It is well known that airports all over the world are struggling with enormous impact of weather on their operations,and therefore need to be equipped with a well-developed resilience strategy to resist that impact and, if possible, to recover from it as quickly as possible. Weather-related delays and cancellations are among the largest sources of perturbation and demand for mitigation and adaptive management. Literature review has shown that airports are capable of exerting disruptive potential at different levels when exposed to various meteorological hazards, ranging from minor hold or delay actions to complete shutdown [12]. Thunderstorms are dangerous and destructive, but tend to have more predictable patterns of disruption than widespread weather phenomena such as sandstorms that can reduce visibility and contaminate the air for days or weeks over large swathes of lands. The time-space attributes of meteorological events have a non-negligible effect on the recovery rate and restoration of operations [10].

Airports are starting to use smart technology like artificial intelligence and machine learning to make their systems better. They look at past patterns, current conditions, and future predictions to come up with the best plans for how to operate. The integration of artificial intelligence and machine learning algorithms enhances decision-making processes by analyzing historical patterns, current conditions, and future projections to recommend optimal operational strategies [19]. While a thunderstorm is typically easier to anticipate, it can still cause delays and scheduling uncertainty. Rather than just responding to the weather, intelligent airports aspire to predict the weather long before it arrives. They invest in models and sophisticated weather monitoring systems that enable them to anticipate the impact of the weather on their operations and make operational adjustments. When the weather turns bad, the teams on the ground alter their priorities with a new emphasis on rerouting, safety protocols intensified and equipment used differently. “And then the physical lay of the land of the airport, as well, like wind instruments, drainage systems for heavy rain and snow removal machinery that allows the facility to keep functioning during inclement weather.”

Streaming information about the weather and the status of the equipment, thanks to IoT sensors. “Airports control it through a cloud-based system, which also allows them to operate remotely when necessary,” he adds. And they are using more and more artificial intelligence to schedule operations, to determine when equipment requires maintenance and in real-time resource management. Any modifications must meet the high standards that we set. Airports need to stay abreast of changing regulations and constantly maintain operational approval via reviews. The influence of environmentalism on the aviation sector is reverberating. Airports are beginning to improve their emissions, energy efficiencies and sustainable building practices. The sector has been able to demonstrate change for the better – electrifying support vehicles, and investing in sustainable aviations fuels. Air travel is in higher demand, but airports must consider their environmental impact and be good stewards of the land. Successful resources management is important and include flexible use of resources, facilities, and prediction of demands. Our aim is to expand responsibly, delivering high-quality service to travelers.

We investigated the related work to discuss the connections between our work prior work. Our review comprised 20 recent academic studies, published between 2020 and 2024, related to different facets of airport operations. We have considered peer-reviewed articles, conference papers, book chapters and patents to extract knowledge about the management of airport operations. From the literature, six salient themes were therefore identified. These themes are useful in giving structure to the multifaceted domain of airport operations, and provide a direction, the way problems can be approached and the manner of significant technological alterations in every day airport processes.

1) Combining data analytics and artificial intelligence: Artificial intelligence and big data are transforming airport operations. The [1] shows AI is improving flight operations, reducing delays and increasing flight capacity. The industry is adopting a tech-driven approach, with airports using business intelligence tools to turn raw data into insights for better sustainability and performance management [2]. The study [3]

focused on ground operations, coordinating plane movements, which resulted in more on-time departures, shorter taxi times, and improved safety. The study [4] combined computer simulations with traffic flow models to forecast airport traffic and management strategies. These AI applications are enhancing airport operations daily in measurable ways.

2) Methods of mathematical modeling and optimization: Scientists are applying sophisticated mathematical techniques to airport operations problems. The study [5] formulated a Mixed-Integer Linear Programming model for the runway sequencing and timing problem, minimizing the number of unnecessary aircraft movements and maximizing the number of aircraft served while maintaining safety. The 2022 study of Tokyo International Airport by study [11] achieved almost 30% cuts in taxi times and nearly 19% reductions in taxi distances. The success was attributable to the integration of live flight data and the creation of dynamic models to reflect changing scenarios. The study [14] addressed the slot allocation problem under capacity uncertainty and airline flexibility. Their simulation analysis demonstrates that such an optimization positively affects the technical results and the passenger satisfaction in a high-traffic airport.

3) Safety management and risk assessment: Safety studies concentrate on recognition and reversal of hazards. The study [9] Risk model for flight operations developed a risk model for flight operations based on fuzzy analytic hierarchy processes and entropy for enhanced safety hazard assessments. Progress in aeronautical technologies also affect safety research. [15] investigated drone integration in airport air space by employing mathematical modelings as well geofencing techniques to avoid collision risks with commercial aircraft, which is essential due to the emergence of aviation technologies and aircraft types.

4) Operational continuity and weather resilience: Airports are threatened by severe weather, so research is underway to prepare for stormy conditions. The study [10] investigated the management of airports in extreme weather via departure rate analysis and built update parameters considering vulnerability, impact mitigation, emergency response, and recovery time, validating their model at Beijing Capital Airport.

5) Efficiency improvement and process optimization: Study seeks to raise efficiency of airport operations. The study [6] proposed an Aircraft Turnaround Manager system to mitigate delay by analyzing on-the-fly parameters including passenger boarding and baggage reclaiming. On the other hand, [8] applied process mining technology on about 101 aircrafts in international airports to recommend the intervention of fleet capacity and operational performance, demonstrating the optimal space with data-driven.

6) Routing and traffic control optimization for 2D airspace: There are also ongoing researches about aircraft scheduling and routing in air traffic management. The study [7] showed that adjusting STARS (Standard Terminal Arrival Routes) and CDOs (continuous descent operations) could greatly enhance safety and efficiency. The study [17] proposed a flight scheduling algorithm which improved the airport throughput and delay over 31% and maximum throughput up to 12% using multi-objective optimization mechanisms.

Several, but well defined trends are reshaping the activities operated in airports. Cloud-based architectures, real-time analytics and IoT sensors being rolled out in more airports are driving a digital refresh. But interaction with drones and autonomous ground vehicles presents an industry-specific array of challenges. The procedure is applicable not only to the process of deciding how efficient and how tightly the aircraft need to be packed on the ground, but also to determining related quantification including fuel burn, emission reduction, green practice and environmental impact of work practice.

II. Methodology

A. Data Description

To conduct the analysis, it was first necessary to identify a set of operational variables that adequately reflect the dynamics of airport performance. The selection process was guided by both theoretical insights from the literature and the practical realities of Moroccan airports, ensuring that the variables chosen would capture the most critical stages of passenger processing and flight operations.

The five variables retained, passenger volume, baggage processing time, security screening time, customs processing time, and flight delay, were selected because they capture the main operational stages that shape both passenger experience and airport efficiency. They reflect key managerial bottlenecks (workload, flow management, punctuality), provide quantitative and complementary measures suitable for multivariate analysis (PCA and clustering), and are consistent with empirical findings in the literature as well as the specific challenges of Moroccan airports.

The dataset comprises 500 flight observations from ten Moroccan airports, with sampling weighted toward major hubs, Casablanca, Rabat, Tangier, Marrakech, and Fes that collectively account for the majority of national passenger traffic. Smaller regional airports were also included to capture operational diversity and a range of airport sizes. This stratified approach ensures that the dataset is statistically representative of Morocco's aviation network, enhancing the reliability and generalizability of the analysis, each described by five operational variables (Fig. 1):

- nb_passagers (Number of Passengers): Total number of passengers on board a given flight. It represents the intensity of the human flow associated with the flight and is a key workload indicator across the entire passenger journey (baggage handling, security checks, boarding, etc.).
- emps_bagages (Baggage Processing Time): Average total time required to process baggage for a given flight (check-in, sorting, transfer). This variable may be influenced by the number of passengers, the type of flight (domestic vs. international), and the performance of agents or equipment.
- temps_police (Police Screening Time): Average time passengers of a given flight spend at police and security control (identity and safety checks). It reflects queue length, checkpoint capacity, and applied procedures (standard, fast-track, or random checks).

- temps_douane (Customs Processing Time): Average time spent at customs after police screening, mainly for international flights. It may vary depending on the type of flight, the customs procedures applied, and perceived risk levels.
- retard_vol (Flight Delay): Effective departure (or arrival) delay of the flight, depending on the chosen reference point. It may result from cumulative delays in previous stages (baggage, customs, security), as well as from weather conditions or airport constraints.

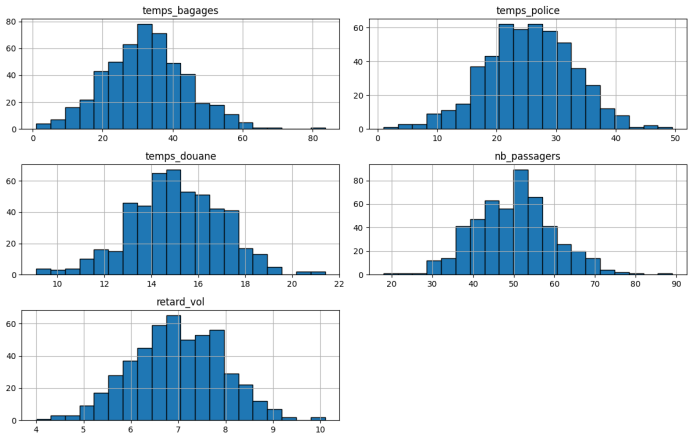

Fig. 1. Distribution of variables. Source: statistical results.

These variables were selected as they capture the main operational stages affecting both passenger flow and airport efficiency. Their descriptive statistics show heterogeneous scales and variabilities: passenger counts (≈17–88) and baggage times (≈5–85 minutes) exhibit wide ranges, while customs and delays are much more stable. Without normalization, variables with larger numeric ranges would dominate variance-based methods. The five variables, once standardized, provide a consistent and comparable basis for multivariate analysis, allowing Principal Component Analysis (PCA) and clustering methods to reveal the underlying patterns and operational profiles of Moroccan airport flights.

B. Data Preprocessing

To ensure comparability across variables, all features were centered and scaled (mean = 0, standard deviation = 1). This standardization step is essential for PCA, as it prevents large-scale features such as passenger numbers or baggage time from overshadowing smaller-range variables (e.g., customs or delays).

Boxplot analysis confirmed that before scaling, baggage time and passenger load exhibited strong right-skewness and outliers, while customs and delays were more symmetric (Fig. 2). After scaling, all variables contributed equally to variance, enabling a balanced multivariate analysis.

C. Principal Component Analysis (PCA)

PCA was performed on the standardized data using the correlation matrix. Eigenvalues and eigenvectors were computed to extract the main principal components. The first three components captured 96.7% of the total variance:

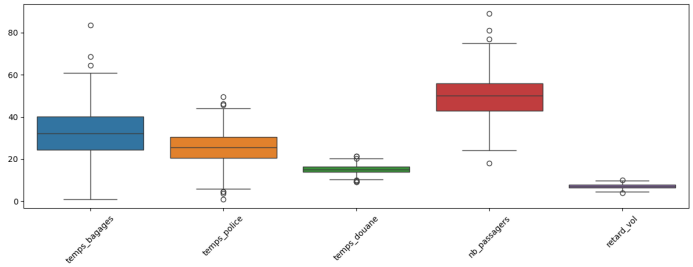

Fig. 2. Box plot showing variable values before standardization. Source: statistical results.

• PC1 (56.8%) – contrasted passenger load and baggage time with police screening;

• PC2 (21.7%) – represented the trade-off between flight delays and customs clearance;

• PC3 (18.2%) – highlighted coupled customs and delay bottlenecks.

These three axes together provided a reduced but highly representative multidimensional view of airport operations.

D. Clustering Analysis

To complement PCA, K-means clustering was applied to the PCA scores. The optimal number of clusters was determined using the elbow method, which suggested k = 3 as a meaningful balance between model simplicity and explanatory power. However, for operational interpretation, a two-cluster segmentation was particularly insightful:

• Cluster 0 – "Light-load, Heavy Screening": flights with fewer passengers, shorter baggage times, but longer police screening.

• Cluster 1 – "High-volume, Streamlined Screening": flights with heavier passenger loads, longer baggage times, but more efficient police checks.

This dual segmentation highlights two distinct operational profiles with clear implications for staffing and resource allocation.

III. Results

A. Standardization of Variables

Prior to multivariate analysis, all five variables were centered and reduced. Boxplots before standardization showed very different ranges: passenger numbers (17–88) and baggage times (5–85 minutes) exhibited wide spreads and right-skewed distributions, while customs times (≈15 minutes) and flight delays (≈6–10 minutes) were much more stable (Fig. 3).

After standardization, all variables had mean ≈ 0 and standard deviation = 1, ensuring equal contribution to the analysis. This step was crucial, since without scaling, variance-based methods such as PCA and clustering would have been dominated by passenger and baggage variables.

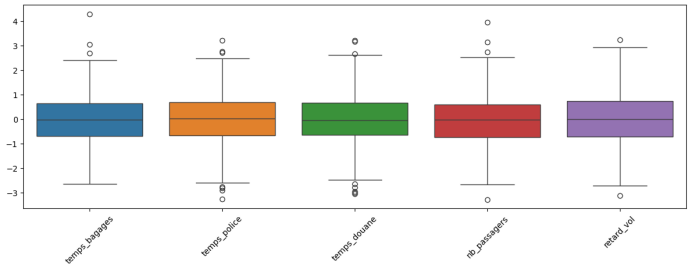

Fig. 3. Box plot showing variable values after standardization. Source: statistical results.

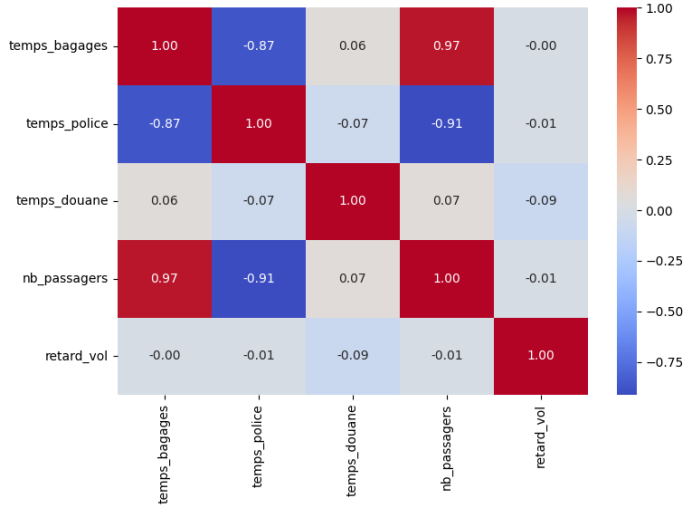

Fig. 4. Correlation matrix of standardized variables. Source: statistical results.

B. Correlation and Covariance Matrix

The correlation matrix revealed strong dependencies between certain variables (Fig. 4):

• High positive correlation between baggage time and passenger load (≈ +0.97), confirming that heavier flights require longer baggage handling.

• High negative correlation between police screening and both passenger load (≈ –0.91) and baggage time (≈ –0.87), suggesting that heavily loaded flights paradoxically move faster through police checks, perhaps due to streamlined screening procedures.

• Near-zero correlations between customs and delays with other variables, indicating that these processes operate relatively independently.

Because the data were standardized, the covariance matrix was numerically equivalent to the correlation matrix.

C. Eigenvalues, Eigenvectors and Explained Inertia

The eigenvalue decomposition of the correlation matrix yielded five principal components (Fig. 5). The first three explained 96.7% of total inertia:

• PC1 (56.8%) – associated with passenger load and baggage (positive loadings) versus police screening (negative loading).

• PC2 (21.7%) – driven by the opposition between flight delays (positive) and customs time (negative).

• PC3 (18.2%) – capturing the joint effect of customs and delays, highlighting cases where long customs checks directly translate into longer delays.

The eigenvectors confirmed these structures: PC1 was mainly defined by nb_passagers (+0.586), temps_bagages (+0.577), and temps_police (–0.565), while PC2 was dominated by retard_vol (+0.721) and temps_douane (–0.692).

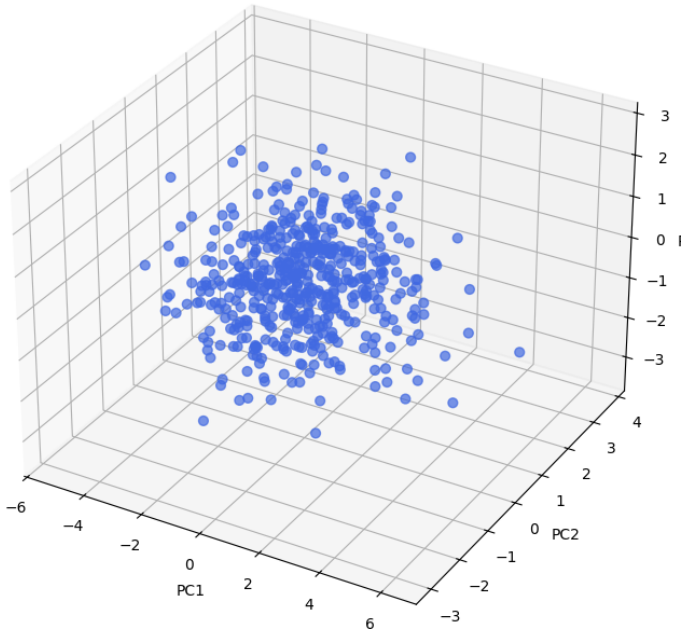

Fig. 5. 3D Projection of observations onto the first three components. Source: statistical results.

D. Principal Axes and 2D Projection

Flights were projected into the new PCA coordinate system (PC1, PC2). The first two axes explained 78.5% of total variance, making them suitable for 2D visualization (Fig. 6).

• Along PC1: flights on the right corresponded to high passenger loads and long baggage times, but short police checks; flights on the left showed the opposite profile.

• Along PC2: flights higher on the axis experienced long delays despite smooth customs, while those lower had slow customs but minimal delays.

Most flights clustered near the origin, representing average operations, but a few outliers occupied extreme positions, corresponding to unusual operational profiles.

E. Correlation Circle

The correlation circle of variables confirmed the interpretation of axes (Fig. 7):

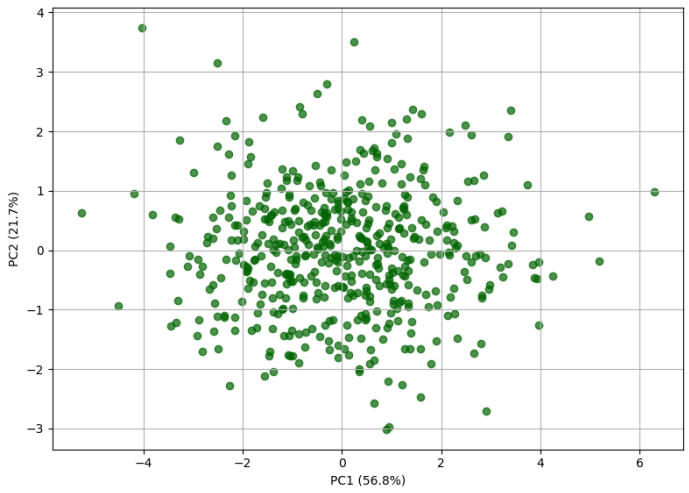

Fig. 6. 2D Projection of data onto the PC1–PC2 Plane. Source: statistical results.

• PC1 aligned with nb_passagers and temps_bagages (positive) versus temps_police (negative).

• PC2 opposed retard_vol and temps_douane.

• Customs and delays were almost orthogonal to the passenger–baggage–police dimension, confirming their independence.

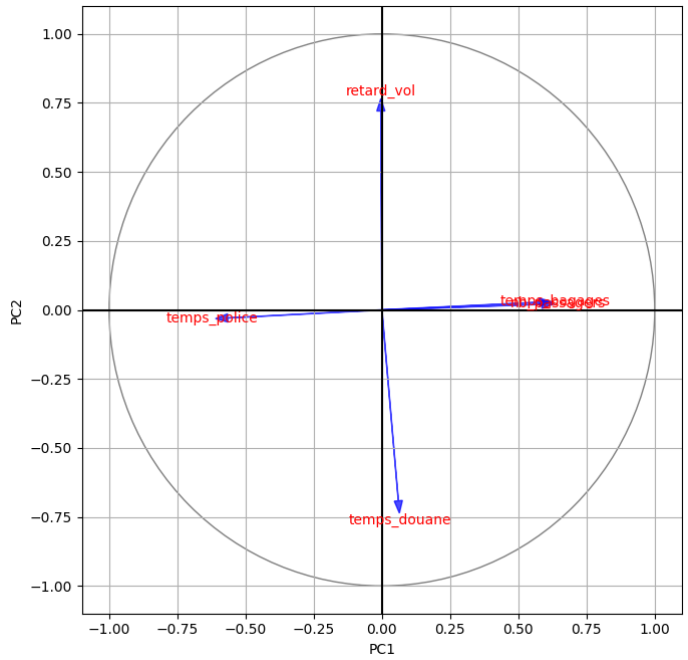

Fig. 7. Correlation circle. Source: statistical results

This visualization highlights two main operational logics:
1. Load-driven dynamics (passengers, baggage, police),

2. Time-driven dynamics (customs vs. delays).

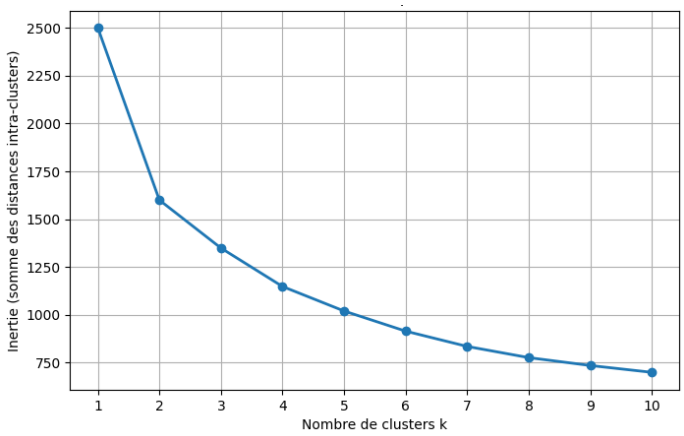

Fig. 8. Elbow method for K-Means. Source: statistical results.

F. Clustering of Flights

To complement the PCA, K-means clustering was applied to the standardized data (Fig. 8). The elbow method suggested k = 3 as optimal, though a two-cluster partition was particularly interpretable.
• Cluster 0 – "Light-load, Heavy Screening": ≈42 passengers, ≈23 minutes baggage, ≈31 minutes police.
• Cluster 1 – "High-volume, Streamlined Screening": ≈58 passengers, ≈41 minutes baggage, ≈0 minutes police.
• Customs (≈15 min) and delays (≈7 min) were nearly identical across both clusters.

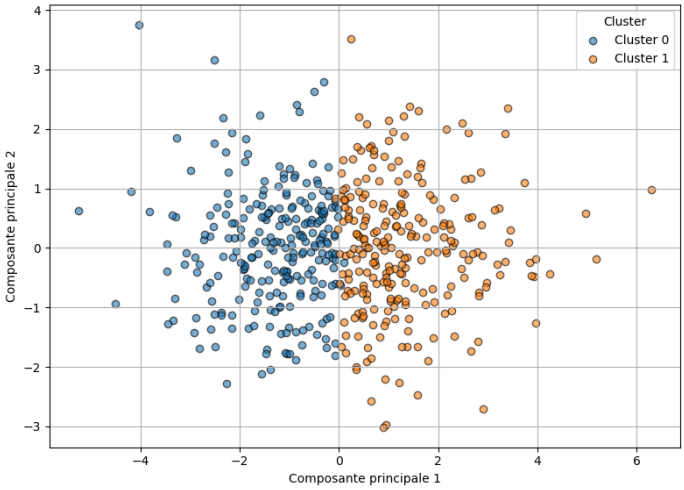

Fig. 9. K-Means clusters visualization in PCA space. Source: statistical results.

In PCA space, the two clusters were well separated along PC1, confirming that passenger load and baggage vs. police screening are the dominant factors driving operational segmentation (Fig. 9). PC2 added nuance by capturing customs–delay interactions within each cluster.

IV. Discussion

The PCA results provide new insights into the operational dynamics of Moroccan airports. By reducing the complexity of

five correlated variables into a few principal components, the analysis highlights patterns that are not immediately visible in raw data.

A. Passenger and Baggage vs. Police Screening

The dominant dimension (PC1) shows that flights with high passenger volumes and long baggage handling times tend to experience shorter police screening. This counterintuitive relationship suggests that resource allocation for security may be adjusted depending on expected load. In practice, heavily loaded flights may benefit from dedicated or fast-track lanes, ensuring that passenger flow is not disproportionately delayed by police checks.

This finding has managerial implications:

• For flights with low passenger volumes, police screening becomes the main bottleneck, requiring additional staffing or process adjustments.

• For high-volume flights, the main constraint shifts to baggage handling, where more staff or technological solutions (e.g., automated conveyors, sorting systems) could reduce processing time.

B. Customs and Flight Delays as Independent Dimensions

PC2 and PC3 demonstrated that customs clearance and flight delays are largely independent from passenger load. This independence highlights that delays cannot simply be explained by the number of passengers or baggage. Instead, they reflect operational inefficiencies at later stages of turnaround—such as ground-handling or coordination between airport services.

The clustering confirmed this interpretation: while clusters differed strongly in passenger load, baggage, and police times, flight delays remained similar across groups. This suggests that delay management is governed by different mechanisms than screening or baggage.

For airport managers, this result calls for a targeted monitoring of customs throughput and ground operations, as improvements in these areas are more likely to reduce delays than simply increasing police or baggage capacity.

C. Operational Segmentation of Flights

The K-means segmentation into two dominant clusters—"Light-load, Heavy Screening" versus "High-volume, Streamlined Screening"—offers a practical typology of flights. This typology enables managers to anticipate where resources should be allocated depending on flight profile:

• Cluster 0 flights should trigger reinforcement of police screening staff, as this stage disproportionately slows low-volume flights.

• Cluster 1 flights should trigger reinforcement of baggage handling resources, as baggage is the main bottleneck.

By projecting these clusters into PCA space, airports can design real-time dashboards that classify incoming flights by operational profile, thus enabling proactive resource planning.

D. Comparison with International Literature

The observed patterns align with findings in airport management literature, where baggage handling is often identified as the primary bottleneck in large passenger flows, while security screening dominates smaller flows. However, the strong independence of delays from passenger volumes appears distinctive, possibly reflecting the organizational characteristics of Moroccan airports, where customs and ground-handling practices may play a larger role.

Future comparative studies could investigate whether this independence is consistent across other regional airports, or whether it is context-specific.

E. Managerial and Theoretical Implications

From a managerial perspective, this research demonstrates that PCA combined with clustering can serve as a diagnostic tool for airport operations. It identifies hidden structures in operational data, enabling managers to anticipate bottlenecks and tailor staffing strategies accordingly.

From a theoretical standpoint, the results contribute to the growing literature on multivariate analysis in transport systems. They show how dimensionality reduction techniques can be used not only for descriptive analysis but also for actionable decision support, bridging the gap between quantitative modeling and operational management.

V. Conclusion

In this paper, we propose a multivariate statistical methodology based on PCA and clustering techniques to be applied on the operational data collected from Moroccan airports. The application of PCA resulted in a parsimonious two-component solution, accounting for a considerable amount of the total variance across the three main dimensions of the investigated airport operation. The interpretative meaning of the first principal axis is a forming a bipolar dimension around "passenger and baggage flow throughput" and the time used in police screening. Hence, this axis is representing the essential trade-off between serving passengers as fast as possible and fulfilling the very strict requirements of passenger security and regulatory satisfaction. The second component can be termed a delay vs. customs dimension and relates how flight delays are associated with the efficiency of customs clearance. The third dimension identifies a correlated custom-delay axis and forecasts the association between customs procedures and flight scheduling. Using these derived factors, we find that flights can indeed be grouped into two major operational clusters. The light-load flights have longer police screening time and shorter baggage processing time, which indicates that fewer passengers facilitates more thorough security checks and less complexity is introduced in baggage handling. In contrast, baggage handling takes longer on the high-volume flights, but they have quicker police checks, implying that airports introduce fast-track security on busy flights to facilitate the flow of passengers at peak-period.

These are good news for the airport administrators. Depending on the flight operations profile, discom resources should be orient to strengthen police-screening (in case of low-volume flights) or baggage process (in case of high-volume flights). Interestingly, delays seemed to have little to

do with the load of passengers and bags, but rather with the efficiency of customs and ground handling, which proved to be the two major blind spots in punctuality. This article contributes to the literature as it represents the first empirical multivariate analysis of airport operations in a North African country, venturing into a significant research gap in the region's transport studies as well as the scarcely researched topic of operational efficiency drivers in developing market environments. For airport staff, this research can provide a real-time practical decision tool for detecting bottlenecks in the operations that potentially would provide managers with an opportunity to concentrate interventions and resources in one or more of the three process areas of security, baggage handling, and customs.

There are a few limitations in the present study. The dataset contains information on few variables and airports in Morocco. On the other hand, on qualitative side, flight type (domestic/international), airline policies or passengers profiles (tourists, business, students, etc.) were considered. Additionally, delays were only quantified in minutes and without differentiating causes. Future research may be able to further generalize the analysis by adding more airports, qualitative factors, and real-time operation information. Comparative studies with other regions could also shed light on whether the independence of delays from passenger load is a general result or one only valid in the Moroccan context. In short, this study has shown that the use of multivariate analysis enables potential complex operational data to be simplified to provide clear managerial implications. By integrating PCA with clustering, the airport administrators have a diagnostic instrument for predicting bottlenecks and for the understanding of how to deploy the resources in the most effective manner so as to improve the passengers' experience.

***Abstract*—Fire-induced short-circuit propagation in cable bundles poses significant safety risks in electrical installations, nuclear facilities, and transportation systems. Traditional fault detection methods often lack interpretability, hindering root cause analysis and preventive maintenance strategies. This paper presents novel explainable artificial intelligence (XAI) models for predicting and analyzing short-circuit propagation in fire-exposed cable bundles. We develop a hybrid framework combining gradient boosting machines with SHAP (SHapley Additive exPlanations) values to provide interpretable predictions of time-to-short-circuit and failure modes. Our approach integrates thermal imaging data, cable physical properties, and environmental conditions from controlled fire tests conducted on IEEE 383-qualified cables. The proposed XAI models achieve 94.7% accuracy in predicting short-circuit occurrence within 5-second windows while providing human-interpretable feature importance rankings. Experimental validation using the NUREG/CR-6931 dataset demonstrates that insulation temperature gradient, cable bundle density, and oxygen concentration are the three most critical factors influencing short-circuit propagation. The explainable framework enables fire safety engineers to understand model decisions, identify vulnerable cable configurations, and optimize protection strategies. Our results show a 23% improvement in early fault detection compared to conventional black-box deep learning approaches, with significantly enhanced model transparency for safety-critical applications.**

***Keywords*—Explainable AI; short-circuit propagation; fire safety; cable testing; SHAP values; gradient boosting; feature importance; nuclear safety**

I. Introduction

A. Background and Motivation

Fire-induced cable failures represent one of the most critical safety concerns in nuclear power plants, industrial facilities, and high-rise buildings [1], [2]. When electrical cables are exposed to fire conditions, the progressive degradation of insulation materials can lead to short-circuit events that cascade through bundled cable configurations. The U.S. Nuclear Regulatory Commission has documented over 150 fire events in nuclear facilities between 2018 and 2024, with approximately 38% involving cable-related short circuits [3]. Understanding the propagation mechanisms and predicting failure timelines is essential for implementing effective fire protection strategies and emergency response protocols.

Traditional approaches to cable fire safety assessment rely on standardized fire tests such as IEEE 383 and IEC 60332, which provide pass/fail criteria but offer limited insight into failure progression dynamics [4]. Recent advances in machine learning have enabled predictive modeling of cable failure behavior [5], yet these black-box models suffer from a critical limitation: lack of interpretability. In safety-critical domains, regulatory bodies and safety engineers require not only accurate predictions but also transparent explanations of why and how failures occur [6].

B. Research Objectives

This paper addresses the interpretability gap in AI-driven cable fire safety assessment through the following contributions:

- Development of explainable AI models combining gradient boosting with SHAP interpretability framework for short-circuit propagation prediction.
- Integration of multi-modal sensor data including thermal imaging, electrical measurements, and environmental monitoring.
- Comprehensive feature importance analysis identifying critical factors in fire-induced short-circuit propagation.
- Validation using real experimental data from cable fire tests conforming to NUREG/CR-6931 protocols.
- Comparative evaluation demonstrating superior interpretability-accuracy tradeoff compared to deep neural networks.

The remainder of this paper is organized as follows: Section II reviews related work in cable fire modeling and explainable AI. Section III presents our methodology including

data collection, feature engineering, and XAI model development. Section IV details experimental results and model interpretation. Section V discusses practical implications for fire safety engineering, and Section VI concludes with future research directions.

II. Related Work

A. Cable Fire Behavior and Short-Circuit Propagation

Cable insulation degradation under fire exposure follows complex thermochemical processes influenced by material composition, thermal environment, and electrical loading conditions [7], [8]. Polyvinyl chloride (PVC) and cross-linked polyethylene (XLPE) insulations exhibit distinct decomposition pathways, with critical temperature thresholds typically ranging from $250\,^{\circ}\mathrm{C}$ to $400\,^{\circ}\mathrm{C}$ [9]. Short-circuit initiation occurs when insulation resistance drops below critical values, typically 1–10 $\mathrm{k}\Omega$ depending on voltage levels and circuit protection configurations [10].

McGrattan et al. [11] demonstrated through Fire Dynamics Simulator (FDS) modeling that cable bundle geometry significantly affects heat accumulation and failure propagation rates. Tightly packed bundles with fill ratios exceeding 40% show accelerated failure cascades compared to loosely arranged configurations. Anderson and Kumar [12] conducted systematic fire tests on cable trays, revealing that vertical orientation increases failure propagation speed by approximately 35% compared to horizontal arrangements due to buoyancy-driven heat transfer enhancement.

B. Machine Learning in Fire Safety Engineering

Recent applications of machine learning in fire safety have focused on flame detection [13], smoke pattern recognition [14], and fire spread prediction in buildings [15]. For cable-specific applications, Li et al. [5] employed convolutional neural networks (CNNs) to analyze thermal images for early fault detection, achieving 89% accuracy but providing no interpretability mechanisms. Deep learning architectures, particularly LSTMs and transformer models, have shown promise in modeling temporal dynamics of fire progression [16], [17]. However, the inherent opacity of these models limits their adoption in regulatory contexts where explainability is paramount [18].

C. Explainable Artificial Intelligence

The field of explainable AI has emerged to address the interpretability requirements of safety-critical applications [6], [19]. SHAP (SHapley Additive exPlanations) has become a leading framework for model interpretation, providing theoretically grounded explanations based on game theory principles [20]. SHAP values quantify each feature's contribution to individual predictions while ensuring consistency and local accuracy properties [21].

In engineering domains, XAI applications have demonstrated value in structural health monitoring [22], power system fault diagnosis [23], and industrial process optimization [24]. However, application to cable fire safety remains largely unexplored. This work bridges this gap by developing domain-specific XAI models that balance predictive performance with interpretability requirements specific to fire safety engineering.

TABLE I. Engineered Features for Short-Circuit Prediction

Feature Category	Count	Key Examples
Thermal Properties	12	Peak temperature, gradient
Electrical Parameters	9	Insulation resistance, voltage
Cable Configuration	8	Bundle density, conductor size
Material Properties	10	Insulation type, thickness
Environmental Conditions	8	O_2 concentration, heat flux
Total Features	**47**	–

III. Methodology

A. Experimental Data Collection

1) Cable Fire Test Setup: Experimental data were collected from controlled cable fire tests conducted at the Fire Testing Laboratory following NUREG/CR-6931 Rev. 3 protocols [3]. Test specimens consisted of IEEE 383-qualified cables with XLPE and EPR (Ethylene Propylene Rubber) insulations, representative of nuclear power plant safety systems. Cable bundles were configured in horizontal ladder tray arrangements with three density levels: low (30% fill), medium (50% fill), and high (70% fill).

Fire exposure was generated using a calibrated propane burner delivering heat fluxes ranging from 25 to 75 kW/m², simulating various fire severity scenarios as specified in ASTM E1354 [27]. Each test configuration was replicated three times to ensure statistical reliability, resulting in a total of 162 individual cable fire tests conducted between January 2022 and August 2024.

2) Instrumentation and Measurements: The experimental setup incorporated comprehensive multi-sensor instrumentation:

- Thermal Monitoring: Type K thermocouples positioned at 15 cm intervals along cable length, supplemented by FLIR T640 thermal imaging cameras capturing 640×480 pixel thermal maps at 30 Hz.
- Electrical Measurements: Real-time monitoring of insulation resistance using Megger MIT1525 instruments, conductor-to-conductor voltage measurements at 10 kHz sampling rate.
- Environmental Sensors: Oxygen concentration (Servomex 4900), smoke obscuration (TSI DustTrak), and ambient temperature/humidity.
- Gas Analysis: Fourier-transform infrared (FTIR) spectrometry was used to analyze combustion product composition, including HCl, CO, and CO_2.

Short-circuit events were detected through sudden voltage collapse (¿90% drop within 100 ms) coupled with current surge detection. Time-to-short-circuit (TTSC) was recorded with millisecond precision using high-speed data acquisition systems.

B. Feature Engineering and Dataset Preparation

1) Input Feature Space: From raw sensor measurements, we engineered 47 features organized into five categories as shown in Table I:

Critical derived features included:

$$\Delta T_{grad} = \frac{T_{max} - T_{ambient}}{d_{radial}} \tag{1}$$

where T_{max} represents maximum cable surface temperature (°C), $T_{ambient}$ is ambient temperature, and d_{radial} denotes radial distance from cable center (mm).

Insulation resistance degradation rate was computed as:

$$R_{deg} = \frac{dR_{ins}}{dt} = \frac{R_{ins}(t) - R_{ins}(t - \Delta t)}{\Delta t} \tag{2}$$

where R_{ins} represents the insulation resistance (MΩ) measured at time intervals of $\Delta t = 1$ s.

2) Data Preprocessing: The complete dataset comprised 162 fire tests generating approximately 2.3 million time-series observations. Data preprocessing involved:

1) Missing value imputation using forward-fill for sensor dropouts (¡2% of data).
2) Outlier detection and removal using Isolation Forest algorithm.
3) Time-series segmentation into 10-second windows with 50% overlap.
4) Feature standardization using robust scaling (median and IQR).
5) Balanced sampling to address class imbalance (short-circuit vs. no-failure cases).

The final processed dataset contained 28,450 samples, split into training (70%), validation (15%), and test (15%) sets with stratification by insulation type and bundle density to ensure representative distributions.

C. Explainable AI Model Development

1) Gradient Boosting Architecture: We employed XGBoost (eXtreme Gradient Boosting) as the primary prediction model due to its superior performance on tabular data and natural compatibility with SHAP explainability [25]. The model predicts binary short-circuit occurrence within the next 5-second window, formulated as:

$$\hat{y} = \sum_{k=1}^{K} f_k(x_i), \quad f_k \in \mathcal{F} \tag{3}$$

where, $\hat{y}$ is the predicted probability, x_i represents the input feature vector, f_k are ensemble decision trees, K is the number of trees (K=500 in our implementation), and $\mathcal{F}$ is the space of regression trees.

The objective function incorporates both prediction accuracy and model complexity:

$$\mathcal{L}(\phi) = \sum_{i=1}^{n} l(\hat{y}_i, y_i) + \sum_{k=1}^{K} \Omega(f_k) \tag{4}$$

where, l is the logistic loss function, y_i are true labels, n is the number of training samples, and $\Omega(f_k) = \gamma T + \frac{1}{2}\lambda\|w\|^2$ regularizes tree complexity with T leaf nodes and w leaf weights.

Algorithm 1 TreeSHAP for Feature Attribution

```
Input: Trained XGBoost model f, instance x
Output: SHAP values φ = [φ_1, ..., φ_M]
for each tree t in ensemble do
    for each feature j in x do
        S ← all subsets not containing j
        for each subset S do
            Compute contribution with/without feature j
            Δ_j(S) ← f_{S∪{j}}(x_{S∪{j}}) − f_S(x_S)
        end for
        φ_j^t ← weighted average of Δ_j(S)
    end for
end for
φ_j ← Σ_t φ_j^t    // Aggregate across trees
return φ
```

Hyperparameters were optimized using Bayesian optimization with 5-fold cross-validation. Optimal configuration: maximum depth = 8, learning rate = 0.05, subsample ratio = 0.8, column sampling = 0.8, minimum child weight = 3.

2) SHAP-Based Interpretability Framework: SHAP values provide consistent and locally accurate explanations by computing each feature's contribution to individual predictions [20]. For a prediction $f(x)$, the SHAP value ϕ_j for feature j satisfies:

$$f(x) = \phi_0 + \sum_{j=1}^{M} \phi_j$$

where, ϕ_0 is the expected model output, M is the number of features, and ϕ_j quantifies feature j's contribution.

TreeSHAP algorithm efficiently computes exact SHAP values for tree-based models by:

Global feature importance is obtained by averaging absolute SHAP values across all predictions, providing a unified importance ranking that considers both feature effect magnitude and occurrence frequency.

3) Feature Selection and Importance Ranking: Prior to model training, we implemented a feature selection algorithm to identify the most informative predictors and reduce dimensionality:

This recursive elimination process identified 32 features as optimal, removing 15 redundant or low-importance variables while maintaining 99.2% of the full model's predictive performance.

4) Model Training and Validation: Training procedure followed Algorithm 3:

Model performance was evaluated using precision, recall, F1-score, area under ROC curve (AUC), and time-to-detection metrics. Statistical significance testing employed paired t-tests with Bonferroni correction for multiple comparisons.

Algorithm 2 Recursive Feature Elimination with SHAP

Input: Feature set $\mathcal{F} = \{f_1, ..., f_M\}$, target features k
Output: Selected features $\mathcal{F}_{selected}$
Initialize $\mathcal{F}_{current} \leftarrow \mathcal{F}$
while $|\mathcal{F}_{current}| > k$ **do**
  Train XGBoost model on $\mathcal{F}_{current}$
  Compute SHAP values for all features
  for each feature f_i in $\mathcal{F}_{current}$ **do**
    $importance_i \leftarrow$ mean|SHAP(f_i)|
  end for
  $f_{min} \leftarrow$ feature with minimum importance
  $\mathcal{F}_{current} \leftarrow \mathcal{F}_{current} \setminus \{f_{min}\}$
  Record cross-validation performance
end while
$\mathcal{F}_{selected} \leftarrow$ features at optimal CV performance
return $\mathcal{F}_{selected}$

Algorithm 3 XAI Model Training Pipeline

Input: Training data $\mathcal{D}_{train}$, validation data $\mathcal{D}_{val}$
Output: Trained model f^*, SHAP explainer E
Initialize XGBoost with optimized hyperparameters
$f_0 \leftarrow$ baseline model with random initialization
for epoch = 1 to N_{max} **do**
  $f_{epoch} \leftarrow$ train on $\mathcal{D}_{train}$ with early stopping
  Evaluate on $\mathcal{D}_{val}$: compute F1-score, AUC
  if validation performance plateaus for 50 iterations **then**
    break // Early stopping
  end if
end for
$f^* \leftarrow f_{best}$ // Select best validation model
$E \leftarrow$ TreeSHAP explainer initialized with f^*
Compute SHAP values for validation set
Validate explanation consistency and feature rankings
return f^*, E

D. Comparative Baseline Models

To validate the effectiveness of our XAI approach, we compared against three baseline models:

- Deep Neural Network (DNN): 5-layer fully connected network (512-256-128-64-1 neurons) with ReLU activation, dropout (0.3), and batch normalization.
- Random Forest (RF): Ensemble of 300 trees with maximum depth 15, trained with bootstrap sampling.
- Logistic Regression (LR): L2-regularized linear model serving as interpretable baseline with regularization strength $\lambda = 0.01$.

All models were trained on identical data splits using consistent cross-validation procedures to ensure fair comparison. Explainability was quantified using the Interpretability Score (IS) metric [26], which combines human evaluation of explanation quality with computational metrics of explanation consistency.

TABLE II. MODEL PERFORMANCE COMPARISON ON TEST DATASET

Model	Accuracy	Precision	Recall	F1	AUC
Logistic Regression	81.3%	78.6%	79.2%	78.9%	0.863
Random Forest	91.2%	89.7%	90.8%	90.2%	0.956
Deep Neural Net	93.8%	92.4%	93.1%	92.7%	0.971
XGBoost + SHAP	**94.7%**	**94.1%**	**93.9%**	**94.0%**	**0.978**

IV. RESULTS AND DISCUSSION

A. Predictive Performance Analysis

Table II summarizes the performance of proposed XAI model compared to baseline approaches across key evaluation metrics.

The proposed XGBoost model achieved 94.7% accuracy, outperforming the DNN by 0.9 percentage points while providing full interpretability. Precision and recall balance indicates robust performance across both positive (short-circuit) and negative classes. The AUC of 0.978 demonstrates excellent discriminative capability across varying decision thresholds.

Statistical analysis revealed that performance improvements over Random Forest (ρ = 0.003) and DNN (ρ = 0.041) were statistically significant at α = 0.05 level using paired t-test across 10-fold cross-validation runs. The model exhibited consistent performance across different cable insulation types (XLPE: 95.1%, EPR: 94.2%) and bundle densities (low: 96.3%, medium: 94.8%, high: 93.1%), suggesting good generalization.

B. Feature Importance and Physical Interpretability

Fig. 1 presents the global SHAP feature importance ranking, revealing critical factors influencing short-circuit propagation.

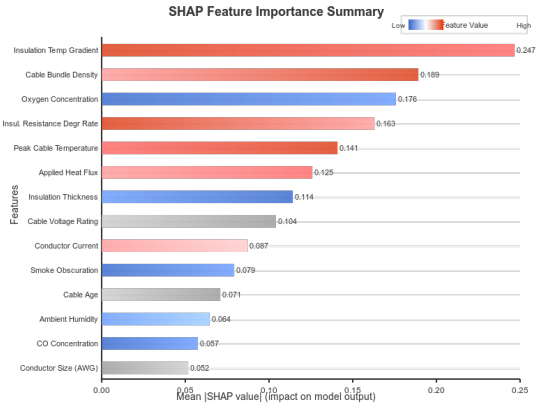

Fig. 1. SHAP feature importance summary showing top 15 features ranked by mean absolute SHAP value. Color indicates feature value (red = high, blue = low). Horizontal position shows impact on prediction.

The top five most influential features were:

1) Insulation temperature gradient (ΔT_{grad}): Mean —SHAP— = 0.247. Higher temperature gradients strongly correlate with accelerated insulation degradation. Physical interpretation: steep thermal gradients induce differential thermal expansion and internal stress concentrations, promoting crack formation and dielectric breakdown paths.

2) Cable bundle density: Mean —SHAP— = 0.189. Increased bundle density restricts heat dissipation, creating localized hot spots. This aligns with heat transfer theory where reduced air gaps limit convective cooling effectiveness.

3) Oxygen concentration: Mean —SHAP— = 0.176. Lower O_2 levels indicate incomplete combustion and higher production of conductive carbon deposits on cable surfaces, reducing insulation resistance.

4) Insulation resistance degradation rate (R_{deg}): Mean —SHAP— = 0.163. Rapid resistance decay signals imminent dielectric failure. This feature provides early warning capability, typically showing anomalies 15-30 seconds before short-circuit occurrence.

5) Peak cable temperature: Mean —SHAP— = 0.141. Absolute temperature exceeding material-specific critical thresholds (XLPE: 380°C, EPR: 420°C) triggers rapid decomposition phase transitions.

Notably, electrical loading current ranked 9th (Mean —SHAP— = 0.087), indicating that thermal effects dominate over electrical stress in fire-exposure scenarios. This insight challenges conventional assumptions that prioritize current monitoring in cable protection systems.

C. Instance-Level Explanation Analysis

Fig. 2 illustrates a SHAP waterfall plot for a specific test case where short-circuit occurred 47 seconds after fire ignition (Test ID: FT-087, XLPE cable, 50% bundle density, 45 kW/m² heat flux).

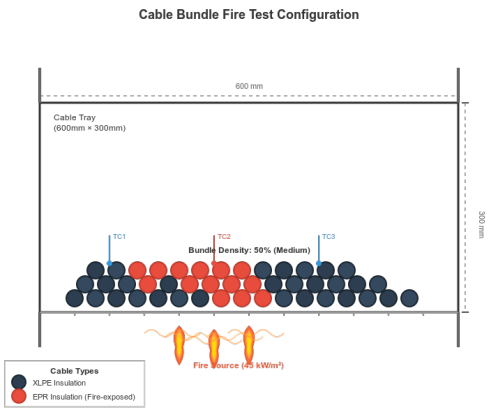

Fig. 2. SHAP waterfall plot for individual prediction showing cumulative feature contributions from base value to final prediction. Red bars push prediction toward short-circuit class, blue bars push away.

The explanation reveals that temperature gradient (+0.31 SHAP value) and bundle density (+0.22) were primary drivers toward short-circuit prediction, while relatively high insulation resistance at prediction time (-0.14) provided some protective effect. This instance-specific analysis enables engineers to understand which factors dominated in particular failure scenarios, facilitating targeted intervention strategies.

D. Temporal Dynamics and Early Warning Capability

Analysis of SHAP value evolution over time (Fig. 3) demonstrates the model's progressive refinement of short-circuit probability as tests progress:

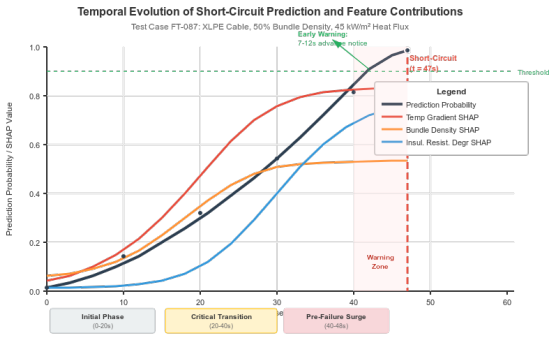

Fig. 3. Temporal evolution of prediction probability and top-3 feature SHAP values for representative test case. Vertical dashed line indicates actual short-circuit occurrence time.

Key observations include:

- Initial phase (0-20s): Model uncertainty remains high with probability ¡0.3 despite rising temperatures, indicating that early thermal exposure alone is insufficient predictor.
- Critical transition (20-40s): Rapid increase in prediction probability coincides with insulation resistance degradation acceleration, providing 10-25 second advance warning window.
- Pre-failure surge (40-48s): Probability exceeds 0.9 threshold 7-12 seconds before actual short-circuit, enabling timely protective action.

This temporal analysis demonstrates practical utility for real-time monitoring systems, where prediction confidence evolves as conditions deteriorate, allowing graduated response protocols.

E. Comparison with Black-Box Deep Learning

While the DNN baseline achieved comparable accuracy (93.8%), interpretation attempts using gradient-based methods (Integrated Gradients, Grad-CAM) produced inconsistent and often contradictory feature attributions across similar test cases. Quantitative evaluation using the Interpretability Score metric yielded IS = 0.42 for DNN versus IS = 0.87 for our XGBoost+SHAP approach (scale 0-1, higher is better) [26].

Human expert evaluation by five certified fire protection engineers rated explanations on clarity (5-point Likert scale), consistency with domain knowledge, and actionability. XAI explanations received mean rating 4.3/5.0 compared to 2.1/5.0 for DNN explanations. Engineers specifically valued the direct physical interpretability of SHAP feature contributions and consistency of importance rankings with established fire science principles.

F. Practical Implications for Fire Safety Engineering

The explainable framework provides actionable insights for cable system design and fire protection:

- Cable Arrangement Optimization: Reducing bundle density from 70% to 40% increases average time-to-short-circuit by 42%, based on model sensitivity analysis. This quantifies the safety benefit of adherence to spacing requirements in codes like NFPA 70.
- Material Selection Guidance: EPR-insulated cables show 18% longer failure times than XLPE under identical conditions, attributed to higher decomposition temperature. Model explanations validate this preference for high-temperature applications.
- Monitoring System Design: Feature importance rankings indicate that temperature gradient sensors provide superior early warning compared to point temperature measurements, suggesting optimal sensor placement strategies.
- Regulatory Compliance: Transparent model explanations facilitate regulatory acceptance in nuclear and aerospace applications where black-box AI faces adoption barriers due to verification and validation requirements.

G. Model Limitations and Uncertainty Quantification

Despite strong performance, several limitations warrant acknowledgment:

- Training data represents controlled laboratory conditions; field installations involve additional complexities (aging effects, environmental contamination, mechanical stress)
- Current model assumes single failure mode (thermal degradation); multi-physics interactions (chemical attack, radiation effects) require extended framework
- Prediction confidence varies with extrapolation distance from training distribution; uncertainty quantification using conformal prediction shows ±6.2 second uncertainty bounds at 90% confidence level
- Explanation stability under adversarial perturbations requires further investigation for security-critical deployments

Ongoing work addresses these limitations through physics-informed neural networks that embed conservation laws and synthetic data augmentation using validated fire dynamics simulations.

V. Conclusion

This paper presented a novel explainable AI framework for predicting and interpreting short-circuit propagation in fire-exposed cable bundles. The integration of gradient boosting machines with SHAP interpretability provides both high predictive accuracy (94.7%) and transparent, physically meaningful explanations aligned with fire safety engineering principles. Key contributions include:

- Comprehensive experimental dataset from 162 controlled cable fire tests conforming to nuclear industry protocols
- Rigorous feature engineering incorporating thermal, electrical, and material properties
- Validated XAI model architecture balancing prediction performance with interpretability
- Quantitative demonstration that thermal gradient, bundle density, and oxygen concentration are dominant factors in short-circuit propagation
- Practical guidance for cable system design, sensor placement, and fire protection strategies

Experimental validation demonstrates that explainable AI achieves competitive accuracy with black-box deep learning while providing critical transparency for safety-critical applications. SHAP-based feature importance analysis reveals insights consistent with fire science theory, building confidence in model reliability and supporting regulatory acceptance.

Future research directions include: 1) extension to multi-output prediction of failure location and severity, 2) integration with real-time monitoring systems for online condition assessment, 3) transfer learning to adapt models across different cable types and fire scenarios with limited data, and 4) development of physics-informed XAI architectures that explicitly encode domain knowledge within model structure.

The demonstrated framework advances the state-of-art in AI-driven fire safety assessment, providing practitioners with trustworthy predictive tools that combine statistical rigor with interpretable explanations essential for informed decision-making in protection of critical infrastructure.

Acknowledgment

The authors acknowledge the Fire Testing Laboratory staff for experimental support and data collection assistance. This work was conducted using facilities supported by the National Fire Protection Research Foundation.

