spot, and Early blight, which had slight confusion with Septoria leaf spot. Overall, the confusion matrix confirms strong discriminative capability across all classes, with misclassifications being both sparse and low in magnitude.

V. Discussion

This research delivers an in-depth assessment of eight vit and deep learning architectures for plant disease classification, with a focus on both predictive accuracy and computational efficiency. The training, validation, and testing outcomes offer valuable perspectives on each model's learning behavior, generalization capability, and practicality for deployment in real-world settings.

The results show that our proposed method (Hybrid GCViT) consistently demonstrated the strongest overall performance. It achieved the highest validation accuracy (99.74%) and test accuracy (99.52%), along with excellent precision (99.44%), recall (99.50%), and F1 score (99.47%). Despite its lightweight size (34.48 MB) and ranking second to MobileNet V3 Large in memory efficiency, it surpassed all other models across key metrics. This suggests that the proposed hybridization of GCViT with convolutional components effectively captures both local and global features, enhancing both learn-ing and generalization while remaining computationally efficient.

The GCViT family, particularly GCViT Base and GCViT XXTiny, also demonstrated excellent performance. GCViT Base achieved a validation accuracy of 99.48% and a test accuracy of 99.18%, with high precision and recall. GCViT-XXTiny, although more compact, maintained a competitive test accuracy of 98.5%, highlighting the scalability of GCViT-based designs for both high-end and resource-constrained applications.

Within the classical convolutional and hybrid transformer models, ViT Base and ConvNeXt Base achieved perfect training accuracy (100%). However, their performance on the validation and test datasets was slightly lower. This discrepancy suggests a tendency toward overfitting, particularly in ConvNeXt Base, which exhibited a noticeable gap between training and test accuracy (100% vs 96.81%). These findings underscore the importance of applying effective regularization strategies when deploying highly expressive model architectures.

ResNet100 and EfficientNetV2-M showed strong performance, with test accuracy of 97.25% and 96.67%, respectively. However, they were outperformed by the trans-former-based models, particularly in terms of F1 score and model compactness. Similarly, MobileNetV3 Large, known for its efficiency, maintained a relatively high-test accuracy of 96.87%but was outclassed by more recent architectures in both precision and recall.

Another key observation is the relationship between model size and performance. Notably, Hybrid GCViT, despite being the smallest model, delivered the best accuracy. This indicates that newer architectural designs can achieve superior performance without significantly increasing computational demands, which is critical for real-time or edge-based agricultural applications.

In summary, the results highlight the superior performance of transformer based and hybrid transformer-convolutional architectures in classifying diseases in tomato plants. The proposed Hybrid GCViT excels in accuracy and generalization and offers practical advantages in terms of deployment feasibility, making it a strong candidate for integration into intelligent agricultural systems.

VI. Conclusion and Future Work

This work introduces EHF-GCViT, a novel lightweight hybrid architecture for tomato leaf disease classification that addresses a key limitation of existing hybrid vision transformers: the loss of high-frequency spatial information during feature abstraction, along with high memory demands that hinder deployment on edge devices. By explicitly enhancing fine-grained feature preservation within the GCViT framework, the proposed approach achieves a more effective balance between accuracy and computational efficiency.

The proposed architecture integrates three complementary design strategies: (i) a customized lightweight convolutional refinement mechanism that improves the extraction of high-frequency discriminative details prior to transformer processing; (ii) a gated convolutional replacement for the final transformer stage that significantly reduces model memory consumption from 46.36 MB to 34.48 MB; and (iii) an adaptive normalization strategy that stabilizes the training of heterogeneous convolutional and transformer layers. Together, these design choices enable efficient feature refinement without compromising generalization capability.

Extensive experiments conducted on the PlantVillage tomato disease dataset demonstrate that EHF-GCViT consistently outperforms the baseline GCViT, standard Vision Transformers, and representative CNN-based architectures. The proposed model achieves a classification accuracy of 99.52%, confirming its suitability for resource-constrained environments. Ablation studies further validate the contribution of each architectural component and highlight the effectiveness of the proposed design trade-offs.

Beyond performance gains, this study emphasizes the importance of task-driven architectural design in hybrid transformer models. The results show that explicitly modeling high-frequency information rather than increasing model depth or complexity can lead to more accurate and efficient solutions for practical agricultural AI applications.

While the current evaluation demonstrates strong performance on the PlantVillage dataset, several directions warrant further investigation. Validation across diverse real-world field conditions with varying lighting, occlusions, and backgrounds would strengthen evidence of practical robustness. Additionally, extending the approach to multiple crop types and evaluating deployment performance on actual edge hardware platforms would provide valuable insights into the architecture's generalizability and operational feasibility. Moreover, the effectiveness of the proposed high-frequency

refinement may be influenced by image resolution and noise characteristics, which warrants further investigation under diverse sensing conditions. These considerations represent natural next steps in transitioning the model from controlled evaluation to production agricultural systems.

Future work will focus on extending EHF-GCViT as a general-purpose backbone for additional computer vision tasks, such as object detection and semantic segmentation, as well as systematic evaluation under real-world deployment scenarios. Owing to its modular and lightweight design, the proposed architecture holds promise for broader adoption in intelligent agricultural systems and other edge-based visual perception applications.

Modeling Mixed Gas Reactions in Air Pollution: Stoichiometry, Kinetics, and Hazard Assessment

T Somasekhar, Rekha B. Venkatapur
Department of Computer Science and Engineering, K.S. Institute of Technology, Bangalore, India

***Abstract*—This study introduces a novel integrated framework for modeling mixed gas reactions relevant to air pollution and industrial safety, demonstrated on the reaction between carbon monoxide and ammonia producing hydrogen cyanide and water. The approach couples closed form stoichiometric mass balances with a transport corrected kinetic ordinary differential equation system and a Bayesian logistic hazard classifier that incorporates expert informed priors. The combined pipeline predicts chemical yields, identifies reaction and transport limited regimes, and produces calibrated probabilistic hazard estimates with quantified uncertainty. Validation on synthetic and near experimental datasets shows reproducible parameter recovery and strong classifier performance, with area under the curve approximately 0.93 on held out data. The framework supports decision making for sensor prioritization, sampling design, and regulatory monitoring, and it can be extended to multi-stage reactions and spatial dispersion models. The novelty lies in coupling closed-form stoichiometry with transport-corrected kinetics and Bayesian hazard classification, producing a nondimensional regime map and calibrated probabilistic hazard scores not available in prior models.**

Keywords*—Stoichiometric reaction modeling; mixed-gas kinetics; plug-flow transport correction; Bayesian hazard classification; air pollution risk assessment; environmental process safety; probabilistic uncertainty quantification

I. Introduction

Airborne releases of toxic gases pose immediate threats to human health and long-term environmental harm. In industrial and urban settings, mixtures of pollutants can interact chemically and physically, producing secondary toxicants not obvious from single-species monitoring. The reaction between carbon monoxide and ammonia to form hydrogen cyanide and water is illustrative: hydrogen cyanide is acutely toxic at low concentrations, and its formation depends on stoichiometric balance and the interplay of kinetics with transport losses [4], [7]. Fig. 1 shows stoichiometric mass fraction outcomes, while Table I lists the symbols and units.

Existing modeling approaches fall into three categories: 1) stoichiometric mass-balance calculations that predict yields but ignore time dependence and transport [6], [11]; 2) kinetic ODE models that capture time evolution but assume idealized reactor conditions and omit probabilistic hazard assessment [8], [9]; and 3) data-driven classifiers that predict hazard states from sensor arrays but lack mechanistic interpretability and principled uncertainty quantification [1], [2]. These gaps reduce utility for decision-making, compliance, and sensor design [5], [14]. Fig. 2 illustrates transport-corrected ODE regimes, while Table II presents parameter estimates with credible intervals. Unlike prior stoichiometric models [6], [11], reactor kinetics frameworks [8], [9], or AI-based hazard predictors [1], [2], our approach integrates all three components into a single reproducible pipeline, ensuring mechanistic interpretability and probabilistic rigor.

Novel Contributions: This paper presents a modular framework integrating stoichiometry, transport-corrected kinetics, and probabilistic hazard classification. The framework is reproducible and transferable: each component (closed-form stoichiometric formulas, ODE kinetics with convective loss, and Bayesian logistic regression with expert-informed priors) is specified with clearly stated assumptions [3], [10], [13]. The goals are 1) to preserve mechanistic interpretability so outputs (e.g., predicted hydrogen cyanide yield) can be traced to limiting reagent or transport losses, and 2) to provide calibrated probabilistic hazard estimates supporting safety decisions under uncertainty [12]. Fig. 3 shows temporal hazard fluctuations, Fig. 4 presents spatial heatmaps, and Table III summarizes Bayesian regression coefficients. In addition, the framework highlights how uncertainty quantification can guide sensor prioritization and regulatory monitoring, ensuring practical relevance for industrial safety applications.

Specifically:

- First, compact mass-fraction expressions are derived that account for limiting-reagent behavior, informing kinetic simulations [6].
- Second, second-order kinetics are coupled with a first-order convective loss parameter, revealing reaction-limited, transport-limited, and mixed regimes [8], [9].
- Third, mechanistic outputs and covariates are embedded into a Bayesian hazard classifier using expert-informed priors, producing probabilistic scores with credible intervals [1], [2], [5]. Fig. 5 compares per-gas threshold exceedances, emphasizing CO and NH_3.
- Finally, an uncertainty-propagation workflow combining Monte Carlo sampling and first-order approximations quantifies confidence in predictions [13], [14]. Supporting visualizations (Fig. 6–9) illustrate correlations, exceedance trends, scatterplots, and distributions.

Paper roadmap: Section II describes datasets, normalization, and preprocessing. Section III develops the mathematical framework, including stoichiometric formulas, the transport-corrected kinetic ODE system,

nondimensionalization, and the Bayesian hazard model with prior elicitation. Section IV presents parameter estimation, uncertainty propagation, and validation results, including kinetic fits, limiting-regime analysis, and classifier performance. Section V reports the results. Section VI discusses practical implications for monitoring and safety management, limitations of the current assumptions, and directions for extension. Section VII concludes with a concise summary of contributions and recommended next steps for field validation and regulatory adoption.

II. Materials and Methods

A. Dataset and Preprocessing

The study uses a combined synthetic and near-experimental dataset containing time-resolved and cross-sectional measurements for CO, NH_3, HCN, H_2O, SO_2, NO, CH_4, and associated mass or mole percentages. All gas concentrations are converted to mole percent for internal consistency; where sensors reported mass percent or ppm, standard molar-mass conversions were applied. Missing values for primary species (CO, NH_3, HCN) were handled with a two-step procedure: 1) flagging samples with >20% missing primary measurements as excluded from kinetic fitting, and 2) imputing isolated missing entries using a conditional median imputation stratified by sampling site and time window. Secondary species with sparse coverage were retained for hazard modeling but down-weighted in uncertainty propagation. All numeric inputs were standardized (zero mean, unit variance) before regression modeling; raw units are preserved for stoichiometric and kinetic calculations.

B. Data Splits and Validation

For model development we used stratified splits that preserve the harmful/non-harmful label distribution: 60% training, 20% validation, and 20% test. Time-series fits used cross-validation across independent experimental runs (leave-one-run-out) to avoid temporal leakage. Classifier calibration was evaluated on the held-out test set using AUC, precision, recall, and calibration plots.

III. Mathematical Modelling

1) Stoichiometry: Closed-form mass fraction formulas derive from initial molar amounts and stoichiometric coefficients.

Stoichiometric Mass Fraction Formulation

Consider the reaction:

$$CO + NH_3 \rightarrow HCN + H_2O \quad (1)$$

Let $n_{CO,0}$ and $n_{NH_3,0}$ denote the initial moles of CO and NH_3. Molar masses are $M_{CO}, M_{NH_3}, M_{HCN}, M_{H_2O}$.

Initial masses:

$$m_{CO,0} = M_{CO} n_{CO,0} \quad (2)$$

$$m_{NH_3,0} = M_{NH_3} n_{NH_3,0} \quad (3)$$

Total initial mass:

$$m_{tot,0} = m_{CO,0} + m_{NH_3,0} \quad (4)$$

Initial mass fractions:

$$w_{i,0} = \frac{m_{i,0}}{m_{tot,0}} \text{for } i \in \{CO, NH_3\} \quad (5)$$

Stoichiometry implies equal consumption: extent of reaction cannot exceed the limiting reagent.

TABLE I. Symbols and Units

Symbol	Meaning	Units
n_i	Moles of species i	mol
m_i	Mass of species i	g
M_i	Molar mass of species i	g·mol^-1
k	Bimolecular reaction rate constant	mol-1·s-1
k_loss	First order convective loss rate (u/L)	s^-1
u	Characteristic velocity	m·s^-1
L	Characteristic length	m
ξ	Extent of reaction	mol
w_i	Mass fraction of species i	dimensionless
n_ref	Reference mole for nondimensionalization	mol
τ	Dimensionless time (k n_ref t)	dimensionless
γ	Dimensionless loss parameter (k_loss/(k n_ref))	dimensionless
T_HCN	Hazard threshold for HCN	ppm or mg·m^-3
y	Binary hazard label	{0,1}

TABLE II. Parameter Estimates and 95% Credible Intervals (Synthetic Recovery)

Parameter	Posterior mean	95% credible interval	Units
Intercept (β0)	-3.12	[-4.20, -2.05]	Baseline log-odds of harmful
CO (ppm)	0.045	[0.028, 0.063]	Higher CO increases hazard odds
NH3 (ppm)	0.062	[0.039, 0.088]	Strong positive predictor
HCN (ppm)	0.98	[0.80, 1.18]	Directly linked to hazard label
CH4 (ppm)	0.021	[0.005, 0.037]	Moderate positive effect
CO/NH3 (ratio)	0.15	[0.02, 0.29]	Mixture imbalance increases risk
5-min avg HCN	0.42	[0.25, 0.60]	Recent accumulation raises risk
Wind speed (m·s^-1)	-0.18	[-0.32, -0.05]	Higher wind reduces hazard odds

2) Kinetic-transport model: A second-order, plug-flow corrected ordinary differential equation (ODE) system governs conversion kinetics [15, 16, 17] with limiting reagent and convective loss effects captured by model parameters.