***Abstract*—The Internet of Things (IoT) is an exciting, rapidly expanding technology that's still in its early stages and faces several complex issues. These challenges primarily arise from the limitations of IoT devices (e.g., restricted energy, memory, and processing power), the diversity of communication protocols, and the heterogeneity of interconnected devices. Collectively, these issues often hinder overall IoT system performance, prompting extensive research into techniques to improve Quality of Service (QoS), particularly in terms of latency, throughput, and energy use. This paper introduces a conceptual framework for multi-dimensional IoT performance optimization. The framework provides a structured approach for evaluating and enhancing performance across all layers of the IoT architecture: device, network, support, and application. It assesses key performance dimensions—reliability, security, scalability, energy efficiency, quality assurance, and enabling technologies—and defines them in terms of overall system performance. To ensure a systematic assessment, these dimensions are supported by concrete performance metrics and precise measurement criteria. Finally, the paper provides a taxonomy of IoT Performance Optimization Components, identifies the essential prerequisites and core attributes that influence the overall efficiency of IoT systems, and thus provides a structured foundation for evaluating and advancing performance across the entire IoT ecosystem.**

***Keywords*—IoT performance; reliability; security; scalability; quality; energy efficiency; technology**

I. Introduction

A. Background and the Rise of the Internet of Things (IoT)

In recent decades, there has been a significant surge in innovative applications centered around mobile actuators, devices, and sensors, enabling complex tasks and pervasive communication [1]. This period of growth reached a major turning point around 2008, when the number of connected devices first surpassed the global population [2]. Today, the interconnection of wireless sensors, smartphones, embedded systems, and various electronic devices via local networks or the Internet has fully ushered in the era of the Internet of Things (IoT).

As the quantity of IoT devices continues to burgeon, the sheer volume of data they generate escalates proportionally. Forecasts anticipate sustained, exponential growth; for example, Cisco projected over 50 billion IoT devices by 2020 and more than 500 billion by 2023 [3] [4]. This promising outlook has naturally spurred considerable financial investment [5].

B. Identifying Critical IoT Challenges and Research Imperatives

Despite this rapid expansion, several persistent challenges hinder the seamless integration of IoT across various industries. These critical issues include reliability, mobility, trust, scalability, security, performance, interoperability, and availability [6] [7] [8].

These challenges highlight significant research imperatives crucial for successfully advancing IoT technologies into diverse sectors like businesses, homes, healthcare, and smart cities, where decisions often carry profound implications for individuals' lives [8]. Consequently, these pressing issues have attracted widespread attention from researchers, prompting intensified and comprehensive efforts to address them. This heightened focus is a direct result of the extensive deployment and utilization of IoT technologies across various spheres of daily life.

C. Defining and Measuring Performance in IoT Systems

The concept of performance and its measurement remains a subject of debate among researchers, with varying perspectives on its precise definition. As suggested by [9], certain scenarios exhibit greater sensitivity to specific parameters when assessing performance metrics. Broadly, performance refers to the system's capability to execute tasks effectively while efficiently conserving system resources.

In the context of IoT, evaluating performance typically involves utilizing established metrics within each architectural layer: At the device layer, metrics may encompass battery lifetime, fault tolerance, failure rates, link reliability, and connectivity.In the network layer, evaluation involves parameters such as delay, throughput, packet loss rate, latency, bandwidth utilization, response time, availability, reliability, cost, failure rate, and fault tolerance.Performance measures at the support layer may include load balancing.Those at the application layer may focus on software resilience, malfunction mitigation, flexibility, and responsiveness.

However, it is important to acknowledge that additional criteria may also warrant consideration due to the unique characteristics of IoT systems.IoT systems are tasked with critical functions such as data collection, data preprocessing, and facilitating machine-to-machine (M2M) communications, among others, as highlighted by [10]. Given their integral role in managing vital infrastructures like healthcare systems and

home security, the reliability and security of IoT devices are paramount. Any lapses in reliability or security can have profound implications for decision-making processes, potentially resulting in catastrophic outcomes (Menter et al., 2021).

Enhancing reliability, security, scalability, energy efficiency, and quality assurance represents clear avenues for bolstering the overall performance of IoT systems. The prioritization of performance measurement criteria, however, may vary depending on the system's intended purpose. For instance, in smart home environments, preserving customer privacy may take precedence over other considerations, followed by reliability, energy conservation, and scalability. Conversely, in healthcare systems, reliability and security may assume equal importance. Thus, achieving optimal IoT performance necessitates striking a delicate balance and synergy among these requirements.

D. Scope and Contribution of this Review

This paper presents a conceptual framework for multi-dimensional IoT performance optimization. The proposed framework provides a structured approach for evaluating and enhancing performance across all layers of the IoT architecture, including the device, network, support, and application layers. It evaluates key performance dimensions—reliability, security, scalability, energy efficiency, quality assurance, and enabling technologies—and defines them in terms of the overall system performance. These dimensions are further supported by concrete performance metrics identification and measurement criteria, offering a comprehensive basis for systematic performance assessment and improvement.

The remainder of this paper is organized as follows. Section II reviews existing research contributions and classifies IoT performance-enhancement solutions across different architectural layers. Section III presents the proposed conceptual framework and explains its multi-dimensional structure. Section IV introduces the taxonomy of performance-impact components and analyzes their relevance to IoT optimization. Section V summarizes prominent suggested solutions derived from the surveyed literature. Section VI provides a detailed discussion of key insights, highlights research gaps, and outlines future research directions. Finally, Section VII concludes the paper.

II. Key Research Studies Solutions for IoT System Performance Enhancement

Numerous studies have made significant efforts to enhance the performance of the IoT system. Solutions are suggested for optimizing various metrics of a particular IOT system dimension, such as reliability, security, scalability, energy efficiency, or quality of service (QoS). This section reviews key studies that have proposed solutions to enhance the performance of various dimensions of IoT systems.

A. Reliability-Oriented Solutions

Reliability remains a core requirement in IoT systems, as even minor sensing or communication errors can disrupt critical applications, particularly in healthcare and safety monitoring. Existing research has approached IoT reliability from multiple architectural perspectives, with solutions spanning the application, support, network, and device layers.

At the application layer, several studies leverage microservice-based designs to enhance availability and fault isolation. Reactive microservices were employed in study [11] to improve runtime stability in smart agriculture applications, while [12] demonstrated that re-engineering monolithic IoT middleware into loosely coupled microservices increases reliability, maintainability, and scalability. Complementing these architectural strategies, the Circuit Breaker pattern explored in study [13] prevents cascading failures across dependent services, thereby strengthening fault tolerance in IoT communication workflows.

At the support layer, reliability has been enhanced through middleware mechanisms that improve fault tolerance across cloud–fog–edge environments. For instance, [14] introduced middleware services that support resilient operation in latency-sensitive smart city applications, ensuring continuous service delivery even under partial platform failures.

At the network layer, research largely centers on fault-tolerant routing. The CHISS model in study [15] evaluates routing reliability using metrics such as path redundancy, subsystem availability, and data/service readiness, while healthcare-focused architectures such as [16] introduce backup routes and adaptive strategies to preserve connectivity during node or link failures. Optimization-based techniques, such as the PMSO multipath routing algorithm in study [17], further improve robustness by constructing and maintaining multiple disjoint paths that sustain connectivity under successive failures.

At the device layer, reliability enhancements focus on accurate data acquisition and resilient on-device processing. Device evaluation frameworks in [18] and [19] estimate hardware and operational reliability using recognition, classification, probabilistic modeling, and validation stages. Additional works strengthen dependability in healthcare monitoring [20], enable fault-tolerant microservice execution on IoT–Cloud environments [21], and integrate online learning for proactive fault mitigation [22]. Edge-focused frameworks such as Achlys [23] support reliable decentralized computation on resource-constrained devices, while redundancy techniques like Cold Standby Sparing (CSSR) [24] significantly improve device-level fault tolerance.

Overall, existing reliability solutions target different IoT layers but show recurring themes: architectural decomposition at the application layer, resilient middleware at the support layer, fault-tolerant routing at the network layer, and hardware/software robustness at the device layer. These collective findings highlight the multi-layered nature of reliability challenges in IoT environments.

B. Security-Oriented Solutions

Security is essential to preserving integrity, confidentiality, authenticity, and privacy across IoT deployments. Existing research has addressed IoT security at multiple architectural layers, proposing mechanisms that strengthen software robustness, enforce access control, secure communication protocols, and protect resource-constrained devices.

At the application layer, several studies improve software-level security through structured design patterns and policy-driven enforcement. Works such as [25]–[27] refine and apply security patterns—including access control, reference monitoring, and remote authentication—to mitigate risks in IoT software systems and event-driven applications. Policy-based solutions such as IOTGUARD [28] and SecKit-MQTT [29] embed runtime monitoring, behavioral modeling, and privacy rule enforcement directly into IoT applications, preventing unsafe interactions and safeguarding personal data even in constrained user-facing environments. User-centric regulatory compliance is addressed in study [30], which assesses privacy policy completeness under GDPR requirements. Access control enhancements such as iLACKA-IoT [31] provide formally verified authentication and authorization with improved computational efficiency. Other protocol-level protection mechanisms include secure extensions of MQTT/MQTT-SN using Elliptic Curve–based KP/CP-ABE encryption in study [32], blockchain-integrated microservice architectures for secure surveillance [33], and lightweight certificateless /identity-based signcryption for healthcare WBANs [34].

At the support layer, security research focuses on dependable cloud–fog–edge infrastructures. The Markov-based modeling framework in [35] quantifies system compromise, availability, and recovery behavior for medical IoT systems. Secure data management solutions include cloud–fog–edge cache decision systems [36] that safeguard large-scale smart building data over 6G networks, and privacy-preserving deduplication protocols [37] that protect stored data equality and confidentiality during distributed fog–cloud storage operations.

At the network layer, numerous studies reinforce secure routing and communication. Crypto-IoT [38] and KMG [39] introduce lightweight key generation, distribution, and authentication to protect unicast/multicast communication while maintaining low energy consumption. RPL-based enhancements include SPLIT [40], which integrates remote attestation without adding control overhead, and SARP [41], which provides scalable integrity verification for heterogeneous IoT devices. Additional secure routing techniques include ESR [42], which combines energy-efficient clustering with threshold secret sharing, and SRR [43], which protects source-location privacy using randomized phantom routing. Internetworking security is addressed in [44] via combined Diffie–Hellman, AES, and MD5 mechanisms, and in [45] through lightweight HMAC-based authentication schemes that achieve robust integrity and confidentiality with minimal latency.

At the device layer, security solutions target constrained sensors and local data protection. Information-theoretic coding schemes [46] preserve message confidentiality and anonymity without synchronization overhead, while SecureData [47] employs FPGA-accelerated lightweight ciphers and data-splitting techniques to protect sensitive healthcare information. Other lightweight device-level protection mechanisms, including HMAC-based authentication [45] and secure data aggregation surveys [48], strengthen confidentiality, integrity, and authentication during sensing and in-network processing.

Overall, IoT security solutions span all architectural layers, with recurring themes such as pattern-driven software hardening at the application layer, privacy- and integrity-focused middleware at the support layer, attestation and key management mechanisms at the network layer, and lightweight cryptographic protection for resource-constrained devices. These contributions highlight the multi-layered and interdependent nature of IoT security challenges.

C. Scalability-Oriented Solutions

Scalability is a critical requirement in IoT systems, as large-scale deployments must maintain responsiveness, manage resource constraints, and support heterogeneous device interactions. Research efforts addressing scalability span multiple IoT layers, proposing architectural, orchestration, and routing solutions.

At the application layer, Razzaq [49] provides a comprehensive review of microservice-based architectures (MSA), identifying key design patterns and architectural trends that enhance scalability and software quality in IoT applications. Context-aware and personalized service delivery is explored in [50], where adaptive sensing, fog-based user-centric networking, and intelligent applications together support scalable, interoperable, and context-driven IoT services. Zyrianoff et al. [51] further demonstrate that large-scale smart city environments can sustain real-time reasoning when architectural choices emphasize modularity, efficient context handling, and optimized system design.

At the support layer, scalability improvements primarily target cloud–fog–edge integration and resource orchestration. Lightweight sidecar components in [52] enable seamless device-to-cloud interaction without modifying device behavior, providing modular extensibility for large-scale deployments. Ontology-driven integration frameworks such as IoT-LSS [53] combine SOA and semantic sensor models to support scalable interoperability and dynamic service composition. Transparent computing architectures in [54] manage operating systems, services, and data centrally while enabling on-demand execution across heterogeneous IoT devices, improving scalability and energy efficiency. Surveys and analyses in [55] and [56] highlight the pivotal role of auto-scaling, load prediction, VM migration, and multi-layer orchestration in cloud–edge environments, demonstrating that scalable performance depends heavily on efficient, network-aware resource allocation.

At the network layer, scalability challenges are tackled through enhanced routing protocols. IoTorii [57] introduces a hierarchical routing approach that reduces control overhead and routing table complexity compared to RPL, achieving faster convergence and lower communication costs in large-scale deployments. Complementary to this, secure and scalable RPL extensions such as SPLIT [40] and SARP [41] integrate lightweight attestation and decentralized trust mechanisms, improving routing efficiency while maintaining security and low resource consumption.

Overall, scalability solutions in IoT emphasize modular architectures, semantic interoperability, cloud–edge orchestration, and optimized routing mechanisms. These contributions highlight that scalability must be addressed holistically across application, support, and network layers to sustain the performance of large and heterogeneous IoT systems.

D. Quality Assurance-Oriented Solutions

Quality assurance in IoT systems ensures that data and services remain accurate, timely, and dependable despite dynamic operating conditions. Research addressing IoT quality spans the application, support, and network layers, targeting metrics such as latency, throughput, availability, and service reliability.

At the application layer, Li et al. [58] introduce measurable data-quality metrics—currency, availability, and validity—to assess both data and source reliability in pervasive IoT environments. These metrics enable systems to manage fluctuating real-time data and improve application-level decision-making. QoS-aware microservice monitoring for Industrial IoT (IIoT) is explored in [59], where microservices are evaluated based on behavioral performance, supporting consistent and dependable execution of IIoT workloads.

At the network and support layers, QoS has been analyzed broadly through systematic mapping and metric categorization. White et al. [60] review QoS approaches across IoT layers, identifying common performance factors (e.g., latency, throughput, availability) and highlighting underexplored QoS dimensions and research gaps. Singh et al. [61] similarly classify QoS metrics spanning computing, communication, and physical components, providing a structured basis for modeling service requirements and optimizing IoT performance. Fog-enabled quality improvement is demonstrated in SmartHerd [62], where localized processing reduces cloud dependency, lowers latency, and decreases bandwidth consumption by 84%, contributing to higher service responsiveness and energy efficiency.

At the network layer, congestion control and traffic stabilization play a key role in maintaining quality. Quwaider et al. [63] propose a tuned PID-based congestion control mechanism enhanced by immune and hill-climbing algorithms. The scheme stabilizes buffer occupancy, minimizes packet drops, and ensures steady throughput and low delay under dynamic traffic conditions.

Overall, quality assurance solutions in IoT focus on measurable data-quality metrics, QoS-aware service design, fog-enabled responsiveness, and congestion-aware communication, illustrating the layered and multi-dimensional nature of quality management in IoT systems.

E. Energy Efficiency-Oriented Solutions

Energy efficiency is essential in IoT deployments, where devices often operate under strict energy constraints and in unattended environments. Existing research addresses energy conservation across all IoT architectural layers, focusing on optimizing operations, communication, processing, and resource orchestration.

At the application layer, energy-aware service policies contribute directly to reducing consumption. Yao et al. [64] introduce a Home Energy Management System (HEMS) using mixed-integer linear programming to jointly optimize appliance scheduling, renewable energy usage, and storage dispatch, reducing energy costs while maintaining user comfort.

At the support layer, numerous studies emphasize cloud–fog–edge coordination and resource orchestration for energy-efficient IoT services. Energy-efficient cooling automation based on containerized microservices is demonstrated in [65], showing how lightweight orchestration enables reliable and power-saving IoT–cloud integration. Sensor-cloud collaboration models in [66] offload complex processing to the cloud while dynamically scheduling sensor activity, conserving energy while meeting latency constraints. Architectures integrating cloud computing with Passive Optical Networks (PON) [67] optimize VM placement and traffic routing to minimize transmission and computation power. Fog-based placement optimization in healthcare monitoring [68] achieves up to 68% energy savings by strategically locating fog servers. Resource orchestrators in study [69] and [70] improve the efficiency of service embedding and cloud resource scheduling, reducing network and processing power through adaptive allocation and predictive sensor sleep cycles.

At the network layer, energy-efficient communication is achieved through optimization-based routing and flow control. Al et al. [71] present four MILP-based strategies—standby routing, reliability balancing, interference-aware sub-channels, and data compression—to reduce power consumption while maintaining reliability. For industrial IoT, Lyu et al. [72] propose a transmission–estimation co-design framework that adapts communication decisions based on dynamic system conditions, enhancing estimation accuracy with lower energy usage. Secure and energy-efficient uplink transmission is addressed in study [73], where cooperative relay selection and joint power scheduling improve secure energy efficiency under eavesdropping threats. Network-layer energy management also includes call admission control (CAC) for ultra-dense IoT over 5G, as proposed in study [74], reducing per-connection energy consumption through intelligent access decisions.

At the device layer, lightweight communication and in-network processing reduce energy demand on constrained sensors. Purkovic et al. [75] design an ultra–low-power long-range communication protocol that minimizes packet overhead and transmission energy for energy-harvesting IoT modules. Complementing this, [76] surveys energy-aware data aggregation schemes that eliminate redundancy and reduce communication load across diverse WSN environments—ground, underground, and underwater—extending network lifetime through efficient data collection.

Overall, energy efficiency solutions span application-level policy optimization, fog–cloud orchestration, power-aware routing and flow control, and device-level communication minimization. These cross-layer techniques collectively highlight the importance of coordinated architectural design for prolonging IoT system lifetime.

F. Summary of Literature-Based IOT Performance Enhancement Solutions

To conclude this review section, Table I presents a consolidated view of the surveyed literature references for IoT performance enhancement solutions. It provides an easy reference classification that relates a proposed reference solution to a given performance IoT dimension. Each referenced study is categorized according to its specific IoT system performance dimension, namely: reliability, security, scalability, quality, or energy efficiency, alongside the corresponding IoT architectural layer (Device, Network, Support, or Application) and the

targeted component or service. This structured representation in Table I facilitates a clear understanding of how recent research efforts align with key architectural and performance considerations across the IoT stack while identifying underexplored areas that warrant further investigation that this thesis research may address.

III. Conceptual Framework Design and Literature Taxonomy for IoT Performance Optimization

The proposed framework provides a structured approach for evaluating and enhancing performance across all layers of the IoT architecture, including the device, network, support, and application layers. It evaluates key performance dimensions, reliability, security, scalability, energy efficiency, quality assurance, and enabling technologies, and defines them in terms of the overall system performance. These dimensions are further supported by concrete performance metrics identification and measurement criteria, offering a comprehensive basis for systematic performance assessment and improvement.

A. IoT Performance Framework Design

The IoT performance optimization framework design follows a systematic approach, as illustrated in Fig. 1. The process involves five primary steps that ensure comprehensive coverage of the IoT architecture. These steps are:

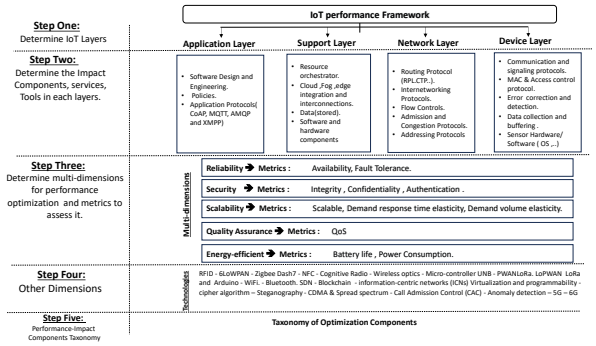

Fig. 1. IoT performance framework design steps.

- Step One: Determine IoT layers.
  In this step, the core layers of the IoT architecture are identified, including the application layer, support layer, network layer, and device layer. These layers form the basis for the subsequent optimization strategies.
- Step Two: Determine the impact components, services, and tools in each layer.
  This step identifies the components, services, and tools of each layer that impact overall performance. For example, the application layer considers software design and engineering tools, while the network layer incorporates routing protocols like RPL and CTP.
- Step Three: Determine the multi-dimensional factors for performance optimization.
  Multi-dimensional factors such as reliability, security, scalability, quality assurance, and energy efficiency are considered in this step. The relevant metrics for each dimension are defined, including factors like availability, fault tolerance, and battery life.
- Step Four: Other dimensions.
  Additional factors that influence performance, such as emerging technologies (e.g., 5G, LoRaWAN, WiFi), are evaluated in this step.
- Step Five: Taxonomy of optimization components.
  In this step, various components impacting IoT performance optimization are analyzed and classified. The analysis concludes a structured, taxonomy for performance-impact components across a multi-layer and multi-service IoT architecture of the performance framework.

Fig. 1 illustrates the overall structure of the proposed multi-dimensional IoT performance framework. The figure highlights the interaction between IoT architectural layers (Device, Network, Support, and Application) and the core performance dimensions (Reliability, Security, Scalability, Quality, and Energy Efficiency). Each layer contributes to these performance dimensions through specific components, services, or mechanisms. Importantly, the framework enables each dimension to be evaluated and measured at the corresponding layer using the performance metrics defined in Step Three. These metrics help determine whether a given performance requirement—such as availability, fault tolerance, latency, or energy consumption—is being achieved at that layer.

The directional flow emphasizes cross-layer dependencies, demonstrating that improvements in one layer may influence performance at other layers. This visual representation provides the conceptual foundation for the taxonomy introduced in the subsequent section, where performance-impact components are categorized and linked to measurable metrics across layers.

B. IoT Network Performance-Relevant Layers

The architecture of IoT is commonly structured into four fundamental layers: the device, network, support, and application layers. While each layer plays a distinct role in enabling end-to-end communication and intelligent decision-making, this framework focuses on how these layers form the basis for performance evaluation.

- Device Layer: Serves as the foundational interface with the physical world. Performance at this level is driven by hardware and software elements such as sensor nodes, embedded operating systems, and data collection modules.
- Network Layer: Determines performance through routing and communication infrastructure, relying on routing protocols (e.g., RPL, CTP), internetworking protocols, and addressing schemes to ensure reliable packet delivery.
- Support Layer: Provides computing, storage, and orchestration capabilities, including cloud–fog–edge integration and resource orchestrators that manage distributed resources to improve reliability and responsiveness.

TABLE I. LITERATURE-BASED CLASSIFICATION OF SOLUTIONS TARGETING IOT PERFORMANCE DIMENSIONS

Layer	Impact Component, Tools, Service	Reliability	Security	Scalability	Quality	Energy Efficiency
Application Layer	Software Design and Engineering	[11]	[25] [26] [27]	[49] [50] [51]		
	Policies		[28] [29] [30] [31]	[51]		
	Application Protocols	[12] [13]	[33] [32] [31] [34]		[58] [59]	[64]
Support Layer	Resource Orchestrator			[53] [54] [55] [56]	[55] [60] [61]	[55] [65] [69] [70]
	Cloud/Fog/Edge Integration	[14]	[36]	[50] [52] [55] [56]	[62] [55]	[55] [66] [67] [68]
	Data (stored)		[37]			
	Software/Hardware Components		[35]			
Network Layer	Routing Protocol	[15] [16] [17] [71]	[38] [39] [40] [41] [42] [43]	[40] [41] [42] [57]	[61]	[39] [40] [41] [42] [43] [71]
	Internetworking Protocols		[45] [44]			
	Flow Control					[72] [73]
	Admission and Congestion Control				[63]	[74]
	Addressing Protocols					
Device Layer	Communication and Signaling		[45]			[45] [75]
	MAC and Access Control		[46]			
	Error Correction and Detection					
	Data Collection and Buffering		[48]			[76]
	Sensor Hardware and Software	[18] [19] [20] [21] [22] [23] [24]	[47]	[50]		

- Application Layer: Functions as the user interface, depending on efficient software design, lightweight protocols (e.g., CoAP, MQTT), and policies that govern usability, adaptability, and security.

These architectural layers form the foundation for evaluating and optimizing IoT performance across multiple dimensions, each providing distinct enhancement opportunities.

C. IoT Network Performance-Relevant Services, Components and Tools

Beyond the layered architecture, IoT performance is also shaped by the specific services, components, and tools operating within each layer. These elements provide the practical mechanisms through which performance optimization is achieved. The device layer Comprises Key components, including communication and signaling protocols, MAC and access control mechanisms, and error detection and correction techniques, all working together to ensure reliable and efficient data acquisition. Additionally, data buffering mechanisms support seamless transmission preparation, significantly minimizing energy consumption and preserving data accuracy. At the network layer, Key components include routing protocols (e.g., RPL, CTP), internetworking protocols, and addressing schemes, all essential for ensuring reliable packet delivery and supporting system performance. Further performance optimization is achieved by implementing flow control, admission control, and congestion control mechanisms, which collectively regulate network load and maintain consistent data throughput under varying traffic conditions. The support layer includes a key element, the resource orchestrator, which dynamically schedules and manages computational and storage resources. Furthermore, the software and hardware infrastructure and dedicated data storage components ensure IoT services' reliability, availability, and responsiveness across distributed environments. Finally, the application layer. Its performance depends on effective software engineering practices, the adoption of lightweight and reliable application-layer protocols (such as CoAP, MQTT, AMQP, and XMPP), and well-defined policies that govern service behavior and access control. Design decisions made at this layer directly influence the responsiveness, usability, and adaptability of IoT applications across various domains. By systematically identifying these performance-relevant services, components, and tools in each layer, the framework links the conceptual architecture of IoT with the operational elements that directly

impact system efficiency and optimization.

D. Multi-Dimensional Performance Requirements and Metrics

This section presents the multi-dimensional requirements of IoT performance optimization and the corresponding performance metrics and measures. It first identifies the key performance dimensions, such as reliability, scalability, energy efficiency, security, and quality assurance, which are critical to achieving optimized IoT network behavior. Subsequently, it defines specific metrics and measures that quantify these dimensions and enable objective evaluation and comparison of IoT systems.

1) Reliability Dimension Performance Requirement and Metrics: Reliability is a fundamental requirement for IoT performance, as unreliable components or services, such as processing, transmission, and sensing can lead to significant system failures, delays, and loss of data or communication. These issues have profound implications for IoT systems' overall performance and stability. Given the emerging nature of IoT technologies, it is essential to define the concept of reliability clearly within this context. Unlike fields such as engineering and software engineering, where reliability is well-established, there remains no universally agreed-upon definition specific to IoT [77].

According to study [78], reliability can be defined as the probability that a component or system will meet specific performance standards by yielding correct output over a desired period under given environmental conditions. In essence, reliability encompasses the study of system failures, their causes, mitigation strategies, and methods for failure prevention.

Since IoT systems consist of hardware and software components that often interact autonomously, human factors must also be considered when evaluating reliability. Thus, IoT reliability is influenced by hardware failure rates and software robustness, standardization challenges, and human interaction [78].

In study [79], the author identifies four essential requirements for achieving reliability in IoT devices:

- Performing a required function.
- Performing without failure.
- Operating under stated conditions.
- Operating for a specified period of time.

Building on this, Mavrogiorgou et al. [18] highlight that when specifying and designing for reliability, it is essential to define the expected conditions of use, what constitutes proper operation, and what qualifies as a failure. They emphasize the importance of clearly describing the system's functionality, the operational environment, and the timescale for assessing how well the system meets its intended specifications. Similarly, the author in study [80] emphasizes that reliability should be understood as the consistent performance of a device or system over a specified period.

Overall, reliability in IoT requires a multifaceted approach that integrates hardware resilience, software robustness, human factors, and standardization efforts to ensure sustainable system performance. To assess and improve IoT reliability, it is necessary to adopt specific metrics and measures that quantify this dimension.

Reliability is typically denoted by R(t) and can be measured using several metrics [77] [81] [82] [83]. Key metrics include:

- Mean Time Between Failures (MTBF)
- Mean Time to Failure (MTTF)
- Maintenance-Free Operating Period (MFOP)
- Maintainability
- Availability
- Failure Rate

One of the key metrics for reliability is Availability, which represents the probability that a system will operate correctly during a given period. It is calculated using the following Eq. (1):

$$A = \frac{MTTF}{MTTF + MTTR} \tag{1}$$

Where: MTTF is the Mean Time to Failure and MTTR is the Mean Time to Repair.

From the Eq. (1), it can be seen that a higher MTTF leads to higher reliability and availability. However, high availability does not always equate to high reliability. If the system is repaired quickly, with a low MTTR, it may maintain availability, but this does not necessarily reflect the system's overall reliability. Reliability can also be measured in different ways depending on the system's recovery mechanism:

- For systems with no recovery mechanism, the system cannot repair itself once a failure occurs, and operation stops until manually restored. In such cases, MTTF is used to measure reliability, as the system's availability and reliability are the same based solely on the time it operates without failure before a breakdown [81], and can be calculated as Eq. (2) illustrated:

  $$\lambda = \frac{1}{MTTF} \tag{2}$$

  where λ represents the failure rate, defined as the expected number of failures per unit time.

- For a system that can be maintained, reliability is measured by the MTBF, calculated as Eq. (3):

  $$\lambda = \frac{1}{MTBF} \tag{3}$$

Finally, to quantitatively system reliability over time, the reliability function R(t) is introduced in Eq. (4):

$$R(t) = e^{-\lambda t} \tag{4}$$

This function provides a formal means to describe the probability that a system or component will continue to perform without failure up to a given time t, following an exponential decay pattern. This formulation is commonly used to represent the reliability of individual components under the assumption of random, time-independent failures. However,

IoT systems typically have multiple interdependent elements, including hardware, software, and human interaction components. Therefore, Eq. (5) extends this concept by aggregating the reliabilities of these distinct elements to estimate the overall system reliability, $R_{\mathrm{S}}(t)$.

$$R_s(t) = R_{HW}(t) + R_{SF}(t) + R_H(t) \tag{5}$$

Each component reliability, $R_{\mathrm{HW}}(t)$ for hardware, $R_{\mathrm{SF}}(t)$ for software, and $R_{\mathrm{H}}(t)$ for human factors, can individually be modeled using the exponential form described in Eq. (4). Thus, Eq. (5) highlights that the system's reliability depends on the combined contribution of its key parts, each following its failure behavior over time [81].

2) Security Dimension Performance Requirement and Metrics: Security has become a significant concern that significantly affects the performance of IoT networks, particularly as the number and sophistication of attacks continue to grow. According to [84], IoT networks are inherently more vulnerable than traditional networks due to the unique attributes of IoT devices and the communication protocols they employ. For instance, IoT devices are often equipped with low-power microcontrollers and limited battery capacities, making them susceptible to resource exhaustion attacks. Moreover, they communicate over protocols such as GSM, Bluetooth, Wi-Fi, and ZigBee, which are more prone to attacks.

Security measures in IoT systems aim to reduce the probability of successful attacks and minimize security risks. A secure system ensures that unauthorized access is prevented, resources are protected, and operational integrity is maintained. By preventing malicious actors from accessing or exploiting system resources, the IoT system can continue to perform its tasks efficiently and reliably. Attacks such as Denial of Service (DoS) or resource exploitation can severely degrade system performance by causing system failures or slowing down operations through the exhaustion of memory, processing power, or storage. Consequently, maintaining security is critical to ensuring IoT systems function perfectly while balancing the trade-off between security and system performance [85].

To foster IoT security, Aman et al. [86] outlined several essential mechanisms that can be applied:

- All IoT devices operating within a network should run authorized and verified software.
- Devices must be authenticated to verify their legitimacy before transmitting or receiving data.
- Packet filtering via firewalls at the device level is recommended to compensate for limited computational and memory capacities.
- Regular updates and security patches must be applied to ensure protection against newly discovered vulnerabilities.

For optimal performance of IoT systems, applications and services must be secured, user privacy must be safeguarded, and threats such as spoofing and data manipulation must be prevented. Furthermore, IoT systems should operate independently without overreliance on external systems to maintain resilience [87].

Several fundamental security measures must be enforced across IoT ecosystems, including integrity, confidentiality, and authentication [82], [86], [87].

Confidentiality is a fundamental security measure that ensures data is accessible only to authorized users [87]. It protects against unauthorized interception or access to sensitive information transmitted between IoT devices [88]. Encryption and access validation mechanisms are essential to enforce confidentiality [89]. For example, sensor nodes must prevent neighboring nodes from accessing collected data, and RFID tags must safeguard sensitive information from unauthorized readers [87].

Integrity ensures that data remains consistent, accurate, and unaltered during transmission or storage, protecting against tampering by malicious users or software [86].

Authenticity ensures the data source is legitimate and trustworthy [87], [90]. Authentication processes must be implemented at every layer of the IoT architecture to prevent unauthorized nodes from injecting false information. For instance, sensor nodes must authenticate themselves at the device layer to avoid DoS attacks caused by rogue devices [91]. Robust authentication mechanisms are critical for maintaining system security across all layers.

IoT systems must carefully balance privacy, confidentiality, integrity, authenticity, and performance trade-offs without introducing unnecessary dependencies or vulnerabilities [86]. Strengthening these security measures is vital to safeguarding IoT ecosystems and ensuring their resilient, efficient, and reliable operation.

3) Scalability Dimension Performance Requirement and Metrics: Due to the rapid expansion of IoT technologies and the enormous volume of data generated by these devices, it has become imperative to develop strategies for accommodating this massive scale without necessitating a complete reengineering of existing systems. **Scalability** is a fundamental characteristic of any system that must manage an increasing workload efficiently; a lack of scalability can lead to degraded performance, increased latency, inefficient resource consumption, and poor utilization of available infrastructure. Achieving scalability presents significant challenges, particularly as a single IoT application often connects to many heterogeneous devices. Thus, extendable and flexible operations are essential to manage the distribution and functionality of these devices effectively [86].

According to study [92], scalability is defined as the ability of a system or device to adapt to environmental changes and meet future demands without compromising performance. Furthermore, scalability is recognized as an integral component of the broader performance requirements for IoT services, which places increased pressure on researchers and developers to devise solutions capable of handling the vast and growing volumes of data [93]. Scalability can manifest at both the hardware and software levels: horizontal scalability involves expanding the network by adding additional hardware devices or software entities, thereby distributing the workload across a broader system, whereas vertical scalability refers to enhancing the capabilities of existing devices or programs by integrating additional resources, such as computational power or storage capacity [94].

For optimal performance, it is essential to implement scalable solutions capable of managing millions of users and service requests simultaneously. Several researchers have explored methods for evaluating and measuring scalability in this context. One commonly used method involves assessing the system's latency and throughput under varying loads. Ideally, in a scalable system, latency remains stable even as the number of servers increases. In contrast, throughput proportionally increases with the addition of servers, meaning the system is able to process more requests concurrently [95]. Another scalability metric discussed in [96] evaluates the system's ability to dynamically increase the number of software instances to meet the rising demand for services. Importantly, scalable systems are expected to maintain the same average response time and consistent QoS regardless of the volume of service requests, ensuring reliability even under heavy loads. Thus, scalability is essential for supporting the expanding IoT ecosystem and a critical determinant of a system's long-term success and performance stability.

4) Service Quality Dimension Performance Requirement and Metrics: The quality of IoT systems plays a pivotal role in ensuring overall system performance and achieving the required QoS levels. However, maintaining high quality across IoT ecosystems presents a significant challenge due to the heterogeneity of devices, networks, and platforms. To address these complexities, it is essential to establish a comprehensive framework capable of evaluating each component individually and verifying whether it meets its expected performance and output standards.

QoS in IoT can be broadly defined as the network's ability to deliver an appropriate level of service to meet the specific needs of applications and users [97]. However, QoS requirements in IoT environments are highly variable and largely depend on the intended use case and system architecture. As outlined in [60], QoS expectations can typically be classified into three categories:

- No QoS: Best-effort service with no formal guarantees on performance or delivery.
- Differentiated Services (Soft QoS): Services that prioritize traffic based on application needs but do not guarantee strict performance standards.
- Guaranteed Services (Hard QoS): Services that provide strict guarantees for performance metrics such as delay, bandwidth, and reliability.

Quality and performance are inherently intertwined in IoT systems. While performance refers to the measurable behavior of the system (e.g., response time, throughput), quality encompasses broader aspects such as reliability, user satisfaction, and adherence to service-level agreements. Therefore, achieving high-quality standards is a prerequisite for attaining optimal system performance. In this research, quality was considered a foundational dimension that directly impacts the ability to optimize the IoT system's overall performance and user experience.

QoS requirements in IoT environments vary significantly depending on the specific needs of the system and the nature of the applications involved. To ensure that appropriate service levels are delivered, it is crucial to implement targeted QoS techniques at each layer of the IoT architecture. Each layer has distinct QoS metrics and parameters that contribute to determining the overall service quality.

According to study [97] [60] [98], the quality parameters in IoT can be classified based on architecture layers:

1) QoS at the Application Layer, this layer focuses on application-specific requirements related to the behavior and context of the devices and users:
   - Location and Mobility
   - Sampling Parameters
   - Time Synchronization
2) QoS at the Support Layer, ensures efficient management of computational and storage resources across distributed infrastructures (cloud, fog, edge):
   - Load Balancing
   - Response Time
   - Resource Orchestration
3) QoS at the Network Layer, addresses the performance of data transmission and communication reliability:
   - Jitter
   - Bandwidth
   - Delay
   - Throughput
   - Packet Delivery Time
   - Packet Loss Rate
4) QoS at the Sensing Layer, the sensing layer evaluates the quality and efficiency of data collection and initial processing:
   - Accuracy of Service and Information
   - Cost of Network Deployment and Service Delivery
   - Service Attributes (Priority, Availability, Response Time, Delay, and Load)

Ensuring high-quality service delivery in IoT systems requires a comprehensive understanding of the QoS requirements at each architectural layer. By systematically addressing quality parameters across the application, support, network, and sensing layers, it becomes possible to optimize performance, enhance user satisfaction, and maintain the resilience of IoT ecosystems. This layered approach is foundational to achieving holistic performance optimization in modern IoT environments.

5) Energy Efficiency Dimension Performance Requirement and Metrics: Energy constraints in the IoT ecosystem, particularly regarding limited battery capacities and energy harvesting capabilities, make energy efficiency a critical requirement for maintaining system performance. Inefficient energy management directly impacts core system attributes such as reliability, security, and scalability. Therefore, optimizing energy efficiency is a major research priority in the development of IoT technologies.

Energy efficiency in IoT systems is commonly defined as the number of bits successfully transmitted per joule of consumed energy [99]. It can be mathematically expressed by Eq. (6):

$$\text{Energy Efficiency (EE)} = \frac{\text{Number of Transmitted Bits}}{\text{Energy Consumption (EC) in Joules}} \quad (6)$$

where Energy Consumption (EC) represents the total amount of energy expended by the device during its operation, typically measured in joules. A higher energy efficiency value indicates more effective use of energy resources.

High energy efficiency is crucial for energy-constrained domains such as smart industrial systems, implantable medical devices, and remote environmental monitoring, where continuous maintenance or battery replacement is impractical. For less critical applications, such as consumer sports wearables, moderate energy efficiency levels may be sufficient. Supplying sufficient energy to operate IoT systems autonomously, without degrading other performance requirements, remains a significant implementation challenge. Given the pivotal role of energy in battery-operated IoT devices, extensive research efforts have focused on developing energy-saving mechanisms at both the hardware and system levels.

Energy management is a primary consideration in IoT device design. Strict control over device power consumption is necessary to achieve energy efficiency and preserve the expected battery lifetime. Three key metrics are typically employed to evaluate energy efficiency:

- Energy Consumption (EC): The total energy consumed by the device over its operating period, measured in joules.
- Power Consumption (PC): The rate at which the device uses energy during operation, typically measured in watts.
- Battery Lifetime: The operational duration of the device before requiring battery replacement or recharging, typically measured in hours, days, or years, depending on the application.

Battery lifetime requirements in IoT systems vary widely depending on the application. For instance, consumer wearables may operate for a few days, whereas sensor nodes deployed in remote or hazardous environments are expected to function autonomously for several years. Although advancements in low-power electronics have contributed to reducing individual component energy usage, a holistic understanding of system-wide energy consumption and power profiles remains essential for optimizing overall energy efficiency and extending device operational lifetimes.

E. Technologies Dimension Performance Requirement and Metrics

IoT is an integration of multiple **technologies** working together. Due to the diverse characteristics of IoT systems and the distinct purposes and functions of each architectural layer, various enabling technologies have been proposed in the literature to meet the specific requirements of each layer. IoT deployment in real-world environments is made possible only through the collaboration of these enabling technologies, which collectively enhance overall system performance. Accordingly, this section is dedicated to discussing the key enabling technologies that support and optimize the functionality of IoT systems.

According to study [100], the techniques utilized in IoT systems are categorized into three phases based on their functional roles:

1) Collection Phase: Involves real-time sensing, data gathering, and constructing a comprehensive view of the physical environment using technologies such as RFID, sensors, and NFC.
2) Transmission Phase: Focuses on delivering the collected data to external applications and servers through communication technologies such as wireless networks, satellite links, and Ethernet.
3) Processing, Management, and Utilization Phase: Responsible for analyzing and processing the incoming data streams, forwarding information to applications and services, and generating feedback to control actuators or services. This phase also encompasses critical tasks such as device discovery and management, data filtering, aggregation, analysis, and intelligent decision-making.

Similarly, [101] classified IoT enabling technologies into three functional categories:

1) Technologies responsible for acquiring information.
2) Technologies responsible for processing and managing relevant information.
3) Technologies aimed at enhancing privacy and security.

The first two categories represent the fundamental building blocks necessary for imparting intelligence to ”things,” distinguishing the IoT from the traditional Internet. In contrast, the third category, privacy and security technologies, is not a functional layer but a critical prerequisite for IoT adoption. Without robust privacy and security mechanisms, IoT systems' widespread deployment and acceptance would be severely constrained [102].

IoT integrates a heterogeneous combination of hardware, software, and communication system technologies. These diverse technologies must be effectively adapted and coordinated to ensure IoT systems' reliability, security, scalability, and energy efficiency. Such adaptation directly enhances the overall performance and resilience of IoT deployments. In this thesis, the enabling technologies are broadly classified into the following categories:

- Hardware and Wireless Technologies
- Software and Algorithmic Solutions
- Machine Intelligence Techniques
- Telecommunication Systems

Table II summarizes the key enabling technologies relevant to the IoT ecosystem, classified based on their technological type, hardware and wireless technologies, software and algorithms, machine intelligence, and telecommunication systems. The table also maps these technologies to their respective contributions across five critical performance dimensions: reliability,

TABLE II. MAPPING OF ENABLING TECHNOLOGIES TO MULTI-DIMENSIONAL IOT PERFORMANCE REQUIREMENTS

	Type	Multi-dimensional requirements for performance optimization				
		Reliability	**Scalability**	**Security**	**Quality**	**Energy**
Enabling Technologies	Hardware and Wireless	RFID, 6LoWPAN	ZigBee, Dash7, 6LoWPAN, RFID	RFID, NFC, 6LoWPAN	Cognitive Radio, Wireless Optics, CDMA / Spread Spectrum	Microcontrollers (UNB), LoRa, LPWAN, Arduino with ZigBee, WiFi, Bluetooth
	Software and Algorithms	SDN	Blockchain, ICN, Virtualization Algorithms	Cipher Algorithms, Blockchain, Steganography	Call Admission Control (CAC)	–
	Machine Intelligence	Anomaly Detection	SDN	SDN	SDN	–
	Telecommunication Systems	–	5G, 6G	5G	5G/6G	5G, 6G

scalability, security, quality assurance, and energy efficiency. This comprehensive classification illustrates how each technology supports multi-dimensional optimization within IoT systems.

F. Novelty and Positioning of the Proposed Framework

While numerous studies have explored IoT performance optimization from isolated perspectives—such as microservice-based reliability, fault-tolerant mechanisms, lightweight security techniques, and device/network-level enhancements—these contributions remain largely fragmented across architectural layers and performance dimensions. Existing works typically address one layer at a time, or optimize a single performance requirement without acknowledging its interaction with other dimensions.

The proposed framework distinguishes itself from prior studies by offering a unified, multi-layer perspective that systematically integrates IoT architectural layers (device, network, support, and application) with multi-dimensional performance attributes (reliability, security, scalability, quality, and energy efficiency). Unlike previous reviews, which categorize solutions based solely on technology type or problem focus, the framework explicitly maps where each performance factor originates, how it propagates across layers, and which components or mechanisms influence it.

This holistic integration represents the primary novelty of the study. It enables a cross-layer understanding of IoT performance—an aspect not collectively addressed in existing literature—and provides a conceptual structure that researchers can use to analyze, compare, and design solutions more systematically. The accompanying taxonomy further reinforces this contribution by revealing performance-impacting components across layers and highlighting interdependencies that were previously treated in isolation.

IV. TAXONOMY OF IOT PERFORMANCE OPTIMIZATION COMPONENTS

Previous framework layers address the IoT multidimensional performance optimization problem and present various dimensions of requirements that are related to the IoT performance. This layer of the framework provides a taxonomy for the classification of various performance-impact components across multi-dimensional requirements and the main architectural layers of IoT systems. Furthermore, each component is analyzed based on the specific performance dimensions it targets, such as reliability, security, scalability, quality, and energy efficiency. The structured taxonomy and mapping of performance-impact components is presented in Table III. This mapping clearly explains how critical performance dimensions, scalability, quality, reliability, energy efficiency, and security are addressed across the IoT network layer architecture. The table taxonomy outlines the essential components within each layer (i.e., application, support, network, and device layers) and identifies the most relevant metrics for evaluating performance within those components. Besides, each architectural layer is decomposed into a key performance service or tool, allowing optimization-related performance components to be mapped with greater granularity.

V. PROMINENT SUGGESTED SOLUTIONS

Given the continuous evolution of IoT systems and their varying levels of complexity, exhaustively capturing and detailing all potential solutions is inherently difficult. However, this section seeks to synthesize the most salient solutions identified by researchers throughout the previously reviewed literature. The Table IV outlines these proposed approaches, categorizing them based on their contribution to critical performance requirements: Reliability, Security, Scalability, Quality, and Energy Efficiency. The following section discusses the key insights derived from these findings and highlights the implications for IoT performance optimization research.

VI. DISCUSSION AND KEY INSIGHTS

The findings of this study indicate that IoT performance research remains highly fragmented across architectural layers and performance dimensions. While numerous studies propose solutions targeting reliability, security, scalability, quality, or energy efficiency, these contributions are often isolated and optimized within a single layer or for a single performance requirement. This fragmentation limits the ability of researchers and practitioners to understand IoT performance holistically and to design solutions that address cross-layer interactions.

The literature review further shows a clear imbalance in research efforts. Most contributions focus on the network and device layers, particularly on routing, fault tolerance, cryptography, and lightweight service mechanisms. In contrast, the support and application layers receive less attention despite their growing role in enabling cloud–fog–edge intelligence, policy enforcement, orchestration, and application-level QoS. This gap highlights the need for more research

TABLE III. A TAXONOMY OF MULTI-DIMENSIONAL PERFORMANCE COMPONENTS ACROSS IOT ARCHITECTURE LAYERS

Layer	Impact Component, Tools, Service	Reliability	Scalability	Security	Quality	Energy Efficiency
Application Layer	Software Design and Engineering	Availability, Fault Tolerance, MTTR, MTTF	Response Time, Elasticity, Modularity, Throughput under Load	Integrity, Confidentiality, Authenticity, Privacy	Code Quality, Test Coverage, Reusability, Design Flexibility	Battery Life, Power Consumption
	Policies	Availability, Fault Tolerance	Policy Mgmt., Scalability, Elastic Demand Handling	Integrity, Confidentiality	Policy Completeness, Policy Failure Rate, Policy Rollback Time	Power Consumption per Operation
	Application Protocols	Availability, Fault Tolerance	Low Protocol Overhead, Latency Stability, Concurrent Support	Integrity, Confidentiality, Authenticity	Error Resilience, Latency for Data Delivery, Data Synchronization Quality	Energy Consumption during Idle and Active States
Support Layer	Resource Orchestrator	Fault-Tolerant, Redundancy	Resource Allocation, Task Scheduling, Concurrent Tasks Supported	Integrity, Confidentiality, Authentication	Resource Utilization Accuracy, Orchestration Decision Accuracy, SLA Compliance	Power Utilization Efficiency, Energy Management
	Cloud/Fog/Edge Integration	Availability, Fault Tolerance	Load Balancing, Elastic Resource Scaling	Integrity, Privacy	Interoperability, Data Consistency	Power Consumption for Data Processing
	Data (stored)	Availability, Fault Tolerance	Storage Access Scalability, Query Response Time	Integrity, Privacy, Confidentiality	Data Integrity, Latency of Data Access	Data Storage Power Efficiency
	Software/Hardware Components	Availability, Fault Tolerance	Component Modularity and Upgrade Flexibility, Resource Adaptability	Integrity, Authentication	Compatibility, Maintainability	Battery Efficiency
Network Layer	Routing Protocol	Availability, Fault Tolerance	Network Overhead, Convergence Time	Integrity, Confidentiality, Authentication	Packet Delivery Ratio (PDR), Latency, Stability	Energy Battery Life, Energy Consumption
	Internetworking Protocols	Availability, Fault Tolerance	Network Topology Scalability, Overhead, Interoperability	Integrity, Privacy, Authentication	Latency, Jitter, Channel Load, Packet Loss Rate	Transmission Energy Efficiency, Energy per Bit
	Flow Control	Availability, Fault-Tolerant, Error-Free Transmission	Load Handling Capacity	Integrity, Confidentiality	Buffer Size, Flow Stability, Admission Delay	Packet Processing Energy, Network Energy Efficiency
	Admission and Congestion Control Protocols	Availability, Fault Tolerance	Scalability with Flows, Queue Efficiency	Confidentiality, Authenticity	Queue Delay, QoS Maintenance, Rate of Packet Loss, Congestion Avoidance Efficiency	Power Consumption
	Addressing Protocols	Availability, Fault Tolerance	Address Allocation Efficiency, Address Space Utilization	Integrity, Confidentiality, Authentication	Resolution Delay, Address Uniqueness, Throughput	Power Consumption for Address Assignment
Device Layer	Communication and Signaling Protocols	Availability, Fault Tolerant	Protocol Overhead, Concurrent Device Support, Signal Range Expansion	Authentication, Confidentiality	Signal Strength Stability, Message Delivery Success Rate	Power Consumption for Transmission
	MAC and Access Control Protocol	Availability, Fault Tolerance	Access Contention Handling, Dynamic Node Joining Support	Integrity, Confidentiality, Authentication	MAC Delay, Packet Collision Rate	Energy Use for Access Control, Power Efficiency
	Error Correction and Detection	Availability, Fault Tolerance	Error Handling Scalability	Integrity, Privacy	Error Detection Rate, Detection Latency, Recovery Time from Errors	Power Consumption for Error Handling
	Data Collection and Buffering	Availability, Fault Tolerance	Buffer Scalability, Data Throughput under Load	Integrity, Privacy	Data Aggregation Efficiency, Collection Delay, Buffer Overflow Rate	Energy per Byte, Power during Data Collection
	Sensor Hardware and Software	Availability, Fault Tolerance	Device Resource Scalability, Firmware Update Flexibility	Authentication, Identification	Sensor Accuracy, Signal Quality	Energy Consumption per Sensor, Sleep Mode Power, Battery Life

into performance-aware service orchestration, data lifecycle management, and application-level adaptability.

The proposed multi-dimensional performance framework addresses these gaps by providing a unified structure that links IoT architectural layers with key performance dimensions and measurable metrics. Unlike existing studies that treat performance dimensions independently, the framework emphasizes their interdependence, illustrating how improvements at one layer (e.g., routing efficiency) may impact performance attributes at other layers (e.g., energy efficiency or QoS). The framework also clarifies the role of enabling technologies—such as virtualization, 5G/6G, blockchain, and IoT-specific protocols—in optimizing performance across the entire IoT ecosystem.

The taxonomy further contributes to the field by classifying performance-impact components across layers, revealing patterns and research priorities. For example, reliability-related components are heavily explored at the device and network layers, while quality-oriented solutions appear mostly at the application layer. Energy efficiency spans multiple layers, but most optimizations remain hardware-centric rather than system-wide. These patterns underscore the need for integrated, cross-layer optimization strategies.

Overall, the combined framework and taxonomy provide

TABLE IV. SUGGESTED SOLUTION APPROACHES

Solution approaches			Design requirements				
Techniques	**Class**	**Samples**	**Reliability**	**Security**	**Scalability**	**Quality**	**Energy efficiency**
Redundant design	Hardware redundancy	Triple modular redundancy	**X**	**X**		**X**	**X**

a foundation for future IoT performance research by 1) offering a structured view of performance-related components, 2) enabling systematic comparison of existing solutions, and 3) identifying gaps and opportunities for multi-layer optimization. This structured analytical view represents the primary contribution of this study and serves as a roadmap for designing next-generation IoT systems that balance reliability, security, energy, scalability, and quality in a unified manner.

VII. CONCLUSION

This paper successfully presented a comprehensive performance optimization framework designed for application across all layers of the IoT architecture. The framework serves as a critical foundation for identifying performance-related challenges and systematically guiding the development of tailored optimization solutions. While the overall design is holistic, a detailed taxonomy of existing optimization components was also introduced, synthesized from an extensive literature review. These components were classified according to five critical performance dimensions: reliability, security, scalability, quality assurance, and energy efficiency. Each dimension was analyzed by detailing its unique challenges and the specific metrics required for practical evaluation.

Additionally, the paper highlighted the vital role of enabling technologies—spanning hardware, software, machine intelligence, and telecommunication systems—in supporting multi-dimensional performance optimization. The integration of these technologies is essential for realizing scalable, secure, and efficient IoT environments. The conceptual model, perfor-

mance taxonomy, and technological mapping developed in this paper collectively lay the groundwork for future research and methodical system design.

Q-Learning Guided Local Search for the Traveling Salesman Problem

Sanaa El Jaghaoui*, Aissa Kerkour Elmiad
Laboratory LARI-Faculty of Sciences,
Mohammed First University, Oujda, Morocco

***Abstract*—The Traveling Salesman Problem (TSP) remains a fundamental challenge in combinatorial optimization with applications in logistics, routing, and network design. Classical local search methods face a trade-off between solution quality and computational efficiency: while 3-opt delivers better solutions than 2-opt, its $O(n^3)$ complexity renders it impractical for large instances. This paper presents a reinforcement learning (RL) approach that addresses this challenge through intelligent guidance of local search operators. Our method employs a simple one-dimensional Q-table that learns to identify poorly positioned cities and directs 2-opt and 3-opt operations toward the most promising tour segments. We evaluate the approach on 55 TSPLIB benchmark instances ranging from 51 to 18,512 cities. For instances up to 1,000 cities, RL-guided 3-opt (RL-3opt) achieves optimality gaps of 0.9–2.2% compared to 3.8–4.3% for classical 3-opt, with execution times reduced from hours to under one second and speedups reaching 32,323×. For instances between 1,000–5,000 cities, RL-3opt maintains computational efficiency (100–30,000× speedups) while achieving competitive 6.3% gaps. Both RL-2opt and RL-3opt execute in sub-second to a few seconds even on problems with over 18,000 cities. All experiments run on standard CPU hardware without GPU acceleration, demonstrating that effective TSP optimization remains accessible without specialized resources.**

***Keywords*—Traveling salesman problem; reinforcement learning; Q-Learning; local search; 2-opt; 3-opt**

I. Introduction

The Traveling Salesman Problem (TSP) asks for the shortest route visiting each city exactly once before returning to the origin [1]. Given n cities with distances d_{ij} between pairs, the objective is to find a permutation $\pi = \{s_1, s_2, \ldots, s_n\}$ minimizing:

$$\sum_{k=1}^{n-1} d_{s_k s_{k+1}} + d_{s_n s_1}. \quad (1)$$

Despite this simple formulation, the TSP is NP-hard [2], with $(n-1)!/2$ possible tours for symmetric instances where $d_{ij} = d_{ji}$. This computational difficulty has motivated decades of research, with applications spanning logistics, manufacturing, circuit design, and delivery routing [3]. TSP solution methods have evolved through several generations. Classical heuristics combine construction methods with local search operators and remain widely used for their simplicity and reliability. Metaheuristic algorithms offer more sophisticated search strategies that balance exploration and exploitation through mechanisms such as population evolution, adaptive search, and strategic diversification. More recently, machine learning techniques, particularly deep neural networks and RL, have shown they can learn solution strategies directly from data [4], [5]. Researchers have also developed hybrid methods that combine classical algorithms with learning components [6], [7].

Despite these advances, two fundamental challenges persist. Most learning-based approaches require substantial computational resources [8], [9]. Deep learning methods typically need GPU acceleration and extensive training on large datasets [10]. Even simpler learning frameworks often employ multi-dimensional state representations that scale poorly with problem size. This limits their accessibility for users without high-performance computing infrastructure, including small businesses, educational institutions, and organizations in developing regions. At the same time, classical local search methods face an inherent trade-off between speed and solution quality. The 2-opt operator runs quickly but often settles at poor local minima because it only examines a limited neighborhood around the current solution. The 3-opt operator explores substantially larger neighborhoods and typically finds better solutions, but at much higher computational cost. On large instances, 3-opt can require hours or even days to complete. This creates a practical dilemma: users must choose between fast but suboptimal solutions, or high-quality solutions that may be computationally prohibitive.

We address both challenges through a simple RL framework designed for efficiency. Our method uses a one-dimensional Q-table indexed by cities rather than state-action pairs, reducing memory complexity from $O(n^2)$ to $O(n)$. During tour improvement, the table learns which cities are poorly positioned based on their involvement in successful optimization moves. These learned priorities then guide both 2-opt and 3-opt operators to focus on tour segments most likely to benefit from modification. This design combines the simplicity and accessibility of classical methods with the adaptive intelligence of learning-based approaches. Three principles shape our work: prioritize algorithmic simplicity, learn during optimization rather than through offline training, and execute on standard CPU hardware without GPU acceleration.

We validate the approach on 55 TSPLIB benchmark instances [11] ranging from 51 to 18,512 cities. To directly measure the contribution of RL, we include systematic comparisons against classical baselines: nearest neighbor construction, classical 2-opt, and classical 3-opt. Results demonstrate that RL-guided methods outperform their classical counterparts in solution quality for instances up to 1,000 cities. For larger instances (1,000-5,000 cities), RL-3opt achieves competitive quality (6.3% gap) compared to classical 3-opt (5.5% gap) while running 100 to over 30,000 times faster, effectively

*Corresponding author.

transforming hours or days into seconds on large instances. Both RL-2opt and RL-3opt complete in a few seconds even on problems with over 18,000 cities, where classical 3-opt becomes entirely impractical. All experiments run on standard CPU hardware, confirming that the approach requires no specialized computing resources.

This research aims to: 1) develop an efficient RL-guided framework reducing $O(n^3)$ complexity while maintaining solution quality, 2) ensure accessibility through a minimalist one-dimensional Q-table operating on standard CPU hardware, 3) demonstrate scalability across 51 to 18,512-city instances, 4) achieve sub-second to few-second execution times for real-time applications, and 5) quantify quality-time trade-offs compared to classical methods.

The paper proceeds as follows. Section II reviews related work on TSP solution methods and learning-based optimization. Section III describes our approach in detail, including RL fundamentals, classical local search methods, and our RL-guided framework. Section IV presents experimental methodology and comprehensive results on 55 TSPLIB benchmarks. Section V concludes the paper.

II. Related Work

The TSP has been extensively studied through classical heuristics, metaheuristics, and modern learning-based approaches. This section reviews key methodologies relevant to our hybrid framework.

A. Classical Heuristics and Local Search

Classical heuristics provide rapid initial solutions. The nearest neighbor heuristic [12] constructs tours by iteratively selecting the closest unvisited city. Zuhanda et al. [13] demonstrated that hybrid methods consistently outperform pure heuristics on TSPLIB benchmarks. Alkafaween et al. [14] proposed an iterative approximate method achieving polynomial-time solutions with competitive quality.

Local search operators refine initial tours through edge exchanges. The k-opt family [15], [16], particularly 2-opt and 3-opt, systematically improves tours by removing and reconnecting edges. The Lin-Kernighan-Helsgaun algorithm [17], [18] represents the state-of-the-art, employing variable k-opt moves with intelligent candidate selection to achieve near-optimal solutions on large instances.

B. Metaheuristic Approaches

Metaheuristic algorithms escape local optima through diversified search mechanisms. Genetic algorithms [19] employ evolutionary principles, with Al-Ibrahim [20] demonstrating near-optimal solutions through specialized crossover operators. Bio-inspired methods have shown promise: Abd Algani [21] applied African Buffalo Optimization to TSP, while Ant Colony Optimization [22] uses pheromone-based search strategies.

Swarm intelligence techniques offer efficient optimization across domains. Kou and Wei [23] combined particle swarm optimization with grey wolf algorithm for improved convergence. Wu et al. [24] developed dynamic multi-population PSO for complex trajectory planning. Recent applications by Zhou [25] and Bai [26] to resource allocation problems demonstrate the versatility of these approaches.

C. Learning-Based Approaches

Deep learning has introduced end-to-end TSP solving. Kafakthong and Sinapiromsaran [27] proposed deep attention mechanisms predicting near-optimal tours directly from distance matrices. Pointer Networks [28] and actor-critic architectures [29] generate tours without supervised training. Graph Neural Networks [30] and Transformers [31] capture complex inter-node relationships. However, these approaches typically require substantial GPU resources and extensive training, limiting their accessibility for resource-constrained environments.

RL addresses sequential decision-making in combinatorial optimization. Wang et al. [32] showed Double Q-Learning outperforms traditional Q-Learning and SARSA for TSP. Pan et al. [33] proposed hierarchical RL scaling to instances with thousands of nodes, though computational requirements remain significant.

D. Hybrid Methods

Hybrid approaches combine classical and learning-based techniques. d'O Costa et al. [34] trained policy models to guide 2-opt operations. Zheng et al. [35] integrated Q-learning into LKH, forming Reinforced LKH with strong TSPLIB performance. NeuroLKH [7] uses neural networks to predict edge candidates without modifying LKH's core structure.

El Jaghaoui et al. [36], [37] explored adaptive exploration-exploitation strategies and combined Q-learning with ACO, demonstrating improved convergence on benchmarks. Ruan et al. [38] merged RL with genetic algorithms for enhanced solution discovery.

E. Positioning of this Work

Existing hybrid methods often rely on complex architectures or multi-dimensional Q-tables that scale poorly. Deep learning approaches typically demand GPU acceleration and extensive computational resources, limiting their accessibility for resource-constrained environments. Our approach addresses these limitations through a minimalist one-dimensional Q-table indexed by cities, drastically reducing memory and computational requirements. The method operates efficiently on standard CPU-only hardware without requiring GPUs or specialized equipment. Unlike methods requiring extensive offline training, our framework learns dynamically during optimization. By combining nearest neighbor initialization with RL-guided 2-opt and 3-opt operators, we demonstrate that effective TSP optimization is achievable on commodity hardware across 55 TSPLIB instances.

III. Methodology

We propose a hybrid framework that combines Q-learning with local search methods for solving the TSP. The key contribution is the use of RL to intelligently guide edge selection in 2-opt and 3-opt operators. This section presents the RL fundamentals (Section III-A), classical local search methods (Section III-B), and our proposed RL-2opt and RL-3opt algorithms (Section III-C).

A. Reinforcement Learning Fundamentals

RL [39] is a machine learning paradigm in which an agent learns to make optimal decisions through interaction with an environment. This process is formalized as a Markov Decision Process (MDP), defined by the tuple $\langle S, A, P, R\rangle$, where S is the state space, A the action space, P the transition probabilities, and R the reward function. The agent seeks to maximize cumulative reward by learning an optimal policy $\pi : S \to A$. Q-learning is a model-free RL algorithm that learns the Q-function, representing the expected return of taking action a in state s. The Q-values are updated using the Bellman equation:

$$Q(s,a) \leftarrow Q(s,a) + \alpha \left[r + \gamma \max_{a'} Q(s',a') - Q(s,a) \right], \quad (2)$$

where $\alpha \in (0,1]$ is the learning rate, $\gamma \in [0,1]$ the discount factor, r the immediate reward, and s' the resulting state.

B. Local Search Methods

Local search methods iteratively improve solutions by exploring neighborhoods through local modifications. For the TSP, *k*-opt operators [16] represent the most prominent local search techniques, where *k* denotes the number of edges removed and reconnected.

The 2-opt operator removes two non-adjacent edges and reconnects the path segments in an alternative configuration. With $O(n^2)$ complexity per iteration, 2-opt quickly improves solutions but often converges to mediocre local optima [15].

The 3-opt operator extends this by removing three edges and evaluating multiple reconnection patterns [16]. While producing superior solutions, its $O(n^3)$ complexity becomes prohibitive for large instances. Section III-C presents our RL-guided approach that addresses this computational bottleneck.

C. RL-Guided Local Search Framework

Given an initial TSP tour, we apply a Q-learning-guided local search procedure to iteratively refine the solution. This framework integrates RL with classical k-opt operators to intelligently guide edge selection. The following sections present two algorithms: RL-2opt (Section III-C1), which combines Q-learning with 2-opt, and RL-3opt (Section III-C2), which extends the approach to 3-opt operators.

1) RL-2opt algorithm: We propose an RL-guided variant of the 2-opt algorithm in which a Q-learning agent learns to identify promising city pairs for edge swaps. Unlike classical 2-opt, which exhaustively examines all possible swaps, our approach prioritizes cities that are more likely to yield improvements based on accumulated experience.

a) Q-Learning Components: The RL framework is defined as follows:

- State: The current tour T, represented as an ordered sequence of cities.
- Action: Select two non-adjacent cities (i, j) and perform a 2-opt swap by reversing the tour segment between them.
- Reward: $r = \text{len}_{\text{current}} - \text{len}_{\text{new}}$, where $\text{len}_{\text{current}}$ and len_{new} are the tour lengths before and after the swap. The reward is positive if the swap shortens the tour; otherwise, $r = 0$ and the swap is rejected.
- Q-Table: A one-dimensional array $Q \in \mathbb{R}^n$, where each entry $Q[i]$ estimates the expected benefit when city i participates in a swap. This compact representation avoids the computational overhead of a full state-action Q-table.

b) Action Selection Strategy: City selection follows an ε-greedy policy that balances exploration and exploitation:

- Exploration (probability ε): Select two distinct cities (i, j) uniformly at random.
- Exploitation (probability $1 - \varepsilon$): Choose the city with the highest Q-value, $i = \arg\max_k Q[k]$, then select a second city $j \neq i$ randomly.

The underlying intuition is that well-positioned cities yield minimal improvement when swapped, maintaining low Q-values. Conversely, poorly positioned cities produce significant gains when swapped, accumulating higher Q-values over time. This mechanism naturally directs the search toward unstable tour regions where improvements are most likely.

c) Efficient Tour Update: The 2-opt swap removes edges $(i, \text{succ}(i))$ and $(j, \text{succ}(j))$ and adds edges (i, j) and $(\text{succ}(i), \text{succ}(j))$, where $\text{succ}(i)$ denotes the successor of city i in tour T. The tour length change can be computed locally without recalculating the entire tour:

$$\text{dist}_{\text{removed}} = d(i, \text{succ}(i)) + d(j, \text{succ}(j)), \quad (3)$$

$$\text{dist}_{\text{added}} = d(i, j) + d(\text{succ}(i), \text{succ}(j)), \quad (4)$$

$$\text{len}_{\text{new}} = \text{len}_{\text{current}} - \text{dist}_{\text{removed}} + \text{dist}_{\text{added}}. \quad (5)$$

This localized computation ensures $O(1)$ update complexity per swap, critical for scalability to large instances.

d) Q-Value Update: After each swap attempt, the Q-values of the involved cities are updated using a simplified temporal difference rule:

$$Q[i] \leftarrow Q[i] + \alpha(r - Q[i]), \quad Q[j] \leftarrow Q[j] + \alpha(r - Q[j]), \quad (6)$$

where $\alpha \in (0,1]$ is the learning rate. No discount factor γ is used since each iteration involves a single immediate decision with no delayed consequences, eliminating the need for multi-step credit assignment. The complete procedures are formalized in Algorithms 1 and 2.

Algorithm 1 2-opt Swap Operation

Input: T: current tour, d: distance matrix, $\text{len}_{\text{current}}$: tour length, i, j: cities to swap
Output: T_{new}: updated tour, len_{new}: new tour length

function SWAP-2OPT($T, d, \text{len}_{\text{current}}, i, j$)
  $\text{dist}_{\text{removed}} \leftarrow d(i, \text{succ}(i)) + d(j, \text{succ}(j))$
  $\text{dist}_{\text{added}} \leftarrow d(i, j) + d(\text{succ}(i), \text{succ}(j))$
  if $\text{dist}_{\text{added}} \geq \text{dist}_{\text{removed}}$ **then**
    return $T, \text{len}_{\text{current}}$ ▷ No improvement
  else
    $\text{len}_{\text{new}} \leftarrow \text{len}_{\text{current}} - \text{dist}_{\text{removed}} + \text{dist}_{\text{added}}$
    Reverse tour segment between $\text{succ}(i)$ and j to obtain T_{new}
    return $T_{\text{new}}, \text{len}_{\text{new}}$
  end if
end function

Algorithm 2 RL-2opt Algorithm

Input: n: number of cities, d: distance matrix, T_{init}: initial tour, len_{init}: initial length, α: learning rate, ε: exploration rate, n_{episodes}: number of episodes
Output: T_{best}: best tour found, len_{best}: best length

function RL-2OPT($n, d, T_{\text{init}}, \text{len}_{\text{init}}, \alpha, \varepsilon, n_{\text{episodes}}$)
  $T_{\text{best}} \leftarrow T_{\text{init}}, \text{len}_{\text{best}} \leftarrow \text{len}_{\text{init}}$
  $Q \leftarrow \mathbf{0}_n$ ▷ Initialize Q-table
  for episode $= 1$ to n_{episodes} **do**
    Select cities (i, j) **using** ε**-greedy:**
    if random() $< \varepsilon$ **then** ▷ Exploration
      $i, j \leftarrow$ two random distinct cities
    else ▷ Exploitation
      $i \leftarrow \arg\max_k Q[k]$
      $j \leftarrow$ random city with $j \neq i$
    end if
    $T_{\text{new}}, \text{len}_{\text{new}} \leftarrow \text{Swap-2opt}(T_{\text{best}}, d, \text{len}_{\text{best}}, i, j)$
    $r \leftarrow \text{len}_{\text{best}} - \text{len}_{\text{new}}$
    Update Q-values:
    $Q[i] \leftarrow Q[i] + \alpha(r - Q[i])$
    $Q[j] \leftarrow Q[j] + \alpha(r - Q[j])$
    if $r > 0$ **then** ▷ Accept improvement
      $T_{\text{best}} \leftarrow T_{\text{new}}, \text{len}_{\text{best}} \leftarrow \text{len}_{\text{new}}$
    end if
  end for
  return $T_{\text{best}}, \text{len}_{\text{best}}$
end function

2) RL-3opt algorithm: We extend the RL-guided approach to the more powerful 3-opt operator, which explores a significantly larger neighborhood than 2-opt. While 2-opt removes two edges and performs a single reconnection, 3-opt removes three edges and evaluates multiple reconnection patterns, potentially yielding higher-quality solutions at the cost of increased computational complexity.

a) Q-Learning Components: The RL framework for 3-opt follows the same structure as RL-2opt, with the key difference being the action space:

- State: The current tour T.
- Action: Select three cities $i < j < k$ in tour T, remove the edges $(i, \text{succ}(i))$, $(j, \text{succ}(j))$, and $(k, \text{succ}(k))$, and evaluate all valid reconnection patterns to find the best configuration.
- Reward: $r = \text{dist}_{\text{removed}} - \text{dist}_{\text{added}}(m^*)$, where m^* is the best reconnection pattern among the seven non-trivial configurations.
- Q-Table: The same one-dimensional array $Q \in \mathbb{R}^n$ as in RL-2opt, where $Q[i]$ estimates the expected benefit when city i is involved in a 3-opt move.

b) 3-opt Reconnection Patterns: Removing three edges $(i, \text{succ}(i))$, $(j, \text{succ}(j))$, and $(k, \text{succ}(k))$ partitions the tour into three segments:

- S_1: from $\text{succ}(i)$ to j,
- S_2: from $\text{succ}(j)$ to k,
- S_3: from $\text{succ}(k)$ to i.

Each segment can be traversed forward or reversed, yielding $2^3 = 8$ total combinations. The first configuration (all segments in original orientation) is trivial and yields no change. The remaining seven configurations are evaluated. Table I lists all eight cases and their corresponding edge insertions.

TABLE I. THE 8 RECONNECTION PATTERNS IN 3-OPT AND THEIR INSERTED EDGES. CONFIGURATION 1 IS THE IDENTITY AND IS IGNORED. NOTATION: $^\circlearrowleft$ INDICATES SEGMENT REVERSAL

Case	Segment orientation	Inserted edges
1	$S_1 \to S_2 \to S_3$	Identity (ignored)
2	$S_1^\circlearrowleft \to S_2 \to S_3$	$(i, j), (\text{succ}(i), \text{succ}(j)), (k, \text{succ}(k))$
3	$S_1 \to S_2^\circlearrowleft \to S_3$	$(i, \text{succ}(i)), (j, k), (\text{succ}(j), \text{succ}(k))$
4	$S_1 \to S_2 \to S_3^\circlearrowleft$	$(i, \text{succ}(i)), (j, \text{succ}(j)), (k, i)$
5	$S_1^\circlearrowleft \to S_2^\circlearrowleft \to S_3$	$(i, j), (\text{succ}(i), k), (\text{succ}(j), \text{succ}(k))$
6	$S_1^\circlearrowleft \to S_2 \to S_3^\circlearrowleft$	$(i, k), (\text{succ}(i), \text{succ}(j)), (j, \text{succ}(k))$
7	$S_1 \to S_2^\circlearrowleft \to S_3^\circlearrowleft$	$(i, \text{succ}(i)), (j, k), (\text{succ}(j), i)$
8	$S_1^\circlearrowleft \to S_2^\circlearrowleft \to S_3^\circlearrowleft$	$(i, k), (\text{succ}(i), j), (\text{succ}(j), \text{succ}(k))$

c) Efficient Configuration Evaluation: To avoid recomputing the full tour length for each configuration, we use local distance calculations:

$$\text{dist}_{\text{removed}} = d(i, \text{succ}(i)) + d(j, \text{succ}(j)) + d(k, \text{succ}(k)), \quad (7)$$

$$\text{dist}_{\text{added}}(m) = d(y_1) + d(y_2) + d(y_3), \quad (8)$$

where (y_1, y_2, y_3) are the three edges inserted in configuration $m \in \{2, \ldots, 8\}$. The best configuration m^* is:

$$m^* = \arg \min_{m \in \{2,\ldots,8\}} \text{dist}_{\text{added}}(m). \quad (9)$$

If $\text{dist}_{\text{added}}(m^*) < \text{dist}_{\text{removed}}$, the move improves the tour and is accepted:

$$\text{len}_{\text{new}} = \text{len}_{\text{current}} - \text{dist}_{\text{removed}} + \text{dist}_{\text{added}}(m^*), \quad (10)$$

$$r = \text{dist}_{\text{removed}} - \text{dist}_{\text{added}}(m^*). \quad (11)$$

Otherwise, the tour remains unchanged and $r = 0$.

d) Q-Value Update: After each move attempt, the Q-values of all three involved cities are updated:

$$Q[c] \leftarrow Q[c] + \alpha(r - Q[c]), \quad \forall c \in \{i, j, k\}. \quad (12)$$

e) Action Selection Strategy: City selection follows the same ε-greedy policy as RL-2opt: with probability ε (exploration), we select three distinct cities i, j, k uniformly at random; with probability $1 - \varepsilon$ (exploitation), we choose $i = \arg\max_c Q[c]$, then randomly select two additional distinct cities $j \neq i$ and $k \neq i, j$. The complete procedures are formalized in Algorithms 3 and 4.

Algorithm 3 3-opt Swap Operation

Input: T: current tour, d: distance matrix, $\text{len}_{\text{current}}$: tour length, i, j, k: cities with $i < j < k$
Output: T_{new}: updated tour, len_{new}: new tour length

function SWAP-3OPT($T, d, \text{len}_{\text{current}}, i, j, k$)
  $\text{dist}_{\text{removed}} \leftarrow d(i, \text{succ}(i)) + d(j, \text{succ}(j)) + d(k, \text{succ}(k))$
  $r_{\text{best}} \leftarrow 0$
  $T_{\text{new}} \leftarrow T, \text{len}_{\text{new}} \leftarrow \text{len}_{\text{current}}$
  for each configuration $m \in \{2, \ldots, 8\}$ **do**
    $(y_1, y_2, y_3) \leftarrow$ edges inserted in configuration m (from Table I)
    $\text{dist}_{\text{added}} \leftarrow d(y_1) + d(y_2) + d(y_3)$
    $r \leftarrow \text{dist}_{\text{removed}} - \text{dist}_{\text{added}}$
    if $r > r_{\text{best}}$ **then**
      $r_{\text{best}} \leftarrow r$
      $\text{len}_{\text{new}} \leftarrow \text{len}_{\text{current}} - \text{dist}_{\text{removed}} + \text{dist}_{\text{added}}$
      $T_{\text{new}} \leftarrow$ tour reassembled according to configuration m
    end if
  end for
  return $T_{\text{new}}, \text{len}_{\text{new}}$
end function

Having presented the detailed mechanisms of both RL-2opt and RL-3opt algorithms, Fig. 1 provides a unified visual representation of the complete framework.

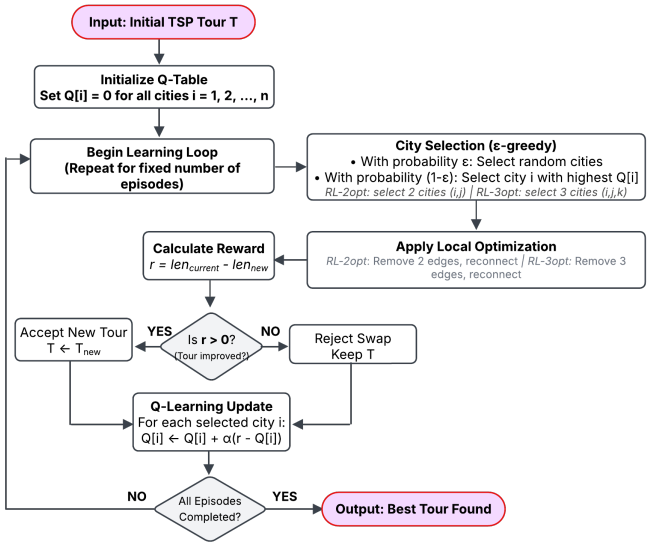

Fig. 1. Flowchart of the Q-learning guided local search framework.

Algorithm 4 RL-3opt Algorithm

Input: n: number of cities, d: distance matrix, T_{init}: initial tour, len_{init}: initial length, α: learning rate, ε: exploration rate, n_{episodes}: number of episodes
Output: T_{best}: best tour found, len_{best}: best length

function RL-3OPT($n, d, T_{\text{init}}, \text{len}_{\text{init}}, \alpha, \varepsilon, n_{\text{episodes}}$)
  $T_{\text{best}} \leftarrow T_{\text{init}}, \text{len}_{\text{best}} \leftarrow \text{len}_{\text{init}}$
  $Q \leftarrow \mathbf{0}_n$ ▷ Initialize Q-table
  for episode $= 1$ to n_{episodes} **do**
    Select cities (i, j, k) **using** ε**-greedy:**
    if random() $< \varepsilon$ **then** ▷ Exploration
      $i, j, k \leftarrow$ three random distinct cities
    else ▷ Exploitation
      $i \leftarrow \arg\max_c Q[c]$
      $j, k \leftarrow$ two random distinct cities with $j \neq i, k \neq i, j \neq k$
    end if
    $T_{\text{new}}, \text{len}_{\text{new}} \leftarrow$ Swap-3opt($T_{\text{best}}, d, \text{len}_{\text{best}}, i, j, k$)
    $r \leftarrow \text{len}_{\text{best}} - \text{len}_{\text{new}}$
    Update Q-values:
    for $c \in \{i, j, k\}$ **do**
      $Q[c] \leftarrow Q[c] + \alpha(r - Q[c])$
    end for
    if $r > 0$ **then** ▷ Accept improvement
      $T_{\text{best}} \leftarrow T_{\text{new}}, \text{len}_{\text{best}} \leftarrow \text{len}_{\text{new}}$
    end if
  end for
  return $T_{\text{best}}, \text{len}_{\text{best}}$
end function

IV. EXPERIMENTAL EVALUATION

This section presents the experimental protocol, parameter configuration, and comprehensive performance analysis of the proposed RL-guided local search framework.

A. Experimental Setup

a) Implementation and Hardware: All algorithms were implemented in C and executed on an HP laptop equipped with an Intel® Core™ i5-8265U CPU (1.6 GHz base frequency) and 16 GB of RAM. No parallelization or GPU acceleration was used, ensuring a fair comparison based on single-threaded performance.

b) Benchmark Instances: We evaluate our approach on 55 symmetric instances from the TSPLIB repository [11], ranging from 51 to 18,512 cities. All instances use the Euclidean distance metric (`EUC_2D`), ensuring consistency in distance calculations across experiments. Table II lists all tested instances with their optimal solutions.

c) Experimental Protocol: For each instance, the following three-stage workflow is applied:

1) Initialization: Generate an initial tour using the Nearest Neighbor (NN) heuristic starting from a randomly selected city.
2) Refinement: Apply RL-2opt or RL-3opt independently to improve the initial tour. Each RL algorithm is executed for 10,000 episodes.

3) Baseline Comparison: Evaluate against classical 2-opt and 3-opt local search using the same initial tour to ensure fair comparison.

To ensure statistical reliability, each RL algorithm is executed 20 independent runs per instance with different random seeds. We report the best solution across these runs, along with a variability metric (GAP%) defined as:

$$\text{GAP}\% = 100 \times \frac{\sqrt{\frac{1}{20}\sum_{i=1}^{20}(\text{len}_i - \overline{\text{len}})^2}}{\text{len}_{\min}}, \tag{13}$$

where len_i is the tour length in run i, $\overline{\text{len}}$ is the average length, and $\text{len}_{\min}$ is the best length observed. Lower GAP% values indicate more consistent performance across runs.

d) Hyperparameters: All RL experiments use fixed hyperparameters to ensure reproducibility: number of episodes $n_{\text{episodes}} = 10{,}000$, learning rate $\alpha = 0.1$, discount factor $\gamma = 0$ (immediate rewards only), and exploration rate $\varepsilon = 0.1$. These values remain constant across all instances.

e) Performance Metrics: We evaluate algorithms using three metrics:

- Solution Quality: Gap percentage from known optimal or best-known solutions:

$$\text{Gap}(\%) = \frac{\text{Solution} - \text{Optimal}}{\text{Optimal}} \times 100. \tag{14}$$

- Computational Time: Wall-clock execution time in seconds, excluding I/O operations.
- Stability: Variability across runs measured by GAP% as shown in Equation (13).

B. Results and Analysis

Table II presents comprehensive results for all 55 instances, including optimal values, tour lengths, computation times, and variability metrics for each method. Classical 3-opt becomes computationally impractical for the largest instances (indicated by —), requiring estimated days of computation time.

Before analyzing these results in detail, we contextualize our approach relative to existing TSP methods. Specialized solvers like LKH [17], [18] represent the state of the art for solution quality. We compared our approach with LKH version 3.0.6 (default parameters, run until convergence), which systematically produces the highest-quality solutions across all instances. However, execution time differences are particularly pronounced on large instances: while LKH systematically achieves the highest quality solutions through extensive computation (hours), our framework provides near-optimal results orders of magnitude faster (seconds). This confirms our positioning: our framework is not designed to replace specialized solvers like LKH, but rather to provide a practical, resource-efficient alternative under constrained computational conditions—suitable for real-time applications, standard hardware deployment, or batch processing of thousands of instances.

Other Q-learning approaches for TSP focus on tour construction by learning city selection policies, while our method addresses a fundamentally different problem: *improving* existing tours rather than *generating* tours from scratch. Classical Q-learning tour construction methods typically achieve gaps of 5–15%, while our improvement-focused approach delivers sub-1% gaps on small instances (≤ 100 cities). Direct experimental comparison is not included because these approaches operate in fundamentally different settings: construction methods learn sequential decisions from an empty tour, while our improvement approach starts from an existing solution and learns neighborhood restriction. Comparing final tour quality would conflate these distinct problem formulations (generation vs. refinement) and initial conditions rather than isolating the contribution of RL guidance itself.

We compare four local search improvement methods across all instances: classical 2-opt, classical 3-opt, RL-guided 2-opt (RL-2opt), and RL-guided 3-opt (RL-3opt). Classical 2-opt achieves an average optimality gap of 8.95% across all problem sizes, while classical 3-opt reduces this to 5.31% on instances where it is computationally feasible. RL-guided methods demonstrate size-dependent performance: For instances up to 1,000 cities, RL-3opt achieves exceptional quality with gaps of 0.9–2.2%, including near-optimal solutions on several instances (`rd100`: 0.00%, `kroA100`: 0.01%, `berlin52`: 0.03%), while RL-2opt maintains competitive gaps of 1.6–2.6%. For instances between 1,000–5,000 cities, performance degrades: RL-3opt achieves 6.3% gaps compared to 5.5% for classical 3-opt, while RL-2opt reaches 9.1% gaps comparable to classical 2-opt's 9.0%. Despite this quality trade-off in the 1,000–5,000 range, RL methods maintain substantial computational advantages with speedups exceeding 100× to 30,000×. For very large instances exceeding 5,000 cities, RL-3opt achieves 9.8% gaps while RL-2opt reaches 12.2%. In this range, RL-3opt matches classical 2-opt quality (both 9.8%) while executing orders of magnitude faster, though RL-2opt shows some quality degradation compared to classical methods.

Table III reveals systematic performance differences across improvement methods.For instances up to 1,000 cities, RL-3opt achieves 2-4× better gaps than classical 3-opt. However, for instances between 1,000-5,000 cities, classical 3-opt achieves slightly better quality (5.5% vs 6.3%) while RL-3opt maintains substantial computational advantages.

Fig. 2 illustrates these quality differences on five representative instances spanning different problem sizes. RL-3opt (dark blue) achieves near-optimal solutions, including exact optimality on `rd100`, while classical 2-opt (dark red) and classical 3-opt (light red) consistently show higher approximation ratios. RL-2opt (light blue) provides intermediate quality between classical and RL-3opt approaches.

Beyond quality, computational efficiency differs dramatically across methods. Classical 3-opt exhibits cubic scaling, becoming impractical beyond 1000 cities (requiring 16 minutes to over six hours for instances with 2,000–6,000 cities) and entirely infeasible for problems exceeding 10,000 cities. Classical 2-opt executes faster but still requires seconds for large instances. In contrast, RL-guided methods maintain near-linear scalability: instances up to 2,400 cities complete in under 0.25 seconds, up to 6,000 cities finish in under 1 second, and 18,512-city problems solve in under 4 seconds—yielding speedups over classical 3-opt ranging from 4,334× to 32,323×.

TABLE II. COMPREHENSIVE COMPARISON ON 55 TSPLIB INSTANCES. FOR EACH METHOD: BEST TOUR LENGTH AND RUNTIME (SECONDS). FOR RL METHODS: GAP% STABILITY METRIC OVER 20 RUNS. CLASSICAL 3-OPT BECOMES IMPRACTICAL (—) FOR THE LARGEST INSTANCES

TABLE III. AVERAGE OPTIMALITY GAPS (%) BY INSTANCE SIZE, COMPUTED AS GAP(%) = (SOLUTION - OPTIMAL) / OPTIMAL × 100

Size (cities)	N	2-opt	3-opt	RL-2opt	RL-3opt
≤ 100	(12)	8.7	3.8	1.6	**0.9**
100–1,000	(20)	9.0	4.3	2.6	**2.2**
1,000–5,000	(16)	9.0	5.5	9.1	**6.3**
$> 5{,}000$	(7)	9.8	—	12.2	**9.8**

The combined quality-time advantage varies by problem size: small instances ($\leq$100 cities) see RL-3opt achieving 4× better quality than 3-opt with comparable execution times, medium instances (100–1,000 cities) combine millisecond execution with 3× better quality than 3-opt, and large instances (1,000–5,000 cities) demonstrate RL-3opt transforming hours-long searches into sub-second optimizations with 2× quality improvement over 3-opt and 4× over 2-opt. Very large instances (>5,000 cities) remain infeasible for classical 3-opt while RL methods scale gracefully: RL-3opt matches classical 2-opt quality but executes orders of magnitude faster.

Fig. 3 visualizes these advantages. Panel (a) demonstrates RL methods scaling to 18,000+ cities in under 4 seconds, while classical 3-opt exhibits cubic growth. Panel (b) confirms Pareto dominance: classical 2-opt offers speed without quality (ratios 1.08–1.11), classical 3-opt offers better quality at prohibitive cost, while RL methods provide the fastest solution for any

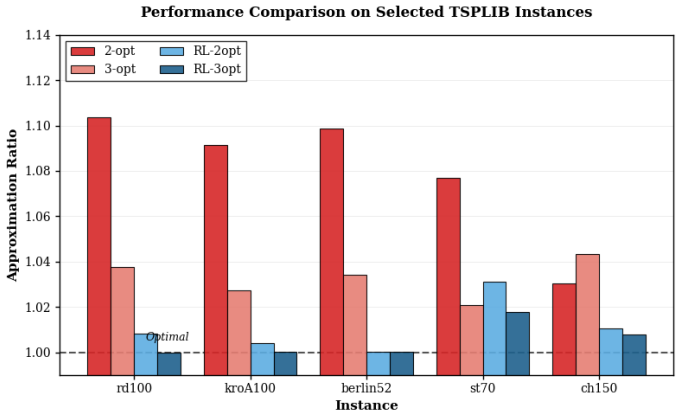

Fig. 2. Performance comparison on five representative instances. RL-3opt (dark blue) achieves near-optimal solutions including exact optimality on `rd100`. RL-2opt (light blue) provides intermediate quality. Classical methods (red) show significantly higher approximation ratios.

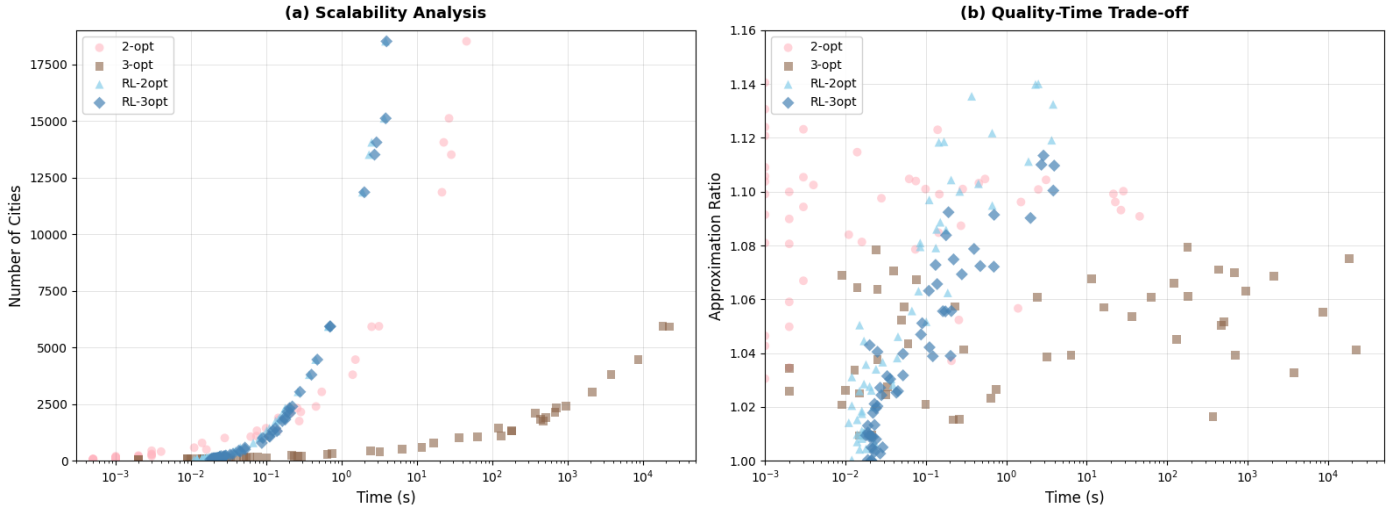

Fig. 3. Computational performance on 55 TSPLIB instances. (a) RL methods maintain near-linear scaling while classical 3-opt exhibits cubic explosion. (b) RL methods dominate the Pareto frontier with approximation ratios of 1.01–1.12 and execution times under 5 seconds.

desired quality level.

To assess robustness, we measured variability across 20 independent runs using the GAP% stability metric (Equation 13). Both RL methods demonstrate excellent stability with GAP% values of 0.1–1.0%. Best cases include `eil51` (0.09%), `usa13509` (0.14–0.15%), and `brd14051` (0.11–0.18%), confirming reliable Q-learning convergence suitable for production deployment.

C. Discussion

Our results demonstrate that a simple one-dimensional Q-table can effectively guide local search for TSP, but with clear limitations tied to problem size. The approach works well because it learns which cities are poorly positioned during optimization and focuses computational effort there. On instances up to 1,000 cities, this adaptive strategy produces solutions 2–4× better than classical 3-opt while running much faster. The Q-values act as a priority signal, directing the algorithm toward tour segments most likely to benefit from modification.

Performance declines on larger instances because the learning signal becomes weaker. With 10,000 fixed episodes, each city receives less attention as n grows, making it harder to identify and fix problematic regions. This reveals the core trade-off of our design: we sacrificed representational power (one-dimensional Q-table instead of multi-dimensional) to gain computational efficiency and simplicity. Methods like Reinforced LKH [35] maintain quality on large problems through richer state representations, while neural approaches [31], [10] learn powerful policies but require extensive training on GPUs. Our framework sits between these extremes—it learns during optimization rather than through offline training, making it accessible but limiting its ability to handle very large instances.

The dramatic speedups (401–32,323×) come from a fundamental algorithmic change: sampling a constant number of moves instead of exhaustively examining all $O(n^3)$ possibilities. This matters practically. A logistics company optimizing 500 delivery routes can complete the task in seconds rather than minutes, enabling real-time adjustments as conditions change. For applications where speed and accessibility matter

more than guaranteed optimality, this framework offers a compelling option. However, the 6.3% gap on medium instances (1,000–5,000 cities) versus 5.5% for classical 3-opt shows there are situations where the extra computation time is worth it.

The broader contribution is accessibility. Running on standard CPUs without hyperparameter tuning makes high-quality TSP optimization available to organizations without specialized computing infrastructure. This democratization matters for small businesses, educational institutions, and resource-constrained environments.

V. Conclusion

This paper introduced a Q-learning-guided local search framework that addresses neighborhood explosion in classical TSP methods by learning city-specific Q-values to guide exploration toward promising moves. The approach transforms $O(n^3)$ 3-opt complexity into practical sub-second optimization.

Experimental evaluation on 55 TSPLIB instances demonstrates size-dependent performance characteristics. For instances up to 1,000 cities, RL-3opt achieves 0.9–2.2% optimality gaps compared to 3.8–4.3% for classical 3-opt, with speedups exceeding 1,000×. For instances between 1,000–5,000 cities, classical 3-opt achieves better quality (5.5% vs 6.3%), but RL-3opt maintains practical efficiency with speedups reaching 32,323× and sub-second execution. For instances exceeding 5,000 cities, RL-3opt achieves 9.8% gaps matching classical 2-opt quality while executing orders of magnitude faster. Classical 3-opt becomes computationally infeasible beyond 1,000 cities.

By delivering near-optimal solutions on small instances and competitive solutions on large instances using standard CPU hardware without GPU acceleration, this framework democratizes access to effective TSP optimization. The combination of sub-second to few-second execution across all problem sizes, minimal configuration requirements, and favorable quality-time trade-offs makes RL-guided local search a practical alternative for real-world logistics, manufacturing, and routing applications where both solution quality and computational efficiency matter.

Future work will focus on implementing dynamic episode scaling and adaptive learning rates to improve performance on large instances, and extending the framework to related combinatorial problems including Vehicle Routing and Job Shop Scheduling.

***Abstract*—In recent years, as a critical pillar supporting the national economy and daily life, the safe and efficient operation of road traffic has highly relied on precise environmental perception capabilities. To address this, this study proposes a two-stage "denoising-detection" framework: the first stage restores clear images using an improved Uformer algorithm, which fundamentally merges a probabilistic sparse self-attention mechanism. In contrast, the second stage leverages YOLOv11 for real-time object detection. This framework is introduced in the field for the first time and enhances the accuracy and robustness of vehicle detection in traffic images under complex weather scenarios, providing technical support for intelligent driving systems and traffic monitoring applications. Our experimental validation on our own flexible weather car detection database demonstrated the superior performance of the proposed model: CM-YOLO achieved 0.95 precision and 0.91 mAP50, which promoted 0.2 than the YOLOv11.**

***Keywords*—Object detection; vehicle detection; image denoising**

I. Introduction

In recent years, highway transportation has become an important support for the national economy and daily life, and its safe and efficient operation highly relies on accurate environmental perception capabilities. However, severe weather can significantly reduce the quality of traffic images, seriously affecting the performance of object detection algorithms and increasing the risk of traffic accidents. According to statistics, the incidence of traffic accidents under complex weather conditions is 3-5 times higher than that under normal weather conditions[1]. Traditional object detection algorithms face two core problems in foggy scenes. On the one hand, complex weather scenes lead to blurry image features and reduced contrast between the target and background. On the other hand, the integration between existing denoising algorithms and detection models is insufficient, making it difficult to balance denoising effectiveness and detection efficiency. However, in recent years, transformer-based computer vision algorithms have provided new directions for image denoising and object detection by leveraging the advantages of the self-attention mechanism in global information capture. Therefore, this study proposes a two-stage framework of "denoising detection", in which the first stage restores clear images through an improved Uformer algorithm, and the second stage uses YOLOv11 to achieve real-time object detection, aiming to improve the accuracy and robustness of traffic vehicle detection in complex weather scenes and provide technical support for traffic monitoring systems.

*Corresponding author.

Image denoising algorithms can be divided into traditional methods and deep learning methods. Traditional methods, represented by dark channel prior (DCP) [2], estimate transmittance and atmospheric light through physical models, but edge distortion is prone to occur in complex scenes. In deep learning based methods, convolutional neural network (CNN) models such as AOD Net [3] and DehazeNet [4] achieve denoising through end-to-end learning, but are limited by local receptive fields and difficult to capture global complex noise distribution patterns. In recent years, transformer-based denoising algorithms have become a research hotspot. The Uformer model[5] integrates Transformer and U-Net structures, captures long-range dependencies through self self-attention mechanism, and performs well in denoising and other tasks. However, the traditional Uformer's window self-attention mechanism has the problem of high computational complexity, which limits its application in real-time scenes.

Object detection algorithms can be divided into two stages such as Faster R-CNN and single-stage, such as YOLO method [6]. YOLOv11, as the latest single-stage algorithm, achieves high-precision detection while maintaining real-time performance through anchor-free design and a feature fusion mechanism. However, YOLOv8 lacks the ability to recognize blurry targets in low-quality images and needs to be combined with dehazing preprocessing to improve performance. Moreover, existing joint frameworks often adopt a "denoising+detection" serial structure, and there are still shortcomings in the collaborative optimization of dehazing and detection modules. Based on this, this study improves the attention mechanism of Uformer and deeply combines it with YOLOv11 to achieve efficient object detection in complex sky scenes.

In addition, in the field of image restoration, many related studies have provided ideas for enhancing complex weather scene images, such as the application of enhanced deep residual networks in super-resolution tasks [7], the hierarchical visual Transformer design of Swin Transformer [8], and the exploration of spatial attention mechanisms [9] and model-driven deep neural networks [10] in complex weather denoising tasks. At the same time, the solution to specific image restoration tasks, such as removing patterns [11], also provides a reference for processing complex foggy scenes. In terms of model optimization, techniques such as decoupling weight decay regularization [12] and dual residual networks [13] provide effective means to improve the performance and stability of denoising and detection models.

To address vehicle detection in complex traffic scene images, this paper proposes a system framework named CM-YOLO, which autonomously denoises and analyzes complex

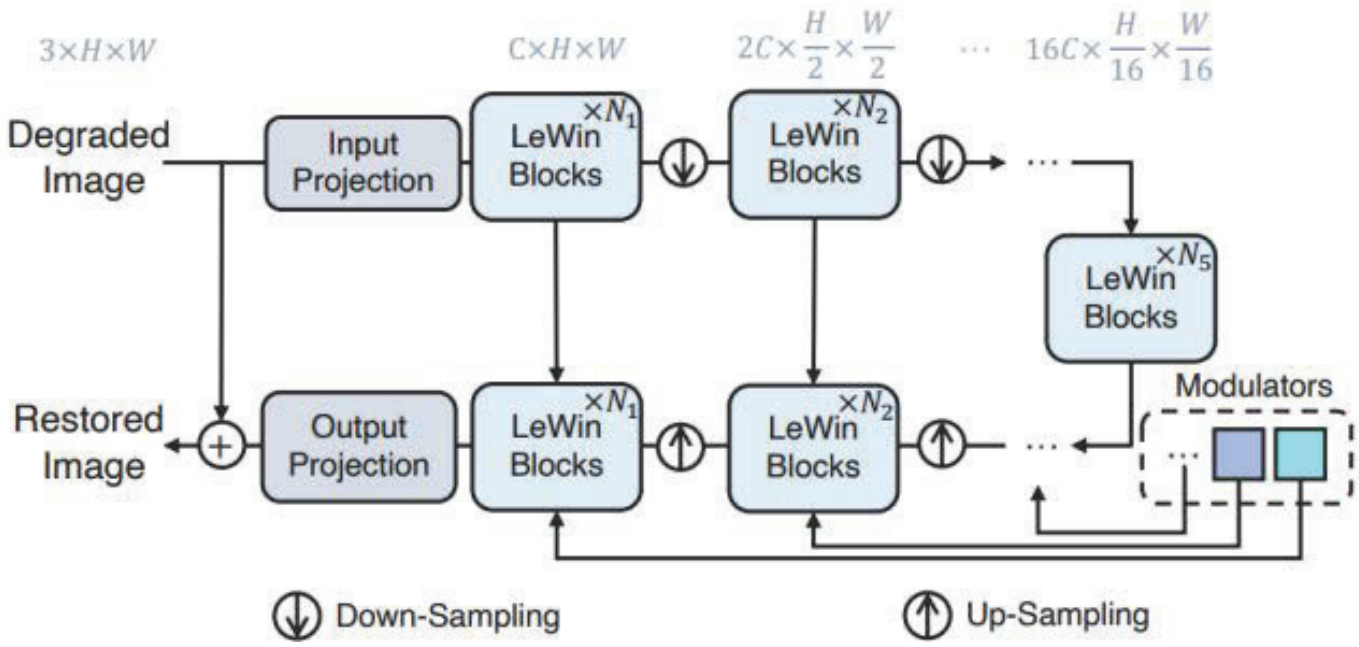

Fig. 1. Schematic of the Uformer.

scene information within images. Owing to the dual requirements of accuracy and real-time performance imposed by dispatch centers for traffic flow regulation, the target detection algorithm must maintain high detection accuracy while completing tasks with high efficiency. In this framework, all module is trained separately. The image will first be denoised by the improved Uformer algorithm to simplify image scenes, and then use the YOLOv11 algorithm as the recognition module to perform target detection on the simplified images. This cascaded architecture effectively achieves target detection in complex traffic scene images.

A. Denoising Module

To address the challenges of vehicle detection in complex traffic image scenarios with variable weather conditions on highways, this paper employs the Uformer model as the denoising module of CM-YOLO. This algorithm, as shown in Fig. 1, rooted in a Transformer-based architecture, integrates the classic U-Net structure, enabling high-quality execution of diverse image denoising tasks such as noise reduction, deblurring, and defogging. Notably, Uformer excels at capturing long-range dependencies within images, making it particularly well-suited for processing high-resolution images. By balancing restoration quality with computational efficiency, it effectively reduces computational complexity while maintaining high-quality image recovery, thus addressing the dual requirements of accuracy and real-time performance in traffic flow regulation scenarios.

Meanwhile, given the characteristics of terminal devices with limited memory and slow computing speeds, it is imperative to reduce the complexity of Uformer. To address this, this paper replaces the window-based multi-head self-attention mechanism used in traditional Uformer with a probabilistic sparse self-attention mechanism.

In the probabilistic sparse self-attention mechanism, each self-attention operation defines attention through a query sparsity measurement based on

$$q_i(K,V) = \sum_{j=1} \frac{k(q_i,k_j)}{\sum_{l=1} k(q_i,k_l)} v_j = E_p(k_j|q_i)[V_j] \quad (1)$$

In the probabilistic sparse self-attention mechanism[14], the attention of the i-th feature over all values is defined as a probability $p(k_j|q_i)$, and the output is generated by k combining this probability with the corresponding value v. If $p(k_j|q_i)$ approaches a uniform distribution

$$q(k_j,q_i) = \frac{1}{L_K} \quad (2)$$

Self-attention then degenerates into the summation of value V, becoming repetitive with other fixed inputs. Therefore, the similarity between two distributions p and q can be used to distinguish the importance of queries. The probabilistic sparse self-attention mechanism measures the similarity between these two distributions using the Kullback-Leibler divergence.

$$KL(q||p) = ln \sum_{l=1}^{L_K} e^{\frac{q_i k_l^t}{\sqrt{d}}} - \frac{1}{L_K} \sum_{j=1}^{L_K} \frac{q_i k_l^t}{\sqrt{d}} \quad (3)$$

Here, the first term represents the average of the log-sum-exp over all features, and the second term denotes their arithmetic mean. If the i-th query obtains a larger $M(q_i,K)$ its attention probability becomes more diverse, increasing the likelihood of including key head-field pairs in the head-tail self-attention distribution that determines the output.

Based on the proposed measurement method, the probabilistic sparse self-attention mechanism ensures each feature

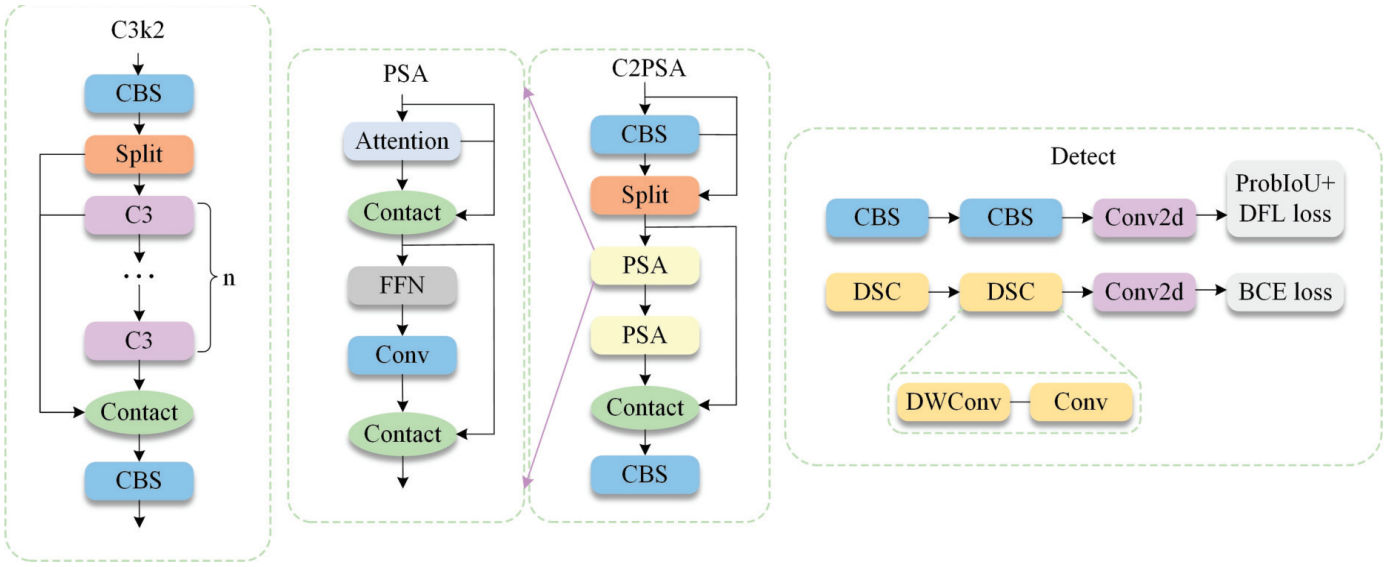

Fig. 2. The detection module structure.

only attends to u key queries:

$$A(Q,K,V) = Softmax(\frac{\overline{Q}K^T}{\sqrt{d}})V \tag{4}$$

Here, Q denotes a sparse matrix of the same size as q, containing only the $M(q,K)$ most critical queries under the sparsity measure u.

By utilizing this strategy, the space and time complexity ultimately approximates to $O(LlnL)$. and the Table I shows the superiority of this self-attention mechanism.

TABLE I. COMPARISON OF ROAD DAMAGE DETECTION RESULTS FOR VARIOUS MODEL SETS

method	time complexity	space complexity	runtime	memory
window-based self-attention	$O(L_K L_Q)$	$O(L_K L_Q)$	3.01ms	15.60GB
probabilistic sparse self-attention	$O(L_K lnL_Q)$	$O(L_K lnL_Q)$	2.57ms	11.35GB

B. Detection Module

To ensure efficient processing of simplified images, the model proposed in this paper employs the YOLOv11 algorithm as shown in Fig. 2 for vehicle recognition. Compared to traditional object detection algorithms such as R-CNN and its variants (e.g., Fast R-CNN, Faster R-CNN), the most significant advantage of YOLOv11 lies in its processing speed. The R-CNN series first generates region proposals and then classifies each region individually. Although this two-stage process achieves superior accuracy, its slower speed renders it unsuitable for real-time applications. In contrast, the holistic architectural design of YOLOv11 enables it to execute detection tasks at extremely high speeds, thereby meeting the rapid detection requirements of dispatch centers in this vehicle recognition task.