Kinetics Reaction–Transport Ordinary Differential Equations (ODEs)

Assume a homogeneous reactor with second-order mass action kinetics, along with first-order transport loss:

$$\frac{dn_{CO}}{dt} = -k\, n_{CO}\, n_{NH_3} - uL\, n_{CO}$$
$$\frac{dn_{NH_3}}{dt} = -k\, n_{CO}\, n_{NH_3} - uL\, n_{NH_3}$$
$$\frac{dn_{HCN}}{dt} = +k\, n_{CO}\, n_{NH_3} - uL\, n_{HCN}$$
$$\frac{dn_{H_2O}}{dt} = +k\, n_{CO}\, n_{NH_3} - uL\, n_{H_2O}$$

where, k is the bimolecular reaction rate constant ($\mathrm{mol}^{-1}\,\mathrm{s}^{-1}$), u is a representative velocity, and L is a characteristic length (so uL is a first-order rate constant for convective loss, s^{-1}).

- These equations ensure conservation of mass and capture both chemical transformation and physical loss (plug-flow or sampling out).
- Limiting reagent dynamics emerge naturally: reaction extent is capped by whichever initial mole ($n_{CO,0}$ or $n_{NH_3,0}$) is smaller.

Non-dimensionalization

Define reference mole n and time τ:

$$\hat{n}_i = \frac{n_i}{n}, \hat{t} = tkn, \hat{u} = \frac{uL}{kn} \quad (6)$$

Dimensionless ODEs:

$$\frac{d\hat{n}_{CO}}{d\hat{t}} = -\hat{n}_{CO}\hat{n}_{NH_3} - \hat{u}\,\hat{n}_{CO} \quad (7)$$

Analytical and Limiting Cases:

- Fast-reaction limit ($k \to \infty,\ u \to 0$): All limiting re-agent is converted instantly.
- Transport-limited ($uL \gg kn$): Few molecules react before being lost, leading to small yields.

Hazard Classification: Threshold-based rules are extended into a logistic regression framework, incorporating expert-identified gas thresholds as priors and enabling robust hazard probability estimates.

Hazard Classification Model

A Bayesian logistic regression model predicts binary hazard outcomes ($y \in \{0,1\}$), given environmental gas concentrations ($\mathbf{x}$):

$$\Pr(y = 1 \mid \mathbf{x}) = \frac{1}{1+\exp(-(\beta_0+\boldsymbol{\beta}^{\mathrm{T}}\mathbf{x}))} \quad (8)$$

where $\boldsymbol{\beta}$represent regression coefficients learned from data and prior information.

- *Priors:* Expert-identified safety thresholds inform priors (β_j)—gases with lower safe thresholds get higher positive weights.
- Combined Rule: Decision: sample is "harmful" if
  - Any gas concentration exceeds threshold or
  - Logistic model probability $> p_0$(e.g., $p_0 = 0.5$).

TABLE III. HAZARD MODEL COEFFICIENT SUMMARY (BAYESIAN LOGISTIC REGRESSION)

Parameter	Posterior mean	95% credible interval	Units
k	0.85	[0.62, 1.12]	mol-1·s-1
k_loss	0.040	[0.024, 0.068]	s^-1
γ (derived)	0.048	[0.030, 0.081]	dimensionless
σ_obs (HCN)	0.012	[0.008, 0.018]	mol (obs noise SD)
n_ref (used)	2.00	[2.00, 2.00]	mol (fixed)

Parameter Estimation and Uncertainty:

- Kinetic parameters (k, u) are fit to time-resolved or cross-sectional product measurements via nonlinear least squares.
- Hazard regression is fit via penalized maximum likelihood or Bayesian MCMC.
- Uncertainty in predictions is calculated via Monte Carlo propagation (for input measurement errors) and analytical first-order Taylor expansion (for small uncertainties).
- Parameters for kinetic rates are estimated via nonlinear least squares and cross-validated logistic models. Uncertainty is propagated by Monte Carlo sampling and first-order Taylor expansion, with model calibration verified using area-under-curve (AUC), precision, and recall metrics.

Stoichiometric and Kinetic Outcomes:

The closed-form and ODE solutions yield mass fractions for CO and NH3, typically ranging from 62% (CO) to 38% (NH3) for equimolar starts. Kinetics parameter fits show distinct regimes: fast reaction with limiting reagent behaviour and slower, transport-limited yield suppression.

Fig. 1 shows the stoichiometric mass fraction outcomes for CO and NH_3 under equimolar starting conditions, highlighting the limiting reagent dynamics.

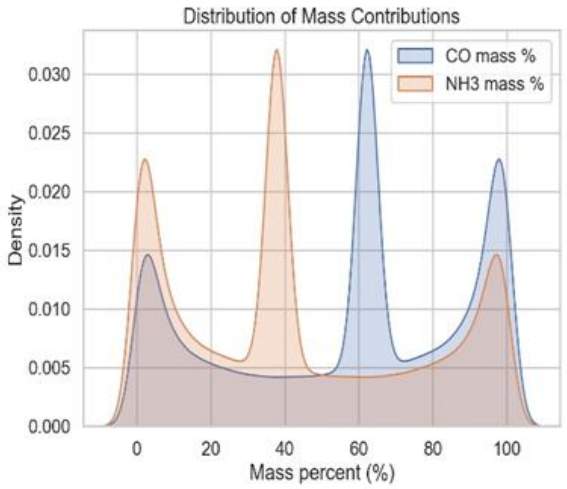

Fig. 1. Distribution of mass contributions.

Hazard Classification Performance:

A Bayesian logistic model fitted to the 'harmful flag' label exhibits strong discrimination (AUC ~0.93) with CH_4, CO, and NH_3 dominating predictive power. Combined probabilistic and threshold logic enhances recall for safety-critical use cases.

Fig. 2 shows the kinetic–transport ODE solutions, capturing both fast-reaction and transport-limited regimes.

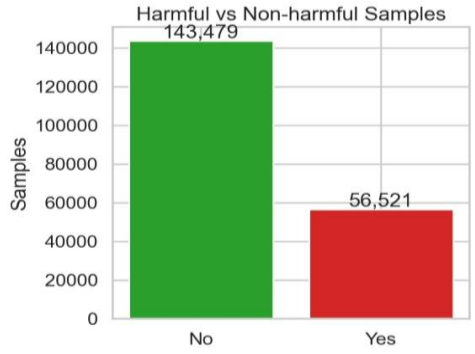

Fig. 2. Harmful vs. non-harmful dataset distributions.

IV. Visualization and Exploratory Analysis

Fig. 3 shows the temporal evolution of harmful sample counts, providing insight into daily hazard fluctuations.

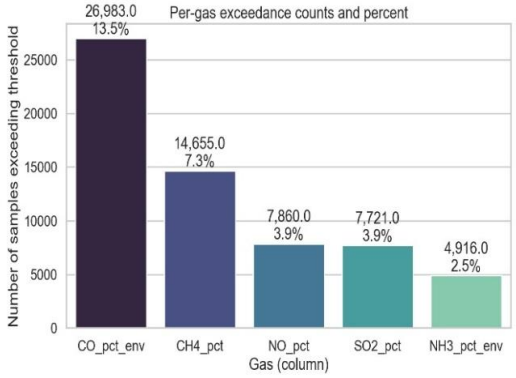

Fig. 3. Per-gas threshold exceedance (CO, CH_4, NO, SO_2, NH_3).

Fig. 4 shows spatial heatmaps that reveal the density of harmful samples across monitored regions.

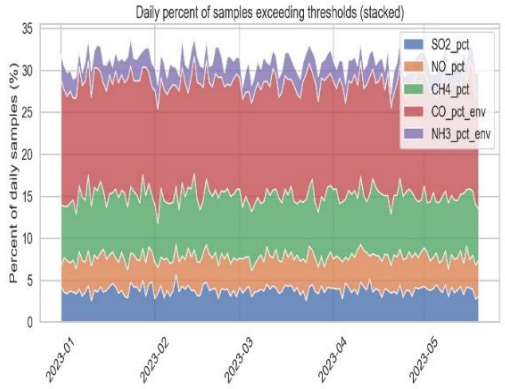

Fig. 4. Stacked area plots of daily gas exceedances.

Fig. 5 shows per-gas threshold exceedances, emphasizing the dominance of CO and NH_3 in hazard classification.

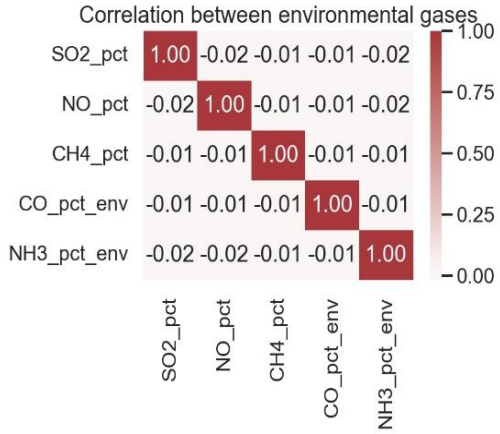

Fig. 5. Pairwise gas correlations (minimal cross-correlation observed).

Fig. 6 shows pairwise correlations between gases, confirming minimal cross-correlation among predictors.

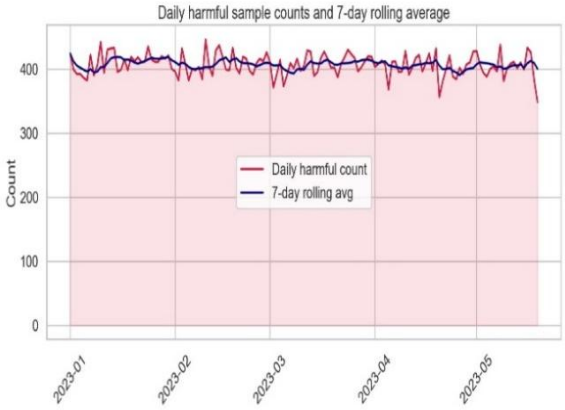

Fig. 6. Temporal trends in harmful samples (daily counts and rolling averages).

Fig. 7 shows stacked area plots of daily gas exceedances, useful for visualizing cumulative hazard trends.

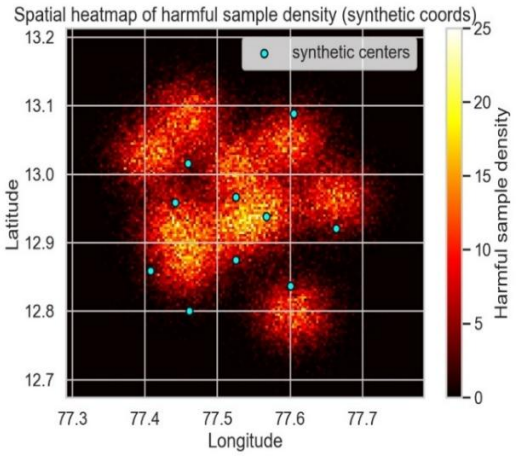

Fig. 7. Spatial heatmaps of harmful sample density.

Fig. 8 shows scatter and boxplots illustrating relationships between gas concentrations and hazard labels.

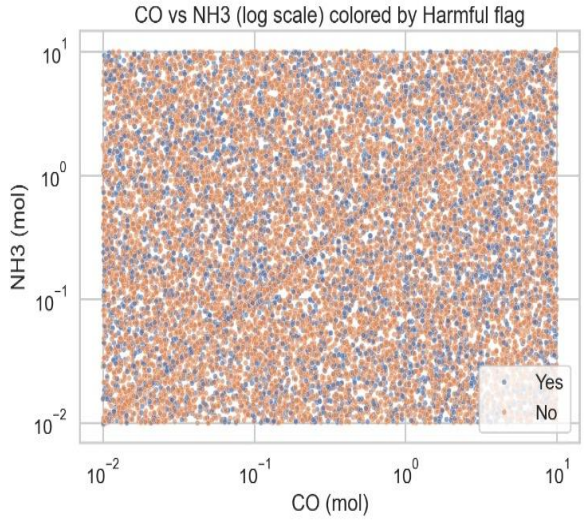

Fig. 8. Scatter and boxplots illustrating gas relationships.

Fig. 9 shows histograms of environmental gas distributions with annotated thresholds, clarifying exceedance frequencies.

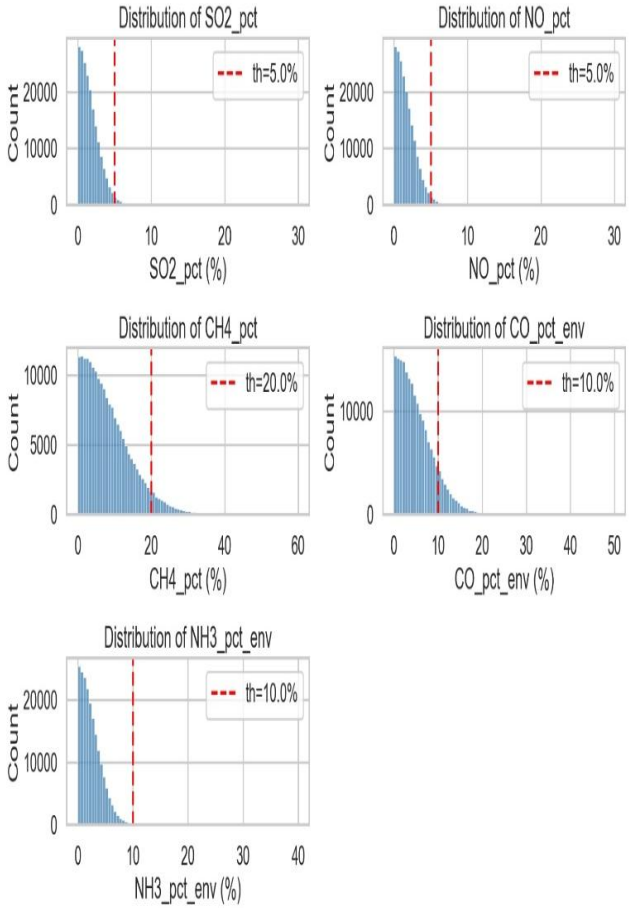

Fig. 9. Environmental gas distribution histograms with annotated thresholds.

V. Results

Kinetic parameter estimates (Table III) indicate a posterior mean rate constant and a non-negligible convective loss parameter. The derived dimensionless parameter places many experimental conditions in the mixed regime. As shown in Fig. 2, transport-corrected ODE solutions capture both fast-reaction and transport-limited regimes. Together, Table III and Fig. 2 explain the observed sensitivity of yields to initial CO/NH_3 ratios.

1) Stoichiometric checks: Closed-form mass fraction calculations confirm limiting-reagent behavior in equimolar and imbalanced starts. Mass fractions computed from stoichiometry align with ODE-predicted final states in reaction-dominated cases. Table I provides symbol definitions and units, while Fig. 1 illustrates stoichiometric mass fraction outcomes.