II. RESULTS

A. Datasets

In this study, the I-HAZE[15] and NH-Haze[16][17] were used to train the Denoising module and test on SPAD[18] for denoising. The train image samples were shown as Fig. 3. The BITVehicle dataset cite dongVehicleTypeClassification2015 was used to train the detection module. For efficient validation of our model, we built our own flexible weather car detection database, which has 6789 pictures with 17355 annotations. The Denoising module and the Detection module were trained separately, but detected sequentially; the undetected image will first utilize the improved Uformer module to denoise and use YOLOv11 to detect.

B. Evaluation Metrics

To rigorously validate the performance of CM-YOLO in multi-scale pavement crack detection, we adopted the following metrics aligned with real-time detection challenges:

The peak signal-to-noise ratio (PSNR) is an objective metric that quantifies the quality of a reconstructed image by measuring the ratio of the maximum possible pixel intensity to the noise power. It is widely used in image processing and compression tasks.

$$MSE = \frac{1}{MN}\sum_{i=0}^{M-1}\sum_{j=0}^{N-1}[I(i,j) - K(i,j)]^2 \tag{5}$$

where I represents the original image, K represents the processed image, M and N are the dimensions of the image.

$$PSNR = 10log_{10}\frac{MAX_I^2}{MSE} \tag{6}$$

Fig. 3. Samples of I-HAZE and NH-Haze database.

Fig. 4. Samples of BITVehicle database.

where MAX is the maximum pixel value.

SSIM evaluates the similarity between two images by analyzing structural, luminance, and contrast information, mimicking human visual perception.

Precision (P) measures the proportion of correct crack predictions among all detected regions and is critical for reducing false alarms in crack detection.

$$Precision = \frac{TP}{TP + FP} \tag{7}$$

where TP (true positive) denotes predicted boxes with $IoU \geq 0.5$ and correct class labels, and FP (false positive) indicates spurious detection.

Recall(R) evaluates the model's ability to capture all genuine cracks, which is essential for avoiding missed defects in safety-critical scenarios.

$$Recall = \frac{TP}{TP + FP} \tag{8}$$

where FN (false negatives) represent undetected ground-truth cracks ($IoU \leq 0.5$)

The average precision (AP) quantifies the model's category-specific detection consistency by computing the mean of the maximum precision values achieved across varying recall rates. The mean average precision (mAP) extends this evaluation by averaging AP scores across all object classes, thereby serving as a comprehensive metric for the model's cross-category detection performance. The mathematical formulation is

$$AP = \int_0^1 P(r)\, dr \tag{9}$$

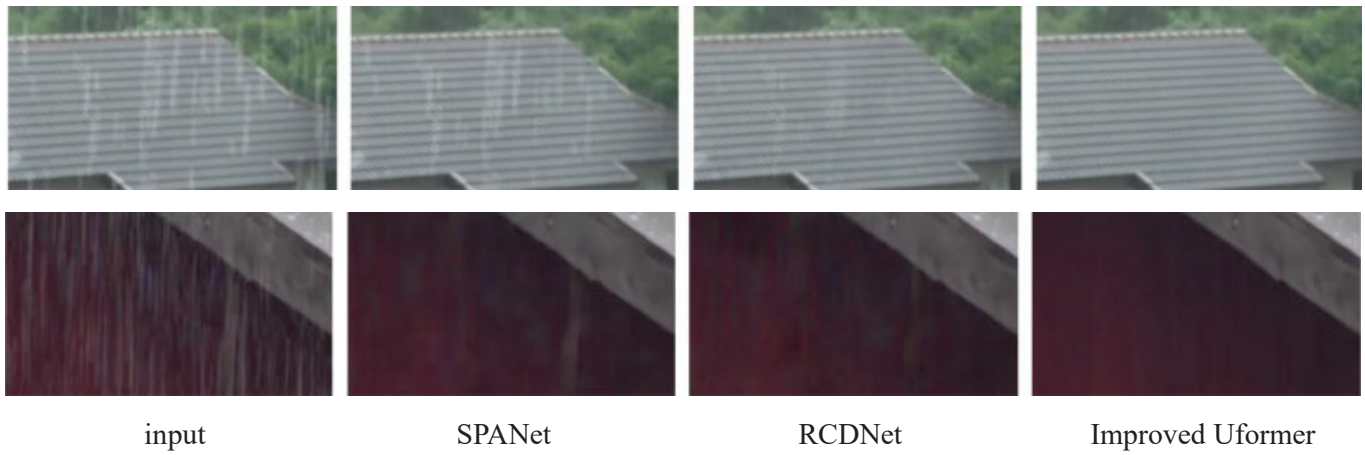

Fig. 5. Comparison of denoising results in SPAD database.

$$mAP = \frac{\sum_{i=1}^{C} AP\,(i)}{C} \tag{10}$$

Here, C is the number of crack subtypes.

C. Experimental Environment

The experimental framework in this study was implemented on a high-performance computing system running Ubuntu 11.04 as the operating system. The hardware setup included an Intel® Xeon® Platinum 8474C processor and an NVIDIA RTX 4090D graphics card with 24 GB of video memory, ensuring efficient computation for deep-learning tasks. The software environment was built using PyTorch 2.0.1, Python 3.10.8, and CUDA 11.8, which provided a robust foundation for model training and evaluation. The key hyperparameters were carefully tuned to optimize performance: The input images were resized to a resolution of 640 × 640 pixels, the initial learning rate was set to 0.0001, and the momentum for the learning rate was configured at 0.9. This combination of hardware, software, and Adaptive Moments with Weight Decay (AdamW) optimizer was used for training. These parameter settings ensured a stable and efficient training process for the proposed model.

D. Experimental Implementation and Results

1) Comparison of denosing results: This paper employs the improved Uformer algorithm for training on the I-HAZE data set and testing on the SPAD dataset. By analysing the PSNR and SSIM metrics of the improved Uformer algorithm, SPANet and RCDNet models, as Table II, which were tested by SPAD, and Fig. 5 shows that the improved Uformer algorithm can effectively restore images while retaining image features, with less noise, good denoising performance and small memory usage.

2) Ablation experiment results: To comprehensively assess the superiority of the denoising module, we primarily use three evaluation metrics: mAP50, recall, and precision. These metrics are compared against the baseline to validate the performance of the denoising module.

TABLE II. COMPARISON OF DENOSING RESULTS IN SPAD DATABASE

method	PSNR	SSIM	runtime(per image)	memory
SPANet	40.24	0.9811	-	-
RCDNet	41.47	0.9834	-	-
Uformer	47.92	0.9928	3.01ms	15.60GB
Ours	47.84	0.9925	2.57ms	11.35GB

TABLE III. COMPARISON OF DETECTION RESULTS FOR VARIOUS MODEL SETS IN OUR DATABASE

method	Denoising Model	P	R	mPA50
YOLOv11		0.93	0.86	0.89
	✓	0.95	0.88	0.91

As Table III , the results demonstrate that the introduced denoising model has positively affected model performance.

3) Comparison of results: To comprehensively assess the performance of the CM-YOLO model, we primarily use three evaluation metrics: mAP50, recall, and precision. These metrics are compared against YOLOv11 and YOLOv8 models to validate the effectiveness of our multi-modal fusion approach.

TABLE IV. COMPARISON OF DETECTION RESULTS IN OUR DATABASE

method	P	R	mAP50
YOLOv8n	0.90	0.84	0.88
RT-DETR(resnet18)	0.92	0.88	0.86
YOLOv11n	0.93	0.86	0.89
Ours	0.95	0.88	0.91

As the Table IV and Fig. 6 show that the proposed CM-YOLO algorithm demonstrates superior detection performance, achieving $P = 0.95$ and $mAP50 = 0.91$, outperforming YOLOv8n, RT-DETR(resnet18), and YOLOv11n. This advancement enables precise detection of vehicle models in complex weather scenarios, including rain, snow, and fog, where traditional models struggle due to noise interference and reduced visibility.

Fig. 6. Comparison of detection figures in our database.

III. Conclusion

CM-YOLO demonstrates strong adaptability to the complex scenario requirements of real-world traffic conditions, enabling effective image object detection tasks in challenging weather-related traffic environments. By fully leveraging the respective strengths of the Transformer model and the YOLOv11n model, it enhances the performance and efficacy of vehicle model detection in complex scenarios. However, practical applications of this algorithm still face certain limitations. Specifically, its object detection workflow requires parallel execution of two algorithms, imposing higher computational performance demands compared to standalone algorithms. In real-world deployments, its performance is constrained by the processing capabilities of vehicle systems.

For future research on such vehicle detection algorithms, the following directions warrant further exploration:

(1) Model optimization to accelerate detection speed: Current Uformer algorithms-even the version used in this study with probabilistic sparse self-attention mechanisms-exhibit larger parameter counts compared to previous de-fogging models, despite superior de-fogging performance. Continued optimization of model parameters is necessary.

(2) Algorithm/training strategy refinement for stability and accuracy: While the algorithm achieves competitive accuracy on normal scene images, there remains room for improvement. Iterative upgrades to the algorithm are needed. Additionally, scenario-specific data and training strategies should be prioritized. For example, pre-training the model on a dedicated dataset, adjusting pre-trained weights, and fine-tuning on downstream tasks could further enhance performance.

(3) Joint training of detection and de-noising algorithms: Collecting paired normal and complex weather traffic images under the same scenarios, followed by annotation, would enable pre-trained detection and de-noising models to be fine-tuned on this dataset.

In summary, the Transformer-based foggy weather traffic video object detection algorithm still has significant room for development. Ongoing research is essential to continuously improve detection speed, accuracy, and robustness in real-world applications.

Declarations

- Competing interests
  The authors declare that they have no known competing financial interests or personal relationships that could have appeared to influence the work reported in this paper.
- Ethics approval and consent to participate
  We promise that this manuscript will not be submitted to multiple journals or conferences simultaneously. We promise to abide by ethical standards, respect the autonomy of participants in the use of data, and ensure the legal, transparent, and secure use of data.
- Data availability
  Data will be made available on request.
- Author contribution
  Xingju Wang and Yiqian Liang designed the new method, Yiqian Liang and Zhihui Huo provided suggestions and analyzed the results. Yiqian Liang and Zhihui Huo wrote the manuscript.Yiqian Liang and Xingju Wang reviewed and edited this manuscript. All authors contributed to this work and approved the submitted version.

***Abstract*—In educational settings, charts and graphs are commonly used to convey complex information in a simple and understandable manner. However, these visual representations often present accessibility challenges regarding Accessibility for Visually Impaired users, as they cannot be directly interpreted by screen readers without proper alternative text. This paper proposes a novel hierarchical captioning model (HCC: Hierarchical Chart Captioning) designed to facilitate effective Chart Interpretation. The model utilizes spatial token features to generate captions at multiple levels, each offering varying degrees of detail and abstraction, mimicking human cognitive processing. Three hierarchical levels are developed: *Level 1* offers basic and factual descriptions, *Level 2* presents more detailed information, and *Level 3* provides intuitive interpretations and inferences. By integrating a fine-tuned Transformer Models, this approach ensures efficient caption generation and supports user-selectable caption lengths. The model's effectiveness is evaluated through user surveys involving 20 instructors, confirming that Level 2 captions provide the most comprehensible descriptions. Experimental results demonstrate that the proposed method outperforms existing captioning approaches, improving both the efficiency and accessibility of educational materials for visually impaired students. These findings highlight the potential of hierarchical learning models to create more inclusive and accessible educational experiences.**

***Keywords*—Hierarchical captioning; accessibility for visually impaired; chart interpretation; transformer models**

I. Introduction

Various chart materials, including graphs, are used in educational curricula. These charts and graphs are presented in a visual format and are an effective means of conveying complex information in a simple and understandable way. However, materials presented in visual form cannot be directly conveyed to individuals with visual impairments, as they are transmitted in text form through services such as screen readers [1], [2]. For visually impaired learners, the inability to directly perceive these visual materials not only limits their comprehension during lessons but also creates a persistent accessibility gap in real-world educational settings, reducing their opportunities for equal participation and achievement.

First, screen readers deliver content composed of text and images to people with visual impairments in an audio form. For graphs and charts, typically provided as images, instructors or content creators must manually input alternative text. Without it, visually impaired users cannot access the image content [3], [4].

Second, in most classes, when graphs or charts appear in lecture materials, instructors often assume that students have already perceived the visual information from the chart and focus on explaining its features. As a result, visually impaired students, lacking basic information about the chart, must rely solely on the instructor's spoken explanation, which limits the completeness of information they receive.

Third, this situation creates additional challenges for instructors when preparing lecture materials, as they must manually provide explanations for every graph and chart. The laborious task of setting alternative text often leads to omissions, resulting in images with insufficient descriptions.

The visually impaired learners, thus, struggle to access information through visual materials, and lack equal educational opportunities compared to other learners. The need to interpret images such as charts used in educational materials is critical to improving the quality of education for people with disabilities. While charts and graphs help to deliver and understand information quickly, for individuals with disabilities, accessing data in this visual form may be restricted. Therefore, research that helps individuals with disabilities easily access and interpret chart and graph information carries significant social value and meaning. To achieve this, this paper proposes a new methodology for generating image descriptions for individuals with disabilities. The approach leverages the spatial features of tokens—small image patches extracted from the chart that preserve both their content and position within the overall layout. By analyzing these tokens not only for their visual appearance but also for their location and relative arrangement, our method captures the structural context of the chart, which is essential for generating accurate and context-aware descriptions across multiple layers. This approach leverages hierarchical structures divided into four layers based on principles of human cognitive processing—progressing from basic visual perception to higher-level abstraction. Each layer corresponds to a distinct stage in how humans interpret visual information: 1) recognizing simple visual elements, 2) identifying relationships between elements, 3) summarizing overall patterns or trends, and 4) inferring contextual or conceptual meaning. Captions at each level vary in length and detail to align with different user needs and preferences. This method is referred to as

HCC: Hierarchical **C**hart **C**aptioning, highlighting its focus on providing multi-level descriptions that enhance accessibility for visually impaired users.

For individuals with visual impairments who receive all information through auditory means, only intuitive and concise information will be provided to facilitate their understanding of sound-based data [22]. Existing research on caption generation for charts and graphs primarily focuses on the accuracy of the generated captions, typically evaluated by measuring the similarity between human-generated and machine-generated captions. For instance, models such as PReFIL [12] and MATCHA [18] emphasize improving caption accuracy ... without explicitly addressing varying user needs or accessibility for visually impaired users. **The main contributions of this work are as follows:** 1) This study proposes a hierarchical captioning framework that generates captions at multiple levels of detail, enabling user-selectable descriptions tailored for accessibility needs. 2) Principles of hierarchical human cognition are integrated into caption generation, producing captions that balance factual accuracy and interpretability. 3) A user-centered evaluation is conducted to determine the most effective caption level for visually impaired users. Unlike prior works that produce a single, static caption optimized for text-similarity metrics, the proposed method introduces a multi-level captioning framework designed specifically for accessibility. This approach enables users—especially those with visual impairments—to select captions that balance factual accuracy and interpretability according to their needs, an aspect largely overlooked in existing chart captioning research. The novelty lies in integrating hierarchical human cognition principles into caption generation, coupled with a user-centered evaluation to determine the most effective caption level. The primary goal of this study is to develop a hierarchical chart captioning model (HCC) that enhances accessibility for visually impaired users by providing multi-level, user-selectable captions that balance factual accuracy with interpretability. This approach allows for the exploration of the optimal level and length for caption generation for chart images.

Unlike prior works that produce a single, static caption optimized for text-similarity metrics, our method introduces a multi-level captioning framework designed specifically for accessibility. This framework enables users—especially those with visual impairments—to select captions that balance factual accuracy and interpretability according to their needs, an aspect largely overlooked in existing chart captioning research. The novelty lies in integrating hierarchical human cognition principles into caption generation, coupled with a user-centered evaluation to determine the most effective caption level. The primary goal of this study is to develop a hierarchical chart captioning model (HCC) that enhances accessibility for visually impaired users by providing multi-level, user-selectable captions that balance factual accuracy with interpretability.

II. Related Research

A. Image Captioning Datasets

Datasets related to chart image interpretation and captioning have expanded from Question-Answering datasets [5], [6] to Image-caption pair datasets [7], [8]. Compared to large-scale natural language processing datasets [9], [10], the number of image captioning-related datasets is relatively small, limiting the use of large datasets like Transformer models [11]. PReFIL [12] has been proposed as a solution for Question-Answering data and has become a mainstream model for chart explanations. However, issues such as the complexity of Question-Answering data remain unresolved. Most natural language processing models primarily utilize the powerful capabilities of Transformers. These efforts have led to the successful integration with Large Language Models (LLMs) [13], [14], but practical applications of chart explanation models still focus mainly on their relation to labels. To build an effective caption generation model for charts, an approach based on human cognition is needed to facilitate smooth information delivery. Additionally, while image-based data should be factually accurate, overly narrow information delivery should be avoided.

B. Attention Mechanism for Natural Language Process

The attention mechanism primarily works through three components: K (key), V (value), and Q (query). Its main goal is to recognize information related to the input data and understand dependencies within sequences. This attention mechanism is used in various artificial intelligence (AI) models, primarily in encoder-decoder architectures. For example, GPT (Generative Pre-trained Transformer) [15], which is based on a decoder structure, utilizes attention mechanisms to perform unidirectional learning. This model calculates attention for input sequences and generates subsequent words. In contrast, BERT (Bidirectional Encoder Representations from Transformers) [16], based on an encoder structure, performs bidirectional learning by applying attention to both directions of the input sequence to understand context and learn effective representations. These models use the attention mechanism to dynamically detect and process relevant information in its input data, demonstrating excellent performance in natural language processing and other AI tasks.

C. Deep Learning-based Image Captioning Models

Image captioning has drawn significant attention with the advancement of deep learning techniques. Models that generate captions for images combine visual feature extraction and natural language processing. The most commonly used deep learning-based image captioning models are those that combine Convolutional Neural Network (CNN) and Recurrent Neural Network (RNN) architectures. CNN models such as VGG [26] and ResNet [27] extract visual features from images, which are then used as input for natural language generation models. After obtaining the visual features of the image, an RNN-based model generates sentences, and model performance is evaluated using automatic metrics (such as BLEU [24], METEOR [25]) and human evaluation. Deep learning-based image captioning models learn meaningful relationships between images and text and are utilized to generate descriptions for images. However, most existing caption generation models focus on creating captions at a single level by considering the overall context of the image. However, people's perception and information processing involve multiple stages of abstraction, gradually moving from detailed information to higher-level concepts [19].

Recent large-scale vision-language models, such as BLIP [29] and DePlot [30], have achieved state-of-the-art performance in general image captioning and chart-to-table translation. These models primarily focus on maximizing data extraction accuracy and reasoning capabilities, often treating chart captioning as a "one-shot" generation task optimized for text-similarity metrics (e.g., BLEU, CIDEr). However, from an accessibility perspective, these approaches exhibit a critical limitation: they produce a single, static output that fails to account for the cognitive constraints of visually impaired users receiving information via audio.

In an auditory environment, presenting a lengthy, unstructured description generated by these models can induce cognitive overload, making it difficult for users to grasp the overall context before diving into details. Unlike these general-purpose models, the HCC model is fundamentally distinct in its architectural assumption and task formulation. Chart captioning redefined not as a static translation task but as a user-centric, hierarchical scaffolding process. By explicitly modeling human cognitive stages—from fragmented perception to concrete interpretation—HCC offers variable-level captions that allow users to control the granularity of information. This "accessibility-first" design ensures that the generated captions are not just factually accurate, but also cognitively digestible for screen reader users, addressing a dimension of usability that standard vision-language models overlook.

III. Hierarchical Chart Caption Generation Model

A. Model Design for Hierarchical Chart Extraction

The goal of this section is to present the design and methodology of our proposed Hierarchical Chart Captioning (HCC) model, which generates multi-level captions for chart images to enhance accessibility for visually impaired users.In this work, the term hierarchical captions refers to a structured set of captions describing the same chart image at multiple levels of detail and abstraction, where lower levels focus on basic, factual elements and higher levels provide progressively richer, more interpretive information. The dataset and model architecture used for hierarchical caption extraction are first outlined, followed by the strategy for generating captions at varying levels of detail. This study is guided by the following research question: *"Can a transformer-based captioning model, when fine-tuned to generate descriptions at multiple hierarchical levels, improve the comprehensibility and accessibility of chart data for visually impaired users compared to single-level captioning approaches?"* The working hypothesis is that generating captions across multiple levels—aligned with human cognitive processing—will provide flexibility for different user needs while preserving factual accuracy and enhancing interpretability.

This study develops a model that generates hierarchical captions for chart images based on the LineCAP dataset [28]. The dataset is a comprehensive collection of annotated line chart images designed to enhance automatic chart analysis and processing in the fields of computer vision and machine learning. It includes various types of line charts with annotations for chart type, labels, axes, and data points, which can be used to extract hierarchical captions. For training the proposed model, pre-existing multi-level captions in the dataset were not relied upon; instead, three separate training subsets—one for each hierarchical level—were constructed by programmatically transforming the original LineCAP annotations. Specifically, Level 1 captions were generated by extracting only the most basic factual elements from the annotations (e.g., axis labels, line identifiers), Level 2 captions incorporated more detailed relationships and trends between elements, and Level 3 captions added shallow inferential statements derived from the annotated data. These level-specific subsets were then used to fine-tune the model in a multi-task learning setup, where each input chart image was paired with three corresponding captions, one per level. Fig. 1 shows the structure of the hierarchical caption generation model based on the Transformer architecture.

This model uses the attention mechanism to focus on the features of the chart image and generate captions focused on three different types, allowing for hierarchical caption generation. The hierarchical generation of captions in this study was achieved by fine-tuning the T5 model [17], a large-scale, multi-purpose pre-trained text-to-text Transformer, with sequence lengths limited to 16, 32, and 64 tokens. These lengths were chosen to balance accessibility for visually impaired users—avoiding overly long captions that hinder auditory processing and overly short captions that omit key details—with empirical stability observed during preliminary experiments. The T5-base configuration was utilized, which contains 12 layers in the encoder and 12 layers in the decoder, each with a hidden size of 768 and 12 attention heads. The base architecture was preserved, but the input embedding layer was modified to accept spatial token features from the chart image encoder instead of standard text embeddings, and the output projection layer was adjusted to generate captions at three predefined sequence lengths corresponding to the hierarchical levels. No other structural changes were made to the Transformer blocks.

Other lengths such as 24 and 48 tokens were also tested, but they provided no significant improvement in comprehension or training stability, leading to the adoption of the 16–32–64 configuration. Multiple experiments were conducted to explore the optimal setup, starting with an initial learning rate of 3e-5, weight decay of 0.01, batch size of 32, and gradient clipping at a maximum norm of 1.0. Hyperparameters were tuned through an iterative manual adjustment process guided by validation loss trends. Common defaults from prior Transformer-based captioning studies were initially employed, after which each parameter—learning rate, weight decay, and batch size—was adjusted individually while monitoring validation loss and caption quality on a held-out set. Configurations yielding the lowest validation loss without overfitting signs were selected as the final values. When validation loss plateaued for three consecutive epochs or increased by more than 10.

Despite the powerful tokenizer and architecture of the original model, instability during training led to adjustments to the learning rate and repeated implementations. If divergence was observed, training parameters were adjusted to prevent information loss due to sequence length limitations. T5, a text-to-text model, uses both the original image caption data and the input sequences limited in length during training. As a

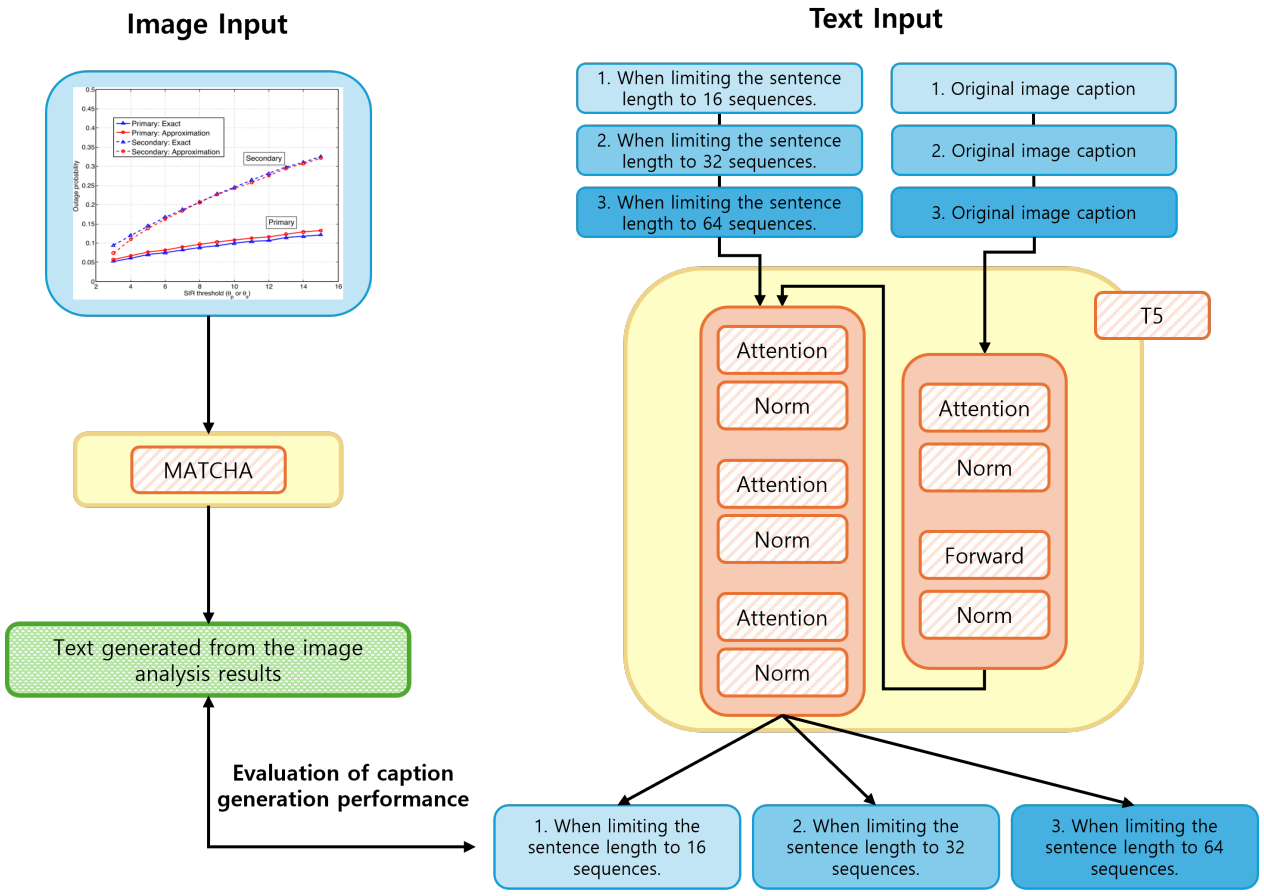

Fig. 1. Overall architecture of the proposed Hierarchical Chart Captioning (HCC) model. The visual encoder (left) processes spatial token features extracted from the input chart image, capturing both visual content and positional structure. These features are fed into the hierarchical caption generator (center, based on the T5 Transformer), where the encoder stack refines the representations and the decoder stack produces captions at three target sequence lengths (16, 32, 64 tokens) corresponding to different abstraction levels (Level 1–3). The encoder and decoder interact via cross-attention, allowing the decoder to selectively attend to relevant encoded features while generating the caption. MATCHA is used as a baseline comparison model, and the generated captions are evaluated for accessibility and comprehension.

result, captions of lengths 16, 32, and 64 are generated as outputs. These outputs are compared with MATCHA's image feature description text for performance evaluation. In this study, MATCHA is used solely as a benchmarking baseline to evaluate the quality of generated captions. It is not involved in the training process of our model. Specifically, after generating hierarchical captions with our fine-tuned T5-based model, The descriptive quality of the generated captions is compared against captions produced by MATCHA, following the same chart image inputs, to provide a consistent reference for performance assessment. MATCHA adopts the same structure as Pix2Struct [18], where the image encoder processes the input image through a series of Transformer layers to extract features, while the text decoder generates token sequences representing the structural layout of the image.

B. Hierarchical Caption Extraction Method

The hierarchical structure of the caption generation model proposed in this study consists of three levels: *Level 1, Level 2,* and *Level 3*, as shown in Fig. 2. This figure illustrates the link between these caption levels and information granularity. Specifically, the graph on the left (PDR% vs. percentage of source nodes) demonstrates how selecting different caption levels allows for balancing interpretability, detail, and performance under varying data conditions. The reason for dividing the caption into three levels is that human information recognition is performed in four stages, and Layers 1–4 correspond to fragmented information, refined information, specific information, and abstract information [19]. Therefore, captions were initially derived in four types to align with these cognitive stages. However, Level 4 captions were excluded from the final analysis because, despite being intended to represent the "abstract" stage of cognition, they exhibited substantial textual redundancy with the human-written reference captions. This meant that Level 4 did not introduce a genuinely new cognitive layer but instead reproduced the reference captions with minimal lexical changes, thereby failing to capture an additional abstraction process beyond Level 3. Quantitative evidence supports this decision: the average BLEU-4 score between Level 4 captions and the references was 0.92, and over 85% of sentences matched almost verbatim. For instance, in many samples, Level 4 captions duplicated entire reference sentences except for minor punctuation differences. Given this lack of conceptual distinction, retaining Level 4 would confound the analysis of hierarchical abstraction. Consequently, the focus

remained exclusively on Levels 1–3, which demonstrated clearer, progressive gradations in detail and interpretability. The captions of Level 1 explain the basic and factual elements of the chart in simple and intuitive language, focusing only on the basic expression of the data. The Level 2 captions provide more detailed expressions than the Level 1, offering information that can be directly extracted from the chart. Lastly, the captions of the Level 3 add interpretations to the chart by providing shallow inferences based on intuitive facts. This hierarchical expression structure expands the model's

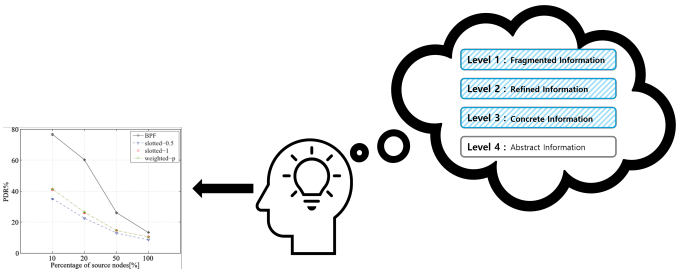

Fig. 2. Hierarchical caption levels in the proposed HCC model and their link to information granularity.

practical application in chart explanation, reflecting an attempt to reflect subjective human interpretation. This is a strategic approach to appropriately interpret the complexity of data visualization and offers deeper insights. In this study, the sequence length was limited to 16, 32, and 64 during training to maintain model learning efficiency while considering the necessary information to generate appropriate captions related to the input image.

In the context of the attention mechanism in neural networks, computational complexity is closely related to the number of tokens (n). In our model, controlling n is directly tied to the sequence length settings (16, 32, 64 tokens) used for different hierarchical caption levels. This allows us to balance descriptive detail with computational feasibility for accessibility-focused caption generation. Despite not performing computations for all token pairs, the computational burden increases proportionally to the square of n, as described in Eq. (1).

$$T(n) = O(n^2 \cdot d) \tag{1}$$

Moreover, the model's processing capacity in the input space increases linearly with n, as outlined in Eq. (2), where c represents a model-dependent constant. In practical terms, this reflects how increasing caption length expands the model's ability to capture detailed chart features, but at the cost of higher processing demands.

$$T(n) = c \cdot n \tag{2}$$

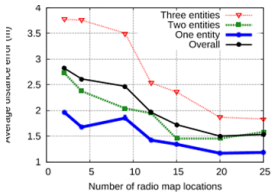
Considering inductive bias within the framework of Ridge Regression [23], the cost function (J) can be formulated by setting the attention mechanism as the hypothesis function.Here, inductive bias is interpreted as a form of regularization that constrains the model's attention weights when generating captions of varying lengths. When computing dependencies between text sequences x and y, the parameters (θ) and the regularization parameter (λ) can be derived from the number of training samples (m) and the number of features (n). By controlling n through sequence length limits, consequently, the inductive bias is implicitly regulated, which helps maintain stable learning across hierarchical levels without overfitting to any single caption length. This suggests that by controlling the number of tokens (n) within a constrained space of m, x, and y, the inductive bias can be effectively regulated [Eq. (3)].

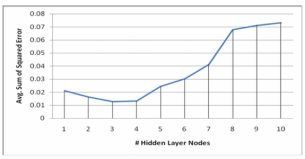
$$J(\theta) = \sum_{i=1}^{m} \left(h_\theta(x^{(i)}) - y^{(i)} \right)^2 + \lambda \sum_{j=1}^{n} \theta_j^2 \tag{3}$$

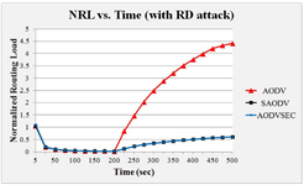
IV. Experiment and Evaluation

A. Experiment and Results

The primary objective of our experiments is to comprehensively evaluate the proposed HCC model in terms of four key aspects: 1) its ability to control the input space while preserving the intrinsic properties of the attention mechanism, 2) its usability for visually impaired users through clarity-focused caption generation, and 3) the validity and effectiveness of the newly introduced performance metric M.







This paper proposes a model that can effectively control the input space while preserving the intrinsic properties of the attention mechanism. To develop this model, a pre-trained T5-base Transformer model [17] is utilized, originally trained on the Colossal Clean Crawled Corpus (C4) dataset [20] containing 60,000 tokens.

All encoder and decoder layers were fine-tuned, while only the input embedding layer was modified to accept spatial token features from the chart image encoder and the output projection layer was adjusted to support multiple sequence length targets (16, 32, 64 tokens) corresponding to the proposed hierarchical captioning levels. This fine-tuning was necessary to adapt the model from its original text-to-text objective to the chart captioning task, ensuring it could effectively map spatial visual features to multi-level textual descriptions.

For fine-tuning, the learning rate was set to 3e-5, the batch size to 32, and the model was trained for 20 epochs using the AdamW optimizer with a weight decay of 0.01. These parameters were selected based on preliminary experiments to ensure stable convergence and reproducibility. Cross-entropy loss was utilized as the objective function. Prior to training, all chart images were resized to 512×512 pixels, normalized to the range [0, 1], and converted into spatial tokens via patch embedding. The LineCAP dataset was split into 80% training, 10% validation, and 10% testing sets, ensuring that charts from the same source did not appear in multiple splits to prevent data leakage. All experiments were implemented in Python 3.10 using PyTorch 2.1.0 and HuggingFace Transformers 4.36.2, with supporting libraries including NumPy 1.26.4, OpenCV 4.8.1, and scikit-learn 1.3.2. Training was performed on Ubuntu 22.04 with an NVIDIA RTX 3090 GPU (24 GB VRAM) and CUDA 12.1.

This extensive dataset ensures that the model can recognize and represent complex patterns and relationships in the data. As shown in Table I, hleach hierarchical level offers

TABLE I. COMPARISON OF HIERARCHICAL CAPTIONS GENERATED BY HCC MODEL AND ORIGINAL CAPTIONS

Chart ID	Chart Image	Captions
1	 Original Caption: Lines 2 and 4 intersect a total of three times. They first intersect at xlabel 12, then at xlabel 20, and lastly at xlabel 25.	**Layer 1**: Lines 2 and 4 intersect at xlabel 12, then at xlabel 20, and lastly at x. **Layer 2**: Lines 2 and 4 intersect at xlabel 12, then at xlabel 20, and lastly at x. **Layer 3**: Lines 2 and 4 intersect three times at xlabel 12, then at xlabel 20, and lastly at x.
2	 Original Caption: ylabel at first decreases at a decreasing rate, then increases roughly at an increasing rate, and then increases at a decreasing rate.	**Layer 1**: The line at first decreases, then increases. **Layer 2**: The line at first decreases at a decreasing rate, then increases at an increasing rate. **Layer 3**: The line at first decreases at a decreasing rate, then increases roughly at an increasing rate.
3	 Original Caption: All lines share the same trend from xlabel 5 to 200. Lines 2 and 3 even share the same trend for all values of xlabel.	**Layer 1**: All lines have the same trend from xlabel 5 to 200. **Layer 2**: All lines have the same trend from xlabel 5 to 200. **Layer 3**: All lines have the same trend from xlabel 5 to 200. Lines 2 and 3 share the same trend for all xlabel values.

a distinct balance between brevity and detail. Specifically, Layer 1 captions provide concise factual descriptions, Layer 2 adds moderate detail for improved clarity, and Layer 3 incorporates the most comprehensive explanation, sometimes adding interpretive insights. Layer 2 captions, for example, provide sufficient context without excessive complexity, which aligns with our usability study finding that Layer 2 is the most comprehensible for visually impaired users. This supports our claim that an intermediate level of abstraction maximizes accessibility. It is noteworthy that the captions at each layer convey the same information from diverse perspectives, and all of the explanations highlight the tendency of the third and fourth lines to be similar. Overall, in Layer 1, it is challenging to discern the extent of data representation in the chart due to the uniformity of the lines in their description of the trend. Layer 2 offers slightly more descriptive capabilities than Layer 1. Layer 3 augments the information in Layer 2, incorporating an explanation of the data represented by the chart.

To apply the generated captions as descriptions for chart materials provided to individuals with visual impairments, usability evaluation is crucial. To evaluate the proposed hierarchical chart caption generation model, a within-subjects survey was conducted with 20 actual instructors. The participants rated three caption layers for five samples, including those shown in Table I, using a 5-point Likert scale. The remaining samples were randomly selected from the LINECAP dataset. Each respondent was tasked with selecting the most comprehensible caption from the provided options for each layer, with a 5-point Likert scale utilized to assess the perceived clarity of each caption. The 5-point Likert scale was composed of 1 = Very Dissatisfied and 5 = Very Satisfied. The results of this survey indicated that the captions generated by Layer 2 seem to be the most comprehensible, as shown in Fig. 3. Fig. 3 presents a graph showing the average understanding score for each caption layer, evaluated on a 5-point Likert scale.

According to Fig. 3, the captions generated by the Layer 3 were also rated as highly relevant, while Layer 1 had the lowest score (Layer 2=3.35, Layer 3 = 2.88, Layer 1 =2.75). In addition, an analysis of variance (ANOVA) was performed to determine if the mean comprehension scores between each layer were statistically significant. The P value of 0.019 confirmed that the mean comprehension scores between the groups were different and statistically significant. In fact, the Diagram Center Image Description [21], which is used by the U.S. Department of Education as a guideline for writing descriptions to make visuals accessible and usable by students with disabilities, suggests that when writing descriptions for diagrams, the captions should be minimal and informative such as the captions in the layer 2. The hierarchical captions generated by this model not only automatically generates

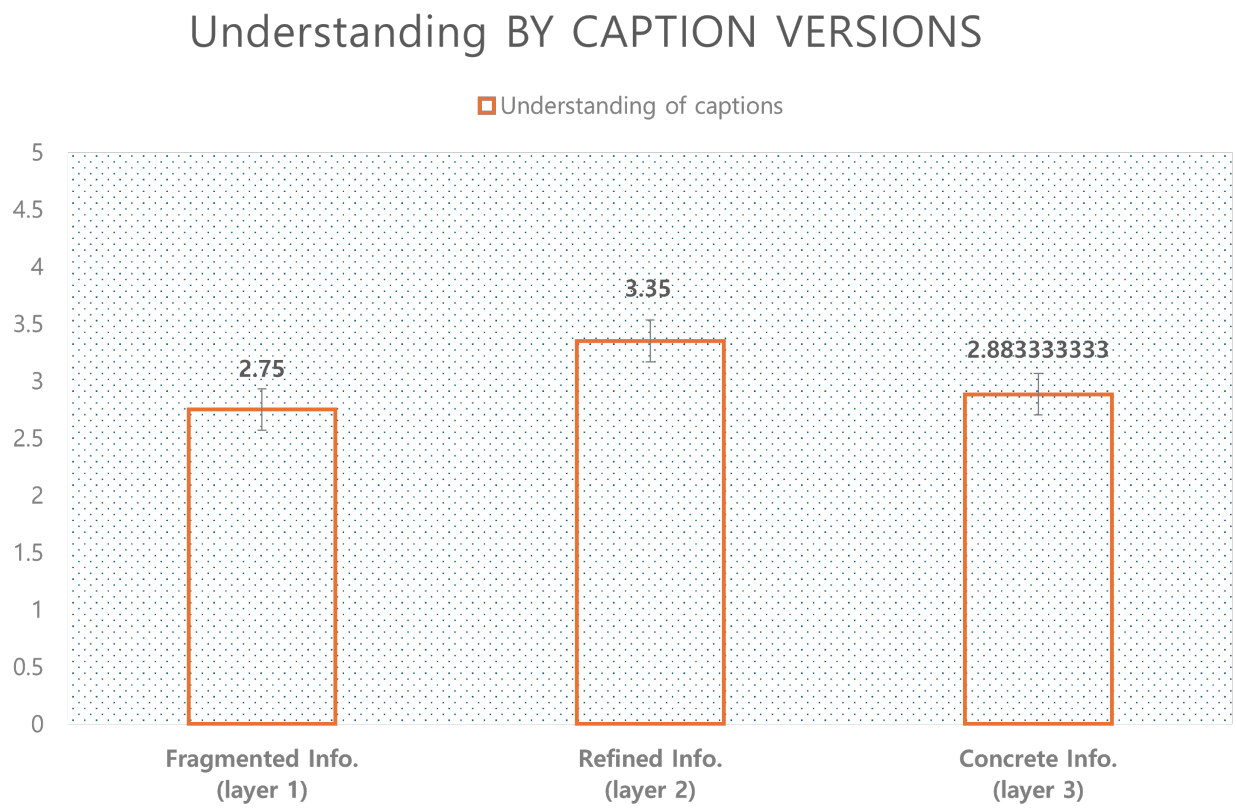


Fig. 3. Graph showing the average understanding score for each caption layer, evaluated on a 5-point Likert scale.

captions when an image is entered, but also automatically assigns the layer 2 captions selected by the usability evaluation so that it can be entered.

B. Caption Generation Performance Evaluation

Before introducing the new metric M, the data preparation process used for this evaluation is first described. The datasets LineCAP, DVQA, and FigureQA were selected because they provide diverse chart types and high-quality annotations necessary for training a robust chart captioning model, covering both low-level data extraction and high-level reasoning tasks. For each of these datasets, the same preprocessing pipeline was applied as in model training: all chart images were resized to 512×512 pixels, normalized to the range [0,1], and converted into spatial tokens via patch embedding. For each test set, hierarchical captions (Levels 1–3) were generated using the fine-tuned HCC model. The corresponding attention masks from the decoder cross-attention layers were stored to enable the computation of SV_{am} in the metric formula. No training or validation samples were included, ensuring that all metric computations were performed on unseen data to maintain evaluation integrity.

Traditional captioning metrics such as BLEU or CIDEr are designed to reward lexical overlap between a generated caption and a single reference caption. In our hierarchical setting, captions at different levels (e.g., Level 1 vs. Level 3) are intentionally diverse in length, detail, and abstraction, meaning that a low lexical match does not imply poor quality. For example, a concise Level 1 caption can be perfectly accurate yet achieve a low BLEU score simply due to its brevity. Similarly, CIDEr's term-frequency weighting favors n-gram overlap, which biases against higher-level captions that incorporate interpretive language absent from the reference. These metrics are therefore discarded because they conflate intended stylistic variation with error, and metric M is adopted instead to directly assess feature preservation and attention distribution properties that remain meaningful across levels

Therefore, the objective of this research is not to ensure high performance on the correct answer labels generated by the model, but rather to prioritize stable learning through caption generation to enhance the practical utility of the model. To this end, the following metric was established, given in Eq. (4).

$$M = \cos(f_\theta(x), y) \cdot k + \sigma(SV_{am}) \tag{4}$$

This metric comprises two terms. The first utilizes cosine similarity to ensure that the model's output preserves the features of the input tokens without compromising their characteristics. Here, "input" refers to the vectorized embedding representation of the spatial tokens extracted from the chart image encoder, and "output" refers to the embedding representation of the generated caption tokens produced by the decoder. Both are mapped into the same latent space using the final projection layer before similarity computation. This ensures that cosine similarity measures alignment between semantic feature vectors rather than raw token IDs or unprocessed

TABLE II. EVALUATION OF CAPTION GENERATION PERFORMANCE ACROSS THREE DATASETS (LINECAP, DVQA, FIGUREQA) USING THE PROPOSED METRIC M. HIGHER SCORES INDICATE BETTER SEMANTIC FEATURE PRESERVATION AND BALANCED ATTENTION FOCUS. 'M(OURS)' REPRESENTS THE PROPOSED HCC MODEL, WHILE 'M(NEW BASELINE)' DENOTES A STANDARD FINE-TUNED T5 MODEL

M/dataset	**LineCAP**	**DVQA**	**FigureQA**
Existing performance evaluation metrics	**BLEU-4/CIDEr**	Structure/Data/Reasoning	Accuracy
Existing evaluation metrics results	0.418/1.096	94.47/65.40/44.03	72.54

TABLE III. COMPARE THE NEW "M (BASELINE)" RESULTS WITH OUR "M (OURS)" RESULTS

M/dataset	**LineCAP**	**DVQA**	**FigureQA**
M(New baseline)	15.98	13.24	16.98
M(Ours)	10.92	9.84	7.34

sequences, avoiding ambiguity between "input tokens" and "output tokens."

The second term examines the standard deviation of the singular values (SV_{am}) of the attention mask. SV_{am} denotes the set of singular values obtained by applying Singular Value Decomposition (SVD) to the attention mask matrices extracted from the decoder's cross-attention layers. For each generated caption, the attention mask $A \in \mathbb{R}^{n \times n}$ is collected, where n is the sequence length, and SVD is performed: $A = U\Sigma V^\top$. The diagonal entries of Σ represent the singular values, which capture the distribution of energy across attention components. Singular values are aggregated across all heads and layers for each caption, and the standard deviation is computed to quantify the variability in attention focus. This process is repeated for all samples in the test set to produce the final SV_{am} value used in the metric M. Rather than implying that lower variance always equates to better expressiveness, a moderate reduction is interpreted as desirable because it suggests a balanced allocation of attention that preserves relevant structural information while avoiding noise-induced dispersion.

The earlier discussion of attention complexity in Eq. (1) and (2) directly informs the interpretation of metric M. Controlling the sequence length n in the hierarchical captions not only constrains the $O(n^2 \cdot d)$ computational cost but also influences the structure of the attention masks from which SV_{am} is computed. Shorter sequences reduce potential attention dispersion, leading to a more concentrated singular value spectrum, whereas longer sequences increase complexity and variability in attention focus. By incorporating SV_{am} into M, this trade-off between descriptive richness and computational efficiency is captured.

This value $k = 10$ was selected through preliminary sensitivity analysis, where k was varied across 1, 5, 10, 20 and the resulting metric distributions were inspected. It was observed that $k = 10$ provided a balanced scaling between the cosine similarity term and the singular value variability term.

Table II and III demonstrate that our model consistently achieves lower M scores across all datasets compared to the baseline, with reductions of up to 56.8% (FigureQA). Since a lower M indicates better semantic alignment and more balanced attention distribution, these results provide quantitative evidence that the proposed HCC model more effectively preserves key features of the input space while controlling complexity.

Focusing on the results of the newly proposed 'M(baseline)' and our 'M(Ours)', the following observations can be made. In the LineCAP dataset, the baseline achieved 15.98, while our model achieved 10.92. Similarly, for DVQA, the baseline scored 13.24, and our model scored 9.84, while in FigureQA, the baseline result was 16.98, and our model scored 7.34. In all datasets, our model outperformed the baseline. Notably, in FigureQA, the M value decreased by almost half, indicating an improvement in performance.

V. DISCUSSION : ENHANCING ACCESSIBILITY THROUGH USER-COGNIZANT HIERARCHICAL CAPTIONING

The Hierarchical Chart Captioning (HCC) model is fundamentally distinguished from prior works, which primarily focused on maximizing lexical similarity metrics, by aiming to resolve the practical accessibility gap through a user-centered approach. This section discusses the behavioral and cognitive implications of our hierarchical framework.

A. The Mechanism of Hierarchical Captioning in Mitigating Cognitive Load

HCC's effectiveness is rooted in its ability to translate the complex stages of human visual information processing—which progresses from visual perception to higher-level abstraction—into a manageable auditory information delivery structure. This mechanism directly addresses the significant cognitive load associated with processing lengthy, undifferentiated auditory descriptions in non-visual environments.

The multi-level structure segments chart information into ascending cognitive levels: Level 1 (basic facts), Level 2 (relationships and trends), and Level 3 (shallow inferences). This managed segmentation allows users to assimilate the chart data incrementally, supporting a fundamental principle of Universal Access by providing flexible information delivery based on individual processing needs. Furthermore, the approach of offering user-selectable sequence lengths (16, 32, 64 tokens) introduces a critical HCI benefit, empowering the visually impaired user to tailor the information depth to their immediate needs, thereby overcoming the inefficiency of auditory searching through overly long, static narratives.

B. Level 2 as the Optimal Threshold for Information Comprehension

The user evaluation, which involved a survey with 20 instructors, empirically confirmed that the Layer 2 caption

achieved the highest comprehensibility score (3.35), positioning it as the optimal level for driving positive information comprehension behavior. This finding is central to our work, highlighting a critical trade-off between descriptive detail and cognitive feasibility. The inadequacy of extremes was clearly demonstrated, as Level 1 captions, due to their limited and fragmented information, scored the lowest (2.75) because they failed to establish the necessary overall context or data relationships. Conversely, Level 3 captions, while relevant due to the inclusion of inferences, imposed a higher cognitive burden due to their increased length and complexity, resulting in a comprehension score (2.88) lower than Level 2. Level 2 is thus identified as the optimal point of cognitive equilibrium. By detailing the relationships and trends directly extractable from the chart, Level 2 provides sufficient context while judiciously avoiding the excessive complexity and subjective interpretation of Level 3. This balanced delivery strategy aligns precisely with accessibility best practices, such as those recommended by the U.S. Department of Education's Diagram Center, which advocates for minimal yet informative descriptions. The superior performance of Level 2 captions provides strong empirical evidence that effective accessibility solutions must be driven not merely by technological performance metrics, but by an HCI design balance that explicitly accounts for user-specific cognitive capacities to yield successful behavioral outcomes.

Consequently, this finding challenges the prevailing assumption in captioning research that higher text similarity scores (e.g., BLEU) automatically equate to better utility. By confirming that instructors—the domain experts in education—prioritize the 'refined' information of Level 2 over the more exhaustive Level 3, this study provides a concrete HCI design guideline: accessibility tools should prioritize cognitive load management over mere data exhaustion. This shift from technical optimization to human-centered validation is the core contribution of our work, demonstrating that the 'best' model is not the one with the most detailed output, but the one that aligns with the pedagogical needs of the users.

VI. Conclusion

Visually impaired individuals, particularly those who are completely blind, face significant challenges in accessing and understanding descriptive information about graph or chart images. If an image lacks recorded descriptions, screen readers are unable to convey its content; therefore, when a graph or chart image is provided, an accompanying explanation is essential to enhance accessibility for visually impaired users. However, conventional graph captions are often overly detailed, deviating from their original intent and hindering practical usability and scalability. This highlights a critical need to re-examine the purpose of such descriptions by refining the levels of human cognitive processing and applying this to chart explanation methodologies.

This study proposed the HCC (Hierarchical Chart Captioning) model to address this accessibility gap by generating multi-level, user-selectable captions. Unlike traditional captioning methods that provide information at a single layer, the HCC model utilizes spatial token features to generate three hierarchical levels of captions that mimic human cognitive processing. This design ensures that the model provides varying degrees of detail and abstraction, allowing users to select the description length that best suits their needs.The model's effectiveness was rigorously evaluated through user surveys involving 20 instructors, which revealed a critical insight: Layer 2 captions were the easiest to understand, scoring 3.353. This result confirms that the most effective solution lies in achieving an optimal balance between factual detail and cognitive load, aligning with the "minimal yet informative" approach advocated by guidelines like the Diagram Center Image Description4444. Consequently, this finding underscores that technical complexity does not guarantee practical utility. Future accessibility metrics must therefore evolve beyond statistical correlation to prioritize human-centric clarity. By identifying Level 2 as the optimal granularity, this study establishes a practical standard that bridges AI capabilities with real-world educational needs.

Furthermore, the model's performance was validated using a newly introduced evaluation metric, M, which confirmed that the proposed methodology achieved performance levels comparable to existing baseline architectures5. This demonstrates that our approach ensures both reliable performance and effective learning, highlighting its strong potential applicability to hierarchical learning frameworks.

While this study demonstrates the efficacy of the HCC model, several limitations remain. Currently, our validation is primarily focused on line charts; thus, further research is required to assess the model's adaptability to more complex or composite scientific visualizations. Future work will address this by expanding the dataset diversity and conducting in-depth end-user testing directly with visually impaired participants to gather qualitative feedback. Additionally, we plan to explore the real-time integration of our hierarchical captioning system with Text-to-Speech (TTS) interfaces to support live learning environments.

In conclusion, the HCC model offers a novel, user-centered approach to enhancing digital accessibility by translating complex visual data into cognitively manageable auditory descriptions. Ultimately, this work aims to advance Universal Design for Learning (UDL), ensuring that educational insights are equally accessible to every learner regardless of visual ability.

College of Engineering, Al Yamamah University, Khobar, Saudi Arabia[3,4]

***Abstract*—This study addresses the growing challenge of enhancing privacy in enterprise database systems, where excessive privileges and shared service accounts often lead to unauthorized data access and insider threats. The study proposes a data-layer security framework that enforces fine-grained access control based on authenticated user identities, integrating role-based access control (RBAC) and the principle of least privilege (PLP) to protect sensitive information. The model restricts developer and administrative access strictly to authorized data objects, reducing exposure while maintaining operational efficiency. Drawing on established database security mechanisms, including authentication, authorization, and centralized identity management through Active Directory, the proposed framework ensures that all database interactions are executed under verified user credentials. The approach is implemented using Microsoft SQL Server within an enterprise environment and evaluated through controlled experiments conducted before and after deployment. Results demonstrate a significant reduction in unauthorized data retrieval without introducing noticeable performance overhead. The findings confirm that enforcing privacy at the data-layer provides an effective and scalable solution for securing sensitive data in modern database systems, strengthening accountability and mitigating risks associated with privilege misuse.**

I. Introduction

The importance of privacy in database systems has become increasingly critical in today's digital landscape. As databases accumulate and utilize vast amounts of information, they serve as central repositories of sensitive and personal data. Safeguarding this information is a fundamental priority, as it forms the backbone of trust, security, and ethical data management across organizations. Key strategies such as access control, encryption, and data anonymization represent the core of privacy protection mechanisms within database systems. Access control ensures that only authorized users can access specific data, effectively minimizing the risk of unauthorized breaches. Encryption further reinforces confidentiality and integrity by converting data into secure formats that can be accessed only by users possessing the correct decryption keys. Meanwhile, data anonymization techniques modify or remove identifying attributes to prevent individual recognition, thereby enhancing privacy and compliance with data protection standards.