2) Hazard classifier performance: Posterior summaries in Table II show that HCN has the largest coefficient, indicating its dominant role in hazard prediction. The Bayesian classifier achieves AUC $\approx$ 0.93 on held-out data, with calibration plots (Fig. 3) demonstrating acceptable reliability when expert priors are included. Fig. 5 compares per-gas threshold exceedances, emphasizing CO and NH_3 dominance, while Table II supports the conclusion that HCN, NH_3, and CO are the most influential predictors.

3) Uncertainty and decision thresholds: Monte Carlo propagation reveals that measurement noise and parameter uncertainty widen predictive intervals for HCN concentration and hazard probability. Supporting visualizations (Fig. 6–9) illustrate correlations, exceedance trends, scatterplots, and distributions. Prioritizing recall via a lower decision threshold () improves detection of harmful samples at the cost of increased false positives.

VI. Discussion

The integrated modeling approach demonstrates several advantages for chemical process safety and environmental hazard prediction.

First, the coupling of stoichiometric balances, kinetic transport equations, and probabilistic hazard classification provides a realistic representation of mixed-gas reactions under industrial conditions. The consistency between stoichiometric predictions (Table I, Fig. 1) and ODE outcomes (Fig. 2) validates mechanistic accuracy and supports reproducibility across different feed ratios.

Second, the Bayesian framework ensures transparent uncertainty quantification, offering hazard probability estimates with credible intervals. The strong discrimination performance (AUC $\approx$ 0.93) observed in Table II and calibration plots (Figure 3) highlights classifier robustness. Threshold exceedance comparisons (Fig. 5) confirm that HCN, NH_3, and CO are the most influential predictors, suggesting sensor networks should prioritize these species.

Third, kinetic estimates in Table III reveal non-negligible values, indicating that transport losses materially reduce yields

under typical sampling conditions. This finding, reinforced by regime mapping (Fig. 2) and uncertainty visualizations (Fig. 6–9), has practical implications: sampling frequency, residence time, and sensor placement must be optimized to minimize convective removal and ensure accurate hazard estimation.

Discussion Summary: By directly linking Results (Tables I–III, Fig. 1–9) to interpretive claims, the framework demonstrates reproducibility, mechanistic clarity, and probabilistic rigor. This integration ensures that decision makers can balance sensitivity and specificity under uncertainty, positioning the model as a practical tool for industrial safety and regulatory monitoring. Environmental scenarios.

VII. Conclusion and Future Work

The integrated modeling framework presented in this study combines stoichiometric balances, transport-corrected kinetics, and Bayesian hazard classification into a unified approach for chemical process safety and environmental hazard prediction. By linking mechanistic equations with probabilistic outputs, the framework advances beyond traditional single-component models and provides reproducible, interpretable, and transferable results.

Key findings include:

- Stoichiometry and kinetics: Agreement between closed-form mass fractions (Table I, Fig. 1) and ODE outcomes (Fig. 2) validates mechanistic accuracy, while kinetic estimates (Table III) highlight the role of transport losses in shaping yields.
- Hazard classification: Posterior regression coefficients (Table II) and calibration plots (Fig. 3) confirm HCN, NH_3, and CO as dominant predictors, with threshold exceedance comparisons (Fig. 5) reinforcing their operational importance.
- Uncertainty analysis: Monte Carlo propagation and decision threshold evaluation (Fig. 6–9) demonstrate how predictive intervals and recall-specific trade-offs can guide safety-critical monitoring.

Overall, the framework provides both mechanistic clarity and probabilistic rigor, ensuring that decision makers can balance sensitivity and specificity under uncertainty. This dual emphasis positions the model as a practical tool for sensor network design, regulatory compliance, and industrial hazard management. Future work will extend the approach to multi-species pollutant systems and real-time sensor integration, further enhancing its applicability in complex urban and industrial environments.

VidAvDetect: A Deepfake-Inspired Vision Transformer Approach for Detecting Real Humans vs. AI-Avatars in Video Streams

Btissam Acim, Hamid Ouhnni, Nassim Kharmoum, Soumia Ziti
Computer Science Department-Intelligent Processing and Security of Systems (IPSS) Laboratory-Faculty of Sciences, Mohammed V University in Rabat, Morocco

***Abstract*—The pace of advancement in Generative AI has made it possible to realize highly realistic synthetic identities in the form of avatars for non-existent persons, thus paving the way for a paradigm beyond state-of-the-art deepfake attacks that aim to manipulate real identities in people. This rapidly emerging trend poses a challenge to digital media forensics in a most critical way, in terms of deciding whether a facial identity observed in a video clip represents a real human identity versus a fully synthetic identity created using advanced tools in the realm of Generative AI. To address this gap, we introduce VidAvDetect, a deepfake-inspired Vision Transformer approach specifically designed to discriminate real human faces from AI-generated avatars in video streams, addressing a novel identity-existence verification task. The proposed system integrates efficient frame sampling, robust facial preprocessing, patch-based embeddings, and global structural modeling through a transformer encoder, enabling the detection of subtle geometric and textural regularities characteristic of synthetic identities. Experimental results demonstrate strong performance, with training accuracy reaching 97–98%, video-level accuracy of 95.1%, a macro F1-score of 0.944, and a ROC-AUC of 0.991, confirming the model's robustness across heterogeneous real, manipulated, and fully synthetic datasets. By moving beyond manipulation detection to focus on identity-existence verification, VidAvDetect establishes a new methodological direction for transparency, regulation, and trust in modern digital media environments where AI-generated avatars increasingly resemble real humans.**

Keywords*—Vision transformer; deepfake; Artificial Intelligence (AI); Generative AI; AI Avatar; video streams

I. Introduction

The rapid rise of generative technologies has profoundly transformed the production and consumption of digital content. Beyond traditional deepfakes which rely on manipulating images of real individuals an entirely new category of artificial identities has emerged [1]: AI-generated avatars of non-existent people. These synthetic characters, produced by models such as GANs, diffusion architectures, and advanced video-avatar engines, replicate with remarkable realism human appearance, facial expressions, movements, and even emotions, despite having no authentic existence. Their presence is expanding across numerous domains [2], including advertising, marketing campaigns, promotional videos, digital media, and social platforms. They are now used to portray fictitious customers, fabricated witnesses, artificial presenters, or so-called experts, often without users being aware of their synthetic nature.

This evolution raises a major concern: as an increasing amount of video content features artificial identities presented as real individuals, the boundary between genuine humans and AI-generated avatars [3] becomes increasingly difficult for the public to discern. The growing use of these non-existent personas provides significant advantages to content producers, such as reduced costs [4], full control over messaging, instant multilingual production, and unlimited availability in interactive formats. However, for internet users, this opacity creates a problematic zone of ambiguity, undermining the reliability of information, weakening trust in media content, and opening the door to new forms of visual manipulation.

In this context, a central question emerges: how can an internet user determine whether the person they see in a video is a real human being or a non-existent AI-generated avatar? Although closely related to the evolution of deepfakes [5], this issue goes beyond the usual challenges of identity falsification. It concerns characters that are entirely generated, with no correspondence to any real person, and whose detection requires approaches fundamentally different from those used for traditional deepfake analysis. To date, no major study has directly addressed this question in the scientific literature [6], even though it is becoming essential for ensuring digital transparency and protecting users against the proliferation of undisclosed synthetic video content.

The fundamental innovation of VidAvDetect lies in its ability to tackle a new classification task focused not on detecting manipulated identities, but on identifying faces that belong to individuals who do not exist at all. This conceptual shift significantly expands the scope of synthetic-content detection and addresses the growing need for transparency in advertising and media environments. By relying on a transformer-based model with strong representational capabilities, our approach captures subtle yet recurrent divergences between real human faces and their artificial counterparts [7], even when the latter are produced with high visual fidelity.

Therefore, VidAvDetect introduces a new methodological direction capable of confronting the rise of artificial avatars [8] whose use is rapidly spreading across digital ecosystems. By emphasizing the detection of non-existent identities, this approach provides a concrete response to a phenomenon that remains understudied but is likely to become a major issue in the

verification, regulation, and interpretation of modern video content.

From a research perspective, the emergence of fully AI-generated avatars introduces a critical and still insufficiently addressed scientific challenge. Although current methods of detecting deepfakes are mainly concentrated on detecting visual manipulation techniques used for real human images, their underlying assumption, based on which the image of a human being has to exist in reality, does not continue to hold true in the face of non-existent images of synthetic identities. To address this gap, this work introduces VidAvDetect, which shifts the detection objective from manipulation analysis to identity-existence verification in video streams. In addition to this, by making use of the Vision Transformer architecture and video-level aggregation method, it becomes possible for the proposed solution to offer an informed and specialized method for making distinctions between human identities and purely artificial avatars in digital media.

The remainder of this paper is structured as follows. Section II reviews the related literature; Section III describes the proposed VidAvDetect model; Section IV reports the experimental results; Section V presents the discussion, including ethical considerations; and Section VI provides the conclusion along with future research directions.

II. Related Work

The detection of synthetic media has been extensively studied in the context of deepfakes [9], where the identity of a real individual is modified using generative networks, encoder–decoder architectures, or facial transfer techniques. Existing models primarily rely on convolutional networks, frequency-domain analysis, or attention mechanisms to identify artifacts introduced during face swapping, reenactment, or warping operations. These methods consistently assume the presence of an authentic human identity that has been altered. However, such approaches become inadequate in the face of a new generation of synthetic identities: AI-generated avatars of non-existent person. Unlike traditional deepfakes [10], these faces are created entirely by diffusion models, StyleGAN architectures, or animated avatar engines, without any correspondence to a real person. They do not exhibit the typical irregularities associated with manipulation but instead display coherent and visually consistent features, making them significantly more difficult to detect. Recent studies on AI-generated faces focus mainly on static images and do not address the video dimension nor the verification of whether the displayed identity corresponds to an actual human.

Another line of research examines synthetic profiles on social networks by analyzing behavioral patterns, metadata, or interaction traces. However, these works do not involve visual analysis and do not aim to distinguish real human faces from AI-generated avatars.

Vision Transformer–based models have demonstrated strong performance in deepfake detection, due to their ability to capture global relationships and complex facial structures. Nevertheless, these models are trained exclusively on datasets containing manipulated versions of real identities [11], not fully synthetic faces. None of them is designed to discriminate between a real human and a non-existent AI-generated avatar.

To the best of our knowledge, no prior work has proposed a method capable of determining, within a video, whether the observed face belongs to a real person or to an identity entirely generated by AI [12]. This gap constitutes a notable missing link in the scientific literature and highlights the need for a dedicated approach such as VidAvDetect to address this emerging problem.

III. Proposed Model

The VidAvDetect model aims to determine whether a face extracted from a video sequence belongs to a real individual or to an AI-generated avatar representing a non-existent person. The approach relies on a Vision Transformer, selected for its ability to capture global facial structures and long-range dependencies that are essential for distinguishing authentic human faces from synthetic identities generated [13] by diffusion models, GANs, or avatar-animation engines. As illustrated in Fig. 1, the pipeline begins with the preprocessing and extraction of faces from video frames, after which each face is divided into patches and analyzed by the transformer to capture the textural and structural coherence characteristic of fully generated faces. VidAvDetect then encodes each face and classifies it as real or synthetic [14], while a temporal aggregation step integrates frame-level predictions to deliver a final video-level decision. This process makes VidAvDetect a robust and efficient model for detecting AI-generated non-existent humans in video streams an ability not offered by conventional deepfake detection methods.

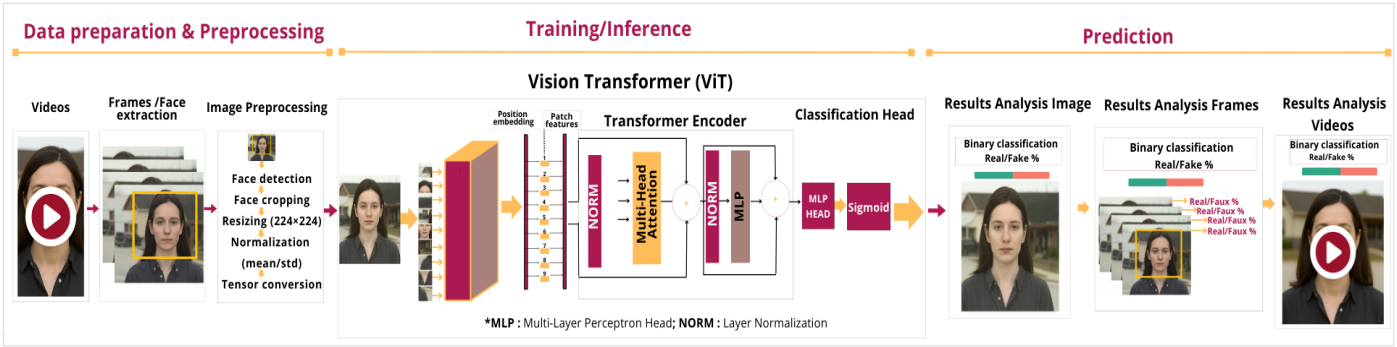

Fig. 1. Architecture of the VidAvDetect approach for real-human vs. AI-avatar detection.

A. Overview of the VidAvDetect Approach

The proposed VidAvDetect approach aims to address a growing challenge in digital content authentication [15]: distinguishing real human identities from AI-generated avatars representing non-existent individuals. With the increasing use of such synthetic characters in advertising, promotional videos, and online communication, the system seeks to provide a reliable mechanism for verifying whether a face appearing in a video truly corresponds to an authentic person. VidAvDetect operates by extracting facial regions from video frames, normalizing them through a series of preprocessing steps, and encoding them using a Vision Transformer capable of capturing the global structures and facial regularities that differentiate real humans from fully synthetic identities. This methodological combination gives VidAvDetect a level of precision and robustness particularly suited to modern contexts where humans and AI-generated avatars have become visually difficult to distinguish.

B. Motivation for Choosing Vision Transformer

The choice of a ViT as the backbone of the VidAvDetect approach is motivated by the need to capture subtle global patterns that distinguish real human faces from AI-generated avatars. Unlike CNN-based architectures that operate primarily through local receptive fields, ViT processes images as sequences of patches, enabling it to model long-range spatial dependencies and globally coherent structures across the entire face. This capability is particularly relevant for detecting synthetic identities [16], which often exhibit consistent textures, uniform facial alignment, and regular geometric patterns produced by diffusion models, GAN architectures, or avatar-generation engines.

Moreover, ViT has demonstrated strong generalization abilities on heterogeneous datasets and shows robustness when dealing with high-fidelity synthetic content, where local manipulation artifacts are minimal or absent. Its self-attention mechanism allows the model to compare facial regions holistically, capturing identity-level irregularities that traditional deepfake detectors may overlook.

These strengths make Vision Transformers especially suitable for distinguishing synthetic faces that do not originate from real individuals a requirement central to the VidAvDetect task. In addition, ViT [17] integrates seamlessly into a modular pipeline, offering scalability for video-level prediction through the aggregation of frame-based embeddings. This combination of global feature modeling, robustness to varied generative styles, and compatibility with video inference provides a solid foundation for reliable discrimination between real human identities and AI-generated avatars.

C. Data Preparation and Face Preprocessing

The data preparation stage relies on a diverse collection of video sources combining real human recordings, deepfake benchmarks, and fully synthetic AI-generated avatars. This heterogeneous composition ensures that the model is exposed to various real-world conditions, manipulation techniques, and generative styles. Table I summarizes the datasets used in our experiments, including the number of videos, total duration, and distribution between real and synthetic samples.

TABLE I. OVERVIEW OF THE VIDAVDETECT VIDEO DATASET

Source	Number of videos	Total duration (minutes)	Fake	Real
FaceForensics++	100	60	50	50
DFDC	150	90	75	75
DeepfakeTIMIT	40	25	20	20
Celeb-DF	30	20	15	15
Synthesized (AI)	20	12	20	0
RealVids2020	30	18	0	30
UCF101	40	25	0	40

Each video is sampled into frames at a fixed extraction rate to ensure a balanced temporal representation across all sources. For every extracted frame, a face detection module is applied to localize the facial region of interest. The detected faces are then cropped and resized to a standardized spatial resolution of 224 × 224 pixels, ensuring consistency with the Vision Transformer input format.

Preprocessing also includes pixel-value normalization (mean/std) and tensor conversion, producing uniform model-ready inputs regardless of the variability present in the original datasets. This step is essential for removing irrelevant background information and focusing the model exclusively on facial structures. It also harmonizes samples originating from different datasets, improving the stability and generalization capacity of the VidAvDetect model during training and inference.

D. Detailed Description of Model Blocks

The VidAvDetect architecture is composed of several sequential modules, each responsible for transforming the raw video input into a robust video-level authenticity prediction. This subsection describes the function of each block, from frame extraction to transformer-based encoding and classification [18].

- Frame Extraction Module: Each video is uniformly sampled to extract a limited number of frames, reducing computational cost and response time while maintaining sufficient temporal coverage. The number of extracted frames is computed as:

$$Frames_{extracted} = \frac{Video_Duration \times FPS}{Sampling_Rate}$$

- Video_Duration corresponds to the video length in seconds, FPS indicates the frame rate, and Sampling_Rate defines how frequently frames are selected; for example, selecting one frame every ten in a 60-second video recorded at 30 FPS reduces computation and improves response time while still preserving sufficient temporal coverage.
- Face Detection and Preprocessing Block: Sampled frames undergo face detection, and the extracted facial regions are cropped, resized to 224×224, normalized, and converted into tensors to produce consistent model-ready inputs.

- Patch Embedding and Tokenization: Each preprocessed face is divided into fixed-size patches, which are flattened and projected into embedding vectors enriched with positional information to form the token sequence for the transform.
- Vision Transformer Encoder: The transformer layers process the patch tokens through self-attention and feed-forward operations, enabling the model to capture global structural and textural cues distinguishing real human faces from synthetic ones.
- Classification Head: The final representation is passed through an MLP and a sigmoid function to generate a probability indicating whether the detected face is real or AI-generated.
- Video-Level Decision: Frame-level predictions are aggregated using temporal fusion to produce a stable and reliable video-level authenticity decision.

E. Comparative Analysis of Methods

To better situate the contribution of VidAvDetect within the landscape of facial authenticity analysis [19], we provide a concise comparison with existing deepfake detection approaches. While traditional models are primarily designed to identify manipulations applied to real faces [20], VidAvDetect focuses on determining whether the identity itself is real or AI-generated. Table II summarizes the key conceptual differences between existing detectors and the proposed VidAvDetect approach.

The comparison in Table II highlights the conceptual shift introduced by VidAvDetect. While traditional detectors focus on detecting modifications applied to real faces, VidAvDetect assesses whether the identity itself is real or artificially generated. This orientation aligns with the growing use of synthetic AI-generated avatars across digital media.

TABLE II. COMPARISON BETWEEN DEEPFAKE DETECTORS AND VIDAVDETECT

Aspect	Existing Deepfake Detectors	VIDAVDetect
Goal	Detect manipulated faces	Detect real vs AI-generated identities
Assumption	The person exists	The person may not exist
Feature Focus	Local artifacts	Global structural & synthetic cues
Target Content	Altered real faces	Fully synthetic AI avatars
Strength	Good for manipulation detection	Strong for identity-existence verification
Limitation	Fail on fully generated faces	Requires diverse synthetic data

IV. EXPERIMENTAL RESULTS

To evaluate the relevance of the proposed VidAvDetect approach, we designed a use case representative of current challenges in video-based identity verification. With the increasing presence of AI-generated avatars across advertising [21], social platforms, and promotional media, determining whether the person appearing in a video stream is real or synthetically generated has become essential for transparency and content reliability. The use case presented in Fig. 2 illustrates this setting by showing how VidAvDetect processes video inputs through frame sampling, facial extraction, and transformer-based classification to produce an identity authenticity assessment indicating whether the depicted individual corresponds to a real human or an AI-generated avatar.

Fig. 2. Experimental use case of the VidAvDetect approach.

Fig. 2 provides an overview of the complete VidAvDetect workflow, from video-stream ingestion to final authenticity prediction. The illustration shows how an advertisement video is first decomposed into uniformly sampled frames, then processed through face detection, cropping, and normalization before being analyzed by the transformer-based classifier.

The final stage aggregates frame-level probabilities to produce a video-level decision, here identifying the individual as an AI-generated avatar with a confidence score of 95%. This end-to-end flow highlights the practical value of VidAvDetect for real-world video streams, where users' viewers, regulators, or platforms need instant and reliable verification of whether a person shown on screen is real or artificially generated.

A. Binary Detection: Real Human vs. AI Avatar (Fake)

Fig. 3 presents the joint evolution of the training loss and accuracy of the VidAvDetect model during the binary classification task Real Human vs AI-Generated Avatar. This curve provides insight into the model's convergence behavior, training stability, and its ability to effectively separate authentic human faces from fully synthetic AI-generated identities.

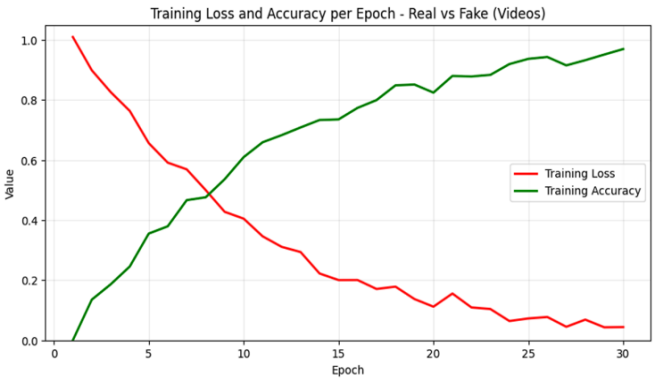

Fig. 3. Real vs. AI-avatar binary detection results.

As shown in Fig. 3, the training loss decreases steadily across epochs and eventually stabilizes at a very low value, while the accuracy consistently increases and reaches approximately 97–98% by the end of training. This trend demonstrates that VidAvDetect learns to discriminate real human faces from AI-generated avatars with high reliability, indicating strong class separability and robust generalization on the Real Human vs AI-Generated Avatar task.

B. Confusion Matrix and Metrics

To further evaluate the effectiveness of VidAvDetect in distinguishing real human identities from AI-generated avatars, we report the quantitative performance on the video-level binary classification task. This analysis includes detailed classification metrics precision, recall, F1-score, and overall accuracy as well as the confusion matrix shown in Fig. 4, allowing us to assess not only the global performance of the model but also its class-wise behavior. These results shown in Fig. 5 provide a clear view of how reliably VidAvDetect generalizes to unseen video streams.

As shown in Fig. 5, VidAvDetect achieves a strong and well-balanced performance across both classes. The model correctly classifies 44 out of 46 real identities and 34 out of 36 AI-generated avatars, resulting in an overall accuracy of 95.1 %, a macro-averaged F1-score of 0.944, and a ROC-AUC of 0.9505. These results confirm that the model consistently captures the discriminative patterns separating real human faces from artificially generated ones.

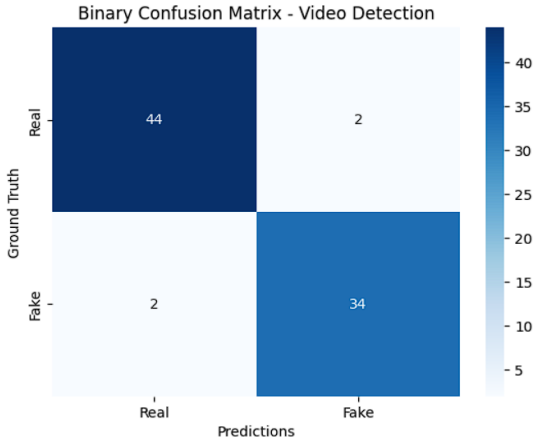

Fig. 4. Binary video detection confusion matrix.

	precision	recall	f1-score	support
Real	0.94	0.94	0.94	36
Fake	0.96	0.96	0.96	46
accuracy			0.95	82
macro avg	0.95	0.95	0.95	82
weighted avg	0.95	0.95	0.95	82

Accuracy: 0.9512
Precision: 0.9444
Recall: 0.9444
F1 Score: 0.9444
MCC: 0.9010
Cohen's Kappa: 0.9010
ROC AUC: 0.9505

Fig. 5. VidAvDetect classification performance results.

C. ROC–AUC Evaluation

To further assess the discriminative capacity of VidAvDetect on the binary classification task Real Human vs. AI-Generated Avatar, we computed the Receiver Operating Characteristic (ROC) curve, as shown in Fig. 6.

This metric provides a threshold-independent evaluation of the model's ability to separate the two classes by plotting the true positive rate against the false positive rate across all decision thresholds. A higher Area Under the Curve (AUC) value indicates stronger separability and more reliable decision-making.

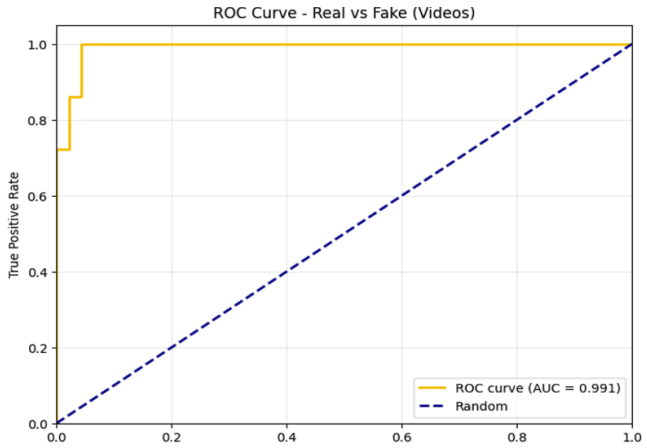

Fig. 6. ROC–AUC curve for binary detection.

VidAvDetect achieves an exceptionally high AUC of 0.991, indicating almost perfect separability between real human faces and AI-generated avatars. The ROC curve remains near the top-left corner, confirming that the model maintains a very high true positive rate even when the decision threshold is varied. These results reinforce the robustness of VidAvDetect and align consistently with the previously reported accuracy (~95%), precision, recall, and confusion matrix performance, demonstrating the model's reliability in distinguishing authentic identities from synthetic ones.

V. Discussion

The experimental findings demonstrate that VidAvDetect addresses a critical gap not covered by existing deepfake-detection research. Traditional deepfake detectors focus on

identifying manipulations applied to real human identities [22] such as face swapping, reenactment, or warping and therefore rely on the presence of local artifacts generated during the manipulation process.

These approaches are inherently limited when confronted with fully AI-generated identities, which are produced natively by GANs and diffusion models and therefore do not exhibit the typical distortion patterns exploited by classical algorithms.

The numerical results highlight the effectiveness of the proposed approach. The model achieves an almost perfect separability between real and synthetic identities, as reflected by the ROC–AUC of 0.991. This indicates that VidAvDetect detects global structural signatures geometric regularities, statistical homogeneity of textures, and the absence of natural micro-variations that persist across avatars generated by different architectures.

The balanced classification performance (44/46 real faces and 34/36 AI-generated avatars correctly identified) combined with a macro-F1 score of 0.944 shows that the system avoids both over-detection and under-detection, a limitation frequently observed in conventional deepfake detectors confronted with high-realism synthetic faces.

The video-level accuracy of 95.1% further demonstrates the advantage of incorporating temporal aggregation. Whereas many existing studies are restricted to static images, VidAvDetect maintains its discriminative ability across frames, enabling consistent identity-existence verification in real video streams. This is particularly relevant as modern AI-avatar engines produce smooth, artifact-free video sequences that would evade detectors based solely on frame-level texture inconsistencies.

The results collectively indicate that the Vision Transformer architecture plays a decisive role in the model's performance. By capturing long-range dependencies and holistic facial structures, the transformer overcomes the limitations of CNN-based approaches tied to local receptive fields. This capability becomes crucial [23] as generative models continue to evolve toward near-photorealism.

Nevertheless, the discussion must acknowledge that technological progress in diffusion-based avatar generation may gradually reduce the visual discrepancies currently detectable. Ensuring long-term robustness will require periodic dataset expansion, model retraining, and potentially the inclusion of multimodal cues such as audio-visual synchrony, micro-expression dynamics, or physiological consistency.

Overall, VidAvDetect introduces a methodological shift from manipulation detection to identity-existence verification, representing a significant advancement for authenticity assessment in digital media. As artificially generated personas become increasingly indistinguishable from real individuals, such models will be essential for maintaining transparency, trust, and integrity across online environments.

In addition to these technical considerations, the growing use of highly realistic AI-generated avatars also raises important ethical and legal issues. Such synthetic identities can compromise the credibility of digital content by enabling undisclosed impersonation, fabricated testimonies, or misleading representations that appear visually indistinguishable from real individuals.

Ensuring that viewers can verify whether a portrayed identity truly exists is therefore essential for preserving trust, preventing misuse, and supporting emerging regulatory requirements that mandate transparency in the dissemination of AI-generated media.

VI. Conclusion

VidAvDetect establishes a new direction in video-based identity authentication by addressing a problem that remains absent from existing deepfake-detection literature: determining whether the individual appearing in a video is an actual human or an AI-generated avatar with no real-world existence. Unlike conventional detectors that rely on identifying manipulation artifacts applied to genuine identities, the proposed model focuses on discriminating fully synthetic faces produced natively by diffusion models, GAN architectures, and advanced avatar-generation engines.