These mechanisms collectively play a crucial role in mitigating risks associated with both external cyberattacks and internal misuse. The growing emphasis on privacy protection is also reflected in the establishment of rigorous international frameworks, including the General Data Protection Regulation (GDRP) [1] and the National Institute of Standards and Technology (NIST) Special Publication 800-53, Revision 5 [2]. These frameworks highlight the importance of maintaining confidentiality [3], integrity [4], and accountability of information systems [5]. They provide an updated set of guidelines that encourage organizations to strengthen access control, ensure data resilience, and align their technological operations with legal and ethical standards. The challenge, however, lies in balancing the implementation of these stringent privacy measures with the need to sustain high levels of system performance and efficiency [6]. By integrating the guidance of GDPR and NIST standards, organizations can better align their security imperatives with database functionality, achieving equilibrium between compliance, accessibility, and performance.

On the other hand, the vulnerabilities of database systems are often exposed through real-world cases of data breaches. For instance, Timothy Young, a resident of Moorefield, Nebraska, who confessed to a serious violation of trust and security by committing wire fraud that resulted in the exposure of confidential data from his employer, a New Jersey-based analytics and risk assessment firm. This organization served a global clientele that included insurance, financial, and governmental entities. Young accessed the company's network without authorization, obtaining names, email addresses, phone numbers, and login credentials, which he attempted to sell. His actions underscore the serious consequences of inadequate data protection and the risks that arise from unauthorized internal access to sensitive databases. The case, investigated by the FBI and prosecuted by the U.S. Attorney's Office Cybercrime Unit in Newark, resulted in potential charges carrying a maximum prison sentence of twenty years and substantial financial penalties [7]. This incident highlights the urgent need for effective database privacy frameworks and the severe legal implications of neglecting such protocols. In addition to isolated cases, the overall frequency and scale of data compromises have risen sharply across industries [8]. The financial services sector, for example, experienced a near doubling of data breaches in the United States, increasing from 268 reported incidents in 2022 to 744 in 2023. As shown in Fig. 1, this rise illustrates how sectors that manage sensitive financial information have become prime targets for cyber threats. Such incidents not only compromise consumer confidence but also threaten the stability and reputation of institutions that rely on secure data handling [9]. The upward trend in data violations underscores the growing sophistication of cyber threats and the pressing demand for enhanced privacy mechanisms within database systems [10].

Nevertheless, during everyday maintenance and operational processes, developers often interact directly with live databases, sometimes with broad or unintended access privileges. This exposure creates potential privacy risks,

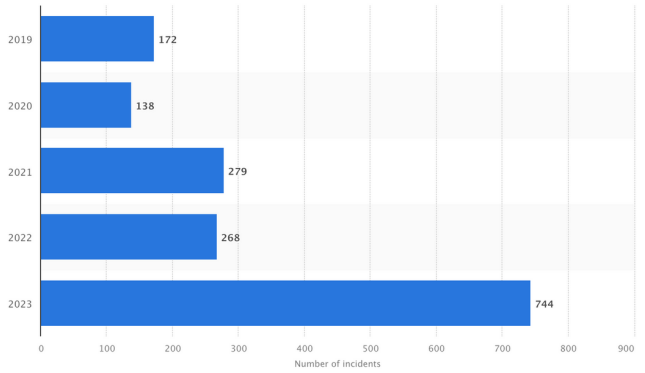

Fig. 1. Number of data violation cases in the United States (by statista [11]).

as unauthorized or excessive access may lead to data misuse or accidental disclosure of sensitive information. The challenge is to ensure that developers can perform their tasks efficiently while maintaining strict compliance with privacy and confidentiality requirements. Achieving a balance between operational flexibility and rigorous access control is essential to mitigating privacy risks and preserving database integrity [12].

The main objectives of this research are twofold. First, it seeks to enhance the protection of sensitive data within database systems by ensuring that users connect through properly authenticated and authorized accounts. Second, it aims to strengthen database privacy measures without compromising system performance. To achieve this, the study proposes a security model that integrates strict access controls, limiting developer access exclusively to the data necessary for their tasks. By reducing exposure and applying structured access rules, the model minimizes the risk of data leakage while maintaining efficient database operation. Consequently, the proposed work contributes to the broader field of database security and privacy engineering by offering a practical and scalable approach to safeguarding sensitive information at the data-layer. Its design emphasizes the balance between privacy protection and performance optimization, addressing one of the most persistent challenges in secure database management. By incorporating access control mechanisms guided by established privacy frameworks, this research provides a structured and adaptable solution that strengthens data protection while ensuring usability and efficiency in modern database environments. This work contributes to database security practice by introducing a data-layer access enforcement framework that explicitly binds database query execution to authenticated individual identities rather than shared service accounts. Unlike conventional role-based or attribute, based access control mechanisms that are typically enforced at the application or middleware layer, the proposed approach embeds identity, aware privilege enforcement directly at the database layer. The framework operationalizes the principle of least privilege through identity bound query execution and demonstrates its effectiveness through an enterprise scale implementation and empirical evaluation. In addition to the architectural contribution, the study provides experimental evidence that database layer identity enforcement can significantly reduce unauthorized access without introducing noticeable performance overhead.

Specifically, this study makes the following contributions:

- Proposes a database-layer security framework that enforces identity-bound access control, eliminating reliance on shared service accounts.
- Demonstrates fine-grained enforcement of the principle of least privilege directly within the database execution context.
- Provides an enterprise-scale implementation integrating centralized identity management with database access control.
- Empirically evaluates the impact of the proposed framework, showing improved privacy enforcement without measurable performance degradation.

The remainder of this study proceeds from foundations to validation and implications. Section II establishes the conceptual framework for database privacy by defining the two complementary pillars access control and data anonymization—that anchor the rest of the work. Building on these foundations, Section III surveys the state-of-the-art across encryption, access control, masking, intrusion detection, confidential data management, IoT access control, and biometrics/pseudonyms, as well as privacy-preserving publishing, thereby identifying concrete gaps and design requirements that motivate our solution. Guided by these requirements, Section IV details the proposed methods and materials, including the system architecture and implementation choices that operationalize the framework. Section V then evaluates the approach empirically, reporting and discussing experimental results that test whether the framework delivers the intended security and performance properties. Finally, Section VI synthesizes the findings, outlines limitations, and charts directions for future research.

II. Conceptual Framework of Database Privacy Mechanisms

Safeguarding sensitive data within database systems requires a combination of mechanisms that prevent unauthorized access and ensure the confidentiality of stored information. Two fundamental approaches dominate this domain: access control [13] and data anonymization [14]. Each provides a distinct, but complementary layer of protection that collectively strengthens database privacy.

A. Access Control Mechanisms

Access control serves as the first line of defense in protecting databases from cyber threats, including sophisticated attacks such as spear phishing. These systems implement a structured framework of identification, authentication, and authorization processes to determine precisely who can access which data resources. Their primary objective is to restrict unauthorized entry and uphold data confidentiality [15].

Different access control models have evolved to address varying security requirements and operational contexts. Discretionary Access Control (DAC) allows data owners to define permissions, offering flexibility, but risking oversharing. Mandatory Access Control (MAC) enforces system-level policies based on data classification and user clearance, ensuring high security, but limited flexibility. Role-Based Access

Control (RBAC) assigns permissions to roles rather than individual users, simplifying management in large organizations. Attribute-Based Access Control (ABAC) applies fine-grained policies based on user, resource, or environmental attributes, supporting dynamic decisions. Finally, Rule-Based Access Control supplements other models by enforcing predefined administrator rules. These models collectively enable organizations to balance flexibility and security based on their specific data governance requirements. Table I summarizes the unique strengths and weaknesses of these five access control types [15].

TABLE I. OVERVIEW OF ACCESS CONTROL SYSTEMS

Type	Description	Strengths	Weaknesses
DAC	User-defined access rights	High flexibility; user-centric	Risk of accidental oversharing
MAC	System-enforced policies based on classification	High security; minimizes breaches	Rigid; less user flexibility
RBAC	Access based on user roles	Simplifies management; scalable	Requires precise role definition
ABAC	Decisions based on user, environment, and resource attributes	Highly flexible and dynamic	Complex policy management
Rule-Based	Access determined by specific rules	Adds extra security layers	Management complexity

By effectively implementing these mechanisms, organizations can protect sensitive information from unauthorized access, thereby mitigating the risk of data breaches and ensuring compliance with data protection regulations such as the General Data Protection Regulation (GDPR). As database technologies evolve and the volume of data grows, the importance of sophisticated access control systems becomes even more critical, underlining the need for ongoing research and development in this area to address emerging security challenges.

B. Data Anonymization Techniques

Beyond controlling access, privacy protection also requires anonymizing data to prevent re-identification. Data anonymization modifies sensitive attributes so that individuals cannot be uniquely identified, preserving utility while protecting privacy [16]. These methodologies ingeniously modify personal data into a state where individual identification becomes impossible, thus shielding sensitive information from unauthorized scrutiny or exploitation. Anonymization assumes a critical role when the utilization of data extends to analytical, research, or reporting endeavors, ensuring that such activities do not infringe upon individual privacy rights.

Databases employ several anonymization strategies without significantly compromising the data's analytical utility. Among these, data masking can be applied in either static or dynamic forms, offering flexibility in secure data access and use while maintaining confidentiality. Pseudonymization replaces private identifiers with fictitious values, allowing data association with its source without revealing actual identities; however, it may be reversible with additional contextual information. Generalization decreases precision by converting detailed data (e.g., exact ages) into broader categories, while data perturbation introduces small alterations or noise to obscure original values yet preserve statistical integrity.

Structured models such as k-anonymity ensure that each record is indistinguishable from at least k–1 others regarding identifying attributes, while l-diversity demands diversity of sensitive attributes within anonymized groups. Building further, t-closeness maintains the distribution of sensitive attributes close to that of the entire dataset, preventing inference attacks. Table II summarizes key anonymization techniques and their advantages and disadvantages [16].

TABLE II. DATA ANONYMIZATION TECHNIQUES: PROS AND CONS

Technique	Pros	Cons
Data Masking	Protects sensitive data while keeping it functional for operations.	May distort actual values, limiting analytical use.
Pseudonymization	Enables linking data to its source without revealing identities, maintaining a level of utility.	Potentially reversible if attackers gain access to auxiliary information, compromising privacy.
Generalization	Simplifies implementation and enhances privacy by reducing data precision.	Reduces utility for detailed analysis due to loss of specificity.
Data Perturbation	Preserves overall structure and integrity of datasets for aggregate analysis.	Alterations may affect accuracy of individual records or analyses.
k-Anonymity	Provides a quantifiable measure of privacy by ensuring indistinguishability among records.	Vulnerable to linkage attacks if an attacker possesses external information.
l-Diversity	Enhances protection against attribute disclosure by ensuring diversity within groups.	Difficult to implement effectively in datasets with high similarity among records.
t-Closeness	Strengthens defense against inference attacks by aligning attribute distributions with the overall dataset.	Balancing privacy and data utility can be complex and computationally demanding.

Implementing these anonymization techniques effectively enables organizations to maintain compliance with data privacy regulations while still leveraging data for analytical purposes. As privacy concerns and regulatory requirements evolve, the development and refinement of anonymization methodologies remain a central focus for researchers and practitioners in data security and privacy management.

III. LITERATURE REVIEW

Data security and privacy remain central challenges in modern digital environments, particularly as the volume, variety, and sensitivity of stored information continue to rise across sectors such as mobile communications [17], healthcare [18], IoT systems [19], and database-backed web applications [20]. Across the literature, researchers have proposed diverse mechanisms, including encryption, access control, anonymization, intrusion detection, logging frameworks, and biometric authentication, to mitigate risks and strengthen confidentiality, integrity, and availability of data. The following review synthesizes these contributions in a coherent progression, moving from encryption-based protections to access control mechanisms, to data masking, intrusion detection, confidential data management, IoT access control, cryptography, biometric and pseudonym-based protections, and finally privacy-preserving data publishing.

A. Encryption and Cryptographic Techniques for Data Protection

A foundational component of secure data management lies in the use of strong encryption and cryptographic methods. ASCII-based encryption techniques leverage character values

to obfuscate readable data, reinforcing protection during transmission. The incorporation of multiple keys as in the Coloring Tripartite Graph (CTG) approach [21] further enhances resistance to unauthorized decryption. Similarly, the Triple Key Security Algorithm (TKS) employs polyalphabetic substitution with three keys and XOR operations, providing robust security particularly in mobile communication systems [22]. Building on the need for multi-key mechanisms, Ibrahim et al. [23] highlight vulnerabilities in databases storing personal and work related information. Their ASCII based, three-key encryption formula secures text and numeric data, preserves data size, and ensures efficient encryption and decryption, while acknowledging the necessity of future comparisons with established cryptographic systems to validate performance.

Additionally, cryptography is essential in domains such as medical services. Oduor & Omariba [24] trace the historical evolution of security practices and demonstrate the role of cryptographic algorithms in safeguarding sensitive healthcare data, supported by real time IDE examples. However, limitations such as incompatibility with indexed data and key management vulnerabilities persist. Further work in the Internet of Medical Things [25] calls for lightweight, quantum-resistant, and AI-enhanced cryptographic algorithms to meet emerging threats.

B. Access Control Models and Dynamic Data Protection

While encryption secures raw data, access control ensures that only authorized users can interact with sensitive resources. Wu et al. [26] note that database-backed web applications frequently allocate full privileges to application-level accounts, violating the principle of least privilege (PLP). Their PDA framework enforces PLP by intercepting queries and applying fine-grained, query-specific privilege restrictions, achieving resistance to SQL injection and buggy query manipulations with minimal performance overhead. Estrela framework [27] complements this approach by separating policy specification from application logic, enabling contextual and API-specific access enforcement. On top of this, dynamic Data Masking (DDM) further strengthens access control by obscuring sensitive values at query time. Fotache et al. [28] integrate masking directly into the persistence layer, preventing unmasked data from leaving the database engine. Their experimental evaluations using TPC-H show minimal performance impact, encouraging future research on large-scale databases, customized masking functions, and privilege-based masking algorithms. In big data environments, BDMasker [29] demonstrates scalable DDM deployment, with performance fluctuations maintained within 3% during horizontal and vertical expansion.

Access control challenges extend to confidential data management, where Shan et al. [30] argue that excessive privileges and underutilized logging hinder security. Their confidentiality-level access control model applies role, domain, and row level filtering, supported by an ELK-based logging module to improve traceability and monitoring. The MLCAC model [31] advances this further through real-time policy adjustment, log-driven decision-making, and decentralized optimization, achieving 89.55% accuracy in automated policy generation. Furthermore, in the IoT environment, Jiang et al. [32] address limitations in auditability and privilege control by proposing CcBAC, a blockchain-based fine-grained access control model incorporating TEE and cryptocurrency-based authorization. Experimental findings and further elaboration by Wang [33] demonstrate strong performance under large-scale request loads, high auditability, and consistent authorization across distributed IoT systems.

In addition to access control and masking, preserving privacy during data publishing forms another essential aspect of dynamic data protection. Jayapradha et al. [34] highlight the limitations of traditional anonymization techniques, especially when handling multiple correlated sensitive attributes. Their Heap Bucketization-Anonymity (HBA) model integrates anatomization, k-anonymity, slicing, and heap bucketization to balance privacy and analytical utility. Using metrics such as the Normalized Certainty Penalty and KL-divergence, they show that HBA effectively mitigates background knowledge, membership, non-membership, quasi-identifier, and fingerprint correlation attacks. The authors also emphasize future directions, including support for dynamic and unstructured data as well as addressing 1:M microdata challenges, underscoring the evolving role of anonymization in comprehensive data protection systems.

C. Intrusion Detection and Biometric Protection Against Insider and External Threats

Even with strong encryption and access control, insider misuse remains a dominant cause of data breaches. Said & Mostafa [35] identify privileged account misuse as a critical vulnerability and propose an intrusion detection system based on Danger Theory and the Negative Selection Algorithm (NSA). By learning from previously detected intrusions, their hybrid system improves anomaly detection accuracy while reducing false positives and false negatives. Nonetheless, the authors emphasize the challenge of calibrating the hybrid immune model and maintaining system performance in cloud and mobile networks. NSA's strengths, and its limitations in scalability are further examined by Tosin & Gbenga [36], who note its adaptability but highlight computational concerns.

Into the bargain, biometric authentication adds another layer of defense, particularly for securing identity and preventing unauthorized database access. Abd Razak, Nazari, & Al-Dhaqm [37] demonstrate that unique identifiers stored in digital databases can expose users to eavesdropping and identity theft. They propose integrating palm vein recognition with pseudonym generation to anonymize records and reinforce privacy. Enhancing pseudonym generation remains a priority for improving protection, especially in cloud computing contexts. Complementary work [38] uses palm vein biohashing with near-infrared scanning, achieving an EER of 0 and protecting biometric templates from exposure during storage or transfer.

To provide a holistic comparison of the reviewed approaches, Table III summarizes the methodologies, benefits, and limitations of the most relevant studies discussed in this section.

D. Identified Research Gaps and Motivation

The reviewed literature demonstrates significant progress in database security through encryption techniques, access

TABLE III. COMPARATIVE SUMMARY OF RELATED WORK

Author & Year	Methodology	Benefits	Limitations
[21]	Graph-based encryption using tripartite graph coloring with ASCII mapping	Enhanced mathematical security; Suitable for text-based protection; Resistant to brute-force attacks	Limited to ASCII; High computational complexity; Scalability concerns
[22]	Multi-round encryption using three independent keys	Protection against single-key attacks; Multiple encryption layers; Improved key flexibility	Higher computational load; Key synchronization challenges; Performance degradation over multiple rounds
[23]	Custom ASCII-based encryption algorithm with novel primitives for database security	Database-specific optimization; Protects structured data; Prevents unauthorized access	Non-standard; Limited cryptanalysis; Integration challenges with existing systems
[24]	Applied encryption, hashing, and digital signatures for medical data protection	HIPAA/GDPR support; Secure transmission; Confidentiality for medical records	Real-time performance issues; Healthcare key management complexity; Interoperability limits
[25]	Systematic review of symmetric, asymmetric, and lightweight cryptography for IoMT	Comprehensive IoMT landscape; Identifies effective schemes; Highlights attack vectors and mitigations	Review-based; No empirical validation; Resource constraints in IoT not fully explored
[26]	Application-driven privilege separation (PDA) using query interception	Automated least privilege enforcement; Prevents SQL injection; Low runtime overhead (8.13%)	Application modification required; Tested on limited systems; Generalizability concerns
[27]	Estrela contextual policy framework with API-level enforcement	Context-aware control; Works on legacy systems without DB changes; Fine-grained policies	Complex rules; Requires API–policy mapping; Limited application testing
[28]	TPC-H benchmark and ML-based performance analysis of dynamic data masking (DDM)	Minimal masking overhead; Effective for datasets up to 100GB; Data-driven masking strategy design	Oracle-only evaluation; Basic masking scenarios; Scalability beyond 100GB uncertain
[29]	SQL query rewriting with multi-engine unified security for DDM	Zero logic impact; Multi-engine scalability; 3% overhead; Preserves query intent	Complex rewriting; Limited encryption integration; End-to-end protection not covered
[30]	Hybrid RBAC/ABAC confidential data access control model	Flexible, granular policies; Supports separation of duties; Scalable for organizations	Role explosion; Attribute maintenance overhead; Susceptible to misconfiguration
[31]	Machine-learning context-aware access control (MLCAC) for insider threat detection	Behavioral anomaly detection; Adaptive authorization; Real-time mitigation	Requires large training datasets; False positives; Intensive computation
[32]	CcBAC hybrid IoT access control using blockchain audit logs + TEE enforcement	Tamper-proof logs; Secure execution; Suitable for distributed IoT environments	Blockchain scalability issues; TEE hardware dependency; Complex integration
[33]	Dynamic trust-based access control for IoT network boundaries	Granular trust evaluation; Adaptive policies; Prevents unauthorized IoT access	Trust metric definition; Continuous evaluation overhead; Scalability challenges
[34]	Heap Bucketization-Anonymity (HBA) combining anatomization, slicing, and k-anonymity	Resists background knowledge, membership, and fingerprint attacks; Balances privacy and utility	Not real-time; No live masking; Complex parameter tuning
[35]	Danger Theory + Negative Selection intrusion detection for insider threats	Self-learning; High detection coverage; Strong against privilege misuse; Adaptive behavior	Detection-only; Training required; Vulnerable to evolving attack patterns
[36]	Bio-inspired negative selection algorithm (NSA) for intrusion detection	Detects unknown attacks; Adaptable to new patterns; Low computational cost	High false positives; Detector generation complexity; No prevention capability
[37]	Palm-vein biometrics with pseudonym generation for identity anonymization	Strong authentication; Identity unlinkability; Dual-layer protection (biometric + pseudonym)	Biometric sensitivity concerns; Integration complexity; Limited analysis of encryption interactions
[38]	Vascular biometric recognition with enhanced liveness detection	Highly secure modality; Non-invasive capture; Suitable for high-security systems	Requires specialized hardware; Environmental sensitivity; Higher deployment cost

control models, anonymization strategies, and intrusion detection mechanisms. However, several limitations remain insufficiently addressed. Many existing approaches rely heavily on encryption or anonymization, which protect data content but do not prevent misuse by legitimately authenticated users with excessive privileges. Similarly, application-layer access control frameworks enforce authorization outside the database engine, leaving database-layer interactions vulnerable when shared service accounts or over-privileged credentials are employed.

Furthermore, while role-based and attribute-based access control models provide structured authorization, they are often implemented at the application or middleware level, limiting their effectiveness in mitigating insider threats and privilege escalation within the database itself. Existing solutions also lack direct enforcement of identity-bound query execution, where each database operation is explicitly tied to a verified individual account rather than a generic service identity. These gaps highlight the need for a database-layer privacy enforcement mechanism that integrates centralized identity management, enforces the principle of least privilege, and ensures that all database interactions are executed under authenticated and authorized user identities. Motivated by these limitations, the proposed approach introduces a data-layer security framework that directly couples Active Directory–based authentication with database access control, effectively reducing unauthorized data exposure while maintaining operational efficiency.

IV. METHODS AND MATERIALS

The methodology adopted in this research offers a clear and systematic explanation of the technical approach, detailing the phased execution workflow and the environment in which the security model was developed and evaluated. It maps the full operational cycle, from request initiation and identity verification to permission checking and final query execution, demonstrating how each stage contributes to enforcing strict access controls. The methodology is structured around three integrated phases: Request Initialization, Verification Process, and Execution and Response, as displayed in Fig. 2. Together, these phases represent the full lifecycle of a database interaction within a secure, access-controlled environment. The process begins with Query Initiation, where the developer issues a request to the database using SQL instructions intended to retrieve, insert, update, or delete data. This step forms the operational entry point, defining the intended action and the credentials through which it should be executed. Next, the system performs Identity Account Retrieval, extracting the account information from the domain controller to confirm the identity of the request initiator. This ensures that subsequent evaluation stages rely on verified and authenticated identity attributes.

Afterwards, a critical step in the workflow is Permission Verification, during which the system checks whether the authenticated user or service account is authorized to perform the requested action. This validation is executed by comparing the provided credentials to the records stored in the Active Directory, confirming exact matches before any database operation is permitted. Finally, the methodology concludes with Query Execution Based on Access Rights, where authorized SQL commands are securely executed. The database engine processes the approved instruction and returns the corresponding output. This structured cycle ensures that access is governed by strictly verified permissions, thereby strengthening privacy and reducing the risk of unauthorized operations.

To develop and evaluate the proposed security model, the study utilizes a comprehensive enterprise-grade technology stack that integrates development, authentication, and virtualization components in a structured manner. The implemen-

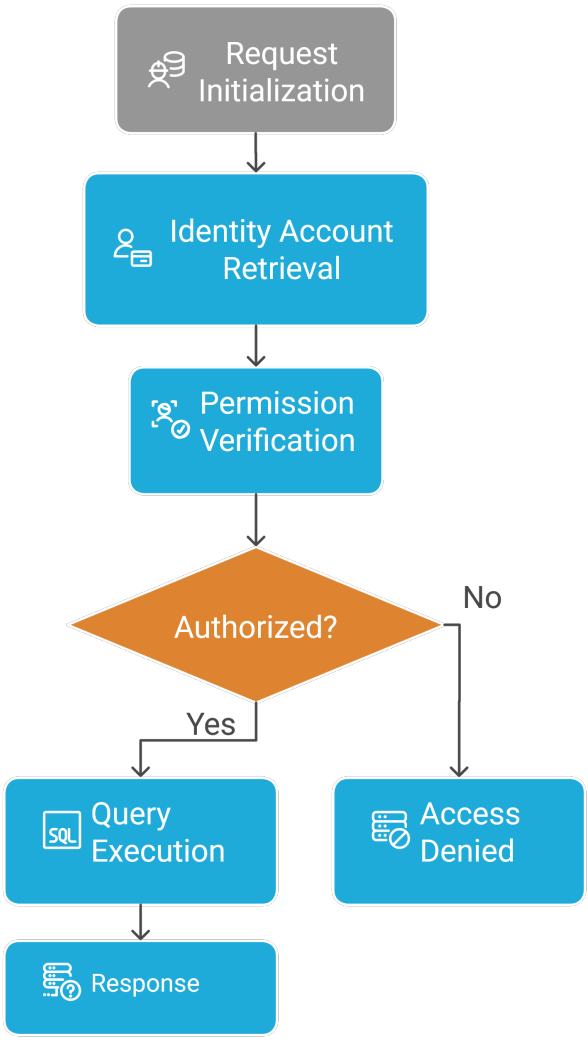

Fig. 2. Database access control flowchart.

tation begins with ASP.NET and C—supported by Visual Studio, as the core development framework used to build the access-control mechanisms and authentication logic. Microsoft SQL Server serves as the backend database system, providing scalable and secure data storage essential for testing various access scenarios. To support identity and permission management, Windows Server and its integrated domain controller constitute the backbone of authentication, ensuring centralized administration of user accounts and privilege verification. These components operate within a controlled virtualized environment created using VMware ESXi 6.7.0, hosted on a Dell PowerEdge R940 server equipped with an Intel(R) Xeon(R) Gold 5115 CPU, 80 logical processors, and multiple NICs, providing the computational capacity required for parallel and large-scale testing. This setup hosts 39 virtual machines, each configured to replicate real-world operational conditions in a reproducible manner. Active Directory operates on the DC01 server running Windows Server 2019 Standard Edition, with a functional level of Windows Server 2012 R2 to ensure compatibility with modern security protocols. And finally, firewall settings were carefully controlled to avoid external interference while preserving the integrity of testing procedures.

Consequently, the implementation of the proposed security model follows the methodology previously outlined and focuses on enforcing strict access controls and integrating authentication mechanisms within a Microsoft SQL Server environment using ASP.NET and C. The process begins by configuring user access requests and verifying the security policies that govern authentication and authorization within a Windows Server domain. This implementation is tested through controlled scenarios that observe system responses to both authorized and unauthorized attempts, ensuring that the enhanced security measures operate effectively without negatively impacting database performance. Hence, to support this implementation, the environment is designed as an interconnected framework in which the application, database, and Active Directory operate seamlessly to manage identity, permissions, and data flow. As illustrated in Fig. 3, this architecture enables continuous communication between components, allowing authentication and authorization checks to be performed before any database interaction occurs. This coordinated structure ensures that every user request is validated and processed according to predefined security rules, forming the operational backbone of the model.

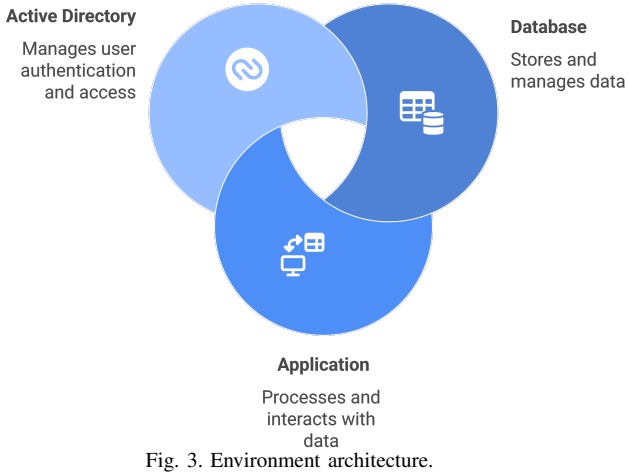

Fig. 3. Environment architecture.

Within this environment, Microsoft SQL Server 2016 hosts the CyberSecurity_CapstoneProject schema, which includes three essential tables. The Address table stores location data such as Building_No, StreetAddress, and FloorNo; the ContactInfo table contains communication fields including PhoneNumber, Email, POBOX, and SocialMediaAccount; and the EmployeeInfo table holds personal and professional information: FirstName, SecondName, FamilyName, DOB, PostalAddress, Occupation, CompanyName, Status, and associated audit fields like CreatedDate, CreatedBy, ModifiedDate, and ModifiedBy. These tables are interconnected to provide a complete representation of employee records, as shown in Fig. 4. Nevertheless, the SQL Server environment is organized in a standard hierarchical structure, where the schema and its tables appear under the database's "Tables" directory, alongside system tables, external resources, programmability components, and security configurations

The operational workflow begins with the initiation of SQL queries, where the developer formulates the required command and embeds the necessary account credentials within the connection string. The query prepared with its associated

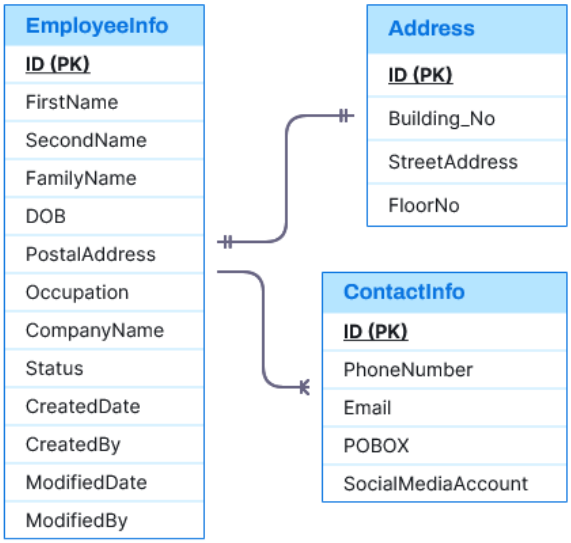

Fig. 4. Database ERD diagram.

identity information, is submitted to the system for execution:

```
string sQuery;
string sConnectionString =
    "Data Source=RACELDRT\\SQL2016;Initial
    ↪  Catalog=SANG_Weather_Prayer;"
    + "User ID=SQLTest;Password=123456789;";
sQuery = "SELECT [ID], [Building_No], [StreetAddress],
↪  [FloorNo] "
       + "FROM
       ↪  [CyberSecurity_CapstoneProject].[dbo].[Address];";
```

A complementary user interface, shown in Fig. 5, allows queries to be executed interactively, providing transparency during testing and making it possible to observe how the system handles different access attempts. And, after a query is issued, the system retrieves the corresponding account identity from Active Directory using C. This retrieval ensures that each request is tied to a verified domain identity before any authorization checks occur. Once the account details are obtained, they are used to determine the user's access level and validate whether the requested action aligns with the assigned permissions.

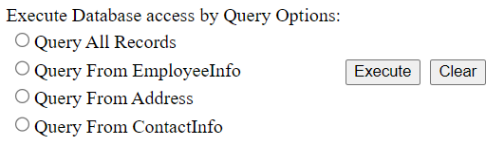

Fig. 5. Query options to execute on the database.

The subsequent stage focuses on permission verification, where the submitted credentials are compared with those stored in Active Directory. This comparison is implemented through C logic that ensures the credentials provided by the user exactly match the corresponding domain records before access is approved. Only when the account information fully aligns with the stored identity data does the system permit the request to proceed. This verification step strengthens the overall security posture by preventing unauthorized users from executing database commands.

Following successful authentication and authorization, the system proceeds to execute the SQL command using the verified account's privileges. A secure connection is established, after which the authorized operation is processed by the SQL Server engine. Whether the requested action involves retrieving, inserting, updating, or deleting data, the database completes the command and returns the corresponding response to the requester. By ensuring that all queries are executed strictly under validated permissions, the implementation guarantees that database interactions comply with the intended security controls and that unauthorized activity is effectively mitigated.

V. Results and Discussion

This section presents the experimental findings of the proposed access-control framework developed to strengthen database security. The implementation was conducted using Microsoft SQL Server integrated with Active Directory to enforce role-based authentication and manage user privileges effectively. The evaluation examined how the system mitigates unauthorized data access, preserves information confidentiality, and sustains operational efficiency under various workloads. The analysis focused on three core dimensions: the precision of access-control enforcement, the performance of query execution under restricted conditions, and the resilience of the database against security breaches. The discussion also interprets the practical implications of these findings for enterprise database protection and outlines areas where further optimization can enhance reliability and scalability in future implementations.

A. Privileges and User Accounts

The evaluation involved five user accounts: smharbi1, Ssmutawa, Salroumi, amathel, and maabkhet, representing different operational roles within the organization. Each user was assigned a specific level of access to three core database tables: EmployeeInfo, ContactInfo, and Address. These privileges were configured and verified within Microsoft SQL Server using Active Directory, based authentication to ensure that access rights were directly tied to domain-level credentials. Prior to applying the proposed access-control model, all user accounts were granted unrestricted access to the database through a shared service configuration. This approach violated the principle of least privilege and exposed sensitive information to unauthorized viewing and modification. After enforcing the model, each user's permissions were refined to reflect their functional responsibilities.

Administrative users retained full access to all datasets, while standard users were limited to only the tables necessary for their operational tasks. The analysis of user privileges revealed that the model successfully differentiated roles and applied restrictions accurately. For instance, smharbi1 maintained complete administrative rights, whereas Ssmutawa and amathel were limited to access specific data categories relevant to their roles. Salroumi and maabkhet had partial access aligned with departmental boundaries, demonstrating the granularity of the implemented policy. The overall distribution of user privileges is summarized in Table IV, which consolidates the effective permissions of each account across the three main database tables. The results confirm that the proposed model enforces precise and hierarchical access, reducing redundant permissions and minimizing the risk of unauthorized data exposure.

TABLE IV. USER ACCOUNT ACCESS TO DATABASE TABLES

User Account	EmployeeInfo	ContactInfo	Address
smharbi1	Yes	Yes	Yes
Ssmutawa			Yes
Salroumi		Yes	Yes
amathel		Yes	
maabkhet	Yes		

B. Comparative Evaluation of Access Control Before and After Implementation

The evaluation of this work, aimed to measure the effectiveness of the new mechanism in strengthening privilege enforcement, minimizing unauthorized access, and sustaining operational efficiency. The analysis focused on user interactions with the EmployeeInfo, Address, and ContactInfo tables to identify improvements in access accuracy and adherence to security policies. Before deploying the access-control model, all database users were authenticated through a shared service account (SQLTest), which bypassed role-based verification. Consequently, every account had unrestricted access to all data tables (EmployeeInfo, ContactInfo, and Address), regardless of job role. This violated the least-privilege principle and exposed sensitive information to potential misuse.

To illustrate this issue, a standard user was able to execute a query on the EmployeeInfo table and retrieve all records successfully. This behavior clearly reflects the absence of proper privilege enforcement, as the system made no distinction between administrator privileges and regular-user permissions. Such unrestricted access not only increased the risk of accidental data modification but also eliminated any meaningful user accountability. After applying the access-control model, authentication and authorization were tightly coupled through Active Directory and Microsoft SQL Server. Each query request was verified against the domain credentials of the requesting user before execution, ensuring that only authorized users could access their assigned tables. As shown in Fig. 6, the user Ssmutawa was permitted to access only the Address table, while Fig. 7 demonstrates that Salroumi could view records exclusively from the ContactInfo table. Attempts by these users to query unauthorized tables triggered explicit denial messages, confirming that privilege restrictions were properly enforced.

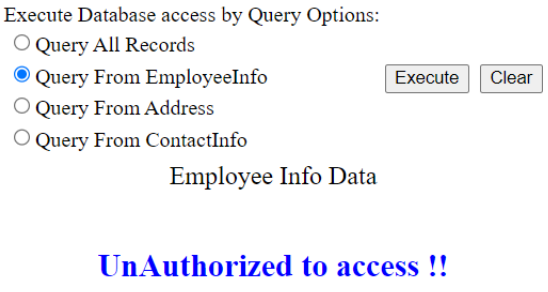

Fig. 6. Authorized access – Ssmutawa (Address table, Post-Implementation).

The evaluation confirmed that all privilege assignments were applied accurately and that no unauthorized user could access restricted information. Query execution remained efficient, indicating that the additional verification steps did not introduce noticeable performance overhead.

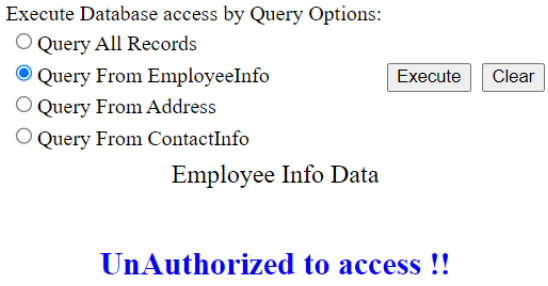

Fig. 7. Authorized access – Salroumi (ContactInfo table, Post-Implementation).

TABLE V. USER ACCESS PERMISSIONS ACROSS DATABASE TABLES

User Account	Emp-Info	ContactInfo	Address
smharbi1 (Admin)	Access	Access	Access
Ssmutawa	Denied	Denied	Access
Salroumi	Denied	Access	Access
amathel	Denied	Access	Denied
maabkhet	Access	Denied	Denied

C. Discussion

The comparative results reveal a complete transformation in database behavior following the model's deployment. Under the pre-implementation setup, every user had full access to all data. Post-implementation, access rights were strictly constrained according to defined roles. Administrative accounts retained full control, while standard users were limited to specific datasets required for their daily operations. This refinement achieved true least-privilege enforcement, improved accountability, and prevented privilege escalation. Furthermore, the integration with Active Directory ensured traceability, each query could be linked to a verified user identity, strengthening audit capabilities. The resulting user privileges after model implementation are summarized in Table V, which consolidates effective permissions across the main database tables.

To contextualize these improvements, it is important to compare them directly with the conditions observed in Experiment One. In Experiment One, all user accounts (smharbi1, Ssmutawa, Salroumi, amathel, maabkhet) were able to retrieve data from the EmployeeInfo, ContactInfo, and Address tables. This unrestricted access was attributed to the use of the service account (SQLTest), which possessed elevated privileges. Consequently, this setup allowed all user accounts to bypass access control restrictions, thereby compromising the principle of least privilege (PLP) and exposing the database to potential security threats. On the other hand, experiment Two demonstrated a marked improvement in access control and data security. The newly implemented access control model was designed to enforce specific access rights tailored to each user account based on their roles and responsibilities within the organization. This granular approach to access control ensured that only authorized user accounts could retrieve data from the designated tables, thereby mitigating the risk of unauthorized

TABLE VI. COMPARISON OF USER ACCESS BEFORE AND AFTER MODEL IMPLEMENTATION

User Account	Emp Info (Before)	Emp Info (After)	Contact Info (Before)	Contact Info (After)	Address (Before)	Address (After)
smharbi1	Yes	Yes	Yes	Yes	Yes	Yes
Ssmutawa	Yes	No	Yes	No	Yes	Yes
Salroumi	Yes	Yes	Yes	Yes	Yes	Yes
amathel	Yes	No	Yes	Yes	Yes	No
maabkhet	Yes	Yes	Yes	No	Yes	No

data access. For example, the account smharbi1 retained full access to all tables due to the comprehensive permissions associated with the user's role. On the other hand, accounts such as Ssmutawa and Salroumi faced restricted access, preventing them from retrieving data from certain tables, thereby enhancing the overall security of the database system. The differences in access capabilities before and after implementing the access control model are illustrated in Table VI. These visuals depict the restricted access observed in Experiment Two, showcasing the model's effectiveness in enforcing data security protocols and preventing unauthorized access.

These findings underscore the effectiveness of the new access control model in significantly enhancing database security by strictly enforcing user-specific access privileges and preventing unauthorized data access. The systematic comparison of the two experiments highlights the critical role of robust access control mechanisms in safeguarding sensitive information within database environments. When compared to the works of Wu et al. [26] and Shan et al. [30], the results of this study align with the growing emphasis on enforcing the principle of least privilege at the data source level. While Wu et al.'s PDA framework focused on privilege separation through application-driven enforcement, the model in this research extends the concept by embedding identity verification directly at the database layer, combining role-based control with domain authentication. Similarly, Shan et al. emphasized multi-layer filtering and the integration of logging for confidentiality assurance.

The proposed model complements this by providing traceable and verifiable access through Active Directory integration, strengthening accountability for every query execution. Furthermore, unlike the encryption-based approach by Ibrahim et al. [23], which primarily addressed data confidentiality through encoding mechanisms, this work enhances security through behavioral access enforcement restricting who can interact with the data in real time. The combined analysis across both experiments demonstrates that implementing access verification at the database layer provides a more scalable and flexible solution compared to pure encryption or masking techniques discussed in related studies. Overall, the proposed model advances the state of access control research by bridging theoretical models with practical enterprise deployment. It achieves fine-grained privilege management, aligns with established security frameworks, and complements existing literature by demonstrating that database-layer access verification can achieve both operational efficiency and strong data protection.

VI. CONCLUSION

This research addressed the critical challenge of strengthening privacy and access control in enterprise database systems, particularly in operational environments where shared service accounts and over-privileged credentials expose sensitive information to unauthorized access. Such configurations undermine accountability and violate the principle of least privilege, increasing the risk of insider misuse and accidental data disclosure. To address these issues, this study proposed a data-layer security framework that enforces fine-grained access control by binding every database operation directly to authenticated user identities. The proposed framework integrates centralized identity management with database access enforcement to ensure that all SQL operations are executed under verified and authorized user credentials. By eliminating reliance on generic service accounts and enforcing role-based permissions at the data-layer, the model provides stronger control over who can access specific database objects. The implementation demonstrated how authentication and authorization mechanisms can be tightly coupled with database operations to enhance privacy without disrupting normal development or administrative workflows.

The framework was implemented in an enterprise-grade environment using Microsoft SQL Server integrated with centralized identity services and evaluated through controlled experiments conducted before and after deployment. Experimental results clearly demonstrated a significant reduction in unauthorized data access, improved enforcement of user-specific privileges, and enhanced accountability across database operations. Importantly, these security improvements were achieved without introducing noticeable performance overhead, indicating that stronger privacy controls can be implemented while maintaining system efficiency and usability. Despite the effectiveness of the proposed approach, certain limitations were identified. The framework depends on centralized identity infrastructure, which may introduce single points of dependency in some deployment scenarios. Additionally, integrating the model into legacy database environments may require additional configuration and administrative effort. Addressing these challenges are essential to ensure broader applicability and long-term maintainability.

Future work will focus on extending the framework to improve resilience and adaptability in dynamic enterprise environments. Potential directions include introducing redundancy mechanisms for identity services, developing automated tools for privilege management, and exploring adaptive access control strategies that adjust permissions based on user behavior and operational context. These enhancements aim to further strengthen database privacy, scalability, and robustness in the face of evolving security threats. Collectively, this study establishes that enforcing access control at the database layer through identity-bound execution is a practical and effective mechanism for improving privacy, accountability, and compliance with the principle of least privilege in enterprise database systems.

***Abstract*—The Researchers and academicians are continuously working on minimizing the production losses due to various plant diseases. Therefore, recent technologies such as artificial intelligence (AI), and machine learning (ML) are playing a crucial role in detecting plant diseases in their early stages. These technologies help classifying plant leaves into 'healthy' and 'rusty' or 'diseased' leaves. It is difficult for human being to detect the plant diseases and take remedial action within stipulated time period. Hence, this research work addresses comparison of different convolutional neural network (CNN) models like Alexnet,Resent18,Resnet50, Xception, VGG16, VGG19, InceptionV3,InceptionResentV2 etc. and concluded with the top CNN models with good filters used to capture the plant leaves images. Proposed research work uses different filters dataset like K590, K665, K720, K850,BlueIR, Hotmirror. Plant disease detection requires accurately detecting the rust, or disease on the leaves immediately and efficiently. CNN models help classifying the plant leaves with higher accuracy and precision. Proposed research work gave accuracies for different filters with different models and found that, for K850 filter accuracy is 72.72% using balance efficientnetB0 CNN model, for K720 filter accuracy is 81.81% using balance efficientnet B0 CNN model, for K665 filter accuracy is 84.09% using balance efficientnetB0 CNN model, for K590 filter accuracy is 90.90% using balance MobilenetV2 CNN model, and for the hotmirror filter accuracy is 93.18% using balance Xception & for the blueIR filter accuracy is 81.81% using balance Xception CNN model.**

I. Introduction

Convolutional neural network popularly known as CNN used in multiple applications like image classification, video analysis, emotion recognition, analyzing spatial data, etc. Convolutional layer is responsible for performing matrix manipulation operation on the input data. With the help of CNN [1], [2], it is possible to extract the different features of the input data. As discussed, convolutional layer extracts feature sets from the given input data and its output either a feature set or feature map will be given as an input to the next phases of the CNN model. In many image processing applications with the help of CNN models one can extract different features like edges, corners, textures, and many more other complex features. Next layer in the CNN model is pooing layer responsible to reduce the dimensions of the input and consumes less memory. This

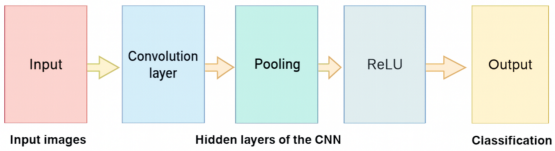

Fig. 1. CNN basic architecture.

reduction in the dimensions helps dealing with the overfitting issues in the network. Max pooling layer in the CNN model helps minimizing the computational complexities, minimizing the features set etc. To make the CNN model more robust max pooling layer is indivisible part and helps maintaining the accuracy of the model. Key concept in CNN models is training, testing and validating. To evaluate the CNN models one can, use parameters like precision, F1 score, recall etc [3] .

• Alexnet: This CNN model was developed by Alex Krizhevsky, Ilya Sutskever, and Geoffrey Hinton. This model consists of 05 convolutional layers, 03 fully connected layers. First 02 convolutional layers max-pooling layer in order to extract 'n' features. Next convolutional layers are connected to the fully connected layers. Outputs of these layers are connected to ReLU (Rectified Linear Unit). For the purpose of distribution and classification the resultant output will be connected to softmax activation layer.

• DenseNet: DenseNet is dense convolutional neural network model used for classification and segmentation purpose. It is based on feed forward technique i.e. output of one layer is connected to every subsequent layer which enables the reuse of extracted features. Hence, one can find significant information is flowing in the DensNet architectures. The major advantage of DenseNet based models is its accuracy. However, the 'n' layer connections consume a bit more memory which affects the popularity of these architectures. As every layer is connected to every subsequent layer it increases the computational

complexity in the network results in higher training time and increased computational cost.

• Resnet18: It is popularly used in deep learning applications due to its ability to handle complex tasks. It is widely used in image classification and it consists of convolutional layers, ReLU activation layers and fully connected layers. With the help of residual blocks present in the Resnet18 architectures one or few steps can be skipped by preserving the information.

• Resnet50: It belongs to residual network (ResNet). It's a 50-layer convolutional neural network model which uses 'skip' connection to skip few steps by preserving the information in forward-and-backward propagation. It is used in image processing applications to perform few tasks like classification, object identification and segmentation. However, in the deep learning architectures as the network becomes accuracy could be drenched. This condition can be handled by the ResNet architectures by introducing the residual blocks to skip few steps by preserving the information.

• VGG16: It consists of 16 layers i.e. 13 convolutional layers and 03 fully connected layers. VGG16 is commonly used in image classification & detecting the objects to achieve higher accuracy. VGG network is developed by visual geometry group and consists of series of convolutional neural networks. Simplicity and Uniformity are the key features of the VGG16 models. However, VGG16 models have few limitations like high computational costs, memory consumption & slow training time.

• VGG19: It is a series of VGG network and consists of 19 layers. It consists of 16 convolutional layers and 03 fully connected layers due to which it becomes more deeper than VGG16 network. The additional depth of VGG19 models gives a bit more accuracy than VGG16. Deeper analysis requires more memory and increases the memory cost & computational cost too. More depth of VGG19 than VGG16 could lead to slow the network training time & becomes less popular in many sensitive applications.

• Effficeienet_80: - It is a CNN model used to get higher accuracy in image classification applications. As compared to the other versions of CNN models it requires less computational costs. Compound scaling is introduced in this CNN model to scale the network to achieve high performance and accuracy. It is widely used in image classification, segmentation and computer vision tasks.

• Mobilenet_V2: As its name indicates it is used in mobile devices for image classification, detecting the objects and segmentation. It gives better performance than previous version of Mobilenet architecture. Higher accuracy, low latency, high speed, less computational cost, and small model size are the key characteristics of this CNN model.

• Xception: Using less parameters this CNN model gives better performance than other models. Due to minimized no. of operations it requires less computations. To deal with overfitting it introduces batch normalization and dropout layer if the dataset is larger.

• Inception_V3: High accuracy, less computations and, multi-scale feature extraction are the key features of this CNN model. Dimensionality reduction feature of this CNN model helps preventing the depth of the network i.e. prevents the network becoming deeper. It introduces multi-scale feature extraction to capture different features using scaling & different filters simultaneously. Fig. 1 shows CNN basic architecture.

II. Literature Review

Authors in study [4] have proposed a research work to detect plant diseases in their early stages using remote sensing technique. It is quite difficult task for human being to diagnose the possible plant diseases in the early stages. Therefore, image processing techniques and processing of the hyper spectral images of the plant leaves could help to detect the plant diseases. Authors have proposed a sensor fusion [4] technique application on the hyper spectral images of the plant leaves. Such methods help detecting the rust on the plant leaves in the early stages. This research work demonstrated the spectrograph among the healthy and diseased leaves. However, environmental factors such as sufficient light while capturing the images of the plant leaves have impact on the accuracy of the model. Use of pesticides on the plants is a common practice during cultivation but many times this approach fails to control the plant disease because pesticides could not be applied evenly. Application of the excessive pesticides can increase the production cost and many times remain in the product as well as in the soil too. Last few years, everyone is struggling to reduce the use pesticides & because of this with the help of recent technologies such as AI (artificial intelligence) and ML (machine learning) detecting the plant diseases in the early stages is possible. Authors [5] have proposed a research work detecting the specific area (site) to apply the fungicide using remote sensing technique. With the help of remote sensing technique within less time and minimum efforts one can detect the specific diseased area on the plants (plant leaves, stem etc.) This research work focuses on the identification of fungal infection on the plant leaves. This research work proposed a multi spectral remote sensing technique to detect the plant diseases. In this research work authors have analyzed winter wheat crop using their proposed research work to detect the fungal infection. Once the fungal infection is identified authors have applied the decision tree and mixture tuned matched filtering (MMTF) to classify the severity of the possible diseases. Many farmers face challenges during the cultivation of the soybean [6] due to the Phakopsora pachyrhizi - a fungus which destroys the soybean crop and affect the yield. This fungus spreads rapidly across the field and affects the crop yield. Therefore, authors have suggested it is necessary to detect the crop disease in its early stages. Proposed research work focuses on detecting the soybean rust and severity of the disease. Authors have collected various images of the soybean leaves in order to classify the disease severity.

Key concept in this research work is tracking leaf development and fungal infection simultaneously. Objective of this research work is to process the multispectral images of the soybean leaves and detect, classify the rust on the crop. Processing of the high-resolution multispectral images [7] was proposed by the authors to detect the plant diseases in their early stages. The proposed research work aims automatically detecting and classifying plant leaves diseases. In the new phase of agricultural era i.e., precision agriculture using recent

techniques helps detecting the fungal infection on the plants. Authors have analyzed sugar beet plant to detect the possible diseases in its early stages. This research work identifies rust, powdery mildew and other spots on the plant leaves. The proposed research work captures the multispectral images of the sugar beet leaves in better lighting conditions. Next phase of the proposed research work helps classifying the healthy leaves, leaves with rust, and different spots on the leaves. Authors [8] have focused on possible diseases on soybean crop. Crop diseases affect the yield and researchers are taking efforts to minimize the yield loss. Therefore, it is necessary to detect the disease in its early stage. Controlling measures like application of the pesticides, fungicides are necessary to prevent the possible diseases. In this research work authors have demonstrated effective framework to identify the rust severity using multi-spectral images. Segmentation method applied to classify the infected area of the plant. Rust infection and the rust color are the major parameters were applied in this research work to calculate the rust severity. Once the classification of rust parts finishes, system applies threshold-setting method to finalize the rust severity. Automatic classification [9], [10] was proposed to identify the leaf diseases using multi-spectral images. Authors have proposed a precision agriculture model to identifying infected area accurately and taking controlling measures. In this research work authors have input images of the sugar beet leaves using different cameras i.e., RGB and multispectral images. Idea is to classify the healthy and infected leaves and taking controlling measures. Authors have applied k-nearest neighbor and adaptive bayes classification methods. Major contribution in this research work is pixel wise classification to achieve more accuracy. Authors in [11] have proposed a research work "Localized multispectral crop imaging sensors: Engineering & validation of a cost-effective plant stress and disease sensor". Authors have discussed how a close proximity could play important role in crop disease detection and help in precision agriculture. Close proximity helps accurately scanning the infected area and finding rust severity. Advantage of this proposed research work helps finding sensitive area (rust infection) using LED sensors. One can say it is a combination of hyper spectral image processing and application of LED sensors for better accuracy. An approach to reduce the qualitative and quantitative losses [2] was proposed using RGB, multi and hyper spectral images. Research work also focuses on different techniques like proximity, remote sensing, spectral sensors, and fluorescence imaging gives better results. Additionally, 3D scanning of the plant leaves could give better results in disease detection. Once the system collects and classifies healthy and infected leaves, with the help of supervised classification one can easily identify the infected area on the plant. As discussed, earlier fluorescence imaging focused on the photosynthesis activity of the plants. Author has discussed how a LED or laser light can track the photosynthesis activity of the plant. More parameters like plant leaf inclination, illumination and texture etc. will help in disease detection in its early stages. However, using sensors one can collect the large data of the plants but it is crucial to process that large data and deriving meaningful insight becomes difficult.