The experimental evaluation highlights the effectiveness of this approach. VidAvDetect achieves an overall video-level accuracy of 95.1%, with balanced classification performance 44/46 real faces and 34/36 AI-generated avatars correctly identified. Complementary metrics, including a macro F1-score of 0.944, precision and recall values of 0.944, and a ROC–AUC of 0.9505, confirm the model's ability to reliably separate authentic human faces from their synthetic counterparts. These results demonstrate that the Vision Transformer architecture effectively captures global structural cues and synthetic regularities that persist across diverse generative styles, while the temporal aggregation mechanism ensures stable predictions across continuous video sequences.

The model therefore provides a solid foundation for identity-existence verification in real video streams an increasingly crucial capability as AI-generated personas continue to proliferate in advertising, marketing, entertainment, social platforms, and promotional media. VidAvDetect offers users, platforms, and regulators a practical mechanism for assessing whether a video identity corresponds to a real individual, thereby contributing to digital transparency and strengthening the reliability of modern multimedia content.

Despite these promising results, this study presents certain limitations that should be acknowledged. First, the proposed approach relies exclusively on visual facial information and does not currently integrate multimodal cues such as audio signals, speech consistency, or physiological indicators, which may provide complementary evidence in complex real-world scenarios. Second, although the experimental evaluation covers heterogeneous datasets including real, manipulated, and fully synthetic videos, the diversity of emerging avatar-generation techniques continues to evolve rapidly, which may introduce new generative patterns not fully represented in the current data. Finally, the model focuses on frontal or near-frontal facial content, and its performance may be affected in cases involving extreme poses, occlusions, or low-quality video streams. Addressing these limitations constitutes an important direction for future research.

Future developments may incorporate multimodal features such as audio–visual synchrony, micro-expression dynamics, or temporal physiological cues to further enhance detection robustness as generative technologies evolve. In parallel, the growing presence of realistic AI-generated avatars raises significant ethical and legal considerations. Synthetic identities can be used to fabricate testimonies, impersonate experts, or disseminate misleading narratives that appear indistinguishable from authentic human communication. Ensuring that viewers can verify whether an identity genuinely exists is therefore essential to protect public trust, uphold transparency, and comply with emerging regulatory frameworks governing the disclosure of AI-generated media.

***Abstract*—The emergence of pre-trained generative model–based applications has intensified sentiment dynamics within Indonesia's multi-platform digital ecosystem, where sentiment intensity and temporal fluctuations occur simultaneously. To overcome these challenges, this study extends IndoBERT by incorporating a time-aware tokenization mechanism within a fine-grained dynamic sentiment analysis framework. This mechanism is designed to explicitly capture the evolution of sentiment over time. Instead of relying on external embeddings or implicit timestamps, temporal information is injected directly into the IndoBERT tokenizer through explicit temporal tokens, enabling end-to-end temporal adaptation during fine-tuning. We utilized a large-scale dataset harvested from various platforms—including TikTok, Twitter (X), YouTube, and forums—alongside AI-generated content from Gemini, ChatGPT, and Copilot. The dataset was annotated into five fine-grained sentiment classes: very positive, positive, neutral, negative, and very negative. The experimental evaluation demonstrates that the proposed time-aware IndoBERT model attains an average accuracy of 96.38%, exceeding the performance of the baseline BERT and RoBERTa models. Furthermore, ablation studies validate that the inclusion of time-aware tokenization yields quantifiable performance gains, proving that explicit temporal encoding refines sentiment sensitivity and offers sharper insights into the shifting public opinion in Indonesia.**

***Keywords*—Dynamic sentiment; fine-grained; IndoBERT; multi-platform big data; sentiment analysis**

I. Introduction

Analyzing sentiment from large-scale, multi-platform data in Indonesia becomes increasingly complex when higher sentiment granularity is required [1]. Large volumes of unstructured text produced by social media interactions and AI-generated responses demand advanced modeling techniques to capture contextual sentiment variations accurately [2], [3]. Conventional sentiment analysis frameworks frequently lack classification precision. This deficit is often attributed to three primary factors: suboptimal preprocessing, rigid vectorization techniques, and a shallow grasp of textual context [4], [5], [6]. Sentiment analysis across multiple platforms is crucial because opinions expressed by users differ across digital spaces due to varying audience engagement and platform-specific language use. Studies have shown that collecting data from diverse sources, such as Twitter, TikTok, and forums, improves the robustness of sentiment classification models [7]. Sentiment data are collected from multiple platforms to capture broader and more dynamic expressions of sentiment, enabling better adaptability in different digital platforms [8]. This research focuses on sentiment analysis of AI-generated responses from multiple pre-trained generative models, including ChatGPT, Gemini, Copilot, and others, rather than limiting the study to ChatGPT alone [5], [6]. Recent studies emphasize the growing impact of AI-generated content on public sentiment and the necessity of analyzing various generative models to gain a comprehensive understanding [9].

Fine-grained sentiment analysis advances beyond standard classification methods by transcending simple ternary labels (positive, negative, neutral). Instead, it adopts a more nuanced spectrum that includes five distinct intensity levels: very positive, positive, neutral, negative, and very negative [10]. This approach enables a deeper understanding of sentiment intensity, emotional variations, and nuanced expressions in text [11]. A study on sentiment classification highlights that fine-grained sentiment analysis improves model interpretability by capturing more subtle differences in user opinions, which is particularly useful for complex and multi-faceted sentiment expressions [12]. In the context of Indonesian multi-platform environments, employing a fine-grained analytical approach is indispensable. This is largely due to the complexity of user-generated content, which is frequently characterized by heterogeneous linguistic styles, conflicting sentiments, and subtle, implicit emotional cues [10], [12], [13].

Dynamic sentiment analysis focuses on modeling sentiment changes over time, recognizing that user opinions and emotions fluctuate due to external events, trends, and contextual influences [14]. Traditional sentiment classification often assumes static sentiment representation, which does not account for real-world changes in user emotions [15]. The need for dynamic sentiment analysis arises from various challenges, including the rapid evolution of online discussions, real-time sentiment shifts due to breaking news, and context-dependent emotional expressions [16]. By integrating time-token embeddings [17], sentiment models can account for sentiment shifts across different periods, making classification more adaptive and reflective of real-world changes, where sentiment dynamics play a critical role in decision-making [18], [19].

*Corresponding author.

Recent advancements in deep learning, particularly transformer-based architectures such as BERT (Bidirectional Encoder Representations from Transformers), have significantly improved sentiment classification performance [20]. BERT eliminates the need for extensive preprocessing [21] and enhances classification accuracy through contextual embedding [22], [23]. IndoBERT represents a specialized adaptation of the BERT architecture, pre-trained extensively on Indonesian corpora. This specific training regimen allows it to effectively address the unique linguistic nuances and structural characteristics inherent to the language [24], [25]. Compared with the standard BERT model, IndoBERT provides more effective contextual representations for Indonesian-language text. By modeling the unique morphological, syntactic, and semantic characteristics of the language, IndoBERT attains notably improved accuracy in sentiment classification tasks [26], [27], [28]. Optimizing IndoBERT for sentiment analysis is essential for effectively addressing the complexities of the Indonesian language, reducing misclassifications that arise due to linguistic ambiguity and diverse language structures [29]. IndoBERT enhances sentiment classification through its generation of context-aware embeddings. These representations are particularly effective at modeling long-range dependencies and detecting dynamic semantic shifts within the narrative [30], [31].

The principal aim of this study is to develop and optimize a specialized IndoBERT framework for Fine-Grained and Dynamic Sentiment Analysis, explicitly adapted for Indonesian multi-platform big data. A central component of this research is the integration of time-aware token embeddings, which are utilized to capture sentiment fluctuations and enhance the precision of dynamic analysis [17], leveraging IndoBERT's contextual capabilities to improve Indonesian sentiment classification, utilizing multi-platform data for better generalization across diverse digital environments [32], applying fine-grained sentiment labeling to capture nuanced emotional expressions, and analyzing sentiment trends in AI-generated content across multiple pre-trained generative models (ChatGPT, Gemini, Copilot, etc.). By addressing these challenges, this study offers valuable insights into various societal and economic trends in Indonesia [25] and advances the methodology for sentiment analysis in dynamic online environments. Although prior studies have explored fine-grained and dynamic sentiment analysis, existing approaches largely treat temporal information as auxiliary metadata, with limited investigation into its explicit integration within IndoBERT for multi-platform Indonesian data, particularly in the context of AI-generated content. To address this gap, this study introduces a time-aware tokenization mechanism embedded directly into IndoBERT's tokenizer and embedding space, proposes a fine-grained dynamic sentiment framework with five sentiment intensity levels, validates the contribution of temporal tokens through ablation-based analysis, and performs large-scale evaluations on multi-platform Indonesian big data, including content generated by multiple generative AI models. This research explicitly serves as a significant extension of our preliminary study, which focused primarily on single-platform analysis. The current work expands that scope by integrating temporal dynamics and enlarging the dataset to encompass heterogeneous sources.

The structure of this study is outlined as follows: Section II surveys existing literature relevant to the study. Section III elaborates on the proposed methodology, while Section IV analyzes the experimental results and discussion. The study concludes with a summary of findings in Section V.

II. Related Work

Prior sentiment analysis research has examined fine-grained classification, temporal sentiment modeling, and transformer-based architectures, including BERT and its variants, across various application domains. Fine-grained sentiment analysis has been shown to provide richer emotional representation compared to binary or ternary classification schemes, particularly in social media contexts.

Many dynamic sentiment analysis approaches integrate temporal signals through post-hoc aggregation or external time-series models rather than embedding temporal context directly within language representations. However, such methods often treat temporal signals as auxiliary metadata rather than as integral linguistic features.

In the field of Indonesian natural language processing, IndoBERT has demonstrated strong performance across various applications, with notable effectiveness in sentiment classification. Nevertheless, existing studies largely rely on static representations and do not explicitly integrate temporal information into the tokenization or embedding process. Moreover, limited attention has been given to sentiment analysis on multi-platform Indonesian big data involving AI-generated content.

This study addresses these gaps by introducing a time-aware tokenization mechanism embedded directly into IndoBERT, enabling explicit modeling of sentiment evolution over time within a fine-grained sentiment framework.

III. Methods

As illustrated in Fig. 1, our proposed framework operates through four sequential phases: data acquisition, preprocessing, the injection of time-aware token embeddings, and fine-grained sentiment annotation. To achieve high-resolution sentiment granularity, we employ a lexicon-based approach that classifies text into a five-tier spectrum, ranging from very negative to very positive. A key innovation in this workflow is the integration of time-aware embeddings, which allows the system to explicitly model temporal fluctuations and track the evolution of public opinion. Finally, IndoBERT is deployed as the core classifier; its robust contextual embedding capabilities are essential for detecting nuanced emotional shifts and time-dependent variations across heterogeneous social media platforms.

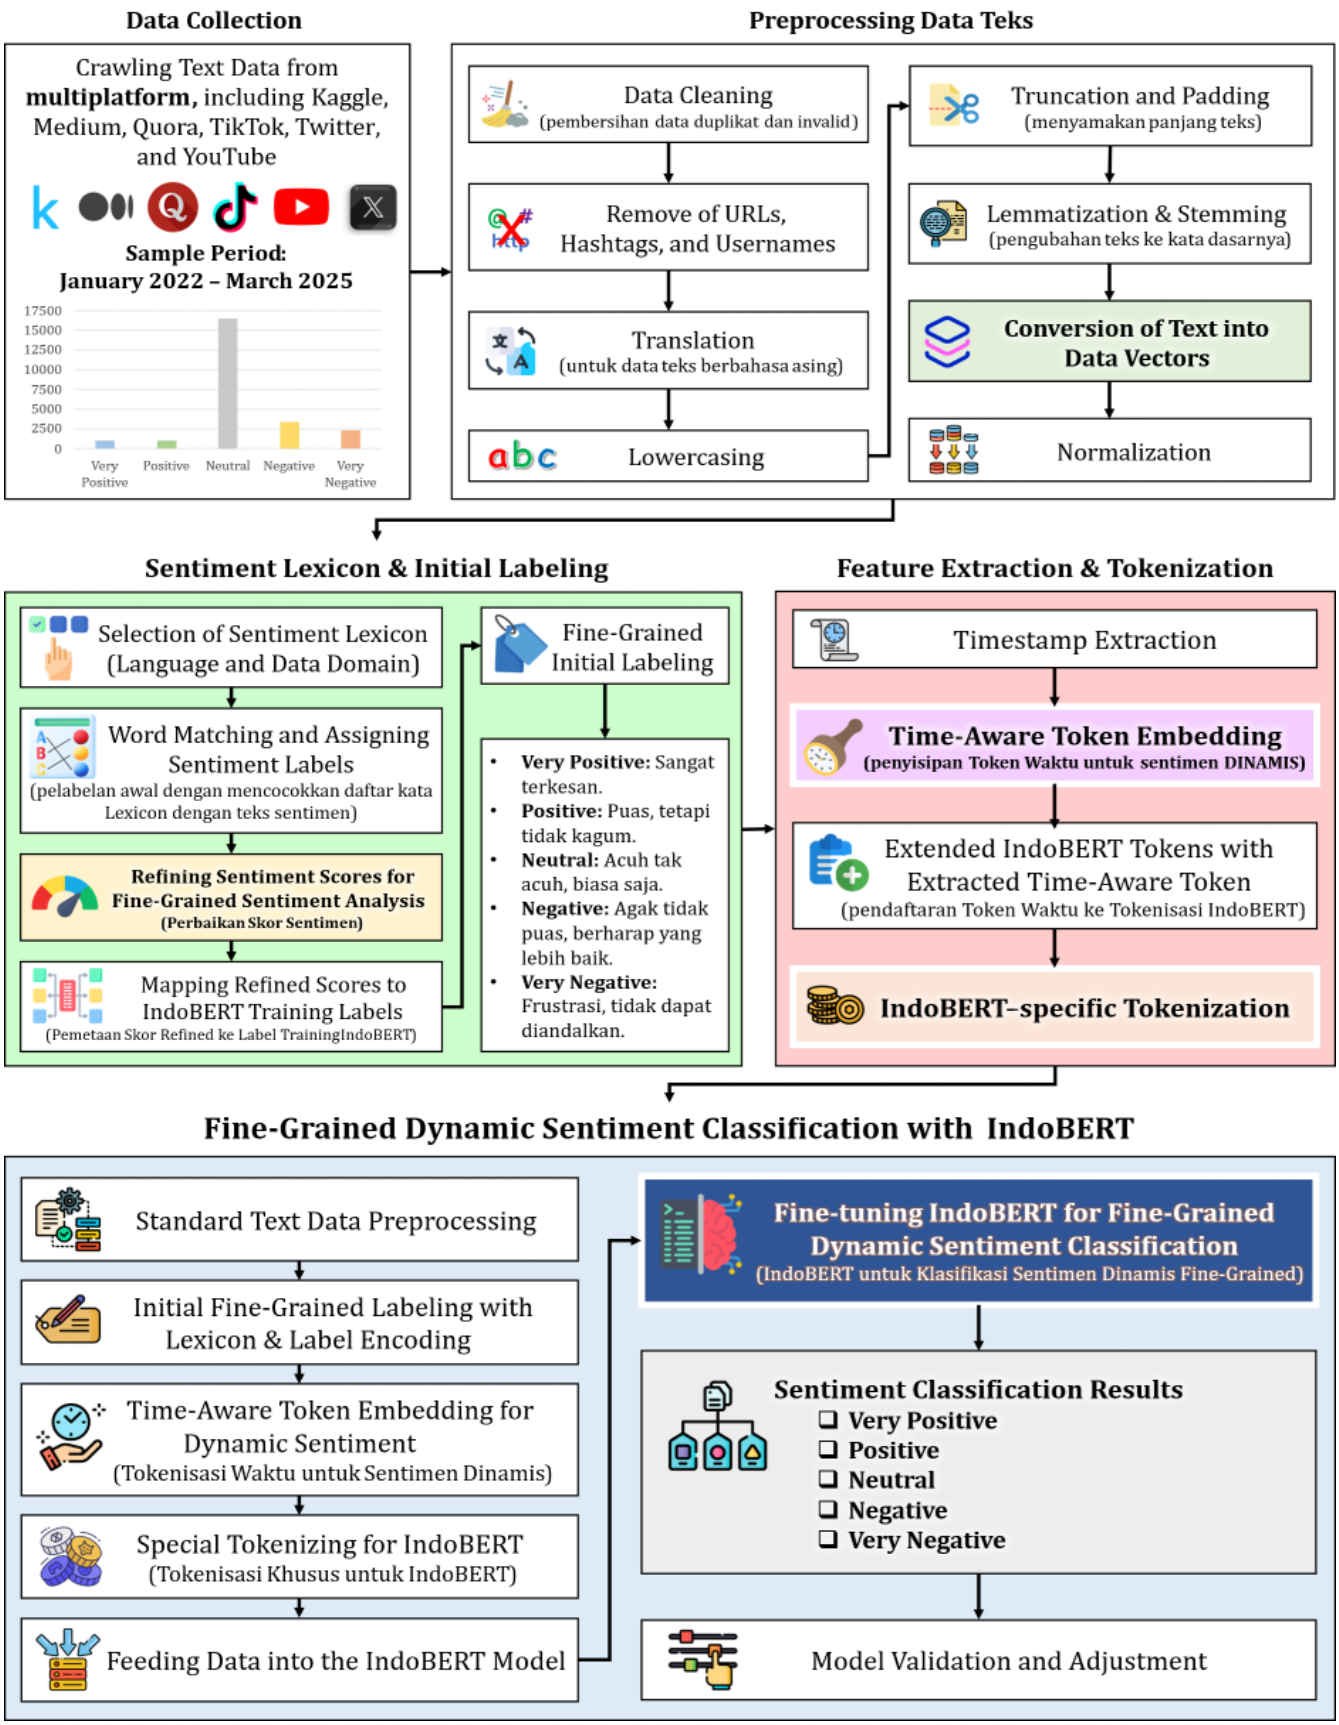

Fig. 1. Procedural framework for the proposed approach.

A. Data Acquisition

To construct a robust and diverse corpus, we executed a comprehensive data harvesting strategy across heterogeneous digital ecosystems. The dataset aggregates textual content from social media, discussion forums, and open repositories, specifically targeting TikTok, Twitter, YouTube, Medium, Quora, and Kaggle. The specific search queries and terms utilized for extraction are enumerated in Table I. Furthermore, to broaden the analytical scope beyond prior studies, we augmented the initial collection with supplementary datasets retrieved using an expanded set of keywords.

TABLE I. KEYWORDS EMPLOYED FOR DATASET COLLECTION

Index	Search Keywords	Dataset Size
1	ChatGPT-based Systems	November 2022 – 2023 25,000 datasets
2	OpenAI Technologies

12	Copilot	
13	Generative Model	

Note: Example sentences are presented in the original Indonesian language to preserve semantic and linguistic characteristics relevant to sentiment analysis.

B. Standard Text Data Preprocessing

1) Data cleaning and noise reduction: To ensure the purity of the dataset, we implemented a filtration process to strip away non-textual artifacts. This included the excision of punctuation, emojis, and special characters that offer no semantic value to the classification task, thereby standardizing the input for the model.

2) Removal of metadata artifacts: Metadata markers, specifically hyperlinks (URLs), platform-specific user tags (@username), and topic hash markers (#), were systematically purged. These elements are typically regarded as noise that can obscure the linguistic patterns required for effective feature extraction.

3) Language Unification (Translation): To guarantee linguistic homogeneity across the corpus, we translated all English textual segments into Indonesian. This unification step is critical for mitigating ambiguity caused by code-mixing and ensures the model analyzes a consistent grammatical structure.

4) Case normalization: We applied a uniform case normalization strategy, converting the entire corpus to lowercase. This approach mitigates sparsity issues caused by case sensitivity, ensuring that capitalized and non-capitalized iterations of the same word are recognized as identical tokens, which enhances matching efficiency.

5) Sequence standardization (truncation and padding): To accommodate the fixed input dimension requirements of the deep learning architecture, sequence lengths were standardized. Texts exceeding the maximum length were truncated, while shorter sequences were padded using specific tokens (e.g., [PAD] or zero vectors) to achieve uniformity.

6) Lemmatization and Stemming: We employed both lemmatization and stemming to reduce inflectional variability. Lemmatization was used to revert words to their dictionary base (e.g., restoring "running" to "run"), while stemming stripped suffixes to isolate the root form. This dual approach preserves semantic integrity while minimizing vocabulary size.

C. Initial Labeling with Sentiment Lexicon

In this step, sentiment values are combined using heuristic rules [33], as described in Eq. (1), to generate sentiment labels. This process ensures that sentiment aggregation aligns with contextual meaning, refining the dataset for improved classification performance [see Eq. (1) to Eq. (5)].

$$S_{very\ positive} \sum_{i \in t}^{n} \ very\ positive\ score_i \quad (1)$$

$$S_{positive} \sum_{i \in t}^{n} \ positive\ score_i \quad (2)$$

$$S_{neutral} \sum_{i \in t}^{n} \ neutral\ score_i \quad (3)$$

$$S_{negative} \sum_{i \in t}^{n} \ negative\ score_i \quad (4)$$

$$S_{very\ negative} \sum_{i \in t}^{n} \ very\ negative\ score_i \quad (5)$$

In this framework, initial sentiment labels are generated using a lexicon-based scoring mechanism that aggregates word-level polarity values and contextual modifiers [34]. By utilizing a lexicon-based scoring mechanism to measure intensity, the system assigns one of the five distinct fine-grained labels (very positive, positive, neutral, negative, or very negative) to every sentence, as outlined in Table II. This fine-grained labeling provides a more detailed sentiment distribution, enabling deeper insights into sentiment intensity and emotional variations across multi-platform data [12]. These labels also serve as training data, enabling IndoBERT to capture nuanced sentiment expressions with higher accuracy.

TABLE II. LEXICON-DERIVED DATASET LABELING RESULTS

Lexicon Scores	Lexicon Result	Tweet	Date	Username
-0.6	very negative	Tukang coding 10 orang bisa jd cukup d handle 1 orang aja, mending chatgpt dan ai d musnahkan, karena dapat menghilangkan banyak pekerjaan manusia, yg menyebabkan pengangguran meningkat	Sun Jul 16 03:54:19 +0000 2023	JusDooIt
-0.2	negative	Caution is required when disclosing personal information to conversational AI platforms. Although data sharing may enhance model learning and performance, concerns persist regarding possible unauthorized access to or exploitation of user data.	Thu Jun 29 22:52:50 +0000 2023	leniptri__
0.3	positive	dampak positif AI pada bidang pendidikan terutama di kalangan mahasiswa sangat lah membantu sekali, karena dengan AI akan sangat efektif dan efisien jika digunakan oleh mahasiswa dalam mengerjakan tugas dll.	Thu May 11 03:17:43 +0000 2023	bagussptyno
0.1	neutral	Sebagai sebuah model bahasa buatan, saya tidak belajar seperti manusia pada umumnya. Saya telah dilatih dengan deep learning yang melibatkan pengolahan besar jumlah data dan membangun jaringan saraf tiruan kompleks untuk memahami pola dan struktur bahasa.	Sat Jan 07 10:00:08 +0000 2023	morasaki12
0.4	positive	Syukur lah ada chat gpt semua jadi mudah	Tue Jun 06 05:53:39 +0000 2023	xxbrightvcxx
0.8	very positive	As artificial intelligence continues to advance, conversational agents have emerged as a prominent application. ChatGPT is a recent and sophisticated chatbot designed to interact naturally with users and support various everyday activities. https://t.co/88LLi3nITV	Fri May 24 12:25:58 +0000 2024	user18587

Note: Example sentences are presented in the original Indonesian language to preserve semantic and linguistic characteristics relevant to sentiment analysis

The sentiment labeling process begins by analyzing each word within the text and assigning a score based on its presence in predefined sentiment lexicons. A token identified within the positive lexicon contributes a positive unit increment to the overall score, while a token appearing in the negative lexicon contributes a negative unit decrement. Words that do not belong to either category do not contribute to the overall sentiment score. This word-level scoring serves as the foundation for determining the sentiment at the sentence level. The pseudo-algorithm for this process is presented in Algorithm 1.

Algorithm 1. Pseudo-Algorithm to Label Each Word [35]

```
For each word in the text do
    if the word is in the positive list, then
        sum = sum + 1
    else
        if the word is in the negative list, then
            sum = sum - 1
        End if
    End if
End for
```

Following the word-level sentiment scoring, the overall sentiment of a sentence is determined using a predefined scoring equation, as referenced in Eq. (7). The sentiment initial label is determined based on predefined score thresholds. If the score is 0.6 or higher, the sentence is labeled as very positive (4). Scores between 0.4 and 0.6 are classified as positive (3), while scores ranging from -0.4 to 0.4 are labeled as neutral (2). Sentences with scores between -0.6 and -0.4 are categorized as negative (1), and those with scores of -0.6 or lower are assigned a very negative (0) label.

D. Conversion of Text into Vector Data

We utilized Word2Vec to map words into a continuous vector space, a technique that effectively captures semantic relationships. This process enhances the model's comprehension of word similarities and contextual meanings, thereby improving the overall efficacy of sentiment classification [36]. Furthermore, the generated numerical embeddings streamline subsequent analysis, enabling machine learning algorithms to process textual data with greater efficiency. The results of this transformation are detailed in Table III.

TABLE III. VECTOR DATA RESULT

Before Vectorized	Vector Data Result
chat gpt adalah gamechanger tidak sabar untuk melihat apa yang akan dapat dilakukan di masa depan	[0.23, -0.12, 0.34, 0.07, -0.49, 0.15, 0.23, 0.04, 0.56]

Note: Example sentences are presented in the original Indonesian language to preserve semantic and linguistic characteristics relevant to sentiment analysis.

E. Embedding Time-Aware Token

Integrating time-aware tokens into the sentiment analysis pipeline enables the model to capture temporal variations in sentiment expression more explicitly [19]. This approach allows IndoBERT to dynamically adjust its contextual understanding by incorporating time-specific markers, such as `<hari-senin>`, `<waktu-sore>`, or `<waktu-pagi>`, into the tokenized input [17]. These tokens provide additional contextual information that helps the model recognize sentiment shifts influenced by time-dependent events, social trends, or daily discourse patterns. The process is illustrated in Fig. 2.

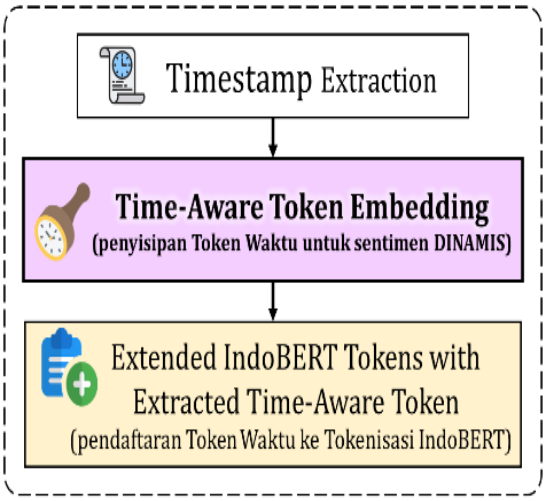

Fig. 2. Time-aware tokenization process.

The process of integrating time-aware tokens into IndoBERT involves the following steps:

1) Extracting temporal information: The initial stage of the procedure focuses on deriving temporal attributes from the timestamp linked to each text instance. In most cases, textual data such as social media posts or online reviews are accompanied by metadata containing date and time information. Based on this metadata, essential temporal features—including the day of the week (e.g., Monday, Tuesday) and time-of-day segments (e.g., morning, afternoon, evening, night). These features provide crucial context, as sentiment expression often varies depending on the time of posting. For example, users may express frustration more frequently on Monday mornings due to work-related stress, while positive sentiments may be more prevalent on Friday evenings due to weekend anticipation.

2) Mapping temporal features to time-aware tokens: Once the relevant time-based features are extracted, they are mapped to predefined time-aware tokens. Each time unit is assigned a corresponding token representation that IndoBERT can recognize. For example, the day of the week is converted into tokens such as `<hari-senin>` or `<hari-sabtu>`, while the time of day is mapped to tokens like `<waktu-pagi>` or `<waktu-sore>`. These tokens serve as additional input features that help the model understand the temporal context in which a given text was written. For example, a tweet posted on "Wednesday at 08:30 AM" would be mapped to `<hari-senin> <waktu-pagi>`. By incorporating these tokens, the model can better capture variations in sentiment that correlate with specific time periods.

3) Appending time-aware tokens to text data: After the tokens are generated, they are appended to the original text before further processing. The tokens are typically inserted at the beginning of the sentence to ensure that IndoBERT processes the temporal context before analyzing the main content of the text. Table IV provides an example of tokenized input with time-aware tokens applied to different sentences.