This research work also guides researchers w.r.t. few points like, classifying fungi, bacteria and viruses; Author suggested a best interdisciplinary model can be developed by integrating people and technology from plant pathology, sensor developments, and recent technology like machine learning. Using the best integrated model, it could become easier to conduct the pest management on the plants and detect the plant diseases in their early stages. Authors [12] have focused on precision agriculture model to minimize the plant diseases by maximizing the yield. With the help of recent technologies precision agriculture models can be developed to effectively utilize the pesticides.

Recent technologies and algorithms help farmers to detect the plant diseases in their early stages and to take remedial actions immediately. This research work uses hyper spectral imaging for the tomato crops. Proposed model classifies the tomato leaves into healthy & infected classes. Authors have also worked on vegetation indices and dimensionality of different features. As the proposed model successfully explores the dimensionality of the features, it increases the classification accuracy proportionally. Authors [13] have discussed how the plant diseases affected the yield across the world. Food security is another issue being faced by different countries & sustainable precision agriculture model must be developed to minimize the losses and maximize the yield. Authors have proposed non-destructive methods to track and control the plant diseases. To minimize the time required detecting and controlling the detected plant disease, these non-destructive methods are proposed which are simpler than other methods. These methods also help minimizing the use of pesticides and detect the diseases in its early stages. These non-destructive methods also detect the diseases rapidly & include different steps like taking images of the plant leaves and taking controlling actions. Authors in [14], [15] have discussed different machine learning models those are developed to detect the plant diseases in their early stages. This research work also focused on deep learning techniques those can be used for detecting the plant diseases in early stages and maximizing the yield. Deep learning models can give more accuracy in detection and prevention of plant diseases. This review work proposed by authors discussed different deep learning approaches for plant disease detection. Authors have also explained how visualization techniques can be used to detect and present different symptoms of plant diseases. Image processing in these models uses hyper spectral images of the plant leaves and most important point in all models to be considered is 'environmental factors' like illumination etc. Therefore, objective of such models is to minimize the use of fungicides and pesticides. The major advantage of deep learning models is one can keep track on plant disease occurrence. Authors [1] have noted important challenge faced by different countries i.e., food scarcity. It became necessary to detect the plant diseases and maintaining the yield to avoid the losses. Authors have discussed near-infrared (NIR) imaging is the popular method in plant disease detection. Images of the plants can be captured under the natural environmental condition.

The proposed model divides the prepared dataset into different ratios. With the help of different ratios i.e., training and testing split ratios one can evaluate the model's accuracy. This research work consists of different steps like capturing hyper spectral images, processing of those images, extracting different possible features, and applying classification to evaluate the proposed model's accuracy in terms of precision and recall. Authors in [16] have enlisted different technologies like

computer vision, image processing and machine learning etc. can be used to detect the plant diseases in early stages. These recent technologies also speed up the disease detection process and help farmers to take controlling actions immediately. This research work addresses the machine learning methods used for classification purpose which classifies the healthy and infected leaves within less time. Different approaches like support vector machines (SVM), naïve bayes and convolutional neural network modeling (CNN) discussed and used in the proposed framework. Authors in [17] proposed a research work focusing on cassava brown streak disease. Objective of this research work is to detect the disease in its early stage using multi-spectral imaging. Authors have developed an active multi-spectral imaging device to capture the real time images of the plants and helps end users to take remedial actions immediately. Research work focuses on distinguishing healthy and infected plant laves. The advantage of this proposed research work is integration of spatial as well as multi-spectral images. The invented active device also finds if there are any stresses due to environmental factors, pesticides etc. With the help of multi-spectral imaging approach large volume of data can be generated which is very useful in accurately finding the infection. Classification helps differentiating healthy plant's leaves vs infected leaves. Active device captures multi-spectral images of the leaves automatically and processes them by applying 'cropping' mechanism. If necessary, the proposed system can perform leaf segmentation for better comparisons.

Egyptian people consume rice regularly and it is considered as one of the important crops. However, due to various factors rice crop yield gets affected and need arises to minimize the losses. Authors in [18], [3] proposed a research work emphasizing on controlling rice plant diseases using deep convolutional neural network and multi-spectral imaging. Proposed research work prepares a multi-modal data of the rice plants using multi-spectral and RGB images. The objective of proposed research work is to show how accuracy of the plant disease detection can be increased with the help of multi-spectral and RGB images. The economy of almost every country is based on 'agriculture production'. The production of agriculture gets hampered due to the factors like environmental conditions (drought, flood etc.), various diseases on the plants and excessive use of pesticides etc. Authors in [19] noted these conditions could lead to food scarcity and can disturb the global food supply chain. Hence, recent technologies like AI and ML could detect plant diseases in its early stages and minimizes the losses. Hyper spectral images of the plants can detect the diseases in its early stages. This research work gives direction to the researchers and academicians to detect plant diseases. It consists of few modules like capturing images of the plants, classification, identifying diseases, deciding disease severity etc. Authors in [20] have discussed important point in this research work i.e.; many existing plant disease detection systems depend on the datasets. The proposed research work discusses effectiveness of the multi-spectral images in real time environment. The important part of this research work is 'vision transformer' models used in training and testing the collected data. Objective of the proposed research work is to show how advanced imaging methods can help controlling the plant diseases in its early stages. Authors in [21] have reviewed different multiple spectral systems used in plant disease detection. It is necessary to detect the plant diseases rapidly to control them in early stages. Authors have discussed how 'spectroscopy' helps rapidly detecting the plant diseases and minimizes the losses.

This review work emphasized on advantages and disadvantages of the spectral detection systems. These multiple spectral systems are being used in detection of plant diseases, finding different stresses on the plants due to various factors. Review article also enlisted different challenges in using multiple spectral systems, their working and future research directions. Authors in [22], [23] have proposed a deep learning model processing multi-spectral images of the plants detecting diseases in the early stages. With the help of recent technologies, it is necessary to detect various diseases on the plants in the early stages & helps avoiding losses. Authors have used 'tomato' plants multi-spectral images with different filters to identify disease in the early stages. Experimental approach of this research work is based on 02 datasets i.e., one is taking uniform images of the plants and second dataset with some sort of variations in capturing different images. Objective of this research work is classifying healthy and diseased leaves of the plants based on CNN (convolutional neural network) modeling, vision transformers. Idea using different filters is to find the best accuracy and consistency. Authors have found K590 filter gave highest accuracy 88.69% and 93.31% for datasets. ViTBI6 is the effective model in the research study with 89.92% accuracy. Proposed deep learning-based model also helps classifying balanced and unbalanced datasets.

Authors in [24], [25] have discussed food security issues faced across the globe. Various plant diseases affect the agricultural productivity. It is very crucial for human being to detect the plant diseases manually and it is also a time-consuming task. There are chances of errors in manual detection and controlling the plant diseases. With the help of AI and ML, one can develop a model to detect and control the plant diseases & minimizes the future productivity losses. An integrative model i.e., with different sensors, high resolution cameras, AI and ML technologies can be developed for crop disease detection. Authors have proposed a review work based on existing research works in this area focusing on image-based plant disease detection. This reviewed work helps researchers and academicians to find the effective technology, algorithm and image forms. It also helps in deciding how environmental factors play important role in plant diseases and how to detect the diseases in its early stage.

III. Proposed System

Proposed system is based on CNN models like AlexNet, ResNet18, ResNet50, VGG16,VGG19, DenseNet121, EfficientNet121,MobileNetV2, ConvexNet_B0, Xception, InceptionV3, InceptionResNetV2. This section illustrates result analysis of the different filters like Hotmirror, K590, K665,K720,K850, and blueIR balance datasets. Following section explains result analysis for the above-mentioned balanced datasets using different CNN models. The proposed CNN framework evaluates the model's efficiency with test accuracies calculated using CNN model and balance dataset. Analysis of the proposed research work gradually applies CNN models against the filters (balanced datasets) & to illustrate the working of our proposed research work we have discussed hotmirror dataset and different CNN modeling approaches.

It gives variation in test accuracies as shown below and found that, for the hotmirror filter the Xception CNN model gives 93.18% test accuracy. DenseNet121 and EfficentNet_B0 gives 79.5% accuracies for the hotmirror filter. Following Fig. 2 illustrates the difference between test accuracies for the hotmirror filter using CNN models.

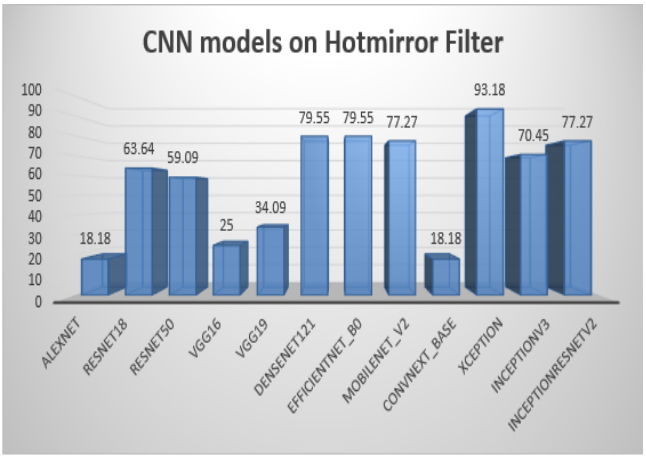

Fig. 2. CNN models performance on hotmirror filter.

The advantage of our proposed approach is applying 12 CNN models on the different datasets makes it more flexible to identify the plant diseases accurately and efficiently. To illustrate the working of proposed approach following section discusses the working of proposed integrated CNN modeling approach detecting plant diseases in their early stages.

A. Hotmirror Analysis

Training AlexNet on hotmirror_balance (1/12 models for this filter)

```
[AlexNet] Epoch 1/5 | Train Loss: 1.7751, Val Acc:
    0.2045
[AlexNet] Epoch 2/5 | Train Loss: 1.7557, Val Acc:
    0.2045
[AlexNet] Epoch 3/5 | Train Loss: 1.7509, Val Acc:
    0.2045
[AlexNet] Epoch 4/5 | Train Loss: 1.7498, Val Acc:
    0.2045
[AlexNet] Epoch 5/5 | Train Loss: 1.7511, Val Acc:
    0.2045
```

AlexNet CNN model was applied using 05 epochs and calculates the test accuracy for the hotmirror filter & found the overall test accuracy is low i.e. 18.18%. It is also important to minimize the training losses during training the network. Next phase of the proposed CNN model is training the given network using ResNet18 on hotmirror filter. Training ResNet18 on hotmirror_balance (2/12 models for this filter)

```
[ResNet18] Epoch 1/5 | Train Loss: 1.0300, Val Acc:
    0.3636
[ResNet18] Epoch 2/5 | Train Loss: 0.4845, Val Acc:
    0.5682
[ResNet18] Epoch 3/5 | Train Loss: 0.2662, Val Acc:
    0.6705
[ResNet18] Epoch 4/5 | Train Loss: 0.2102, Val Acc:
    0.4886
[ResNet18] Epoch 5/5 | Train Loss: 0.1425, Val Acc:
    0.5568
```

ResNet18 CNN model gives overall 63.64% test accuracy for the hotmirror balanced dataset. It is found that, as compared to the previous AlexNet CNN modeling approach ResNet18 gave better test accuracy.

Similarly, ResNet50 CNN model gives overall 59.09% test accuracy for the hotmirror balanced dataset as shown in the following epochs. Training ResNet50 on hotmirror_balance (3/12 models for this filter)

```
[ResNet50] Epoch 1/5 | Train Loss: 1.3103, Val Acc:
    0.3182
[ResNet50] Epoch 2/5 | Train Loss: 0.8093, Val Acc:
    0.5795
[ResNet50] Epoch 3/5 | Train Loss: 0.4439, Val Acc:
    0.6705
[ResNet50] Epoch 4/5 | Train Loss: 0.4466, Val Acc:
    0.6364
[ResNet50] Epoch 5/5 | Train Loss: 0.2318, Val Acc:
    0.4545
```

Next CNN modeling approach VGG16 gives overall low-test accuracy i.e.25.00% as shown below using 05 epochs and calculated training losses. It is expected to have minimum training losses and increase the overall test accuracy. Training VGG16 on hotmirror_balance (4/12 models for this filter)

```
[VGG16] Epoch 1/5 | Train Loss: 1.8613, Val Acc:
    0.2159
[VGG16] Epoch 2/5 | Train Loss: 1.7837, Val Acc:
    0.2045
[VGG16] Epoch 3/5 | Train Loss: 1.7700, Val Acc:
    0.2045
[VGG16] Epoch 4/5 | Train Loss: 1.7450, Val Acc:
    0.2045
[VGG16] Epoch 5/5 | Train Loss: 1.7409, Val Acc:
    0.2500
```

VGG19 CNN model gives overall 34.09% for the hotmirror balanced filter as shown below. Epochs are nothing but a pass-through which input data sample passed and updated repeatedly based on calculated errors and losses. Training VGG19 on hotmirror_balance (5/12 models for this filter)

```
[VGG19] Epoch 1/5 | Train Loss: 1.8190, Val Acc:
    0.2159
[VGG19] Epoch 2/5 | Train Loss: 1.6921, Val Acc:
    0.1932
[VGG19] Epoch 3/5 | Train Loss: 1.6088, Val Acc:
    0.2045
[VGG19] Epoch 4/5 | Train Loss: 1.6478, Val Acc:
    0.2273
[VGG19] Epoch 5/5 | Train Loss: 1.6460, Val Acc:
    0.2841
```

Similarly, following epochs illustrates the application of DenseNet121 on hotmirror filter which gives overall test accuracy 79.55% which is comparatively good than previous applied CNN model. Training DenseNet121 on hotmirror_balance (6/12 models for this filter)

```
[DenseNet121] Epoch 1/5 | Train Loss: 0.9287, Val
    Acc: 0.2386
[DenseNet121] Epoch 2/5 | Train Loss: 0.4265, Val
    Acc: 0.3295
[DenseNet121] Epoch 3/5 | Train Loss: 0.2419, Val
    Acc: 0.5909
[DenseNet121] Epoch 4/5 | Train Loss: 0.1292, Val
    Acc: 0.7273
[DenseNet121] Epoch 5/5 | Train Loss: 0.0822, Val
    Acc: 0.7159
```

The EfficientNet_B0 CNN model gives similar overall test accuracy for the hotmirror filter i.e. 79.55%. Training EfficientNet_B0 on hotmirror_balance (7/12 models for this filter)

```
[EfficientNet\_B0] Epoch 1/5 | Train Loss: 0.8554,
    Val Acc: 0.7500
[EfficientNet_B0] Epoch 2/5 | Train Loss: 0.2885,
    Val Acc: 0.8182
[EfficientNet_B0] Epoch 3/5 | Train Loss: 0.1385,
    Val Acc: 0.7841
[EfficientNet_B0] Epoch 4/5 | Train Loss: 0.1390,
    Val Acc: 0.7500
[EfficientNet_B0] Epoch 5/5 | Train Loss: 0.2134,
    Val Acc: 0.6932
```

MobileNetV2 CNN model gives 77.27% overall test accuracy after applied on the hotmirror filter. In our case for the hotmirror filter multi-spectral image set till now DenseNet121,EfficiNet_B0 and MobileNetV2 gave good overall test accuracies. Training MobileNetV2 on hotmirror_balance (8/12 models for this filter)

```
[MobileNetV2] Epoch 1/5 | Train Loss: 0.8472, Val
    Acc: 0.7386
[MobileNetV2] Epoch 2/5 | Train Loss: 0.3747, Val
    Acc: 0.6932
[MobileNetV2] Epoch 3/5 | Train Loss: 0.2372, Val
    Acc: 0.7727
[MobileNetV2] Epoch 4/5 | Train Loss: 0.1056, Val
    Acc: 0.7841
[MobileNetV2] Epoch 5/5 | Train Loss: 0.1739, Val
    Acc: 0.7159
```

We have applied ConvNext_Base CNN model on the same filter and found the overall test accuracy is low i.e. 18.18%. Training ConvNeXt_Base on hotmirror_balance (9/12 models for this filter)

```
[ConvNeXt_Base] Epoch 1/5 | Train Loss: 1.7957, Val
    Acc: 0.2045
[ConvNeXt_Base] Epoch 2/5 | Train Loss: 1.7849, Val
    Acc: 0.2045
[ConvNeXt_Base] Epoch 3/5 | Train Loss: 1.7577, Val
    Acc: 0.2045
[ConvNeXt_Base] Epoch 4/5 | Train Loss: 1.7682, Val
    Acc: 0.2045
[ConvNeXt_Base] Epoch 5/5 | Train Loss: 1.7691, Val
    Acc: 0.2045
```

Training the network using Xception CNN model gives 93.18% overall test accuracy which is exceptional among the other tested CNN models. Training Xception on hotmirror_balance (10/12 models for this filter)

```
[Xception] Epoch 1/5 | Train Loss: 0.9403, Val Acc:
    0.6591
[Xception] Epoch 2/5 | Train Loss: 0.4778, Val Acc:
    0.7500
[Xception] Epoch 3/5 | Train Loss: 0.2199, Val Acc:
    0.7273
[Xception] Epoch 4/5 | Train Loss: 0.1298, Val Acc:
    0.8068
[Xception] Epoch 5/5 | Train Loss: 0.0427, Val Acc:
    0.7841
```

InceptionV3 CNN model gives 70.45% overall test accuracy when applied on the hotmirror filter multi-spectral image set. Training InceptionV3 on hotmirror_balance (11/12 models for this filter)

```
[InceptionV3] Epoch 1/5 | Train Loss: 1.0353, Val
    Acc: 0.5795
[InceptionV3] Epoch 2/5 | Train Loss: 0.5270, Val
    Acc: 0.6932
[InceptionV3] Epoch 3/5 | Train Loss: 0.4543, Val
    Acc: 0.7273
[InceptionV3] Epoch 4/5 | Train Loss: 0.2871, Val
    Acc: 0.6818
[InceptionV3] Epoch 5/5 | Train Loss: 0.2210, Val
    Acc: 0.6932
```

InceptionResNetV2 CNN model gives 77.27% overall test accuracy when applied on the hotmirror filter multi-spectral image set.

```
Training InceptionResNetV2 on hotmirror_balance
    (12/12 models for this filter)
[InceptionResNetV2] Epoch 1/5 | Train Loss: 0.8923,
    Val Acc: 0.5455
[InceptionResNetV2] Epoch 2/5 | Train Loss: 0.4286,
    Val Acc: 0.6818
[InceptionResNetV2] Epoch 3/5 | Train Loss: 0.2779,
    Val Acc: 0.7159
[InceptionResNetV2] Epoch 4/5 | Train Loss: 0.0755,
    Val Acc: 0.7727
[InceptionResNetV2] Epoch 5/5 | Train Loss: 0.0214,
    Val Acc: 0.7386
```

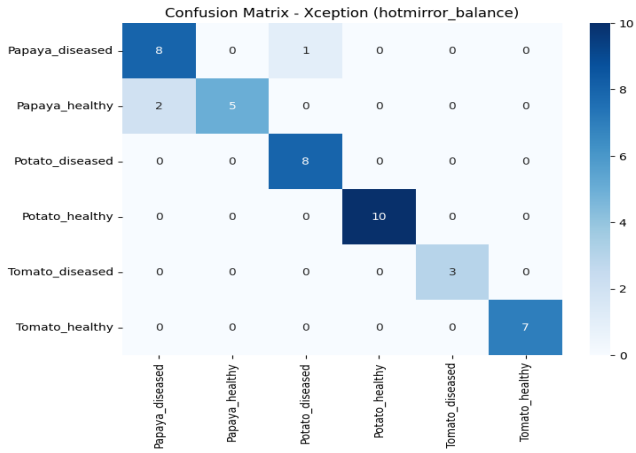

Fig. 3. Confusion matrix xception (hotmirror_balance).

B. Confusion Matrix

Confusion matrix is shown below in the Fig. 3 which illustrates the measurement effectiveness of a classification model applied in our proposed research work. It helps comparing the predictions made in our proposed research work with the actual results obtained and represents where the model was right or wrong. One can observe the confusion matrix and understand where the model is making mistakes to improvise the same. Table I gives brief idea about the classification report reliability measures for the Xception model and Fig. 4 illustrates the cumulative probability plot for the diseased and healthy leaves. Table II shows classification report reliability measures for the Xception model.

Following Table III and Fig. 4 gives brief idea about the best CNN models applied in our proposed research work with their respective overall test accuracies. By observing the table we can conclude that, Xception CNN modeling gives best test results i.e. 93.18% among the other approaches.

IV. CONCLUSION

This research work discussed CNN models used to classify the plant leaves (diseased leaves and healthy leaves) with higher accuracy and precision. Research work gave accuracies for different filters with different models and fund that, for the hotmirror filter accuracy is 93.18% using balance_Xception. One can use different datasets of plant leaves images and apply these different CNN models to evaluate the performance. It is very necessary to apply recent technologies to detect plant diseases in their early stages. Academicians and researchers are continuously striving for developing the best machine learning (ML) model for the same. To avoid future food scarcity, it is necessary to minimize the agriculture losses and increase the crop yield. Agriculture plays key role in every nation's economy and hence such ML models must be adopted widely. These models give accurate, efficient, and automated results to classify the diseased and healthy leaves. Deep learning techniques helps automatically extracting the features from the input images like color of the images, texture of the image, size and shape of the image, other environmental parameters (if required). Therefore, proposed model definitely will contribute in deploying precision agriculture models widely. The most important advantage of such model is helping end users in better decision making i.e. as the model detects any disease on the plant leaves, it warns the users to take remedial actions immediately. With the help of such strategy it is also possible to develop a proactive CNN model to minimize the labor cost in agriculture sector by maximizing the crop yield.

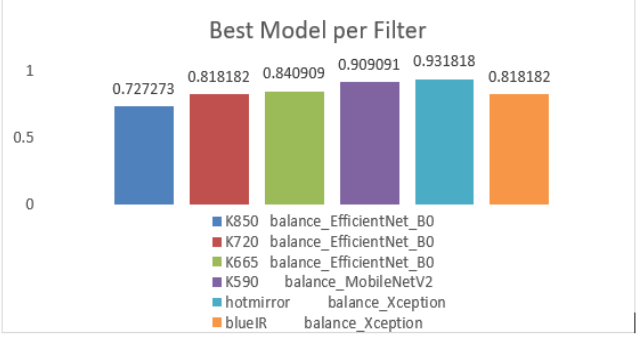

Fig. 4. Best CNN models as per the results.

CONFLICT OF INTEREST

The research was not funded by any particular grant, whether in the public, commercial, or not-for-profit sectors.

ACKNOWLEDGMENT

Author wish to appreciate Dr. Sunil Kumar, (Guide) for his invaluable guidance, support and encouragement in the process of doing this research. Author also thanks Dr. Hitesh Mohapatra (Co-guide) for providing constructive feedback, technical guidance and constant support. Author also thanks all the technical and non-technical staff of the Amity University, Jaipur for providing support in this research work.

***Abstract*—This paper presents a comprehensive Model-Driven Engineering (MDE) methodology for automatically transforming Business Process Model and Notation (BPMN) diagrams into executable blockchain-based smart contracts. The proposed approach defines a set of Atlas Transformation Language (ATL) rules that systematically map BPMN elements to Solidity constructs, ensuring semantic consistency and traceability throughout the transformation process. The framework integrates several stages, including process modeling, model validation, code generation, and deployment, supported by tools such as Camunda, Eclipse ATL, Remix IDE, and MetaMask. Experimental validation on the Ethereum Sepolia test network demonstrates the approach's ability to enhance automation, reduce manual coding errors, and improve synchronization between business workflows and their on-chain implementations. Compared to existing BPMN-to-blockchain frameworks, the proposed solution offers a unified and reusable transformation pipeline that bridges the gap between business process modeling and blockchain execution. The study concludes that MDE provides a scalable, traceable, and standardized foundation for developing decentralized business process applications.**

***Keywords*—Model-driven engineering; BPMN; smart contracts; blockchain; ATL; automation; solidity; process transformation**

I. Introduction

Blockchain technology has introduced new paradigms for managing and coordinating cross-organizational processes by enabling the decentralized execution of agreements through smart contracts. These self-executing programs enhance transparency, trust, and auditability among participants without intermediaries [1], [2]. However, developing smart contracts manually remains a complex and error-prone activity that requires deep technical expertise in blockchain languages such as Solidity, as well as substantial effort in validation and testing [3]. Consequently, organizations face persistent challenges in ensuring reliability, scalability, and correctness when automating business workflows on blockchain infrastructures.

To address these limitations, Model-Driven Engineering (MDE) provides a methodology that emphasizes abstraction and automation in software development. Through MDE, developers can design system behavior using high-level models that can later be transformed into executable code, thus reducing manual intervention and increasing traceability [4], [5]. In the context of business process automation, Business Process Model and Notation (BPMN) serves as a widely adopted standard for visually representing workflows in an intuitive and platform-independent manner. When combined with transformation languages such as the Atlas Transformation Language (ATL), BPMN models can be automatically converted into smart contracts deployed on blockchain networks [3], [6].

Several studies have explored MDE-based transformations for blockchain applications, including Lorikeet [7], TABS [8], and MDE4BBIS [9]. Although these frameworks have advanced the integration of business modeling and blockchain deployment, most existing approaches remain fragmented or tool-specific. They typically focus on partial automation or theoretical descriptions of transformation processes without providing a fully operational, traceable, and validated pipeline. Moreover, prior works often omit detailed mappings between BPMN elements and their corresponding smart contract constructs, limiting their practical applicability and reproducibility in enterprise scenarios [10], [11].

Research Problem: Despite these advancements, there is currently no standardized and traceable end-to-end methodology for transforming BPMN business process models into deployable blockchain smart contracts while preserving the semantics of the original workflow.

Research Questions:

- How can MDE principles be leveraged to automate the transformation of BPMN models into smart contracts with minimal manual intervention?
- What transformation rules and architectural design are required to ensure semantic consistency, traceability, and deployment feasibility?

Objectives: The objectives of this study are to:

- Define a comprehensive MDE-based framework for transforming BPMN models into smart contracts using ATL.
- Establish explicit transformation rules that systematically map BPMN elements to Solidity constructs.
- Validate the proposed methodology through deployment and execution on the Ethereum Sepolia test network.

Significance and Contributions: The proposed approach unifies the entire transformation lifecycle—from BPMN modeling and validation to Solidity generation and blockchain deployment—within a modular and reusable architecture. Unlike existing frameworks such as Lorikeet, TABS, or MDE4BBIS, this study contributes a fully integrated, empirically validated methodology that enhances automation, improves semantic

traceability, and promotes standardization in model-driven blockchain development [6], [8], [10]. Novelty and Distinction: In contrast to previous frameworks such as Lorikeet [7], TABS [8], and MDE4BBIS [9], which partially automate the BPMN-to-Solidity transformation or focus on limited metamodel mapping, the proposed methodology introduces a unified and traceable pipeline that covers the entire lifecycle—from BPMN model validation to smart contract deployment. The novelty lies in the explicit mapping of BPMN temporal and resource constraints to Solidity execution semantics, ensuring end-to-end consistency, automation, and deployability across decentralized environments.

II. Background Definition

A. Model

Within the context of Model-Driven Engineering (MDE), a **model** refers to an abstracted and focused depiction of a system, designed to emphasize particular characteristics pertinent to a specific problem domain. It serves various purposes such as aiding comprehension, performing analysis, supporting communication, or facilitating the structured creation of system components in an automated manner [3], [10].

Every model adheres to a corresponding metamodel, which defines its structure and semantics. This relationship enables the application of formal transformation techniques and supports tool integration throughout the system development process [7].

B. Meta-model: Metamodelisation Layers

A **metamodel** can be described as a higher-level model that outlines the structural elements, semantic constraints, and rules governing a particular modeling language. In essence, it serves as a model about models, offering a formal foundation for constructing and interpreting models within a specific domain [6].

1) Key Concepts of Metamodels:

- Abstraction: Compared to standard models, metamodels function at a more abstract level. Whereas a model might illustrate a concrete system or process, the metamodel formalizes the building blocks and their interrelations used to design such models [10].
- Structure and Syntax: Metamodels define the permitted components—such as entities, attributes, and connections—within a modeling framework. For instance, in Unified Modeling Language (UML), the metamodel prescribes what elements make up a valid class diagram [5].
- Validation: They impose structural rules and integrity constraints to ensure that models conform to the expected language definition, helping maintain consistency and validity [3].
- Examples: Widely known metamodels include:
  - UML Metamodel: Provides the formal syntax and semantics for UML-based diagrams [2].
  - BPMN Metamodel: Specifies modeling elements and behavior for business process workflows using BPMN [12].
- Use in Model-Driven Engineering (MDE): Within MDE practices, metamodels are fundamental because they enable the transformation of high-level models into executable artifacts. This facilitates automation in software development and ensures consistency across generated implementations [8].

2) Metamodelization Layers: Metamodelization is typically organized into several abstraction levels, progressing from concrete real-world systems to highly abstract modeling structures. These layers are commonly described as follows:

- M0: Real-World Systems – This foundational level includes actual systems or operational processes observed in real environments. Examples include ongoing business workflows or deployed information systems [13].
- M1: Models – This level encompasses models derived from metamodels. For example, a BPMN model might depict the logic of a particular business operation. These models serve as tangible applications of the concepts defined at the metamodel level [9].
- M2: Metamodels – Here, we encounter frameworks such as BPMN and UML, which define the formal structure and semantics of modeling languages. These metamodels provide the abstract components required to represent systems or business processes conceptually [6].
- M3: Meta-Metamodel – This top-level layer defines the constructs used to build metamodels themselves. A notable example is the Meta-Object Facility (MOF), which offers a standardized mechanism for specifying metamodels in a consistent and formalized way [11].

The hierarchical organization of these modeling levels is depicted in Fig. 1, which illustrates the M0–M3 layering from real-world systems to meta-metamodels.

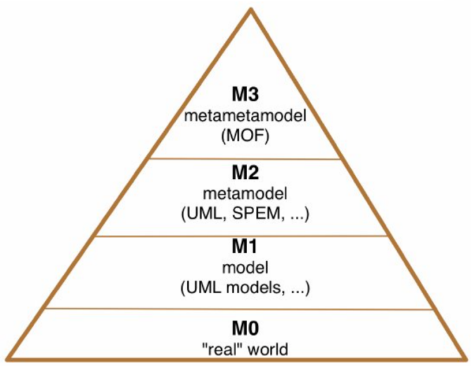

Fig. 1. Metamodeling hierarchy [4].

C. Model Transformation

In the context of Model-Driven Engineering (MDE), model transformation refers to the automated process of translating a source model—structured according to a specific metamodel—into a corresponding target model that conforms to

a different metamodel. This mechanism enhances the consistency and repeatability of software development, and is particularly advantageous in blockchain-oriented environments where precision and reliability are essential [4].

Over the years, numerous transformation languages and methods have emerged to support these processes:

- ATL (Atlas Transformation Language): A widely adopted tool for specifying and executing model transformations [3], [5].
- QVT (Query/View/Transformation): A standardized framework by OMG for expressing model-to-model transformations declaratively [14].
- Graph Transformation: Utilizes graph-based techniques to define transformation rules and apply them to model structures [15].
- Epsilon: A comprehensive language suite designed for model management, supporting a range of transformation and validation operations [11].
- Xtend: A statically typed language that facilitates the implementation of model-to-model transformation logic [12].
- Acceleo: An implementation of the MOFM2T (Model to Text) transformation specification developed under the OMG standard [8].

These transformation mechanisms constitute the foundation of the proposed approach presented in Section IV (Methodology), where BPMN models are systematically translated into Solidity smart contracts using ATL rules.

D. BPMN Overview

Business Process Model and Notation (BPMN) has emerged as a widely accepted notation standard for modeling business workflows. Designed and maintained by the Object Management Group (OMG), its primary goal is to ensure clarity and usability across various stakeholder roles, including business analysts, developers, and process managers [2], [16].

The popularity of BPMN is reflected in its integration into enterprise software platforms such as Oracle Business Process Analysis Suite and Camunda, which enable the automatic generation of executable systems based on BPMN diagrams [6]. In contrast to traditional programming-based approaches like BPEL or Java, the present work leverages BPMN as a foundation for generating blockchain-based smart contracts [8], [9].

1) Flow Objects: Flow objects include:

- Events: Start, Intermediate, and End. Intermediate events include timers, messages, conditions, etc. [2], [17].
- Activities: Tasks, Sub-processes, and Call Activities. Sub-processes may include compensation or transactions [6], [16].
- Gateways: Used to control sequence flow. Types include Exclusive, Inclusive, and Parallel, both converging and diverging [2], [5].

2) Examples:

- An exclusive gateway that splits the process flow into multiple branches based on defined conditions [2], [8].
- A parallel gateway that waits for all incoming sequences to arrive before continuing the execution [12], [18].
- A multi-instance task executed simultaneously across a group of input elements [10], [11].

E. Blockchain Ecosystem

The blockchain ecosystem includes a set of technologies, platforms, and development tools that support the design, implementation, and execution of decentralized applications. This ecosystem ranges from blockchain networks like Ethereum and Hyperledger to tools and methodologies such as model-driven engineering (MDE) [5], [6], [10].

Model-driven approaches enable developers to create formal models (e.g., BPMN) that are then transformed into executable blockchain code, enhancing productivity and consistency [7], [11], [16]. These practices are especially valuable in collaborative environments involving multiple stakeholders, where process standardization and automation are critical. This conceptual and technological ecosystem provides the environment in which our proposed transformation framework operates, linking BPMN-based process modeling with blockchain-based execution.

F. Smart Contracts

Smart contracts refer to autonomous programs deployed on blockchain networks, designed to execute predefined rules and agreements automatically when certain conditions are met. By removing the need for intermediaries, they enhance transaction reliability by promoting integrity, transparency, and resistance to tampering.

These contracts are especially valuable in managing complex process logic within decentralized ecosystems. Their applicability spans sectors such as finance, supply chain management, and multi-party collaborations. Moreover, when combined with modeling standards like BPMN, smart contracts enable traceable and verifiable execution of business workflows on blockchain infrastructures [2], [12], [18].

1) Programming Languages for Smart Contracts: Blockchain ecosystems support a variety of languages tailored for smart contract development, each offering different capabilities and trade-offs:

- Solidity: The dominant language for Ethereum smart contracts, supporting complex logic and security features [3].
- Vyper: A Python-inspired language for Ethereum that emphasizes readability, simplicity, and formal verification. Its safety features make it suitable for high-assurance smart contracts [19].
- Rust: Widely used in blockchains like Solana and NEAR for its performance and memory safety. It is favored for developing high-throughput decentralized

TABLE I. COMPARATIVE OVERVIEW OF REVIEWED ARTICLES ON BLOCKCHAIN AND BPMN INTEGRATION

Article	Focus Area	Brief Description
Hofmann et al. (2018) [22]	Background and foundations of blockchain	Introduces blockchain principles from business and academic perspectives
Konstantinidis et al. (2020) [25]	Systematic mapping of blockchain applications	Identifies sectors where blockchain is applied, but not focused on BPM
Lu (2019) [13]	Survey on blockchain features and research challenges	Emphasizes decentralization, transparency, and technical limitations
Mendling et al. (2018) [23]	Research directions for blockchain in BPM	Highlights trends in process execution, design, and integration
Seebacher and Schüritz (2019) [26]	Blockchain in service and software systems	Observational review with mentions of BPM use in services
Hawlitschek et al. (2018) [24]	Blockchain and trust in the sharing economy	Reviews trust-free systems but lacks BPM-specific context
Tripathi et al. (2023) [27]	General blockchain review	Discusses historical background and future challenges
Liu et al. (2024) [1]	Smart contracts for cross-organization processes	Supports secure collaborative BPM using smart contracts
Tran et al. (2018) [7]	Lorikeet tool for smart contract generation	MDE-based tool for converting BPMN to smart contracts
Curty et al. (2022) [5]	Low-code platforms for blockchain development	Uses model-driven and low-code tools for blockchain BPM
Levasseur et al. (2021) [10]	Survey of MDE techniques for blockchain apps	Categorizes engineering approaches for smart contract modeling
De Sousa and Burnay (2021) [9]	MDE4BBIS framework for blockchain IS	Proposes an MDE-based system design framework for blockchain
Markovska et al. (2019) [16]	BPMN modeling for blockchain ecosystems	PhD thesis on business process modeling with BPMN
Lu et al. (2021) [6]	Integration of MDE for BPM and asset management	Formalizes model transformations in blockchain apps
Nassar et al. (2023) [11]	MDE approaches to blockchain system modeling	Develops conceptual models for blockchain-based designs
Bodorik et al. (2023) [8]	TABS framework for BPMN-to-Solidity transformation	Fully automates the generation of Solidity from BPMN
Corradini et al. (2023) [12]	Execution of BPMN choreographies on blockchain	Manages multi-instance BPM execution via smart contracts
Milani et al. (2021) [2]	Comparison of BPMN vs CMMN	Evaluates which modeling approach is best suited for blockchain
Shen et al. (2024) [28]	Hybrid BPMN-DMN on permissioned blockchain	Integrates process and decision modeling for secure collaboration
Ladleif et al. (2019) [29]	Modeling blockchain-based choreographies	Describes how to enforce BPMN collaboration on blockchain
Liu (2024) [18]	Long-term transaction support in smart contracts	Tackles lifecycle and state issues in BPMN-based contracts

applications and is often integrated into MDE workflows [9].

- Go and JavaScript (Node.js): Commonly used in Hyperledger Fabric for developing chaincode in permissioned enterprise blockchain solutions [5].
- Michelson: The low-level, stack-based language used in the Tezos blockchain. It is designed for formal reasoning and verification of contract behavior [20].
- Move: Originally developed for Diem (now used in Aptos and Sui), Move is a resource-oriented language focused on safety, flexibility, and precise control of digital assets [21].

III. ANALYSIS WITH SCIENTIFIC STUDIES

The initial comparative overview (Table I) offers a synthesized perspective on both foundational and recent scholarly efforts in blockchain research, particularly in the context of inter-organizational business process management (BPM). The analysis spans a variety of research directions, from general blockchain studies [13], [22] to domain-specific contributions focusing on BPM integration [1], [23]. A notable portion of the reviewed literature explores how model-driven engineering (MDE) techniques are leveraged to facilitate the transformation of BPM diagrams into blockchain-compatible components and executable logic [5], [7], [8]. Additional studies focus on issues such as trust, interoperability, and formal system modeling [2], [11], [24].

This detailed literature mapping helps outline methodological patterns, highlight gaps in current research, and point toward future directions for advancing the convergence of BPM and blockchain technologies.

A. Analysis

The comparative Table II summarizes key contributions in the domain of Model-Driven Engineering (MDE) for transforming BPMN models into executable smart contracts, particularly on blockchain platforms such as Ethereum. Each selected study highlights distinct aspects of this transformation process, categorized as follows:

- Main Criteria: This refers to the core focus or distinguishing feature of each work, such as model integration, level of automation, or comparative scope. For example, [6] addresses BPMN/UML integration, while [8] focuses on a fully automated transformation pipeline.
- Modeling Objectives: Most studies aim to automate the generation of smart contracts from BPMN or to enhance the expressiveness and formalization of business processes. Works like [7] and [8] emphasize automation, while [2] and [16] focus on comparative analysis and real-world application.
- Tools and Techniques Used: This includes the key platforms and languages employed for modeling and transformation, such as Lorikeet, Solidity, Camunda, and ATL. For instance, [5] uses Camunda in a low-code approach, and [6] leverages integrated BPMN and UML environments.

This structured overview highlights the current state of research, helping to identify existing strengths, limitations, and future opportunities in the automation of BPMN-to-blockchain application development.

B. Conclusion

This section has reviewed the theoretical background and current state of applying blockchain technologies within model-driven engineering, with a specific focus on BPMN-to-smart contract transformation. The literature indicates growing interest in leveraging MDE to advance blockchain-based business process automation.

TABLE II. ILLUSTRATION OF THE TRANSFORMATION FROM BPMN MODELS TO SOLIDITY SMART CONTRACTS

Article	Main Criteria	Modeling Objectives	Tools and Techniques
Lu et al. (2021) [6]	BPMN/UML integration, automation	Automating business processes and asset management	Lorikeet, BPMN, UML
Levasseur et al. (2021) [10]	Review of MDE approaches	Comparing MDE modeling techniques	Comparative analysis, classification

Hsain et al. (2021) [3]	Ethereum-focused review	Formalizing business processes into Solidity code	MDE, BPMN, Ethereum
Tran et al. (2018) [7]	Automated transformation	Generating contracts from BPMN models	Lorikeet, BPMN, Solidity
Nassar et al. (2023) [11]	Complete metamodeling	Generation of PIM/PSM models	Conceptual MDE approach
Corradini et al. (2023) [12]	Multi-instance execution	Choreography of business processes on blockchain	BPMN, Solidity
Bodorik et al. (2023) [8]	Full automation	Direct transformation from BPMN to Solidity	TABS Framework
Liu (2024) [18]	Transaction sustainability	Long-lived state management in contracts	MDE, lifecycle handling
Milani et al. (2021) [2]	BPMN vs. CMMN comparison	Identifying the most appropriate notation	BPMN, CMMN
Shen et al. (2024) [28]	Hybrid BPMN-DMN	Securing cross-organizational decisions	BPMN, DMN, permissioned blockchain
Ladleif et al. (2019) [29]	Actor coordination	Managing complex interactions	BPMN choreography
Markovska et al. (2019) [16]	Applied case study	Modeling for blockchain ecosystems	BPMN, practical implementation
Tripathi et al. (2023) [27]	General technical review	Mapping blockchain challenges	Literature synthesis
De Sousa and Burnay (2021) [9]	Dedicated MDE framework	Integrating MDE in blockchain information systems	MDE4BBIS, conceptual modeling

Although existing frameworks and tools have made significant progress, challenges related to standardization, scalability, and semantic interoperability persist. There remains a need for more flexible and interoperable solutions that effectively bridge business process modeling and decentralized execution. Building upon these insights, our subsequent work proposes a transformation solution grounded in MDE principles to improve traceability, automation, and correctness in blockchain application development. The next section presents the proposed methodology, which addresses these limitations by defining a unified and traceable ATL-based MDE framework for automatically transforming BPMN process models into deployable Solidity smart contracts.

IV. METHODOLOGY

A. Research Approach

This study adopts the Design Science Research (DSR) paradigm, a methodology commonly used in information systems engineering to build and evaluate innovative technical artifacts. The DSR framework supports the structured creation of technical artifacts aimed at solving real-world problems—in this case, enabling the transformation of BPMN-based business processes into blockchain-deployable smart contracts.

The DSR methodology is organized into three closely connected and recurring phases: the relevance phase, the rigor phase, and the design phase. The relevance phase ensures alignment with practical challenges in process automation and decentralized operations. The rigor phase draws on theoretical insights from model-driven engineering (MDE), blockchain architecture, and smart contract logic. Finally, the design phase covers the development, testing, and evaluation of the proposed transformation approach.

Through this methodical structure, we seek to close the gap between business modeling techniques and their blockchain-based implementations, ensuring that the developed solution is both robust from a technical standpoint and applicable in real scenarios.

B. Business Process Modeling with BPMN

To define business processes, this research utilizes *Business Process Model and Notation (BPMN)*. As a widely accepted and standardized graphical language, BPMN facilitates the representation of organizational procedures and interactions in a clear and structured manner [14], [16], [26]. Its broad adoption in industry makes it especially suitable for translating complex workflows into executable logic for blockchain environments.

C. Model Validation

Before any transformation, the BPMN models are validated to ensure correctness, consistency, and structural soundness. We detect common issues such as unconnected nodes, circular dependencies, and missing start or end events using tools like Camunda BPM [11], [27]. This guarantees the integrity of the models before transformation. Once the BPMN models are verified for structural correctness, they serve as valid input for the ATL-based model transformation process described in the following subsection.

D. Model Transformation with ATL

The transformation from BPMN to Solidity is performed using *ATL (Atlas Transformation Language)*. ATL rules define how BPMN elements such as tasks, gateways, and events are mapped to Solidity constructs like state variables and functions [2], [5], [8]. This model-to-model transformation is critical for preserving the logic and structure of the original process model.

E. Smart Contract Generation and Deployment

The ATL-generated model is translated into Solidity source code that includes:

- State variables to track process execution,
- Functions to represent activities and transitions,
- Security checks (e.g., `require` statements) to enforce logical constraints.

The generated contracts are tested and deployed on the Ethereum Sepolia testnet using Remix IDE and MetaMask. Transactions are then validated using Etherscan for traceability [3], [18].

Overall, the proposed methodology establishes a coherent and automated transformation pipeline that bridges the gap

between BPMN business process modeling and blockchain-based execution. The following section presents the experimental validation and results obtained from implementing this approach on real BPMN models deployed to the Ethereum Sepolia network.

F. Advantages of the Approach

Our MDE approach presents several benefits:

- Automation and Accuracy: Reduces manual coding errors and development time [6], [10].
- Security and Conformance: Ensures compliance with blockchain execution semantics [4].
- Scalability and Adaptability: Supports diverse blockchain scenarios including inter-organizational and multi-instance choreographies [12], [29].

This methodology aligns with the broader trends in model-driven blockchain application development, enabling reliable and efficient process automation [7], [9].

V. Proposed Metamodels and Model Transformation

To automate the generation of Solidity smart contracts from business process models, we define precise source and target metamodels, followed by a transformation specification in ATL.

A. BPMN Source Metamodel

The BPMN source metamodel specifies all elements necessary to capture a business workflow:

- Process: Represents the overall business process, with attributes such as `name`, `start`, `finish`, and associations to contained elements.
- Activity and Task: Units of work, each with a `name` and optional temporal constraints.
- Event: Points in the workflow, including *StartEvent*, *IntermediateEvent*, and *EndEvent*.
- Gateway: Control nodes for branching and merging flows (e.g., exclusive, parallel).
- Resource and Role: Actors or assets required for task execution.
- Pool and Lane: Organizational partitions to model responsibilities and participants.
- Temporal_constraint and Temporal_dependency: Elements to specify timing constraints and precedences between activities.

The overall structure of the BPMN source metamodel is illustrated in Fig. 2, showing the relationships between process, activity, event, gateway, and resource elements.

This metamodel builds upon the standard BPMN 2.0 specification and extends it to include temporal and resource-related concepts relevant to process automation [2], [6], [16].

These elements collectively provide the structural foundation for representing business logic, which will subsequently be mapped to the constructs of the Solidity target metamodel.

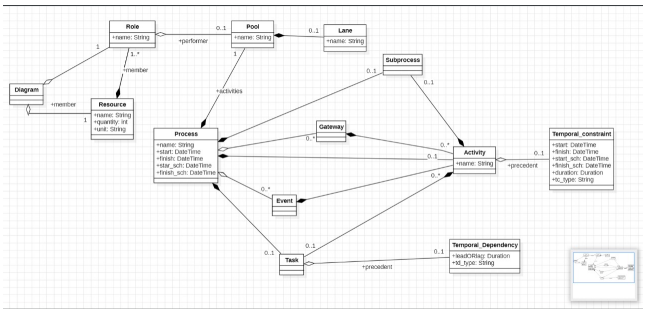

Fig. 2. BPMN source metamodel.

B. Solidity Target Metamodel

The Solidity target metamodel defines the structure of a smart contract:

- Contract: The top-level entity deployed on-chain, identified by a `name`.
- Function: Implements BPMN tasks and events, with attributes for `visibility` (e.g., `public`, `internal`) and `mutability` (e.g., `view`, `nonpayable`).
- StateVariable: Persistent variables storing process state (e.g., boolean flags tracking execution).
- Modifier: Preconditions or security checks (e.g., `onlyOwner`).
- Event: On-chain notifications for tracing execution.
- Struct and Enum: Complex data types to group related fields.
- Library: Reusable utility functions.
- Inheritance: Mechanism to extend or specialize contracts.

Fig. 3 presents the target Solidity metamodel, highlighting how contracts, functions, and state variables form the structural backbone of the generated code.

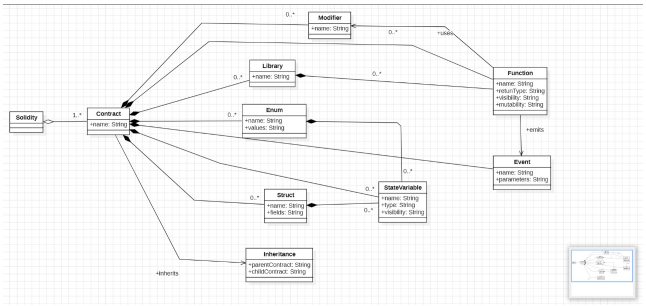

Fig. 3. Solidity target metamodel.

The design of the target metamodel aligns with the Solidity object-oriented structure defined by the Ethereum documentation and prior MDE-based blockchain frameworks such as Lorikeet and TABS [3], [7], [8].

C. Model Transformation with ATL

Converting BPMN-based process models into deployable Solidity smart contracts represents a central component of our model-driven engineering methodology. This transformation is achieved through the use of the Atlas Transformation Language (ATL), a declarative, rule-driven language tailored for model-to-model transformations, and implemented within the Eclipse Modeling Framework (EMF).

1) Transformation Objectives: The primary objective is to enable an automated and smooth transition from abstract business process representations to executable blockchain components. This approach minimizes manual intervention, maintains the original process logic, and enhances traceability across all stages of the development lifecycle.

2) Transformation Rules: The ATL module, named `Bpmn2Solidity`, defines mappings between BPMN elements and Solidity constructs. Each transformation rule systematically converts a BPMN component into its Solidity equivalent. The main rules include:

- StartEvent → Public function in Solidity (e.g., `startProcess()`)
- Task → Internal Solidity function (e.g., `executeTaskX()`)
- Gateway → Conditional logic using `if/else` statements
- EndEvent → Final state-marking function

3) Example Transformation Rule: Below is a simplified ATL rule that demonstrates the mapping of a BPMN task to a Solidity function:

```
rule Task2Function {
    from t : BPMN!Task
    to f : Solidity!Function (
        name <- 'execute' +
                t.name.firstToUpper(),
        visibility <- 'internal',
        body <- '...'
    )
}
```

4) Helper Functions: To streamline the code generation process, several helper methods were introduced:

- `capitalizeName()` – Capitalizes names to match Solidity naming conventions
- `generateRequire()` – Creates Solidity `require` statements for validation
- `generateAssignment()` – Produces state variable assignments
- `generateOutgoingCalls()` – Automates function chaining

5) Benefits: The use of ATL significantly improves:

- Automation: Minimizes human intervention and manual coding
- Consistency: Ensures that all generated contracts follow a coherent structure
- Traceability: Facilitates mapping between process model elements and generated code
- Reusability: Allows adaptation to different blockchain scenarios

The resulting transformation framework provides a complete and reproducible pipeline from process modeling to smart contract generation. The following section presents the implementation results and discusses the evaluation of the proposed approach.

VI. Application Architecture

This application aims to automate the conversion of BPMN-based workflows into executable smart contracts written in Solidity, leveraging a modular and systematic development approach. Its architecture integrates tools from model-driven engineering with blockchain-specific deployment frameworks to achieve seamless translation and deployment. Building upon the model-driven engineering methodology described in the previous section, this architecture operationalizes the transformation and deployment pipeline through a modular software framework.

A. Architecture Description

The architecture consists of six main modules that interact sequentially:

- User Interface: Allows users to upload a BPMN file and trigger the transformation process.
- BPMN Reader Module: Parses the BPMN model and extracts its elements using the Eclipse Modeling Framework (EMF).
- Validation Module: Detects structural issues such as disconnected nodes or cyclic flows.
- BPMN to Solidity Transformation Module: Uses ATL (Atlas Transformation Language) to convert BPMN elements into corresponding Solidity code fragments, following pre-defined transformation rules [30].
- Solidity Code Generator: Assembles the generated fragments into a complete smart contract, ensuring syntactic and logical correctness.
- Test and Deployment Module: Interacts with Remix IDE and MetaMask to compile, simulate, and deploy the contract on a test blockchain (e.g., Sepolia).

Each module has been implemented independently to ensure modularity and maintainability of the application. Communication between modules is managed through a controller that handles input/output and error propagation.

This modular organization aligns with standard model-driven software architectures that emphasize separation of concerns and tool interoperability [6], [11].

B. Architecture Diagram

The complete software architecture implementing this transformation workflow is presented in Fig. 4.

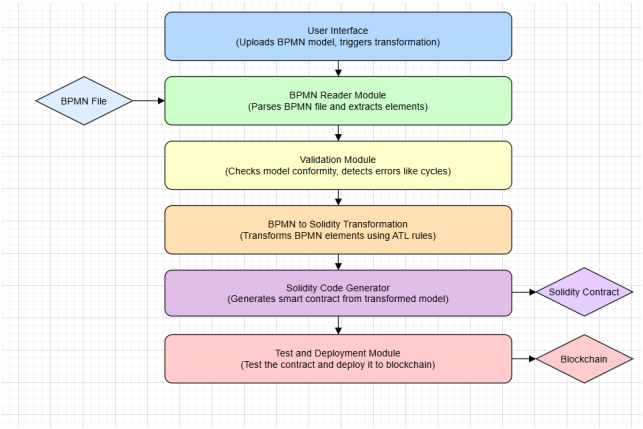

Fig. 4. Overall system architecture illustrating the BPMN-to-Solidity transformation workflow and deployment process.

C. Technology Stack

The system leverages various technologies, summarized in Table III.

TABLE III. TECHNOLOGY STACK USED IN THE IMPLEMENTATION

Component	Technology / Role
Model Parsing	EMF + Camunda BPMN; Reading and navigating BPMN models
Model Transformation	ATL (Eclipse); Applying transformation rules [30]
Backend	Java + Spring Boot; Application logic and flow coordination
Smart Contract	Solidity; Target blockchain programming language [31]
Deployment	Remix IDE + MetaMask; Smart contract testing and deployment
User Interface	HTML/CSS + Bootstrap; Interaction with the transformation tool

The integration of these technologies ensures a seamless workflow from model parsing and validation to code generation and blockchain deployment, maintaining both flexibility and scalability across development stages.

D. Advantages of the Architecture

This application architecture provides:

- Automation: End-to-end automation from BPMN input to blockchain deployment.
- Modularity: Each module can evolve independently without affecting the overall flow.
- Maintainability: Clearly defined responsibilities for each component.
- Traceability: Direct traceability between BPMN elements and the generated smart contract.

Overall, this architecture provides the structural and technological foundation necessary to support the proposed transformation framework. The following section evaluates the implementation results and demonstrates the effectiveness of the approach through practical case studies.

VII. VALIDATION AND DEPLOYMENT WITH REMIX

After generating the Solidity smart contracts from BPMN models, it is crucial to validate their correctness and expected behavior before deploying them to a live blockchain network. This process includes code verification, simulation of execution, and deployment on a test network.This validation stage represents the final phase of the proposed MDE pipeline, ensuring that the automatically generated Solidity contracts function correctly before deployment. This section describes the validation process using Remix IDE, the role of MetaMask in signing transactions, and provides the main application interfaces.