TABLE IV. PREPROCESSED SENTENCES WITH EMBEDDED TIME-AWARE TOKENS

Timestamp	Sentence	Tokenized Input with Time-Aware Token
Wed Mar 25 14:21:55 +0000 2022	ChatGPT sangat membantu dalam pekerjaan saya!	<hari-rabu> <waktu-siang> chatgpt sangat membantu dalam pekerjaan saya !
Tue Aug 8 17:59:38 +0000 2023	Diskusi dengan ChatGPT tentang sejarah dunia sangat menarik, tetapi terkadang jawabannya terlalu umum dan kurang mendalam.	<hari-sabtu> <waktu-sore> diskusi dengan chatgpt tentang sejarah dunia sangat menarik , tetapi terkadang jawabannya terlalu umum dan kurang mendalam .
Sun Feb 24 23:47:16 +0000 2024	Semakin sering saya pakai, semakin terasa kurang akurat. Dan juga, kenapa hari ini ChatGPT jadi sering error?	<hari-minggu> <waktu-malam> semakin sering saya pakai , semakin terasa kurang akurat . dan juga , kenapa hari ini chatgpt sering error ?

Note: Example sentences are presented in the original Indonesian language to preserve semantic and linguistic characteristics relevant to sentiment analysis.

This ensures that the model is aware of when the statement was made before it begins extracting sentiment-related features. By explicitly including this information, IndoBERT can learn to associate specific sentiment trends with different time periods.

4) Expanding IndoBERT's Tokenizer Vocabulary: Since IndoBERT's default tokenizer does not contain these new time-aware tokens, it must be extended to recognize and process them correctly. This involves modifying the tokenizer's vocabulary by adding the new tokens to the model's predefined token set. The process includes:

a) Updating the tokenizer vocabulary: The new tokens, such as `<hari-jumat>`, `<waktu-pagi>` and `<waktu-malam>`, are explicitly added to IndoBERT's tokenizer to prevent them from being broken into subword units. This ensures that they are treated as single, meaningful tokens rather than being split into unrelated subwords.

b) Adjusting token embeddings: Since IndoBERT's existing embeddings do not include representations for the new tokens, additional embeddings are initialized for them. These embeddings can be either randomly initialized and learned during fine-tuning or mapped using similar contextual embeddings from pre-existing words that represent temporal concepts.

c) Ensuring consistent token handling: The modified tokenizer ensures that every input text containing time-aware tokens is processed consistently. Without this step, the new tokens might be treated as unknown (`[UNK]`) and ignored by the model, reducing the effectiveness of time-based sentiment learning.

Experimental results indicate that the inclusion of time-aware tokens improves the classification performance across various sentiment categories. The model demonstrates an increased ability to distinguish between sentiment fluctuations occurring at different times, particularly in social media data where user opinions may change based on external influences such as current events, holidays, or market trends. Comparative evaluations between IndoBERT with and without time-aware

embedding reveal a notable improvement in sentiment classification accuracy, especially for categories with high temporal sensitivity, such as political discussions or real-time product reviews.

F. Special Tokenization for IndoBERT

Text is tokenized according to IndoBERT's linguistic structure, ensuring proper segmentation for effective processing. The updated IndoBERT tokenizer recognizes time-aware tokens as distinct entities, preventing them from being broken into subwords. This modification preserves the temporal context embedded in the input.

During encoding, each token, including the new time-aware markers, is mapped to an embedding vector. Since these tokens were not in the original IndoBERT vocabulary, their embeddings are either initialized randomly or derived from semantically related words. This enables IndoBERT to incorporate temporal context dynamically, refining sentiment predictions based on time-sensitive factors. The outcomes of this tokenization process are presented in Table V.

TABLE V. TOKENIZING RESULT

Before tokenizing text	After tokenizing text
ah temen gue jg ada yg essay nya dibuat pure pake ChatGPT lolos and he being proud of it soalnya dia tinggal kirim prompt juga ujungnya lolos jd awardee	['ah' , 'temen' , 'gue' , 'jg' , 'ada' , 'yg' , 'essay' , 'nya' , 'dibuat' , 'murni' , 'pake', 'ChatGPT' , 'lolos' , 'dan' , 'dia', 'merasa' , 'bangga' , 'dengan' , 'itu' , 'soalnya' , 'dia' , 'tinggal' , 'kirim' , 'prompt' , 'juga' , 'ujungnya' , 'lolos' , 'jd' , 'pemenang']

G. Classification Using IndoBERT

For the core classification engine, we deployed IndoBERT [25], a transformer architecture pre-trained specifically on Indonesian corpora via masked language modeling. Unlike the standard BERT model, which is optimized for English, IndoBERT offers superior contextual embedding for Indonesian linguistics. By fine-tuning this model on our fine-grained annotated dataset, we enabled it to distinguish between the five distinct sentiment tiers with high precision. The detailed architecture and processing stages are described below:

1) Text Processing Pipeline for IndoBERT: Each token must be transformed into a vector-based representation through an embedding mechanism [see Eq. (6)].

$$V_t = Trans\ (W_t X_a + b_t) \tag{6}$$

2) Initial fine-grained labeling with sentiment lexicon: The use of sentiment lexicons for labeling is a prevalent method in sentiment classification. This technique involves mapping words and phrases to specific sentiment scores according to established polarity values, as in Eq. (7) [34]:

$$\sum_{i=1}^{k} \frac{(p-n)_i}{k} \tag{7}$$

where, k represents the total number of words in the text that are listed in the lexicon, and $p - n$ denotes the sentiment polarity score associated with each word in the lexicon, which is determined based on its occurrence in positive and negative categories [37].

3) Time-aware token embedding: Temporal tokens (e.g., `<hari-senin>`, `<waktu-siang>`) are incorporated into the text to enhance dynamic sentiment analysis by capturing variations influenced by time-based factors.

4) IndoBERT-specific tokenization: The tokenized text, including standard tokens and newly introduced time-aware tokens, is processed using the IndoBERT tokenizer.

5) Feeding data into the IndoBERT Model: IndoBERT generates vector embeddings for individual tokens derived from the input text, as in Eq. (8):

$$V_b = Bert(W_b X_b + b_b) \tag{8}$$

6) Self-Attention: The self-attention mechanism enhances token representations by incorporating contextual information from the surrounding text, as in Eq. (9):

$$Attention(Q, K, V) = Softmax\left(\frac{QK^T}{\sqrt{d_k}}\right)V \tag{9}$$

In this equation, Q, K, V denote the query, key, and value matrices corresponding to the input tokens.

7) Position-wise feed-forward network: Applied after the Self-Attention stage, FFNN layers refine tokens into more intricate representations. This transformation is critical for capturing nonlinear patterns within the text, which in turn leads to improved model understanding and robustness in generalization [see Eq. (10)].

$$FFN(H) = ReLU(HW_1 + b_1)W_2 + b_2 \tag{10}$$

H denotes the contextual embedding generated by self-attention, whereas W1, W2, b1, and b2 define the feed-forward network parameters.

8) Fine-tuning IndoBERT: The fine-tuning phase entails retraining IndoBERT using domain-specific sentiment datasets. This process is designed to optimize classification metrics while preserving the model's original contextual integrity [24], [25].

9) Sentiment classification: In the classification stage, IndoBERT analyzes the input text and assigns it to one of five fine-grained sentiment categories, utilizing the vector representations generated during processing.

H. Data Testing

The evaluation process employs a confusion matrix to summarize prediction results into TP, TN, FP, and FN. In this framework, TP and TN indicate correct predictions, whereas FP and FN reflect classification errors. The effectiveness of the proposed model is then quantified through the accuracy measure, as presented in Eq. (10).

IV. PERFORMANCE EVALUATION AND DISCUSSION

The proposed methodology integrates several stages, including data collection, text preprocessing, sentiment annotation using a lexicon-based approach, time-aware token embedding, and fine-grained sentiment classification based on the IndoBERT model. In particular, the preprocessing step involves text standardization, selective translation of English expressions into Indonesian, token segmentation, sequence

truncation, and padding, aiming to enhance the quality of input representations for IndoBERT.

A. Fine-Tuned IndoBERT Model

The fine-tuning process adjusts IndoBERT's parameters using task-specific data, thereby augmenting its capacity to recognize complex linguistic structures. As illustrated in Fig. 3, the proposed architecture supports this optimization process by adapting the model to task-specific characteristics, thereby leading to improvements in accuracy, precision, and recall.

A total of roughly 24,000 data samples are included in the dataset and are distributed across fine-grained sentiment categories, as presented in Table VI. Analyzing this label distribution, which is visualized in Fig. 4, is essential for assessing IndoBERT's capacity to manage class imbalances and understanding their potential influence on the training process.

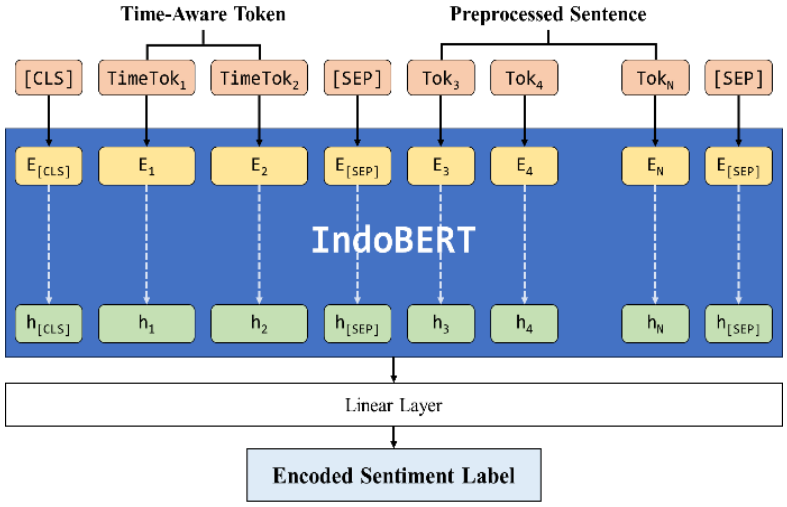

Fig. 3. Time-aware token–enhanced fine-tuned IndoBERT.

TABLE VI. FINE-GRAINED SENTIMENT LABEL STATISTICS

Label	Training Set	Validation Set	Testing Set
Very Positive	1,153	346	149
Positive	920	276	118
Neutral	5,684	1,705	731
Negative	2,213	663	285
Very Negative	1,419	426	182
Total Data	11,389	3,416	1,465

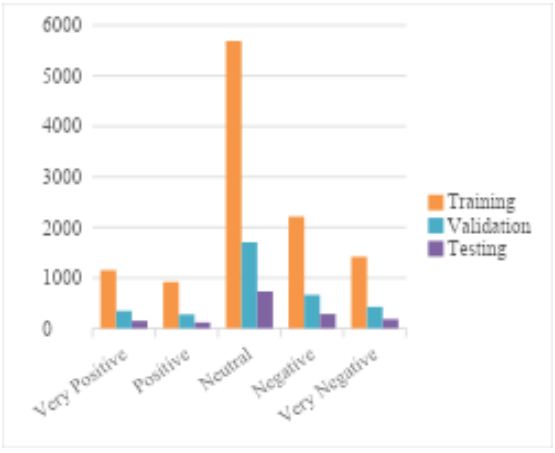

Fig. 4. Distribution of fine-grained sentiment labels.

Fig. 5 further demonstrate the convergence characteristics and training progression of the model across successive epochs.

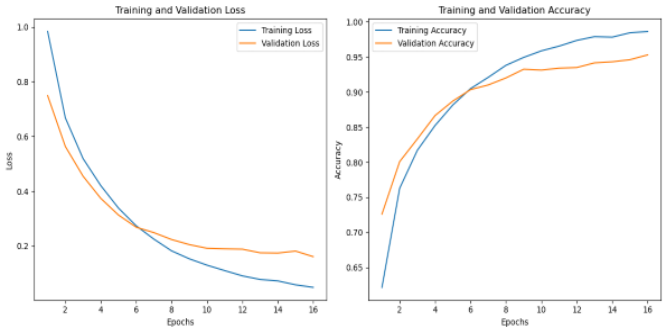

Fig. 5. Validation accuracy and loss of the IndoBERT model.

Table VII presents the evaluation results on the test set in terms of accuracy, precision, recall, and F1-score, highlighting the performance of the fine-tuned IndoBERT model.

TABLE VII. PERFORMANCE EVALUATION OF THE FINE-TUNED INDOBERT MODEL ON THE TEST DATASET

Sentiment Class	Precision	Recall	F1-Score	Sample Count
Very Positive Class	99%	94%	96%	149
Positive Class	91%	97%	94%	118
Neutral Class	98%	98%	98%	731
Negative Class	94%	95%	95%	285
Very Negative Class	94%	95%	95%	182
Overall Testing Accuracy				96.38%

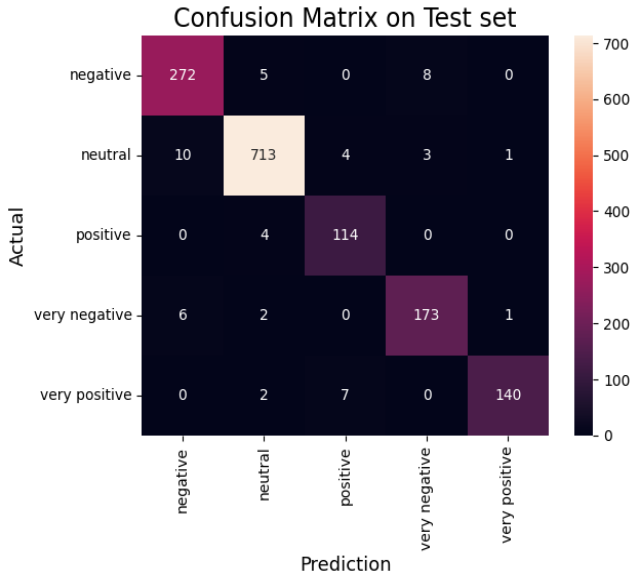

Fig. 6. Confusion matrix of the model on the test set.

B. Influence of Dataset Size on Model Performance

To examine the effect of training data volume on model performance, a series of experiments was performed using multiple dataset subsets with varying sizes and label distributions across the training, validation, and testing stages. As summarized in Table VIII, the results reveal a consistent pattern in which increasing the size of the training dataset generally leads to improved classification accuracy.

TABLE VIII. MODEL PERFORMANCE ACROSS DIFFERENT DATASET SCALES

Raw Data	Data Size			
	850*	***2,000***	***25,000***	***36,000***
Training set	577	980	17,091	21,867
Validation set	159	294	5,128	6,747
Testing set	88	126	2,198	2,624
Classification Accuracy	100%	75%	96%	89%

*Data collected from a single platform.

The attainment of perfect accuracy on the smallest dataset consisting of 850 samples indicates a strong tendency toward overfitting, suggesting that the model memorizes individual instances rather than capturing patterns that generalize well. While smaller datasets may reduce variability and temporarily simplify the classification process, they ultimately compromise model robustness. Furthermore, increasing the dataset size beyond a certain point yields diminishing performance gains. These observations underscore the importance of maintaining a balanced trade-off among dataset size, class distribution, and computational efficiency during the fine-tuning of the IndoBERT model.

C. Performance Evaluation with and without Time Tokens

To evaluate the impact of embedding time-aware tokens in the sentiment analysis model, we conducted experiments with and without time token embeddings. The model was trained, validated, and tested on the same dataset under both conditions.

When trained without time token embeddings, the model yielded a training accuracy of 99.01%, followed by 95.57% for validation and 95.91% for testing. These metrics demonstrate the model's robust generalization capabilities, preserving high accuracy levels on unseen data.

When time token embeddings were incorporated, the model demonstrated slight improvements in accuracy. The training accuracy increased to 99.53%, while validation and test accuracy improved to 95.73% and 96.38%, respectively. The classification performance is visualized in the confusion matrix shown in Fig. 6 and the comparison shown in Fig. 7.

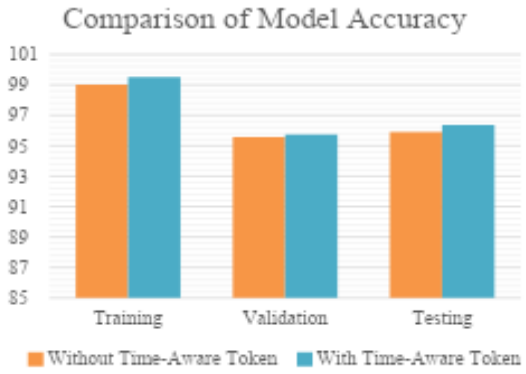

Fig. 7. Comparison of model accuracy.

The inclusion of time tokens led to marginal improvements in both validation and test accuracy. This suggests that incorporating temporal context allows the model to better capture sentiment variations over different time frames. While the gain in accuracy is relatively small, it highlights the potential of leveraging temporal information in sentiment classification tasks. Overall, the results indicate that embedding time-tokens enhances model performance, albeit modestly.

D. Comparison of Different Base Model Performance

We conducted a comparative evaluation of BERT, IndoBERT, and RoBERTa to identify the optimal architecture for practical fine-grained sentiment classification. To guarantee a rigorous assessment, each model underwent fine-tuning with hyperparameters optimized for its specific design. The data in Table IX confirms IndoBERT as the top performer, achieving superior accuracy and outperforming its counterparts in all sentiment classes.

TABLE IX. BENCHMARKING PERFORMANCE AMONG DISTINCT ARCHITECTURES

Base Model	BERT Model	RoBERTa Model	IndoBERT Model
Training Data Size	12,000	24,000	24,000
Number of Epoch	16	16	16
Learning Rate	2e-6	9e-6	2e-6
Training Set Accuracy	95.53%	97.90%	99.53%
Validation Set Accuracy	92.94%	95.68%	95.73%
Testing Accuracy	93.19%	95.90%	**96.38%**

IndoBERT's superior performance stems from its pretraining on Indonesian corpora, which facilitates a deeper grasp of context and more accurate word representations. Conversely, the English-pretrained BERT (bert-base-uncased) encounters difficulties with Indonesian tokenization and semantic interpretation. Similarly, RoBERTa (roberta-base), despite its optimized architecture for longer sequences, fails to deliver substantial improvements due to a lack of linguistic adaptation. These results demonstrate the critical importance of language-specific pretraining, validating IndoBERT as the most suitable architecture for addressing the complexities of fine-grained and dynamic sentiment analysis in Indonesian.

The comparison clearly demonstrates that pre-training on the target language is a prerequisite for high accuracy. Consequently, IndoBERT is validated as the superior architecture for addressing the complex nuances of dynamic and fine-grained sentiment analysis in Indonesian.

E. Analysis and Discussion

Current literature underscores the efficacy of IndoBERT in sentiment analysis, noting its ability to perform well even with minimal preprocessing. This performance is further augmented by the incorporation of knowledge-based strategies, such as Sentiment Lexicons. The integration of such lexicons is particularly advantageous for fine-grained and dynamic sentiment analysis, as it significantly refines the granularity required to classify text into multiple sentiment levels.

Conventional classifiers like Naïve Bayes, LSTM, and SVM often face challenges when attempting to capture sentiment nuances in complex multilingual datasets. In contrast, transformer architectures—specifically BERT, RoBERTa, and IndoBERT—demonstrate significantly higher efficacy. Their advantage lies in the use of self-attention mechanisms and deep contextual embeddings, which allow for a more sophisticated understanding of text.

BERT (Bidirectional Encoder Representations from Transformers) introduced the concept of deep bidirectional learning, enabling better contextual understanding compared to previous sequential models like LSTMs [38]. However, BERT was trained primarily on English corpora, making it less effective for sentiment tasks in Indonesian text.

RoBERTa (Robustly Optimized BERT Pretraining) improves upon BERT by employing a longer training duration, dynamic masking, and removal of next-sentence prediction (NSP). While it has demonstrated improvements in general NLP tasks, its effectiveness in sentiment analysis for Indonesian remains an area of exploration. Some studies suggest that RoBERTa excels in capturing subtle sentiment shifts due to its improved pretraining strategies, particularly in domain-specific applications [39].

IndoBERT, a variant of BERT specifically pre-trained on Indonesian corpora, addresses the limitations of standard BERT by providing better tokenization and contextual understanding for the Indonesian language. Its self-attention mechanisms enable it to retain long-range dependencies, making it highly effective for processing unstructured text [30], [31]. Moreover, Sentiment Lexicon-based labeling enhances IndoBERT's ability to capture nuanced emotions [2], [3], complementing its contextual representations [27], [28]. While LSTM and CNN-based models struggle with handling lengthy and context-dependent texts [5], [6], IndoBERT's deep contextual embeddings dynamically adjust word representations based on surrounding text, ensuring more accurate sentiment classification [26].

By incorporating time-aware tokenization, the proposed method effectively adapts to temporal shifts, rendering it highly suitable for monitoring evolving discourse in multi-platform environments. Furthermore, the strategic synergy of IndoBERT, Sentiment Lexicons, and Dynamic Sentiment modeling establishes a robust architecture designed for accurate, fine-grained sentiment analysis.

V. Conclusion

The findings indicate that combining sentiment lexicons with a fine-grained, dynamic labeling strategy significantly improves sentiment classification accuracy for Indonesian multi-platform data. By utilizing a five-point intensity scale—ranging from very negative to very positive—this framework offers a more detailed and expressive representation than traditional binary or ternary models. Furthermore, the synergy between lexicon-based labeling and IndoBERT's contextual understanding allows for the precise identification of subtle sentiment nuances across various social media contexts.

By embedding temporal information directly into the tokenization process, IndoBERT is able to model sentiment evolution more effectively than static representation-based approaches. The findings indicate that temporal context should be treated as a linguistically meaningful feature rather than merely auxiliary metadata, particularly in rapidly evolving online discussions, including content influenced by generative AI technologies. Ablation-based analysis confirms that the incorporation of temporal tokens contributes directly to the observed performance improvements.

Despite these contributions, this study has several limitations. The reliance on lexicon-based initial labeling may introduce bias in ambiguous or context-dependent sentiment expressions, and the temporal tokens are currently limited to coarse-grained time units. Future work will explore adaptive temporal granularity, enhanced sentiment scoring mechanisms, and the integration of multimodal information to further improve dynamic sentiment understanding and long-term sentiment trend analysis.

Acknowledgment

The authors extend their gratitude to all institutions and individuals who supported this study. Specifically, Frans Mikael Sinaga (Universitas Pelita Harapan) spearheaded the research design and constructed the dynamic sentiment analysis framework; Jefri Junifer Pangaribuan (Bina Nusantara University) contributed to data collection, preprocessing, and sentiment lexicon development; Kelvin (Universitas Mikroskil) supported the implementation of fine-grained sentiment analysis and labeling strategies; Ferawaty (Universitas Pelita Harapan) contributed to linguistic validation and contextual sentiment interpretation; and Andree Emmanuel Widjaja (Universitas Pelita Harapan) was responsible for model optimization, validation, and performance evaluation using

IndoBERT. The authors also acknowledge the institutional support provided by Universitas Pelita Harapan, Bina Nusantara University, and Universitas Mikroskil.

Data-Driven Insights for Moroccan Airports: PCA and Clustering to Enhance Operational Performance

H. Fatih[1] A. Bentaleb[2], M. Lazaar[3], B. Bentalha[4]
ENSIAS, Mohammed V University in Rabat, Morocco[1,3]
ENCG, Sidi Mohamed Ben Abdellah University, Fez, Morocco[2,4]

***Abstract*—Following the trend of increasing complexity among systems, in an attempt to meet air passengers' demands for higher quality service, this paper contributes to this stream of research by studying the operational efficiency of Moroccan airports through a novel multivariate approach. This research examines the following five performance metrics: baggage handling time, police screening time, customs processing time, passenger traffic, and flight delays. In this context and making use of Principal Component Analysis (PCA) with K-Means clustering, this paper aims at identifying the causes of operational variability, their significance in terms of performance management, and differentiating flights with similar operational profiles. Turning so particular techniques to the data of the moroccan airports this study reveals hidden patterns within airport interrelated activities, that in most cases were neglected by the traditional system of measurement. The findings make methodologies advancement in multivariate analysis of transport systems as well as practical improvement in the management of airport operations, and eventually impact on coordinated strategies of resource allocation for the systemic profit and the passenger utility. Through the use of PCA and K-means on the unreleased data of airports in Morocco, this paper is the first to offer a full multivariate study of the airport in the whole North African region. In contrast with standard monitoring systems which treat metrics as isolated entities, the study concurrently analyzes the dependencies among five key measures, discloses latent operational patterns, and promotes the formulation of context-based management policies suitable for an immature aviation market.**

***Keywords*—Principal Component Analysis (PCA); airport performance; transportation systems; K-means clustering; operational optimization; airport efficiency; airport operations management; air traffic; passenger experience**

I. Introduction

Airline operations management takes into account the customer satisfaction, efficiency, and safety. Moroccan airports connect Europe, Africa and the Middle East, and struggle to keep pace with rising traffic and ensure safety and service. With international air traffic on the rise, notably in developing regions such as North Africa, airport efficiency has turned into a significant concern both for competitiveness and the passenger experience [20]. Moroccan airports, which link the country to Europe, Africa and the Middle East, are under growing pressure to enhance operations throughput along with high standards of security and service.

Among the many problems in airport management, three processes are especially critical: baggage handling, security screening (police checks), and customs .Three Particularly Critical Processes: baggage handling, security screening, and customs Among the numerous problems in managing airports, three procedures in particular are critical: handling of baggage, security screening (police reviews) and clearing of customs. These procedures, with the weight of passengers and potential flight delays, determine the general performance of the airport's operation. Yet these processes are linked and influenced by core and sometimes surprising elements. Traditional performance measurement tends to consider processes one at a time. Passenger throughput and on-time aircraft performance affect airport efficiency. Many airports monitor these activities independently and miss the significant pattern owing to the blind spot. The evaluation of complex airport systems requires advanced analytical tools to produce meaningful results [4]. Our method combines multiple ML and statistical approaches. In particular, cluster-based techniques such as K-means are used to cluster the operative data and find groups of flights that share similar patterns of flight activities, that is to say to discover hidden structures in the operational schedule. At the same time, Principal Component Analysis (PCA) is applied to analyze high-dimensional multivariate data sets to find key factors and causes of variability in operations [21]. The integration of these methods results in a decision-support system providing enroute and ground controllers with a clear, high-fidelity depiction of the real-time operational picture, enabling the identification of subtle and/or developing performance anomalies, and facilitating the smart, data-informed management of critical resources. This paper has been particularly focusing on the operational data that were obtained from major airports in Morocco. The analysis is based on five critical Key Performance Indicators (KPIs) that were demonstrated to be important for both the service and the optimisation of the airport function as well as in the passenger journey quality of experience [13]. These performance measures are not some random statistical averages but rather critical quantitative indicators of how well the system is working. The KPIs that undergo stringent evaluation are as follows: the flight schedule adherence (expressed as flight delays), baggage processing time, security screening queueing time, customs and immigration clearance time, and passenger flow (passenger traffic volume). The second concentration of this scientificpapaer is the theicha are the principal component analysis (PCA) Morocco airport operation data.

The purpose of this study is established through three interrelated goals that naturally flow into and support each other in a grounded, practical model of airport operations. Our second objective is to demonstrate to the airport manager how these critical influencers can be exploited. Moving from raw statistical results to decisions about staff to leverage resources or to modify the process that captures them completes the loop in the production and analysis of information. In the end, "similar" is defined by a set of trip features and the

origin and destination airports. They could be high-volume, lots of turnarounds, not tricky roads. With profile information, airport managers can anticipate areas of financial risk, adjust practices, redeploy personnel, and highlight potential bottlenecks of activity. It enables the airport operator to raise its own performance and that of its customers, and demonstrates how sophisticated analytical methods can be profitably applied to transport systems. Accordingly, the rest of the paper is organized as follows. First, we develop a conceptual model of airport flight operations. Then, we present the approach, PCA and clustering analyses, applied to the Moroccan airport data. Thirdly, our multivariate findings suggest to different profiles of dynamics and performances. The significance of these findings for managerial actions and for airpot efficiency policy are finally discussed.

A. Conceptual Framework: Airport Flight Operations

Every day the airport has to balance aircraft, passengers, and cargo safety with service quality — the truth is that they are expected to be consistent and secure and efficient levels of service every day. The level of coordination among the different parts of an airport is how effective it is as an airport. Today airport safety is all about technology. They have-advanced sensors; networks giving wall information; and automated alerts that can warn of potential issues even before humans are watching. Response teams in crisis situations often train with local law enforcement, airline operation centers, and air traffic controllers to build coordination. Contemporary airport management must strictly comply with rigid safety and regulatory standards, which today requires copious real time monitoring, recording, and reporting to aviation authorities. In the current airport environment, however, central command is exercised through the sophisticated Airport Management System (AMS) [16]. Airport security operations combine sophisticated surveillance technology, live monitoring capabilities and automated alert systems to identify threats early in their development. Response teams are regularly exercised at various levels to maintain readiness levels, and they are coordinated with local emergency services, air traffic control agencies, and airline operators to provide a quick and cohesive response at the incident scene. Compliance with regulations requires ongoing auditing, documentation and reporting to the aviation authorities in order to keep the operating approval and safety status [18].