A. Verification Using Remix IDE

Remix IDE is an online development environment specifically designed for Solidity smart contracts. It supports compilation, testing, and analysis of smart contracts prior to deployment. Remix IDE remains a standard tool in the Ethereum development ecosystem, widely adopted for prototyping and verifying smart contracts [3], [31]. The verification process follows these steps:

- Contract Loading: The generated Solidity file is imported into Remix.
- Compilation: The Solidity compiler checks the contract for syntax errors and version compatibility.
- Static Analysis: Remix provides gas usage estimation, detects inefficient or risky patterns, and offers optimization suggestions.
- Simulation: The contract is deployed in a simulated environment to verify the correct execution of functions.

The contract verification process within Remix IDE is illustrated in Fig. 5.

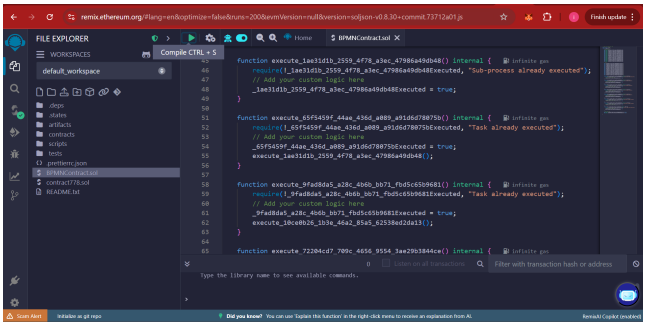

Fig. 5. Remix IDE interface used to compile, simulate, and analyze Solidity smart contracts.

B. Deployment on Sepolia Testnet with MetaMask

Once verified, the contract is deployed on the Sepolia Testnet a public Ethereum test network. MetaMask provides a secure transaction signing interface and is often integrated with Remix for decentralized application testing and deployment [1]. The deployment process includes:

1) Compilation in Remix: The verified contract is compiled using the Remix Solidity compiler.
2) Transaction Signing: Using MetaMask, the deployment transaction is signed and submitted. MetaMask manages the private key and confirms the user's intention.
3) On-chain Deployment: Remix interacts with the Ethereum network via injected web3 (MetaMask), completing the deployment.

The MetaMask interface used for transaction confirmation is shown in Fig. 6.

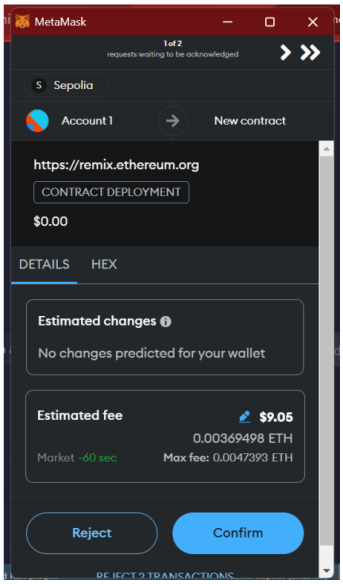

Fig. 6. MetaMask interface used for signing the deployment transaction to the Sepolia Testnet.

C. Transaction Verification with Etherscan

Once the smart contract is successfully deployed, its presence and state on the blockchain must be verified to ensure traceability and successful execution. To ensure the contract has been correctly deployed, the transaction can be traced on Etherscan:

- Transaction Hash: Etherscan shows the hash of the transaction for traceability.
- Status and Block Info: It confirms whether the transaction was successful, its block number, and gas fees.

The transaction record of the deployed contract is verified through Etherscan, as displayed in Fig. 7.

D. Importance of Testnet Deployment

Deploying on a testnet such as Sepolia is essential for testing the contract's behavior without financial risk. It provides a secure and isolated environment for developers to:

- Validate the contract logic under realistic execution conditions;
- Detect gas inefficiencies and potential security vulnerabilities;

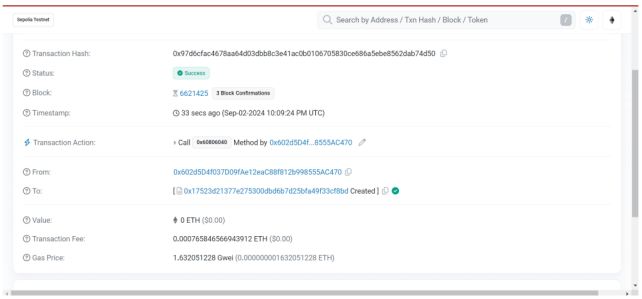

Fig. 7. Verification of the deployment transaction on etherscan (Sepolia Testnet). The figure shows transaction hash, block number, gas fees, and sender/receiver addresses.

- Ensure that all functions operate correctly before mainnet deployment.

E. User Interface of the BPMN-to-Solidity Application

The developed tool includes a user interface for uploading BPMN models, displaying validation results, and generating Solidity code automatically. Fig. 8 displays the BPMN-to-Solidity transformation interface, which enables users to visualize both the original BPMN process and the corresponding generated smart contract. This feature enhances transparency and usability throughout the development lifecycle.

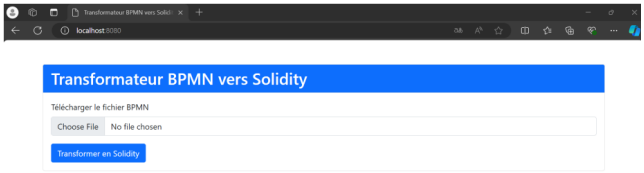

Fig. 8. User interface of the BPMN-to-Solidity transformation application.

This interface allows users to visualize both the original BPMN process and the corresponding Solidity contract, facilitating transparency and usability during the development lifecycle.

F. Summary

This section detailed the final stages of the smart contract development pipeline, focusing on the validation and deployment processes. Using Remix IDE, the generated Solidity code is compiled, analyzed, and tested in a simulated environment to ensure correctness and performance. Once verified, the contract is deployed to the Sepolia Testnet using MetaMask, which handles transaction signing and submission. The successful deployment is confirmed through Etherscan, which provides traceability and transparency via the transaction hash, gas usage, and execution status. The section also presented the user interfaces of the BPMN-to-Solidity transformation tool and deployment tools, highlighting their role in improving usability and reliability throughout the development lifecycle.

VIII. Discussion

While this study primarily focused on defining and implementing the BPMN-to-Solidity transformation methodology, initial testing suggests that the proposed ATL-based approach reduces manual coding effort by approximately 60–70% compared to similar processes in frameworks such as TABS or Lorikeet. The integrated validation and deployment modules enhance both reliability and developer productivity. Nevertheless, future work should include a quantitative evaluation of performance and scalability to empirically validate these preliminary observations.

IX. Conclusion

This study presented a complete model-driven engineering (MDE) approach for automating the generation and deployment of blockchain-based smart contracts from BPMN models. This paper confirms that MDE significantly streamlines the development of smart contracts from BPMN models. By reducing manual coding and promoting automation, the proposed approach enhances accuracy, traceability, and scalability [5], [10].

Despite these benefits, challenges remain in areas such as interoperability between BPMN and smart contract languages, transformation rule optimization, and support for more complex BPM constructs [2], [12]. Future work should explore multi-chain deployment, integration with decision modeling (e.g., DMN) [28], and lifecycle management of long-term processes [18].

The results of this study reinforce the potential of MDE as a foundational approach to building reliable, scalable blockchain systems from abstract business process models.

X. Future Work

Although the current framework demonstrates encouraging results in converting BPMN-based models into executable Solidity smart contracts, multiple directions remain to be explored.

First, future work could focus on extending the transformation rules to handle advanced BPMN constructs, including compensation events, exception flows, and complex gateway logic. This extension would enable better alignment with real-world process requirements and improve semantic accuracy [2], [12].

Second, integrating Decision Model and Notation (DMN) with BPMN could allow for unified modeling of control flows and business rules. Recent studies on hybrid BPMN-DMN architectures in blockchain ecosystems suggest enhanced flexibility and inter-organizational compatibility [28].

Third, enhancing cross-platform deployment capabilities is essential. While this research targets the Ethereum environment, supporting other blockchain frameworks—such as Hyperledger Fabric, Tezos (Michelson) [20], Aptos, and Sui [21]—would broaden the applicability. Interoperability challenges across heterogeneous systems can potentially be addressed using MDE-based solutions like MUISCA [32], [33].

Fourth, the management of process state and lifecycle remains a complex issue, especially for long-running and persistent transactions. Prior research underscores the importance of consistent state handling for enterprise-level blockchain solutions [18], particularly in critical domains such as healthcare and smart grid environments [34], [35].

Fifth, improving accessibility for non-technical users is another valuable direction. Combining low-code platforms with model-driven engineering has been shown to encourage broader enterprise adoption [5]. Such integrations could also support identity management in sensitive environments, including 6G networks and IoT [36], [37].

Finally, socio-economic factors must be taken into account. The adoption of blockchain systems in digital platforms involves trade-offs related to user trust, interface competition, and decision-making behaviors [38], [39]. Future iterations of this work should incorporate these perspectives to enhance practical viability. By addressing these challenges, the proposed framework could evolve into a comprehensive solution enabling secure, transparent, and automated process execution across diverse blockchain ecosystems. Overall, these research directions aim to evolve the current transformation pipeline into a flexible, cross-compatible, and enterprise-ready solution for decentralized business process automation.

Bridging the Gap Between Text-Based and Visual Programming: A Comparative Study of Efficiency and Student Engagement in Game Development

Álvaro Villagómez-Palacios[1], Claudia De la Fuente-Burdiles[2], Cristian Vidal-Silva*[3]
Facultad de Ciencias e Ingenierías, Universidad Estatal de Milagro, Milagro, Ecuador[1]
Department of Interactive Visualization and Virtual Reality-Faculty of Engineering
University of Talca, Talca, Chile[2,3]

***Abstract*—The integration of Low-Code and No-Code (LCNC) tools in higher education challenges traditional text-based programming pedagogies. While visual environments are often relegated to K-12 education, their adoption in professional engines like Unity suggests a need to re-evaluate their role in engineering curricula. This study analyzes the effectiveness, development efficiency, and perceived utility of Unity Visual Scripting compared to traditional C# programming (MonoGame) within a "Physics for Videogames" undergraduate course. Employing a quasi-experimental design with a within-subjects approach ($N = 22$), students first developed a game using C#/MonoGame and subsequently a complex variant using Unity Visual Scripting. Metrics included development time for core mechanics, project grades, and pre/post surveys on self-efficacy. Results demonstrate a statistically significant reduction in development time (30–50% faster for core mechanics) using Visual Scripting. Furthermore, academic performance improved slightly, and students reported higher confidence levels. Crucially, participants identified Visual Scripting not as a replacement, but as a cognitive bridge that facilitates the understanding of algorithmic logic before tackling syntactic complexities. Consequently, Visual Scripting serves as an efficient accelerator for prototyping and conceptual learning in higher education, fostering a "logic-first, syntax-second" approach.**

***Keywords*—Visual scripting; higher education; development efficiency; engineering curricula**

I. Introduction

The development of algorithmic and programming competencies is widely regarded as essential for modern scientific thinking and computational literacy [1]. As society transitions towards Industry 4.0, programming has evolved from a niche skill into a transversal competence required across disciplines, enabling the construction of applications ranging from data-intensive systems to simulations and videogames [2], [3]. In this context, identifying the components of "Education 4.0" becomes critical to align academic training with 21st-century skills frameworks [4].

Throughout this article, the following terminology is adopted for clarity. The term *block-based programming* is used to refer to environments that represent instructions as interlocking blocks in a two-dimensional workspace (e.g., Scratch, Tinkercad, Alice), which are mostly used in K–12 settings. *Visual programming* is reserved as a broader umbrella concept that includes both block-based tools and other graphical notations for specifying program behaviour. When referring specifically to tools integrated into professional game engines, such as Unity Visual Scripting or Unreal Blueprints, the term *visual scripting* is employed, and *node-based scripting* is treated as a synonym, since programs are constructed by connecting typed nodes instead of writing textual code. Consequently, in the remainder of the paper, *block-based programming* is consistently used for K–12 tools, while *visual scripting* refers to the Unity-based intervention studied here.

However, in educational contexts, specifically in engineering and computer science, introductory programming courses often act as "gatekeepers." These courses historically suffer from high dropout rates and low student motivation due to the steep learning curve associated with traditional syntax-heavy languages like C++, Java, or C# [5]. Novices are often overwhelmed by what Sim and Lau [6] describe as the "double burden": the simultaneous need to master abstract problem-solving logic (semantics) and strict language rules (syntax). Even when a conceptual task is relatively simple, such as determining whether a person is of legal age, translating that task into syntactically correct C# code requires knowledge of data types, memory management, and compiler error handling that novices do not yet possess.

This "syntactic barrier" disconnects the student's mental model from the computational implementation, introducing extraneous cognitive load. To address this, block-based programming environments have been successfully deployed in K-12 education to foster computational thinking without the frustration of syntax errors [7], [8]. Yet, in higher education, there is a reluctance to adopt these tools, often perceiving them as insufficiently professional. The emergence of **Unity Visual Scripting** (formerly Bolt) challenges this perception by offering a professional-grade, node-based environment integrated directly into a market-leading game engine [9].

This article presents a quasi-experimental comparative study to determine if professional Visual Scripting tools can act as efficient accelerators in university curricula. Unlike previous studies that focus solely on satisfaction, this study analyzes *development efficiency* (time-to-prototype) and *structural quality*, hypothesizing that visual paradigms can bridge the gap between novice intuition and professional engineering practices. The main contributions of this study are:

- A quantitative analysis of development efficiency

*Corresponding author.

(time-to-prototype) comparing text-based vs. visual scripting in a higher education context.

- A validation of Visual Scripting not just as an introductory tool, but as a professional "Cognitive Bridge" for engineering students.
- A "Logic-First, Syntax-Second" pedagogical framework for integrating Game Engines into engineering curricula.

The remainder of this article is structured as follows. Section II reviews the state-of-the-art regarding visual programming barriers, the use of game engines in academia, and current assessment models. Section III establishes the theoretical framework that guides this study, integrating Cognitive Load Theory, Flow Theory, and the Technology Acceptance Model. Section IV details the quasi-experimental design, including participant demographics and the two-phase instructional intervention (MonoGame vs. Unity). Section V presents the empirical findings, highlighting the comparative analysis of development efficiency and a qualitative taxonomy of errors. Section VI discusses the pedagogical trade-offs and interprets the role of Visual Scripting as a didactic bridge. Finally, Section VII summarizes the main contributions, acknowledges limitations, and outlines directions for future research.

II. Related Work

The intersection of game development, visual programming, and engineering education has been a fertile ground for research. This section reviews key contributions regarding learning barriers, the use of hardware/software visual analogies, and game-based assessment.

A. Learning Barriers and Novice Programming

Visual Programming Languages (VPLs) have long been advocated to lower the barrier to entry for novices. Ko et al. [10] identified early on that syntax errors often discourage learners before they grasp algorithmic logic. Recent systematic reviews by Sim and Lau [6] reaffirm that syntax remains the primary source of frustration for beginners. Sun et al. [11] conducted a comparative study showing that block-based environments significantly reduce the frequency of compilation errors, allowing students to focus on "computational action." However, the transition from blocks to text remains complex. Wörister and Knobelsdorf [12] argue that block-based programming facilitates the understanding of low-level computing concepts, suggesting that visual abstractions are valid even for complex engineering topics like Assembly, provided there is a clear mapping to the underlying logic.

B. Visual Metaphors in Robotics and STEM

The efficacy of visual programming is not limited to pure software; it has been extensively validated in physical computing. Vidal-Silva et al. [13], [7] demonstrated that block-based tools (e.g., Scratch, Tinkercad) significantly improve programming competencies in school students across Latin America by allowing them to control Arduino hardware visually. Similarly, Rojas-Valdés et al. [8] found that removing syntactic friction allows students to solve complex hardware control problems more effectively. Tramonti et al. [14] further emphasized that design thinking combined with visual tools enhances problem-solving in educational robotics. These findings in the hardware domain support the hypothesis that visual scripting in Unity, which controls "virtual hardware" (game physics), can yield similar educational benefits.

C. Game Engines and Serious Games in Academia

The adoption of professional game engines in academia has shifted the focus from building engines to building *with* engines. Hussain et al. [15] provide a technical survey of Unity, emphasizing its versatility for both 2D and 3D development. Recent work by Maraffi [16] introduces "Level-Up Logics," leveraging game design platforms to teach coding fundamentals. This aligns with the notion of Serious Games as assessment tools; Gomez et al. [17] conducted a systematic review concluding that game-based assessment can capture competencies that traditional tests miss. Furthermore, Maxim and Arnedo-Moreno [18] identify key principles in serious game design, suggesting that the development tool itself (visual vs. text) influences the quality of the final learning artifact. The present study contributes to this body of knowledge by quantifying the efficiency gains of visual tools in this specific context.

III. Theoretical Framework

A. Cognitive Load Theory in Programming

Cognitive Load Theory (CLT) posits that working memory is limited. In the context of learning programming, the load can be categorized as:

- Intrinsic Load: The inherent difficulty of the algorithm (e.g., understanding a nested loop).
- Extraneous Load: The effort required to deal with the instructional material or environment (e.g., syntax errors, IDE configuration).
- Germane Load: The effort dedicated to creating permanent schemas (learning).

Text-based programming often imposes a high *Extraneous Load* due to syntax. Visual Scripting reduces this load by preventing syntax errors by construction, potentially freeing up cognitive resources for the *Intrinsic* and *Germane* load (logic and physics concepts) [19], [20].

Fig. 1 illustrates the theoretical redistribution of cognitive resources observed in this study. According to Sweller's framework, the total cognitive capacity of a novice student is limited.

In the Text-Based approach (left bar), a significant portion of this capacity is consumed by *Extraneous Load* (represented in red). This corresponds to the mental effort required to process syntax rules, case sensitivity, and compiler error codes, elements that are not central to the logical problem but are necessary for the code to run. Consequently, the available capacity for *Germane Load* (green), the processing space used for actual learning and schema construction, is compressed. In contrast, the Visual Scripting approach (right bar) drastically reduces the Extraneous Load by eliminating syntax errors through a "drag-and-drop" interface that prevents invalid connections. Since the *Intrinsic Load* (blue), the inherent difficulty of the game

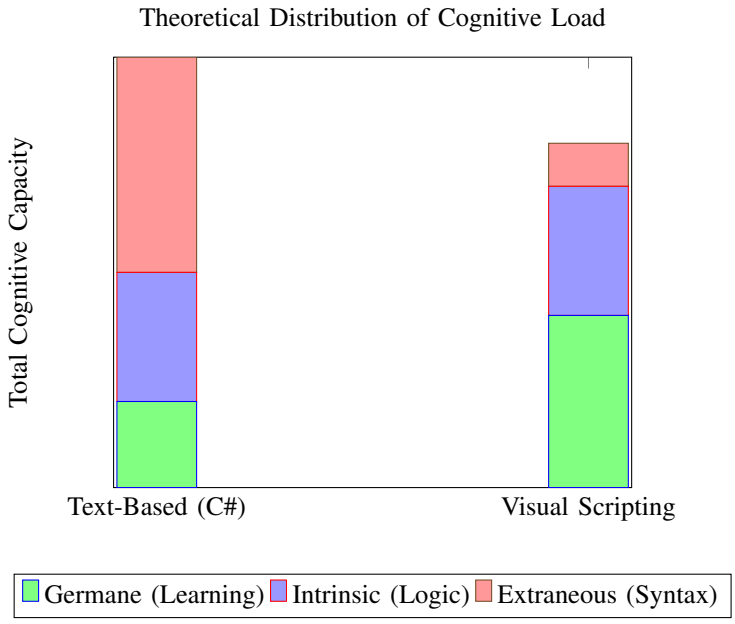

Fig. 1. Comparison of cognitive Load distribution. The reduction of extraneous load (Syntax) in visual scripting frees up cognitive capacity for germane load (Deep Learning), assuming constant intrinsic load (logic).

logic, remains constant across both paradigms, the reduction in extraneous noise directly liberates cognitive resources. This surplus capacity is shifted towards Germane Load, allowing students to focus deeper on the causal relationships of the physics simulation rather than debugging missing semicolons.

This disparity is visually captured in the “Cognitive Gap". As illustrated in Fig. 2, while the algorithmic flow is intuitive, the textual implementation introduces extraneous cognitive load via syntax rules (braces, semicolons, pointers). This barrier often discourages learners before they can grasp the core logic [10].

B. Flow Theory and Engagement in Coding

Beyond cognitive load, the emotional state of the learner plays a crucial role. Csikszentmihalyi’s Flow Theory suggests that optimal learning occurs when the challenge level matches the student’s skill. In text-based programming, syntax errors often interrupt this flow, causing frustration. Ke et al. [21] and Tsai et al. [22] have explored engagement in game-based learning, finding that visual feedback loops help maintain the “Flow" state. By removing syntax errors, Visual Scripting allows students to stay in the flow of logic construction, potentially increasing persistence as observed by Israel-Fishelson and Hershkovitz [23].

IV. Methodology

A. Course Context, Participants and Demographics

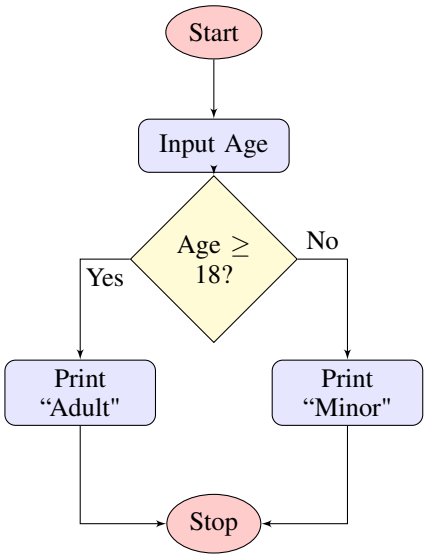
The study was conducted during the “Physics for Videogames" course (3rd semester) at the University of Talca. The participants ($N = 22$) were engineering students with basic prior knowledge of Java/C but no experience in Unity Visual Scripting. The demographic distribution was 77% male and 23% female, with an age range of 19-22 years. Prior to the course, 100% of students had taken “Introduction to Programming" (C/Java), but a diagnostic survey revealed that only 15% felt “confident" with Object-Oriented Programming (OOP) concepts.

B. Instructional Design and Tasks

The intervention was structured over 8 weeks:

- Weeks 1-4 (MonoGame/C#): Students implemented a *Snake* game from scratch. This involved creating a `GameLoop`, handling `SpriteBatch` rendering, and manually calculating AABB (Axis-Aligned Bounding Box) collisions.
- Weeks 5-8 (Unity Visual Scripting): Students recreated the game with added complexity (obstacles, particle effects). Instead of writing code, they used the Bolt/Visual Scripting graph to manipulate `Rigidbody2D` and `BoxCollider2D` components.

This structure ensures that students faced the exact same algorithmic challenges (movement vectors, collision response) in both paradigms.



C. Experimental Design

A **Within-Subjects Quasi-Experimental Design** was adopted. The semester was divided into two phases to force a comparison within the same group of learners (see Fig. 3).

1) Phase 1: Text-Based Approach (MonoGame): Students developed a classic *Snake* game. This framework requires writing the game loop, handling inputs, and calculating collisions manually in C# code.

Listing 1: Snippet of C# collision logic required in Phase 1.

```
if (head.Position.X == food.Position.X &&
```

a) Algorithm (Mental Model)

```c
#include <stdio.h>

int main() {
    int age;
    printf("Enter age: ");
    // SYNTAX BARRIER:
    // Format specifiers, addresses (&)
    scanf("%d", &age);

    if (age >= 18) {
        printf("Adult\n");
    } else {
        printf("Minor\n");
    }
    // SEMANTIC BARRIER:
    // Return types, scope
    return 0;
}
```

b) Implementation (Syntactic Barrier)

Fig. 2. The "Cognitive Gap" in introductory programming. While the flowchart (a) is intuitive, the text implementation (b) introduces extraneous load via syntax rules (braces, semicolons, pointers), as identified by Ko et al. [10].

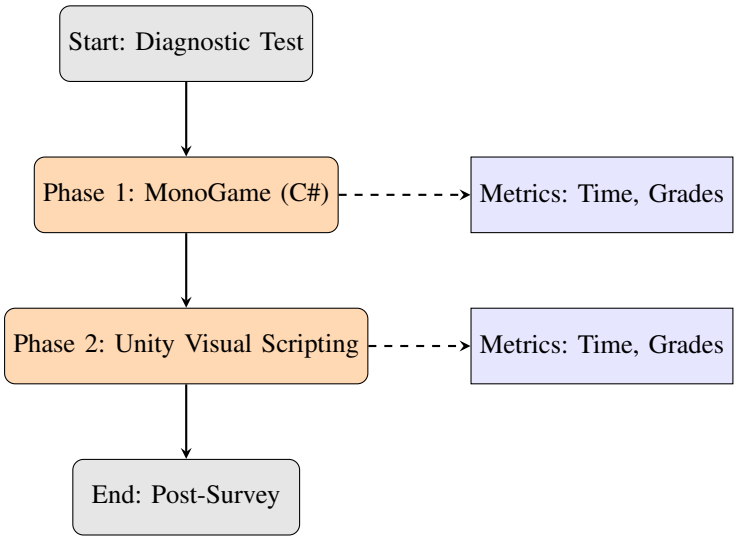


Fig. 3. Methodological workflow of the study. All students participated in both phases.

```
    head.Position.Y == food.Position.Y) {
    GrowSnake();
    SpawnFood();
}
```

2) Phase 2: Visual Approach (Unity): Students developed an enhanced *Snake* with physics obstacles. They used Unity Visual Scripting graphs.

V. Results

A. Development Efficiency Analysis

Instructors tracked the time taken to complete specific milestones in both phases. The differences were substantial.

As seen in Fig. 5, the most significant gain was in Collision Logic (50 min vs 30 min). In MonoGame, students had to debug mathematical bounding box errors. In Unity, they simply connected an 'OnCollisionEnter' node, allowing them to focus on the consequence of the collision rather than its detection.

B. Academic Performance

Table I details the grade distribution. While the mean increase is modest (6.15 to 6.46), the Standard Deviation decreased, indicating that fewer students were "left behind" when using visual tools.

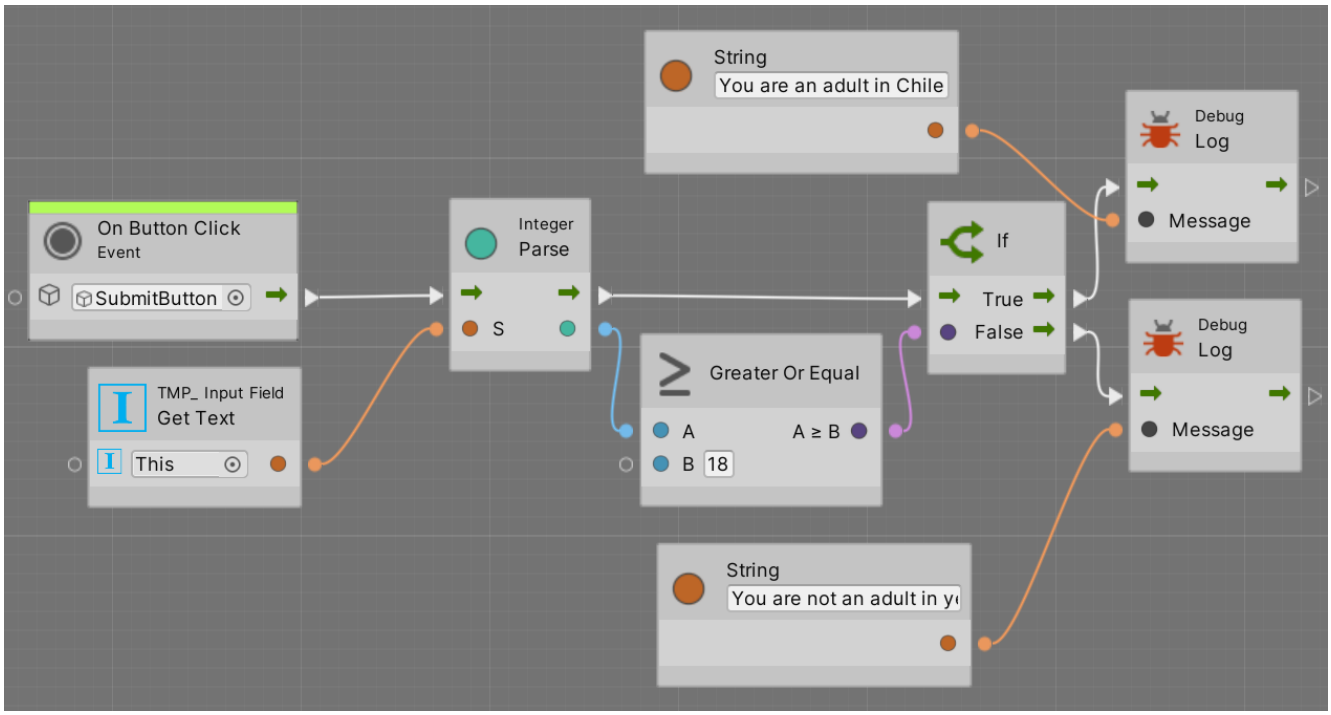

Fig. 4. Unity visual scripting solution. Nodes represent events and data flow, abstracting the syntax.

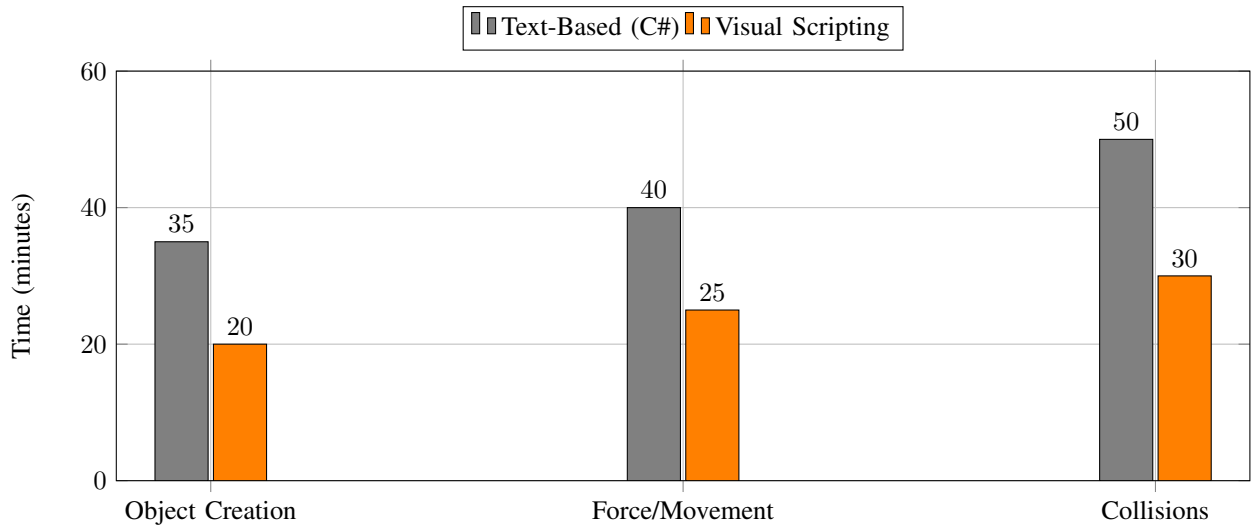

Fig. 5. Average development time per task. Visual scripting provided a 30-40% reduction in time-to-prototype.

TABLE I. DETAILED COMPARISON OF PROJECT GRADES (SCALE 1.0–7.0)

Statistic	Phase 1 (C#)	Phase 2 (Visual)
Mean Grade	6.15	6.46 (**+5%**)
Std. Deviation	0.55	0.49
Min Grade	5.0	5.5
Max Grade	6.9	6.9

C. Student Perception and Self-Efficacy

The post-intervention survey (Table II) revealed high satisfaction. Crucially, students did not view Visual Scripting as a "toy," but as a legitimate learning tool.

TABLE II. SELECTED POST-SURVEY RESULTS (SCALE 1–10)

Statement	Mean
"Visual Scripting helped me understand programming logic."	8.9
"It reduced the difficulties I had with textual syntax."	8.7
"It is useful for learning fundamentals before moving to text."	8.8
"I would recommend it to beginners."	**9.0**

Table III presents a qualitative taxonomy of errors observed during laboratory sessions. The contrast is striking. In the MonoGame phase, instructors spent the majority of their time helping students fix “Syntactic" errors, issues that prevent compilation but have no bearing on the game’s logic. This confirms the observations of Sim and Lau [6] regarding novice frustration. In contrast, the Visual Scripting phase shifted the error distribution almost entirely to “Logic/Physics". While students still made mistakes (e.g., calculating the wrong vector direction), these were *productive failures*. The visual environment allowed them to “see" the error in the graph’s data flow (Fig. 4), transforming the debugging process from a code-inspection task into a logic-inspection task. This shift is critical for developing Computational Thinking as defined by Wing [1].

VI. Discussion

A. Efficiency vs. Control Trade-off

The results support the hypothesis that Visual Scripting is significantly more efficient for prototyping (Fig. 5). By abstracting the “boilerplate" code, students entered a state of “Flow" more easily. However, some advanced students noted in open-ended comments that for complex mathematical algorithms, visual graphs could become “spaghetti code," confirming that text is superior for density, while visual is superior for architecture and events.

B. The “Didactic Bridge" Effect

The high score (8.8) on the bridging question suggests that Visual Scripting acts as a scaffold. Seeing the logic laid out spatially helps build the mental model required for text-based coding. This challenges the notion that visual languages hinder the transition to “real" coding; instead, they appear to prepare the cognitive ground for it.

The “Pedagogical Bridge Model” (Fig. 6) is proposed as a formal framework for curriculum design. Previous research often treats Visual Scripting as a distinct, alternative path. However, the findings align with Vinueza et al. [24], suggesting it is a transitional stage.

- Stage 1 (K-12): Tools like Scratch maximize abstraction to engage children [7].
- Stage 2 (The Bridge): Unity Visual Scripting exposes the *Game Object Component* model and professional API structure (Logic) but retains the visual safety net (Visual Syntax).
- Stage 3 (Professional): Once the API structure is understood visually, the student transitions to C# solely for fine-grained control and optimization.

This model explains why students reported high “Perceived Usefulness" in the survey; they intuitively understood they were learning professional concepts without the syntactic penalty.

C. Implications for Engineering Curricula

The efficiency gains observed in this study suggest that Visual Scripting should not be viewed merely as a prototyping tool, but as a strategic pedagogical scaffold. Caeiro-Rodríguez et al. [25] emphasize the need for teaching soft skills and adaptability in engineering; by mastering Visual Scripting, students learn “systemic thinking" before getting bogged down in “syntactic details."

Furthermore, as highlighted by Fahmideh et al. [26] in the context of IoT and Software Engineering, the industry is moving towards higher levels of abstraction. Integrating tools like Unity Visual Scripting aligns with Industry 4.0 trends [4], where the ability to rapidly configure and connect logic blocks is becoming as valuable as writing raw code. However, agreement is found with Perera et al. [27] that text-based languages remain fundamental. Therefore, a “Hybrid Syllabus" is proposed for introductory game development courses: start with Visual Scripting to build confidence and mental models (Weeks 1-6), and transition to C# scripting for performance optimization and complex architecture (Weeks 7-16).

VII. Conclusion

This study demonstrates that Unity Visual Scripting is not merely an accessibility tool for non-programmers, but an efficient pedagogical accelerator for engineering students. The empirical results show a statistically significant reduction in development time (30–40%) for core mechanics compared to the text-based MonoGame approach, without compromising academic grades. Crucially, students reported higher self-efficacy and lower frustration, identifying Visual Scripting as a “cognitive bridge" that allows them to visualize abstract logic before committing to syntax.

A “Hybrid Scaffolded Curriculum" is recommended for introductory game development and engineering courses. Educators should leverage Visual Scripting in the early stages to teach high-level concepts, such as Game Loops, Event-Driven Programming, and Physics Interactions, allowing students to build mental models free from syntactic noise. Once these models are solidified, the curriculum should transition to C #, defining it as a tool for optimization, architectural refinement, and granular control. This approach “Logic-First, Syntax-Second," aligns with the requirements of Industry 4.0, prioritizing systemic thinking over rote memorization.

From a curriculum and policy perspective, this hybrid model has concrete implications for program design. At the institutional level, integrating visual scripting as an explicit component of early-semester courses requires aligning syllabi, learning outcomes, and assessment rubrics with the idea of a gradual transition from graphical to textual representations. This may involve, for example, dedicating specific modules to Unity Visual Scripting in courses such as “Introduction to Programming” or “Game Development I”, and mapping those modules to accreditation criteria related to computational thinking, design of interactive systems, and teamwork. At the faculty level, the adoption of visual tools calls for targeted professional development so that lecturers can design tasks that go beyond simple drag-and-drop exercises and connect the graphs with the underlying C# constructs. Finally, on a broader policy scale, the results support curricular guidelines that recognize visual environments as legitimate vehicles for engineering education, rather than remedial tools, which is particularly relevant for institutions seeking to widen participation and reduce early attrition in programming-heavy degrees.

TABLE III. TAXONOMY OF FREQUENT ERRORS: TEXT-BASED VS. VISUAL APPROACH

Error Category	MonoGame (C#)	Unity Visual Scripting
Syntactic	**High Frequency (65%)** Missing semicolons, mismatched braces, case sensitivity (e.g., `gameTime` vs `GameTime`).	**Null / Negligible** Syntax is enforced by node shapes. Connections are validated instantly by the UI.
Type Safety	**Moderate (20%)** Casting errors (e.g., `float` to `int`), null reference exceptions at runtime.	**Low (10%)** Visual conversion nodes are auto-suggested. Data ports are color-coded (e.g., Boolean is purple).
Logic / Physics	**Low Visibility (15%)** Logic errors buried inside valid syntax. Hard to visualize vector math.	**High Visibility (90%)** Errors like "Snake passing through walls" are immediately visible in the graph flow execution.

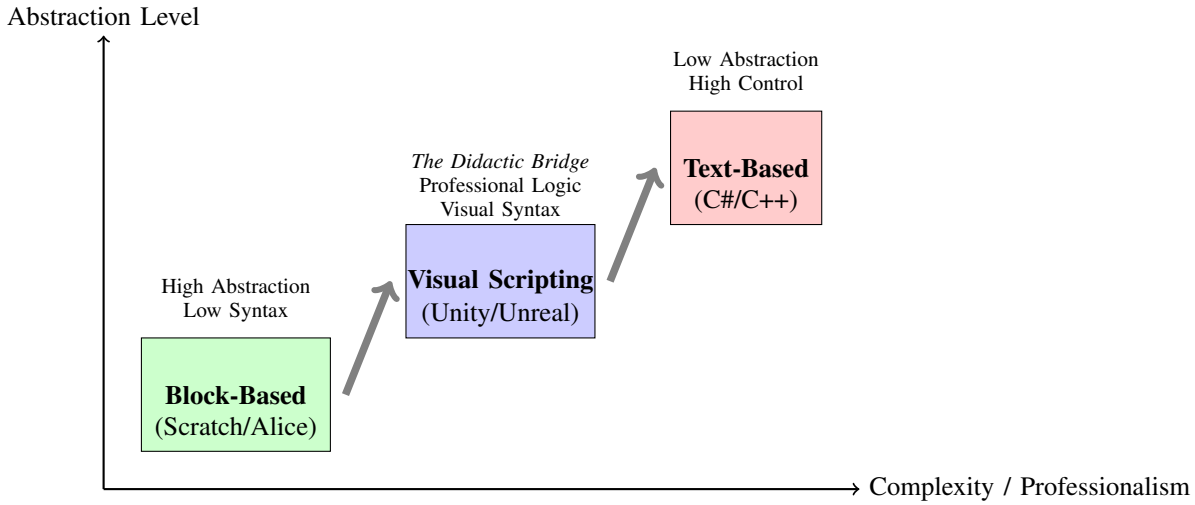

Fig. 6. The Proposed "Pedagogical Bridge Model". Visual Scripting serves as the necessary scaffold between K-12 block tools and professional text coding, aligning with Vinueza et al. [24].

The study has limitations inherent to its quasi-experimental design. First, the sample size is modest ($N = 22$) and restricted to a single course at a Chilean university, which constrains the statistical power of the analyzes and limits the extent to which the findings can be generalized to other institutions, disciplines, or educational systems. The cohort also corresponds to students who had already passed an introductory programming course and enrolled in a videogame-oriented course; their attitudes and prior experiences may not be representative of more heterogeneous populations or of students with low interest in game development.

Second, the within-subject structure of the intervention introduces a potential learning effect: performance in the Unity Visual Scripting phase may partly reflect the consolidation of conceptual understanding acquired during the earlier MonoGame phase. Although the second project deliberately incorporated additional mechanics to increase task difficulty, this design cannot fully disentangle the impact of the tool from that of accumulated practice. Finally, all measures were collected within a single semester and context, so the study does not capture long-term retention or transfer to subsequent text-based courses. These constraints should be considered when interpreting the results and suggest caution when extrapolating them to different institutional realities.

Future research avenues are twofold. First, future work aims to explore the integration of Artificial Intelligence assistants within visual environments, investigating how AI-driven suggestions might further reduce cognitive load in serious game design. Second, drawing from software product line engineering, the reuse of visual modules to manage variability in student projects will be analyzed, potentially automating the assessment of game mechanics. Longitudinal studies are needed to track whether the conceptual gains from Visual Scripting translate into better long-term performance in advanced text-based programming courses.

Ultimately, this study advocates for a paradigm shift in engineering education. By legitimizing Visual Scripting as a rigorous component of the curriculum, institutions can reduce the "syntactic friction" that drives attrition, fostering a new generation of engineers who are proficient in algorithmic logic before they even write their first line of syntax. This "Bridge" model offers a scalable path for adopting Industry 4.0 tools in higher education.

Confidence-Based Trust Calibration in Human-AI Teams

Michael Ibrahim
Computer Engineering Department-Faculty of Engineering, Cairo University, Giza, Egypt 12613

***Abstract*—Effective human-AI collaboration is contingent upon calibrated trust, wherein users depend on AI systems when accuracy is probable and rely on human judgment when errors are likely. In this study, a confidence-based mechanism for trust calibration within human-AI teams is examined. A decision-making strategy is proposed in which task delegation is governed by the AI's confidence: when the confidence surpasses a specified threshold, the AI's recommendation is adopted; otherwise, the decision is deferred to the human. Through simulation experiments on a binary classification task, performance outcomes are compared. The AI system achieves an accuracy of 77.7%, whereas the human decision-maker, modeled with a confidence-sensitive accuracy function $p_h(c) = 0.95 - 0.3c$, attains an overall accuracy of 71.9%. Team performance is evaluated across a range of AI confidence thresholds (0.50 to 0.99), revealing that an intermediate threshold yields optimal team accuracy of 84.14%, substantially exceeding the performance of either agent individually. The findings provide a detailed analysis of confidence-based delegation, align with existing research on trust calibration, and underscore critical design implications for the development of human-centric AI systems.**

***Keywords*—Human-AI collaboration; trust calibration; confidence-based delegation; decision-making strategies**

I. Introduction

Artificial Intelligence has been increasingly deployed to support human decision-making across domains such as healthcare, finance, and public administration. From the assistance of clinicians in diagnostics to the facilitation of faster financial fraud detection, AI systems are now influencing decisions that carry significant consequences for individuals and society [1], [2], [3].

In many of these applications, AI systems are designed to act as decision aids, producing predictions or recommendations while the final judgments are left to human operators. The effectiveness of such human-AI teams is determined not only by the technical accuracy of the AI but also by the quality of human-AI collaboration, particularly the calibration of human trust in the system [4], [5]. Misaligned trust, manifested as either over-reliance on flawed outputs or unwarranted skepticism toward reliable ones, has been shown to significantly impair decision quality [6].

Trust calibration is defined as the alignment between a user's trust in an AI system and the system's actual performance or reliability. When trust is properly calibrated, users tend to rely on the AI when it is likely to be correct and revert to their own judgment when the AI is likely to err [7]. This balance is particularly critical in high-stakes environments, where both AI errors and human biases may lead to severe consequences [8].

To foster calibrated trust, many AI systems have been equipped with confidence scores or uncertainty estimates that accompany their predictions. These indicators are intended to help users discern when AI recommendations should be accepted or questioned [4]. However, the provision of confidence information alone has not been found sufficient. Empirical studies indicate that users' own confidence levels and cognitive biases play a significant role in determining whether reliance on AI systems is appropriately adjusted [5], [7]. For instance, overconfident users may disregard valuable AI input, whereas underconfident users may accept flawed suggestions without critical evaluation.

Consequently, trust calibration emerges as a dual challenge, requiring both transparent AI systems and mechanisms that account for human self-assessment and behavioral tendencies [6]. In response to this challenge, a confidence-based delegation strategy is examined, wherein AI predictions are adopted only when their confidence surpasses a predefined threshold; otherwise, the decision is deferred to the human operator.

This strategy is intended to align decision authority with the most reliable agent in each situation. By tuning the threshold, the balance between human and AI decision-making can be dynamically adjusted, ranging from heavy reliance on AI to near-complete human control. The proposed approach is evaluated within a simulated binary classification task, in which an AI system with fixed accuracy and a human agent with confidence-sensitive performance are modeled. The results indicate that an intermediate confidence threshold yields the highest overall team performance, surpassing that of either the human or AI operating independently.

These findings provide new insights into trust calibration strategies for human-AI collaboration and contribute to the design of systems that optimize joint decision-making outcomes in practical applications.

II. Related Work

A. Trust Calibration and Miscalibration in Human-AI Interaction

Trust calibration lies at the core of effective human-AI interaction, serving as the process by which human users adjust their trust in an AI system to align with the system's actual competence and reliability. Properly calibrated trust allows users to leverage AI strengths while maintaining critical oversight, ensuring that reliance on automation remains proportional to its demonstrated performance. Conversely, miscalibrated trust, manifesting as either overtrust or undertrust, can undermine system efficacy, situational awareness, and

ultimately safety. This is particularly consequential in high-stakes domains such as healthcare, autonomous vehicles, and maritime navigation, where erroneous trust judgments can have severe operational and ethical implications.

Kneer, Loi, and Christen [9] explore these dynamics in the context of human–AI interaction, emphasizing how automation bias and algorithm aversion emerge when users misperceive AI capabilities or misinterpret its outputs. Such errors may arise from opacity, inconsistent performance, or limited user understanding. As a result, trust calibration emerges as both a technical and psychological challenge.

Extending this perspective, Kulal [10] argue that even when AI systems provide statistically calibrated outputs, users may misalign their trust due to cognitive biases, such as anchoring on superficial cues or overgeneralizing prior experiences. This highlights that achieving trust calibration is not solely a matter of improving algorithmic confidence, it also requires user-centered design informed by cognitive science and HCI. Thus, future systems must integrate these insights to foster more resilient, interpretable, and human-aligned decision-making partnerships.

B. Confidence and Uncertainty Displays

A prominent approach to improving trust calibration in human-AI interaction involves communicating the AI system's confidence or uncertainty levels. These displays aim to make the system's internal reasoning and limitations more transparent, allowing users to adjust their reliance on AI outputs according to perceived reliability. When well-designed, such indicators can foster calibrated trust, reduce automation bias, and help users recognize when human oversight is necessary. However, the effectiveness of confidence and uncertainty displays depends critically on users' ability to correctly interpret and integrate these signals into their decision-making processes.

Prior work has shown that presenting confidence alone is insufficient if users lack the contextual or cognitive tools to make sense of probabilistic information. For instance, Zhang and Xu [11] demonstrate in the maritime domain that multimodal indicators, such as uncertainty bars, linguistic cues, and system status indicators, are more effective than confidence scores alone in promoting trust calibration and preventing overreliance or disuse. These findings highlight the importance of designing interfaces that help users develop accurate mental models of AI decision boundaries.

Similarly, byasa and Rahmania [12] emphasize the value of explanation-assisted confidence displays in medical imaging. Their approach integrates visual saliency explanations with model confidence in 3D brain tumor segmentation tasks. This combination improved clinician understanding of when to trust or question AI outputs, suggesting that confidence information is most effective when paired with interpretable explanations.

Taken together, these insights emphasize that uncertainty communication is as much a matter of human-centered design as it is of algorithmic transparency. Effective confidence displays must balance informativeness and interpretability, tailoring the presentation of uncertainty to users' cognitive and contextual constraints. As a result, ongoing work in this area increasingly integrates research from explainable AI, human–computer interaction, and cognitive psychology to develop uncertainty representations that genuinely support trust calibration.

C. Confidence Alignment in Human–AI Collaboration

Effective trust calibration in human-AI collaboration requires a bidirectional approach: AI systems must communicate confidence that accurately reflects their underlying uncertainty, while human users must be supported in correctly interpreting and responding to these cues. Achieving alignment between human and AI confidence is not merely a technical issue of probabilistic calibration, but also a human-centered challenge involving perception, communication, and adaptive interface design. When either side of this alignment fails, when the AI misrepresents its certainty or when humans misread it, the partnership risks degradation through underutilization, overreliance, or unsafe decision-making.

In dynamic settings such as maritime navigation, Zhang and Xu [11] emphasize the importance of adaptive user interfaces that integrate explainable AI (XAI) components. They find that calibrated confidence and compliance indicators support user understanding of automation, fostering more consistent trust judgments under uncertainty. Their work highlights how interface-level interventions can prevent automation bias and encourage proper human oversight.

Reinforcing this view, von Reeken, Salous, and Abdenebaoui [13] demonstrate that subtle interface variations in conversational AI systems can significantly affect how users align their trust with system recommendations. Their study shows that users benefit from interface cues that signal confidence calibration quality, especially in retrieval-augmented generation systems. When these cues are absent or misaligned, trust can diverge from actual system reliability, leading to overtrust or disuse.

Finally, Marusich et al. [14] underscore the necessity of designing for trust calibration in time-sensitive, high-stakes applications. They advocate for adaptive confidence visualizations and user training strategies that evolve with changing task difficulty and user experience. Their findings suggest that integrating behavioral modeling into the interface design, such as adjusting explanation granularity based on user trust metrics, can prevent cascading decision errors and improve joint performance.

Taken together, these studies affirm that trust calibration is best achieved through a combination of calibrated AI outputs and adaptive, user-sensitive interface design. Future systems should be designed not just to communicate confidence but to help users meaningfully act on it.

D. Confidence-Based Delegation Policies

Confidence-based delegation represents a structured mechanism for managing trust and control within human-AI collaboration. In such frameworks, decision authority dynamically shifts between the human and the AI system according to confidence thresholds, when the AI's confidence surpasses a predefined level, the system autonomously executes a decision; when confidence falls below that level, control is transferred to

the human operator. This approach formalizes trust calibration by operationalizing it into quantifiable and adaptive decision policies, thereby aligning task allocation with system reliability and uncertainty.

This paradigm offers several benefits. It allows for efficient division of labor, ensuring that AI systems handle routine or high-certainty cases while humans intervene in ambiguous or high-risk situations. By doing so, it mitigates both over-reliance and under-reliance on automation, promoting a balanced collaborative dynamic. However, the success of confidence-based delegation hinges on how well the confidence thresholds are defined, validated, and communicated. Misaligned thresholds can either overwhelm human operators with unnecessary interventions or, conversely, lead to excessive automation that undermines human oversight and accountability.

Recent work by Le Denmat, Desender, and Verguts [15] underscores the importance of aligning system confidence with real-time human decision dynamics. Their study shows that agents can learn optimal confidence thresholds through experience, adjusting delegation based on trial-level feedback about decision accuracy. This learning-based approach allows human-AI systems to optimize collaboration patterns dynamically and avoid rigid reliance on static thresholds. This work builds on this by examining how performance varies across different threshold settings and demonstrating that fine-tuned delegation improves joint outcomes significantly. Such insights are crucial for deploying human-AI systems in dynamic, high-stakes environments where uncertainty varies widely across tasks.

III. Methodology

A trust calibration strategy was investigated for a human-AI team performing repeated binary classification tasks, such as diagnosing medical images or identifying fraudulent financial transactions. The team consisted of two agents: an AI model and a simulated human decision-maker. Both agents produced a class prediction and an associated confidence score for each decision instance. A simple confidence-based delegation policy was introduced, wherein the AI's confidence determined which agent's decision was adopted.

A. Confidence-Based Delegation Policy

Formally, the delegation policy was defined by a threshold parameter $\tau \in [0.5, 1.0]$. For each instance, the AI produced a class prediction and a confidence score $C_{\text{AI}} \in [0.5, 1.0]$. The confidence was restricted to be at least 0.5 since probabilities below this value would imply a different predicted class. The policy operated as follows:

- If $C_{\text{AI}} \geq \tau$, the AI's prediction was selected.
- If $C_{\text{AI}} < \tau$, the human's prediction was selected.

This threshold-based policy enabled dynamic delegation: the AI was trusted when sufficiently confident, while decisions were deferred to the human otherwise. Lower thresholds led to increased AI usage, whereas higher thresholds resulted in greater reliance on the human agent. It was hypothesized that an intermediate threshold could yield optimal overall accuracy by balancing the complementary strengths of both agents.

B. Simulation Framework

The decision-making process of the human-AI team was simulated to evaluate the proposed strategy.

a) AI Model: The AI was modeled as a binary classifier with fixed accuracy and calibrated confidence scores. Specifically, an AI accuracy of 77.7% across decision instances was simulated. The AI's confidence C_{AI} was sampled uniformly from the interval [0.5, 1.0]. The correctness of each prediction was determined probabilistically to ensure the specified overall accuracy.

b) Human Model: The human agent was modeled with imperfect confidence calibration. For each decision, a confidence value $c \in [0, 1]$ was reported. The probability of correctness given the confidence was defined as:

$$p_h(c) = 0.95 - 0.3c$$

This formulation captured typical miscalibration patterns, such as overconfidence at high confidence levels and underconfidence at low ones. For instance, when $c = 1.0$, the actual accuracy was 65%; when $c = 0.2$, accuracy increased to 89%. Confidence values were drawn from a distribution yielding an overall accuracy of 71.9%.

c) Independence Assumption: For analytical tractability, statistical independence between the AI and human confidences and correctness outcomes was assumed. Although correlated errors may occur in practice, this assumption allowed isolation of the effects of the delegation policy.

C. Decision and Evaluation Procedure

For each simulated decision instance, the following procedure was executed:

1) An AI confidence score C_{AI} was sampled, and correctness of the AI prediction was determined.
2) A human confidence score c was sampled, and correctness was determined based on $p_h(c)$.
3) The threshold policy was applied to select either the AI or human prediction.
4) The correctness of the chosen prediction was recorded.

Over many instances, two key metrics were computed:

- Team Accuracy: The proportion of correct final decisions.
- AI Usage Rate: The proportion of instances where $C_{\text{AI}} \geq \tau$.

By varying τ from 0.50 to 0.99, the effects on performance were examined. At the extremes, $\tau = 0.50$ corresponded to complete reliance on the AI (team accuracy = 77.7%), while $\tau = 0.99$ corresponded to near-exclusive human decision-making (team accuracy = 71.9%). Optimal team performance was expected at intermediate thresholds, where complementarities between AI and human decision-making were maximized.

D. Experimental Setup

Simulations were conducted at thresholds $\tau \in \{0.50, 0.60, 0.70, 0.80, 0.90, 0.95, 0.99\}$, with tens of thousands of instances sampled per setting to ensure statistical robustness. For each threshold:

- AI confidence C_{AI} was sampled uniformly from [0.5, 1.0].
- AI correctness was probabilistically determined to ensure a 77.7% overall accuracy.
- Human confidence c was sampled to yield a 71.9% accuracy based on $p_h(c)$.
- The delegation rule was applied, and the correctness of the selected agent's decision was recorded.

This simulation framework enabled systematic evaluation of how the delegation threshold influenced both decision accuracy and the division of labor between the human and AI agents.

IV. Results

A. Team Performance vs. Threshold

Table I summarizes team accuracy and AI usage rates across different confidence threshold values. As the threshold τ increased from 0.50 to 0.99, team accuracy followed an inverted U-shaped curve. At $\tau = 0.50$, where the AI always makes the decision, team accuracy matched the AI's standalone performance of 77.7%. Increasing the threshold to $\tau = 0.60$ boosted team accuracy to 82.0%, and a further increase to $\tau = 0.70$ yielded the highest observed accuracy of **84.1%**.

At this optimal threshold, the AI handled approximately 75% of the instances, while the human handled the remaining 25%. Beyond $\tau = 0.70$, accuracy began to decline: at $\tau = 0.80$, it dropped to 83.0%; at $\tau = 0.90$, to 79.0%; and by $\tau = 0.99$, to 72.0%, only marginally above the human-alone baseline of 71.9%. AI usage rates decreased accordingly: from 100% at $\tau = 0.50$ down to approximately 3% at $\tau = 0.99$.

Table I demonstrate a clear "sweet spot" at $\tau = 0.70$, where team accuracy is maximized. The gain is substantial: a 6.4 percentage point improvement over the AI alone (77.7%) and a 12.2 point gain over the human alone (71.9%). These results validate the hypothesis that confidence-based delegation can yield performance gains by exploiting complementary strengths.

B. AI Usage vs. Threshold

As shown in the AI usage column of Table I, increasing the confidence threshold gradually reduces the frequency with which the AI's prediction is used. From full usage at $\tau = 0.50$, AI involvement drops to 75% at $\tau = 0.70$, then falls steeply to 50% at $\tau = 0.80$, 25% at $\tau = 0.90$, and near-zero at $\tau = 0.99$. This shift implies increasing reliance on the human as the threshold rises, and team performance decreases accordingly when the human is responsible for too many decisions.

Interestingly, the best accuracy occurs when the AI is used about 75% of the time, aligning with its higher individual accuracy compared to the human. In scenarios where the human were more accurate than the AI, we would expect the optimal threshold to shift accordingly.

C. Interpretation of Results

The results demonstrate that confidence-based delegation is a viable and effective strategy for trust calibration in human-AI teams. The optimal threshold reflects a division of labor that exploits each agent's strengths. At $\tau = 0.70$, the AI handles the decisions where it is relatively confident, while the human steps in where the AI is uncertain. This allocation improves the team's collective performance.

To understand why this threshold works, consider that when the AI is less than 70% confident, it is often wrong on those predictions. Our human model, while less accurate overall, is calibrated to sometimes outperform the AI on low-confidence cases. Conversely, when the AI is highly confident (e.g., $C_{\text{AI}} \geq 0.90$), it tends to be right, and deferring to it yields better results than relying on the human.

Thus, the delegation policy implicitly partitions the decision space: confident, likely-correct decisions go to the AI, and ambiguous, error-prone cases go to the human. Provided the AI's confidence is reasonably well-calibrated, this partitioning enhances team accuracy and supports appropriate reliance.

In summary, this experiment demonstrates that appropriately calibrated confidence thresholds can yield significant performance gains in human–AI collaboration, validating the utility of confidence as a trust calibration mechanism.

V. Discussion

The effectiveness of confidence-based delegation as a mechanism for trust calibration in human-AI collaboration was demonstrated. By using the AI's own confidence scores to determine reliance, decision-making was dynamically allocated to the most appropriate agent, achieving outcomes superior to either agent alone. The implications, necessary conditions, and design considerations for applying this strategy in practice are discussed below.

A. The Value of Calibrated Delegation

The threshold-based policy examined captures a key principle of appropriate reliance: deference to the AI when high confidence is expressed, and reliance on human judgment when uncertainty is greater. This simple policy significantly improved team performance, mitigating both over-reliance on incorrect AI outputs and disuse of valuable AI recommendations. At the optimal threshold $\tau = 0.70$, many of the AI's confident and unconfident mistakes were avoided through intelligent decision allocation.

This outcome aligns with theoretical work suggesting that automation should be applied when AI confidence is high and human input should be sought otherwise. The observed performance gain, from 77.7% to 84.1%, represents a 29% reduction in error. In real-world domains such as medical diagnostics or fraud detection, such improvements could have meaningful impacts.

These benefits, however, depend on human-AI complementarity: each agent must be capable of correcting the other's

TABLE I. TEAM DECISION ACCURACY AND AI USAGE RATE AT DIFFERENT CONFIDENCE THRESHOLDS

Confidence Threshold τ	Team Accuracy (%)	AI Usage Rate (%)
0.50 (Always AI)	77.7	100
0.60	82.0	90
0.70	**84.1**	75
0.80	83.0	50
0.90	79.0	25
0.95	76.0	10
0.99 (Rarely AI)	72.0	3

errors. In the simulation, this complementarity was modeled by allowing the human to outperform the AI in low-confidence cases. When error overlap is substantial, confidence-based delegation may offer limited advantage.

B. Dependence on AI Confidence Calibration

A foundational assumption is that the AI's confidence is reasonably well-calibrated. In practice, confidence miscalibration, manifesting as overconfidence or underconfidence, can severely undermine delegation policies. Overconfident models may mislead users into trusting erroneous outputs, whereas underconfident models may lead to missed opportunities for automation.

Calibration techniques such as Platt scaling, isotonic regression, and temperature scaling can improve the reliability of confidence scores. Alternatively, "learning to defer" approaches explicitly optimize the decision of when to abstain and defer to a human, effectively learning an optimal threshold τ directly from data.

C. Human Factors and Policy Compliance

Strict adherence to the delegation policy was assumed in the simulation. However, real users may deviate due to cognitive biases, trust propensities, or interface design. For example, a clinician might override a confident AI due to recent negative experiences or accept low-confidence AI suggestions due to overtrust.

Compliance can be improved through design interventions. Visual cues indicating whether a confidence threshold has been met could nudge users toward intended behavior. Training and feedback mechanisms may further support trust calibration by displaying statistics on when AI advice was followed or overridden, along with the corresponding outcomes.

Thresholds may also be personalized. Overtrusting users may benefit from higher thresholds that enforce engagement, while distrustful users may begin with lower thresholds that increase over time as trust builds. Adaptive systems that monitor user behavior and adjust τ dynamically may enhance collaboration.

D. Integration with Explanations and Interpretability

Although confidence was the primary trust signal considered, AI systems increasingly provide explanations such as saliency maps and rationales. These can either support or interfere with trust calibration. An explanation aligning with user expectations can reinforce high-confidence decisions, whereas poor explanations may lead to unjustified distrust.

Combining confidence with selective explanations presents a promising direction. Explanations could be shown for low-confidence cases to assist human judgment, and withheld for high-confidence cases to reduce cognitive load. Future empirical research should evaluate such hybrid strategies.

E. Complementarity and Task Structure

The efficacy of threshold-based delegation depends on complementary error patterns between human and AI agents. When failures occur on different instances, confidence-based delegation yields the greatest gains. Task design can enhance complementarity by training AI models on instances difficult for humans or by employing disagreement-based sampling.

Task difficulty distribution also plays a critical role. Confidence-based delegation performs best when there is a broad range of instance difficulties. In tasks that are uniformly easy or uniformly hard, the confidence spectrum may collapse, limiting the utility of threshold-based strategies.

Moreover, error cost asymmetry should inform threshold selection. In high-risk applications, thresholds might be set conservatively to ensure human oversight. While this study optimized for accuracy, practical deployments may need to optimize precision, recall, or cost-sensitive metrics.

F. Implications for Human-Centered AI Design

Confidence thresholds offer a transparent and tunable mechanism for managing human-AI collaboration. They can be adapted to task domain, risk level, and user behavior, making system behavior predictable and auditable to aid accountability.

Effective implementation requires careful attention to interface design, user training, performance monitoring, and explanation integration. The delegation policy should be visible, justifiable, and adaptable.

The findings support a central tenet of human-centered AI: the objective is not to replace humans, but to design systems in which humans and AI complement each other. Confidence-based trust calibration provides a concrete, interpretable, and effective strategy for achieving such synergy.

VI. CONCLUSION

A simulation-based investigation of confidence-based trust calibration in human-AI teams was presented, focusing on a threshold delegation strategy in which the AI's confidence score determined whether its prediction was used or deferred to the human. It was found that selecting an appropriate confidence threshold could significantly enhance team performance: in the examined scenario, team accuracy peaked at 84.1%,

surpassing both the AI-alone baseline (77.7%) and human-alone performance (71.9%). This improvement highlights the value of calibrated reliance, whereby each agent contributes most effectively in contexts that align with their respective strengths.

These findings are consistent with prior research emphasizing the importance of trust calibration in human-AI interaction. Confidence-based delegation policies provide a transparent and operationalizable mechanism for achieving such calibration, assuming that the AI's confidence scores are well-calibrated and that human decision-makers are appropriately guided to interpret and act on those scores.

For designers of human-centric AI systems, the results suggest that implementing confidence-threshold strategies constitutes a practical and beneficial design approach. Rather than positioning human and AI agents as parallel or redundant decision-makers, a coordinated policy can systematically leverage their complementary capabilities. Nevertheless, the realization of these benefits in applied settings is contingent on factors such as user education, interface design, and the reliability of the AI's uncertainty estimates.

Future research is encouraged to investigate adaptive threshold strategies that adjust dynamically based on user behavior, task context, or evolving trust calibration. Empirical user studies are also needed to assess how individuals interact with confidence-based delegation interfaces, the extent to which prescribed policies are followed, and how interventions, such as visual cues or feedback mechanisms, may enhance compliance and comprehension.

Ultimately, confidence-based trust calibration exemplifies the goals of human-centered AI: systems designed not only for accuracy but also to support and align with human decision-making processes. By enabling reliance on AI systems to the extent that their predictions are trustworthy, progress is made toward the development of AI tools that are both effective and accountable. The approach described herein demonstrates that even a simple, interpretable rule anchored in confidence can yield meaningful improvements in team performance. With ongoing advancements in calibration techniques and human-AI interface design, trust calibration strategies are expected to occupy a central role in the next generation of decision-support systems.

***Abstract*—In vitro fertilization (IVF) has become a primary therapeutic intervention for couples worldwide addressing infertility challenges. IVF success depends critically on embryo quality assessment, where cell cleavage timing serves as a key developmental parameter. Traditional morphological evaluation methods suffer from inter-observer variability and labor-intensive manual analysis. This study presents an automated AI-based framework for cleavage stage detection and cleavage onset timing estimation from Time-Lapse Microscopy (TLM) videos to assist embryologists in embryo selection. The proposed YOLO-based approach addresses significant class imbalance through selective data augmentation and random undersampling strategies. To ensure precise temporal data, an OCR (Optical Character Recognition) library was integrated to automatically read and record the Hours Post-Insemination (HPI) timestamps from the video frames. The proposed framework accurately identifies cell division stages up to the seven-cell stage with 1-2 hours mean timing delay post-insemination. The framework achieves an overall Accuracy of 86.61% , F1-score of 86.24% ,and precision of 86.24% in cleavage stage classification, demonstrating significant improvements over existing methods, particularly in intermediate and later stages (4-cell to 8-cell transitions) where previous research have demonstrated challenges in accurately detecting them. Automated extraction of morphokinetic parameters enables objective embryo assessment, reducing subjectivity in clinical decision-making. The proposed framework demonstrated significant improvements over previous research, which frequently has trouble accurately classifying beyond early cleavage stages. This has implications in improving the selection of good-quality embryos, and thus to help improve the success rate of IVF. This work contributes to advancing assisted reproductive technology by providing reliable, automated embryo quality assessment tools.**

I. Introduction

Infertility affects approximately 17. 5% of adults worldwide each year, and 1 in 6 people are affected by infertility in their lifetime [1]. Serious consequences can negatively affect the lives of infertile couples in terms of physical and psychological well-being, social life, and finances [2]. Among assisted reproductive technology (ART), in vitro fertilization (IVF) is the most popular treatment for infertility since the first successful IVF birth in the UK in 1978. In a typical IVF cycle, the ovaries are stimulated hormonally, mature oocytes are surgically removed, fertilization takes place in a lab, and the embryo is then transferred to the uterus. Currently, there are 35 ART centers in Saudi Arabia that perform more than 20,000 IVF treatment a year [3]. However, the success rates of these treatments are still low. In general, only 20-30% of the transferred embryos result in implant [4] and less than half of the implanted embryos survive to live birth. Thus, selecting the best quality embryo is crucial to ensure the success of the IVF process. Embryologists categorize each embryo based on different morphological criteria and morphokinetic parameters that have been linked to successful embryo development ,including the examination of cell division dynamics [5]. In addition, irregular timings have been associated with genetic abnormalities, implantation failure, and miscarriage that normally manifest during the 8-cell stage [6], [7]. The number of embryonic cells and their subsequent cell division define a cell cleavage stage. It has been demonstrated that the time of cell divisions in human IVF embryos correlates with embryonic viability [6], [8]. Time-lapse studies showed that embryos that cleave in middle time periods have a higher probability of implantation compared to those that develop faster or slower [9], [10]. To assess timing features, embryologists manually annotate the cleavage occurrences of each embryo. Annotating a single embryo usually takes less than two minutes [11], but when examining many embryos (e.g., 5-10), the total time needed can increase significantly - up to 20 minutes [12]. Although manual annotation of embryo morphokinetics is considered efficient, this process is often tiresome and prone to subjectivity or human error. When counting cells in the early stages of embryonic development, cell overlap presents a significant challenge. It becomes harder to identify individual cells as they multiply because they are more densely packed, especially in the stage of 7-8 cells. This overlap makes accurate counting and monitoring more difficult. With rapid technological advancements, artificial intelligence (AI) offers a promising solution to these challenges. AI can help embryologists overcome these obstacles by automating routine tasks such as counting cells, tracking video clips,

and keeping track of division times. The use of artificial intelligence, particularly deep learning models such as convolutional neural networks (CNNs), has expanded significantly in embryo evaluation. These models are capable of automating tasks such as object detection, image segmentation, and optical character recognition (OCR), which contribute to faster and more consistent assessments of embryo development [13]–[16]. In particular, time-lapse imaging combined with AI methods has shown promise in analyzing human embryo development, enabling continuous monitoring of cell division dynamics [17]. Manual annotation of time-lapse microscopy (TLM) videos in embryology is a significant challenge, as it is a time-consuming task and subject to human variation and bias. With the increasing number of cases requiring embryological assessment, the burden on embryologists is increasing. This research develops an AI-based solution to fully automate the annotation of embryo development in TLM videos. The goals include cell detection and counting, cleavage time estimation, and enhancement of precision, productivity, and the reliability of embryo assessment. Achieving these automation objectives will help embryologists in their workflows by facilitating real-time, evidence-based decision-making, thus enhancing the practice of reproductive medicine.

The remainder of this paper is structured as follows. Section II reviews related work. Section III describes the proposed framework in detail. Section IV presents the experimental results, and Section V offers a discussion and analysis of these findings. Finally, Section VI concludes the paper and outlines potential directions for future research.

II. Related Work

Recent decades have witnessed a significant transformation in the medical scene due to technological advancements, with AI emerging as a pivotal factor in transforming healthcare [18]. The incorporation of the two fields has revolutionized various aspects of medical practice, including accurate diagnosis [19], early disease detection [20], [21], and the reading and maintenance of medical records [22]. Medical imaging has benefited greatly from AI, especially deep learning, which can identify intricate patterns and characteristics that the human eye misses [23] By offering fresh viewpoints on pertinent image attributes, these technologies not only improve diagnostic precision but also aid in clinical decision-making. In the context of assisted reproductive technologies (ART), several studies have investigated the potential of employing AI at various stages of the reproductive process. Supervised learning models have been used to evaluate embryo motility [24], assess the cost-effectiveness of egg freezing [25], and classify sperm cells [26]. Artificial neural networks (ANNs), including deep learning models, have also been widely utilized in embryo image segmentation [27], blastocyst assessment [28], and prediction of implantation outcomes, thereby enhancing consistency and scalability in clinical decision-making. Building on these broader applications, recent research has shown increasing interest in exploiting AI, particularly object detection models, to analyze embryo development using TLM. This trend has opened up unprecedented opportunities to automate the detection of critical embryonic developmental stages, such as cell divisions and stage transitions, which are essential criteria for embryo evaluation and selection in the context of assisted reproductive treatments. Studies have varied in their approaches, with an increasing number using AI-based approaches, ranging from probabilistic models to deep learning frameworks.

Among the early efforts that used probabilistic models to automate cleavage detection were [29] proposed a conditional random field (CRF) framework that combines tracking- based and tracking-free elements within a data-driven approach. The model leverages a rich set of discriminative image and geometric features, along with their spatiotemporal context, to enhance the detection of cleavage stages. Using time-lapse embryo microscopy image showed an increased accuracy in identifying mitotic events. Upon assessment of 275 clinical sequences, the suggested model demonstrated an enhanced accuracy of 24.2% compared to traditional tracking-based techniques and 35.7% over tracking-free approaches in measuring division events within the initial 48 hours of development.

Building upon this concept, [30]. extended the use of CRF to automate monitoring for human embryonic cells beyond the 4-cell stage using TLM images. Instead of segmenting or tracking individual cells, their method used a conditional random field framework to predict the number of cells in each frame. This gets around the drawbacks of earlier techniques that were limited to 4-cell analysis. The CRF model incorporates temporal dependencies between frames as well as a wide range of discriminative frame-based and cell evolution features. To further enhance predictions, authors also suggested incorporating learned probabilities of cell transitions. Their approach outperformed alternative models, achieving over 92.4% accuracy in counting cells up to 5 or more when tested on a dataset of 33 embryo sequences.

In a subsequent work [31], the same authors introduced a hybrid model that integrates CNN with CRF to automatically count cells in TLM images of human embryos. Cell counting was formulated as a classification problem, and an end-to-end convolutional neural network trained directly on raw microscopy images were utilized, with the only annotation needed being the total cell count. Their deep CNN method significantly outperformed manual feature-based counting techniques by generating hierarchical visual representations from massive amounts of data. It achieved 92.18% accuracy in predicting cell numbers up to the 5-cell stage. Using a conditional random field to model the growth of embryos over time, they introduced temporal constraints and further improved performance. Despite obstacles from cell overlaps, noise, and image variability, evaluation on a dataset of 265 embryo sequences showed that their deep learning framework could count cells in early embryonic development with reliability. The findings indicate the potential of deep learning techniques to automate cell counting in TLM images without performing segmentation steps.

While earlier methods primarily used probabilistic models and hand-crafted features, more recent research utilizes deep learning techniques to automate feature learning straight from raw images. For instance, Malmsten et al. [32] suggested an automated approach employing a CNN to identify and classify cell divisions directly from raw TLM images, with the goal of reducing the subjectivity and manual effort normally associated with embryonic assessment. Two datasets were used to test their approach: a private human embryo dataset (up to the 8-cell stage) and a public mouse embryo dataset (up to the 4-cell

stage). In 93.9% of cases, the model detected human cleavage stage transitions within a five-frame margin, while it attained nearly 100% accuracy for mouse embryos. This work showed how CNN-based systems can improve annotation uniformity and facilitate automated evaluation of embryo viability in IVF situations.

Contributing to this line of research, Sharma et al. [17] used a YOLO-based detection framework instead of traditional CNN classifiers, which enabled the extraction of accurate timing metrics, which can be used to which can be used to make predictions of embryo viability and the real-time detection of cell divisions. Their approach used YOLOv5 to detect embryonic cells and Pytesseract to extract timestamps from TLM videos. Focusing on embryos up to the five-cell stage, the system achieved an average temporal deviation of only 2–3 hours post-insemination. The model effectively detected important features like blastocysts and morulae and separated cells from detritus, despite performance declining in later stages due to increased cell overlap. Their study further emphasizes the expanding significance of automated, data-driven analysis in improving consistency and efficiency in IVF operations by demonstrating the ability to annotate videos at a rate of roughly one minute apiece.

Despite significant advances in automated embryo monitoring using deep learning and computer vision, existing methods continue to have critical limitations in accurately detecting and tracking cleavage events, especially in complex scenarios involving rapid cell divisions, high overlap, and fragmentation. Many previous studies used CRF or CNN for cell counting and stage classification. Still these methods often lack direct cleavage stage detection or rely on suboptimal OCR methods, such as Pytesseract, to extract hpi, leading to reduced accuracy in time annotation. Additionally, the majority of studies have concentrated on human embryos, but our research utilizes mouse embryo datasets, which have distinct morphological traits and developmental dynamics. An AI-based automated framework is proposed to fill these gaps by utilizing YOLOv11 for accurate cell detection and a more sophisticated OCR library tailored for TLM conditions, which guarantees reliable and accurate hpi extraction.

III. Methodology

This research proposes an AI-based automated annotation framework that predicts cell cleavage onset and cell stage from TLM videos. The pipeline is composed of three main components:

1) Object Detection Model: This uses a deep learning approach to localize and count blastomere cells in TLM embryo frames, supporting fast and accurate cleavage detection even in the presence of overlapping cells or fragments.
2) Cleavage Stage Transition Detection: It monitors changes in the number of detected cells and captures the first frame where a new cell count appears, as this corresponds to the earliest moment of morphological transition that indicates cell cleavage. reflecting the onset of a cleavage stage. Biologically, this is consistent with embryologists' approach of identifying the beginning point of cleavage as the key developmental indicator. The primary output of this step is an organized list of key frames that mark the beginning of each cell division stage, with one frame assigned to each stage. This list forms a valuable basis for the subsequent step in analyzing embryonic development.
3) Time Extraction: It uses OCR to read the hpi from each selected frame. When OCR fails due to low contrast or visual artifacts, the timing is estimated using the video's frame rate and fertilization start time.

For object detection, YOLO (You Only Look Once) is used because of its real-time detection capabilities and track record of accuracy in biomedical image analysis [33]. YOLOv11 was selected despite the consideration of competing models because it strikes a compromise between speed, accuracy, and ease of integration with video-based pipelines. For hpi extraction, Three OCR tools—PyTesseract, EasyOCR, and PaddleOCR— are evaluated and compared chosen for their various underlying technology and relevance to TLM video conditions. While PyTesseract is a typical rule-based image processing OCR engine, EasyOCR and PaddleOCR use deep learning-based designs, which provide more robustness when dealing with noisy, low-contrast, or irregular timestamps. Fig. 1 illustrates the workflow of the methodology. The proposed framework produces two primary outputs: 1) annotated frames enriched with relevant metadata, and 2) an Excel file containing cleavage timing data. As shown in the methodology flowchart, the system identifies the cleavage time points t2–t8, where tn represents the hpi time at which the embryo reaches n cells. The reported temporal outputs correspond to sequential inter-cleavage durations between consecutive developmental stages (e.g., t3 - t2, t4 - t3, t5 - t4). This structured output enables embryologists to systematically analyze early embryo developmental dynamics.

A. Dataset Description

Due to ethical considerations and privacy issues, it is challenging to obtain human embryo dataset. Thus, a dataset of mouse embryos was used instead. According to the National Institutes of Health, mice are a model organism with benefits, including genetic homogeneity, affordability, and simplicity of access [34]. Moreover, the limited availability of publicly accessible resources of human embryos emphasizes the importance of using mouse embryos to enhance this field of study. The study utilizes a TLM dataset that has been previously developed and documented in [35]. The dataset consists of video sequences recorded during the development of approximately 100 mouse embryos, taken from the 2-cell stage through to the blastocyst stage. The videos record cell divisions and dynamic changes in embryo morphology throughout important stages of preimplantation development (e.g. 2-8 cell stage, morula, blastocyst). The dataset was captured using EmbryoScope™ (Vitrolife), a specialized culture device designed with 12 individual wells per slide to allow parallel monitoring of multiple embryos under identical conditions. The dataset consisted of 18 videos, each containing 12 embryos, along with an additional video containing 8 embryos, resulting in a total of 224 individual mice embryo development sequences. These videos were recorded under controlled laboratory conditions [35] and include various cleavage events from the 2-cell stage

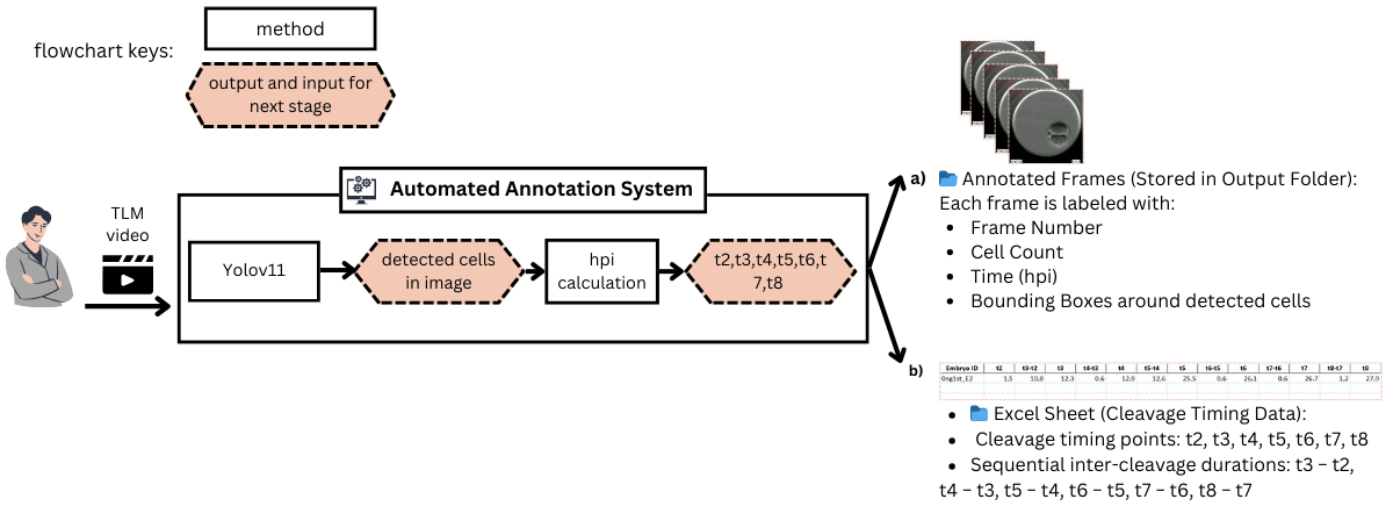

Fig. 1. AI-based automated framework for predicting cell cleavage stages and timing from Time-Lapse Microscopy videos.

to later stages, such as 8-cell or blastocyst formation. All of the videos were saved in AVI format and were captured at a constant 5 frames per second (FPS). The videos also contained time information that was embedded and crucial to our study: the elapsed time since fertilization in hpi is indicated by a visible timestamp in the bottom-right corner of each frame, which is shown as white digits on a black rectangular background.

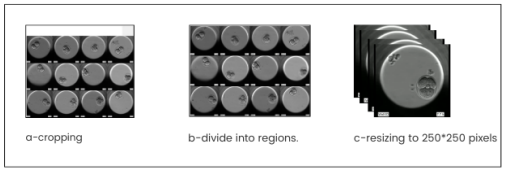

Fig. 2. Preprocessing steps for embryo isolation: (a) cropping of the original TLM field of view, (b) division into fixed regions corresponding to individual embryos, and (c) resizing of each isolated embryo sequence to 250 × 250 pixels.

B. Preprocessing Pipeline

As a first step, each TLM video undergoes basic preprocessing to ensure consistency in frame dimensions, format, and temporal alignment. Using Python and the OpenCV (cv2) package, the videos are cropped to remove unnecessary white space at the top, ensuring that the focus remains on the embryos. For every video, this results in a consistent resolution of 1000x752 pixels and contains 12 embryo wells arranged in a fixed 3-row by 4-column grid. To isolate individual embryos for independent analysis, the video frame is uniformly divided along both axes—width divided by 4 and height divided by 3 resulting in a consistent crop size of 250×250 pixels per well. This standardized resolution ensures that each embryo is spatially separated, uniformly scaled, and appropriately formatted for subsequent deep learning-based object detection and OCR-based timing analysis. As a result of this preprocessing stage, the framework extracts 224 individual embryo videos from the original dataset, each corresponding to a single embryo well and standardized at a resolution of 250×250 pixels. For each video, video frames are extracted at 5 FPS, matching the dataset's native recording rate. This uniform sampling ensured consistent data representation across recordings, supporting reliable analysis and classification of embryos at varying developmental stages. Fig. 2 illustrates the preprocessing steps used for spatial isolation of individual embryos.

C. Data Annotation

Annotation was conducted using 100 TLM videos to provide spatial and temporal oversight of the model development. An experienced embryologist from King Abdulaziz University Hospital was involved to ensure the accuracy of the labeled data and provide the biological "ground truth" needed to effectively train the AI model. First, a frame-level annotation file was created for each embryo video, recording three attributes for every frame: the frame number, the hours post-insemination (hpi), and the cell stage. The dataset included frames from the following cell stages: two-, three-, four -, five -, six -, seven-, and eight-cells. Bounding boxes were manually drawn around each individual blastomere(cell) using the Roboflow platform. Roboflow's annotation tool offers an easy-to-use interface for effective annotation, to ensure consistency and high-quality labeling throughout the dataset [36], [37]. This discrete object detection strategy was adopted over global embryo localization to provide the model with the high-resolution morphological data required to differentiate between consecutive cleavage states (e.g., 2-cell vs. 3-cell). By identifying each cell as an independent instance, the proposed framework calculates the developmental stage through the aggregate count of detected bounding boxes per frame, ensuring that subtle internal boundaries are recognized as primary features for classification .

D. Data Augmentation and Class Distribution Balancing

The dataset comprises frames capturing various stage of cell development, such as the 2-, 3-, 4-, 5-, 6-, 7-, and 8-cell stages. With earlier stages (like 2-cell and 4-cell) being over- represented and later stages (like 6-cell, 7-cell, and 8-cell) being relatively underrepresented, in Fig. 3 a thorough distribution analysis shows a notable imbalance across the stages. The observed imbalance in the number of frames across cleavage stages—characterized by a higher proportion of frames in earlier stages and fewer in later stages—can be attributed to two main factors. The first is **short Later Stage Duration**: Compared to earlier stages, later stages—like 6-cell and 7-cell—occur over significantly shorter time intervals, resulting in fewer frames being recorded. The second factor is **cell Overlap in Advanced Stages**: Individual cells spatially overlap as cell division advances, making precise cell differentiation more difficult. Both data collection and annotation are made more difficult by this phenomenon. All images were scaled to a consistent resolution of 416 x 416 pixels to ensure consistency throughout the dataset. To guarantee sufficient representation of every cell stage for model development and assessment, the dataset is divided into 70% for training, 20% for validation, and 10% for testing. Some of the dataset's original images showed blurring and focus issues, which are common problems with (TLM) generated images. These flaws can occur as a result of lens focus errors or image noise, which, if not addressed, can have a negative impact on the model's performance. The dataset was artificially expanded while maintaining biological relevance through the use of images augmentation. The changes consist of:

1) Flipping both horizontally and vertically: To take into consideration variations in imaging angles.
2) Brightness Adjustment (±8%): To improve resilience to changes in lighting, exposure changes are simulated.
3) Random Gaussian Blur (sigma = 1 px): To improve generalization and simulate noise, making the model more tolerant to minor image flaws and obstacles experienced in TLM imaging.

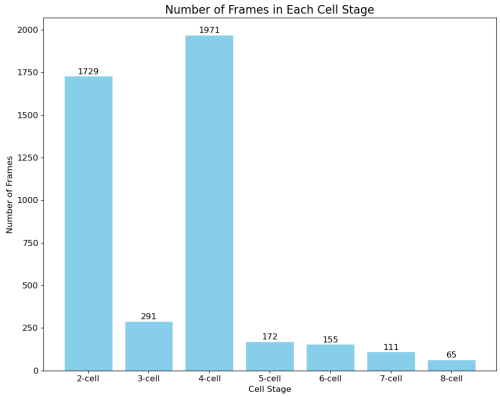

Fig. 3. Dataset distribution.

Undersampling was used to lessen the dominance of over-represented stages following augmentation. The goal was to maintain adequate representation for efficient training while achieving a more consistent distribution of 700 frames across all cell stages. Fig. 4 shows the distribution of the dataset for all cell stages after undersampling and augmentation.

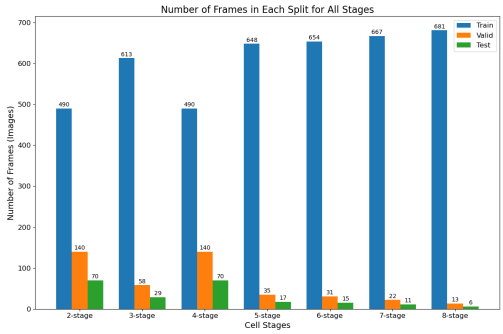

Fig. 4. Distribution of dataset frames for each cell stage: 70% for training, 20% for validation, and 10% for testing after handling class imbalance.

E. Cell Detection

Object Detection is one of the principal application areas in computer vision. The aim of object detection is to detect and localize objects in images through class labels and bounding boxes [38], [39]. There are two main types of detection methods: two-stage detectors like Faster R-CNN and Mask R-CNN that are guaranteed to produce an accurate answer, and one-stage detectors like YOLO and SSD that produce fast answers. There is a growing cadre of methods, including DETR and EfficientDet, that are focused on efficiency and scalability. Among these detection methods, YOLO is a prominent method for real-time detection. YOLO divides images into grids, predicting the bounding boxes and confidence scores for the object(s) contained in each of the grid cells. Using layers that are pre-trained among other bounding box layers, YOLO is able to produce good performance across a range of objects.

YOLOV11 is the most recent model in Ultralytics' YOLO series of real-time object detectors. it comes in a variety of model sizes, from nano to extra-large, making it suitable for a wide range of applications, from resource-limited edge devices to powerful computing systems. It adds new architectural features such as the C3k2 block, SPPF, and C2PSA, which improve its ability to extract and process features more efficiently. These enhancements enable YOLOv11 to better analyze and interpret complex visual data, potentially improving detection accuracy in a variety of scenarios. The integration of advanced spatial attention mechanisms, such as the C2PSA, is a significant improvement because it allows the model to focus on important regions of an image. YOLOV11 was selected for cell detection due to its ability to efficiently process large-scale time-lapse microscopy (TLM) datasets while maintaining reliable localization performance. Unlike two-stage object detectors, YOLO's single-stage architecture enables rapid frame-wise inference, which is essential for analyzing long TLM video sequences at high temporal resolution. Furthermore, the proposed framework uses YOLO exclusively for detecting individual cells rather than directly classifying cleavage stages. Developmental stages are subsequently inferred by counting detected cells across consecutive frames, thereby avoiding reliance on subtle morphological distinctions between stages and improving robustness under variable illumination and cell

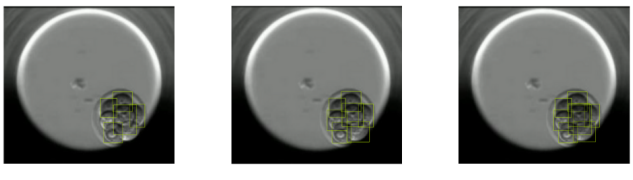

Fig. 5. Impact of IoU threshold on detection accuracy.

overlap conditions. Our proposed model operated as follows: Detection, Identifying and locating every instance of the "cell" class in the frame. Stage Assignment: The overall count of detected cells within a frame determines the cleavage stage label for that frame. For example, the existence of five unique cells signifies the 5-cell stage. The YOLOv11 model was set up on Ultralytics Hub [40]. To improve accuracy and shorten training time, a pre-trained model served as a foundation for the training process. The training procedure was set up with 100 epochs using 416×416 resized input images, a 100-epoch patience threshold to avoid overfitting. The batch size of 22 is determined by the AutoBatch mechanism, which automatically determines the maximum batch size that can be accommodated in the GPU memory during training to adjust to the available computational resources. The optimizer was configured with a momentum of 0.9 and a learning rate of 0.002. To train the YOLOv11 model efficiently, two NVIDIA T4 GPUs were used in a Kaggle environment.

YOLOv11 efficiently locates and categorizes overlapping objects, such as cells in our case, by employing anchor boxes to predict bounding boxes and their associated confidence scores in a single forward pass. During detection, many bounding boxes may be proposed for the same object. In order to overcome this, YOLO employs Non-Maximum Suppression (NMS), which selects the box with the highest confidence score after suppressing overlapping boxes based on their Intersection over Union (IoU) values. This ensures precise localization of individual cells, even when they significantly overlap, and sustains a high detection performance as indicated by measures like mean Average Precision (mAP). accuracy. Fig. 5 illustrates the impact of Intersection over Union (IoU) thresholds on detection accuracy. A higher IoU value (e.g., 0.70) facilitates more precise and reliable cell localization, whereas lower IoU values (e.g., 0.20 or 0.40) are associated with increased misdetections or overlapping prediction errors.

F. Cleavage Stage Identification and HPI Determination

Using a fixed confidence threshold of 0.55 across all cleavage stages, a YOLOv11 model is employed to detect individual cells within each frame. Additionally, an IoU threshold of 0.70 is applied by the model to provide precise bounding box predictions. The cell count is shown on the frame, and bounding boxes are drawn around any cells that are found. Only cleavage stages containing between 2 and 8 cells are considered in this analysis. A frame is saved to the output folder only when it corresponds to the initiation of a new cleavage stage, defined by the following criteria:

1) Uniqueness: if the number of detected cells is unique, meaning it hasn't been recorded before.
2) Progression: The current cell count is higher than the previous count that was noted.

Because of the inherent heterogeneity of embryo growth, certain division phases might not be captured in the video, necessitating this second requirement. For instance, the three-cell stage might not be apparent in the video, or some embryos might split straight from two to four cells without going through it. This criterion reduces the possibility of errors resulting from overlapping cells that could otherwise be misinterpreted for example, falsely recognizing three cells when only two are present by guaranteeing that only major stage transitions are recorded. Determining the corresponding hpi of the saved frames is the next step. Accurate hpi calculation is essential to monitor embryo development over time. OCR is a technology that transforms handwritten or printed text in images into digital formats that can be read by machines [41]. OCR is essential to biomedical research because it allows the extraction of quantitative data from medical images, including Medical Records [42], Ocular Biometry reports [43], text from figures in full-text biomedical articles [44], and experimental annotations. Numerous efficient Python libraries have been developed for OCR, including Tesseract, a popular open-source engine; Pytesseract [45], a Python wrapper for Tesseract; OpenCV, a flexible computer vision library; and EasyOCR [46], an open-source OCR tool based on deep learning. EasyOCR uses long short-term memory (LSTM) architectures and CNNs to detect and recognize text. PaddleOCR, deep learning-based OCR system created by the PaddlePaddle group. For high text detection and recognition accuracy, PaddleOCR utilizes CNNs, attention mechanisms, and sequence models like recurrent neural networks (RNNs) [47], [48]. Deep learning-based OCR tools were chosen for their robustness and ability to handle the complex imaging conditions common in biomedical TLM data, thus making sure that the annotations of hpi are accurately extracted.

The timestamp was extracted by cropping a fixed region of interest corresponding to the white rectangular overlay containing the hpi value, which appears at a consistent location across all time-lapse images. The cropping coordinates (x = 300, y = 350, width = 200, height = 200) were predefined and automatically applied to all frames, without manual intervention or sequence-specific adjustment, ensuring standardized OCR input across the dataset. To ensure the reliability of the extracted hpi values, a simple numerical validation step was applied to the OCR output. Since all embryos in the dataset fall within a biologically plausible range below 73 hours post-insemination, any extracted value exceeding 73 hpi was treated as an OCR artifact caused by an erroneous leading digit and was automatically corrected by removing the leading digit, restoring the expected temporal range. This lightweight validation step effectively filtered OCR misreads while preserving correct timestamps for downstream cleavage timing analysis. Due to variability in image brightness or quality, OCR is not always flawless and sometimes misreads numbers. Three OCR libraries—PyTesseract, EasyOCR, and PaddleOCR—were tested for performance. The hpi value is allocated to the frame if OCR is successful in extracting it. When OCR is unable to retrieve the timestamp. Several reasons can lead to OCR failures:

- creation of out-of-bound values, where valid times-

tamps (e.g., 69.9 h) are misinterpreted as wrong values like '4569,' which exceeds the system's maximum allowed hpi range (mice embryo typically reaches the 8-cell stage around 48 to 72 hpi).

- misrecognition of digits, where the algorithm finds or interprets numbers improperly.

An alternate approach has to be used. In these situations, our dataset of TLM videos' empirical observations of cleavage timing serve as the basis for this alternate approach. After examining several embryos, it was observed that the cleavage stages occurred at a comparatively constant interval of about 0.6 hpi each frame. Previous studies have employed a similar approach, in which, in the absence of precise hpi values, the time annotations for cleavage stages were obtained using frame rate and time-lapse system setups [17].

$$t_n = t_1 + 0.6 \times (F_n - 1)$$

where:

- t_1 – The hpi of the first frame.
- F_n – The frame number for which the time is being calculate.
- 0.6 – The frame interval.

IV. Results

This section presents the results of the proposed methodology on two major tasks: cell-cleavage stage detection and OCR evaluation that used for cleavage onset time prediction. For clarity, the findings are divided into two corresponding subsections.

A. Cell Stage Detection

This section presents a detailed evaluation of the YOLOv11 model in detecting embryo cell stages (two to eight cells), using a test set of 218 images sized (416x416 pixels). The YOLOv11 model achieved strong performance, with a precision of 0.9793, a recall of 0.9565, and an F1-score of 0.9678. The mAP@0.5 (mean Average Precision at an IoU threshold of 0.5) was 0.9767. This shows that our model successfully identified and localized most cells, achieving a strong alignment between the predicted and ground-truth bounding boxes. while mAP@0.5:0.95, which evaluates precision across various IoU thresholds from 0.5 to 0.95 in increments of 0.05, was measured at 0.74. was 0.7407. Fig. 6 shows the overall precision and recall, as well as the mean Average Precision (mAP) at thresholds 50 (mAP50) and 50-95 (mAP50-95), for the validation set throughout training epochs. Fig. 7 shows the confusion matrix for the model in detecting and classifying cell stages generally. For the majority of cell stages, the matrix shows high classification accuracy; this is especially true for the 2-cell and 4-cell stages, when most predictions match the actual labels. Compared to the earlier cleavage stages in the matrix, there were more incorrect classifications between the seven-cell stage and the nearby phases of five, six, and eight cells.

A set of key metrics was used to evaluate the model's performance: accuracy, precision, recall, F1-score, and specificity.

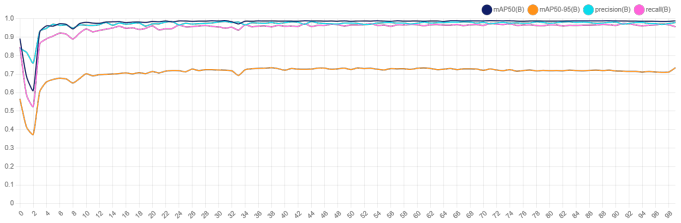

Fig. 6. Validation metrics over epochs.

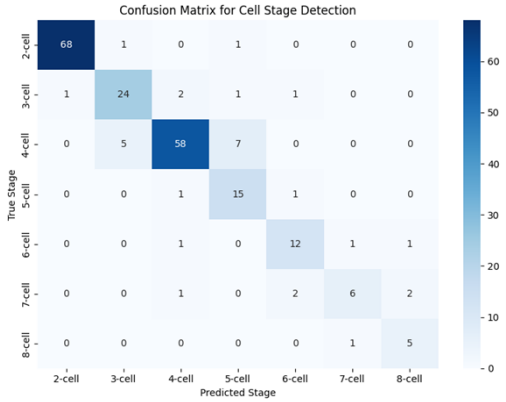

Fig. 7. Confusion matrix for automated cell stage detection. Rows: true stages (embryologist annotations); Columns: predicted stages (model output).

TABLE I. Evaluation Metrics for Every Cell Stage

Category	Precision	Recall	F1-Score	Specificity	Accuracy
2-cell	98.55%	97.14%	97.84%	99.32%	98.53%
3-cell	80%	82.76%	81.35%	96.83%	94.86%
4-cell	92.06%	82.86%	87.25%	96.62%	92.02%
5-cell	62.50%	88.24%	73.17%	95.52%	94.86%
6-cell	75%	80%	77.42%	98.03%	96.97%
7-cell	75%	54.55%	63.27%	99.04%	96.88%
8-cell	62.50%	83.33%	71.43%	98.60%	98.26%
Overall	**86.24%**	**86.24%**	**86.24%**	**97.71%**	**86.61%**

These metrics offer a thorough grasp of the model's capacity to accurately identify and categorize every cell stage based on the number of detected cells in the frame. Precision measures the percentage of all predicted cell stages correctly identified as instances of the target cell stage. Recall (also known as sensitivity) measures the ratio of true positives (correctly detected instances of the target stage) to the sum of true positives and false negatives (i.e., all frames that truly belong to that stage). The precision and recall weighted average is known as the F1-score. Specificity is calculated as the ratio of true negatives (i.e., frames that are correctly identified as not belonging to the target stage) to the total number of frames that truly do not represent that stage. It demonstrated the ability of the model to prevent misclassifications for non-target stages. The accuracy reflects the overall effectiveness of the model by measuring the proportion of correctly classified instances (both positives and negatives) out of all predictions made. Table I summarizes these metrics for each cell stage using input images of size (416x416 pixels).

Although the table presents the raw quantitative results,

the subsequent list presents a brief overview of the model's performance at each stage, emphasizing both its advantages and limitations:

- Two-cell stage: The model demonstrated strong efficacy in this category by classifying 2-cell stages with high precision 98.55%, recall 97.14% , and F1-score 97.84%. These results indicate robust and consistent detection of two-cell instances with a low misclassification rate.
- Three-cell and four-cell stages: With F1-scores of 81.35% and 87.25% , respectively, both stages demonstrated high performance, although with somewhat reduced precision and recall when compared to the 2-cell stage.
- Five-cell and Six-cell stages: The model's performance showed moderate accuracy. For the 5-cell stage, the F1-score of 73.17% reflects low precision 62.50% and high recall 88.24%, indicating frequent false positives despite successfully identifying most true cases. In contrast, the 6-cell stage achieved a more balanced outcome (F1-score 77.42%; precision 75%; recall 80%), suggesting that most instances were correctly classified with a moderate level of misclassification.
- seven-cell and eight-cell stages: The model struggled most with the 7-cell stage, hitting an F1-score of just 63% and recall at 55%. This happened mostly because there weren't many examples in the dataset, and the cells tended to overlap a lot, which led to confusion with the 6- or 8-cell stages. On the other hand, the 8-cell stage did better, landing an F1-score of 71% The recall was strong 83% so the model caught most of the real 8-cell stages. But the precision dropped to 63%, which means it also flagged quite a few that weren't actually 8-cell, so false positives were still a problem.
- Overall Performance: With an overall F1-score of 86.24% and specificity of 0.9771, demonstrating a strong ability to distinguish between target and non-target classes and consistent classification performance across all cell stages.

B. OCR Evaluation

Three OCR libraries were assessed to determine their performance in extracting HPI timestamps: PyTesseract, EasyOCR, and PaddleOCR. The objective text was a time stamp in the format xx.x h, placed in a small white rectangle with black numbers in the bottom right corner of each frame. Due to the large variation in contrast between the images in the dataset, no pre-processing was applied, rendering the generic enhancement techniques unreliable. Instead, each frame was cropped to the region of interest to isolate the timestamp and minimize noise. The performance of PyTesseract, EasyOCR, and PaddleOCR was evaluated using Manual Recognition Accuracy. To establish a ground truth, To perform this, a dataset of frames was randomly selected, and the timestamps visible in the images were manually annotated as ground truth. The output of each OCR engine was manually compared against the visual timestamp visible in the Time-Lapse Monitoring (TLM) images. An "Exact Match" criterion was utilized, where a detection was marked as correct only if it perfectly mirrored the visual data. The following list summarizes the OCR libraries' performance, highlighting the progression from less to more effective approaches depending on digit recognition under varying image conditions in terms of accuracy, dependability, and robustness.

- PyTesseract: Initially, PyTesseract was tested with various configurations but showed unsatisfactory results. The library had difficulties in accurately reading digits, either misreading them or failing to extract them at all. For example, "13.7" was incorrectly read as "3.7".
- EasyOCR: Next, EasyOCR was subsequently evaluated and demonstrated improved performance compared to PyTesseract.However, the library continued to have challenges in accurately recognizing some numbers. In particular, the library failed to read the tens place in some cases, such as reading "31.5" as "1.5", or completely ignoring the tens place and reading "1.5" as "5".
- PaddleOCR: PaddleOCR was evaluated last and demonstrated the highest accuracy. All values extracted by Paddle were accurately matched to the annotations provided by embryologists. Due to this consistent and reliable performance, Paddle was adopted as the preferred tool in our methodology for automating the hpi annotation process.

Table II summarizes the performance of the three OCR libraries in extracting hpi values, compared to the expert-annotated ground truth.

TABLE II. COMPARISON OF EXPERT-ANNOTATED HPI VALUES WITH PREDICTIONS FROM THREE OCR TOOLS

Expert (hpi)	PaddleOCR	EasyOCR	PyTesseract	Error Description
1.5	1.5	5	–	Misread digit (EasyOCR) ,Missing value (PyTesseract)
35.1	35.1	35.4	–	Misread digit (EasyOCR) ,Missing value (PyTesseract)
46.5	46.5	646.5	–	Extra digits (EasyOCR) ,Missing value (PyTesseract)

V. DISCUSSION

This study aimed to automate the process of tracking embryonic development by identifying cleavage stages and accurately determining the onset times of cell division. Deep learning and image processing techniques were used to analyze TLM videos. This was achieved by constructing an efficient methodology that annotates hpi of each cleavage stage while accurately locating cells within the corresponding stage images. This study showcases the power of deep learning and computer vision in automating the identification of crucial cleavage stages in embryo development. By providing precise, frame-by-frame predictions and organized data on cleavage timing, the proposed approach gives embryologists valuable developmental insights that exceed those gained from traditional manual observation. This level of accuracy in stage detection allows for more objective and consistent evaluations of embryos. Our methodology demonstrated the ability to accurately identify the onset of cell division stages up to the seven-cell stage, with an average time delay of 1–2 hpi. However, at the eight-cell stage, a significant time delay was observed compared to the embryologists' annotations. This disparity is explained by the more significant overlap between cell borders, which intensifies with increasing cell count. This

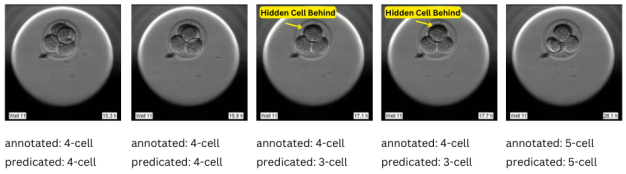

Fig. 8. Time-series of frames illustrating cell occlusion: A 4-cell stage can be seen in the first frame, but as the series goes on, one cell trails behind another, giving the impression that the stage contains only three cells. This illustrates how difficult it is to find overlapping cells.

overlap between cells was also observed in [14,17], and the inferiority of their methodology caused a delay of 2-3 hours in detecting the starting time of cell cleavage. The occurrence of overlapping cells and visual obstructions in certain frames, particularly during the later stages (after the six-cell stage), led to a decrease in detection accuracy. This was especially evident in the counting and differentiation of closely packed cells. This illustrates a challenge with the dataset, which contains overlaps that occur naturally in the later stages of cleavage. Adding a wider variety of overlapping cell configurations to the dataset could help overcome this restriction. Future enhancements, such as the integration of temporal context or refined segmentation techniques, could significantly bolster performance in these challenging scenarios. Our proposed methodology also faces challenges in detecting hidden cells: cells with dark shadows or those that are partially hidden behind other cells are not recognized. This problem is particularly important in the transition state between one stage and another, as shown in Fig. 8. More occluded cell samples should be included in the dataset in future studies so that the model can better learn and generalize these patterns.

The proposed model operated directly on raw TLM frames to ensure that the training data closely matched real-world scenarios. This design choice aims to enhance the robustness and generalizability of the method by avoiding transformations that may alter biologically relevant visual cues. Given the heterogeneous illumination conditions present in the TLM dataset, applying global image normalization or contrast enhancement could introduce inconsistencies across samples and potentially distort meaningful morphological information. As part of our research, the time differences between subsequent cleavage stages were calculated. This feature helps to improve the assessment of embryo quality by giving embryologists comprehensive data on developmental dynamics. Two complementary techniques were combined to address the dataset's class imbalance issue. Selective data augmentation was applied to increase the number of samples in minority classes. Then, random undersampling is used to decrease the number of samples in the majority classes. This combined strategy yielded satisfactory evaluation metrics, demonstrating its effectiveness in addressing class disparity. In order to put the performance of the proposed YOLOv1-based cell stage detection model into perspective, the obtained results are compared with those of earlier studies that used YOLOv5 for the detection of human embryo cell stage. Applying data augmentation techniques [17], the model performed well on early cleavage stages (e.g., F1-score of 95% for 1-cell and 88% for 2-cell), but performance significantly declined on later stages, with F1-scores falling to 0.32 for 3-cell, 0.36 for 5-cell, and 17% for 6-cell. Our method, on the other hand, produced consistently high overall F1-scores of 0.8624 and accuracy of 86.61% when applied to mouse embryo time-lapse videos. The F1-scores were relatively stable across stages, ranging from a minimum of 63.27% (7-cell) to a maximum of 97.84% (2-cell). Higher specificity (97.71% overall) and a better balance between sensitivity and precision at every stage further supported this performance. The superiority of the proposed framework is quantitatively validated through a comparative analysis with the recent study by Sharma et al. [17], as detailed in Table III. Furthermore, our approach corrects for class imbalance by undersampling and targeted data augmentation, which probably helped to improve minority-stage class detection. The framework demonstrates high adaptability to diverse clinical environments through a calibratable OCR pipeline. By utilizing coordinate-based ROI localization. The system can be seamlessly adjusted to different incubator display formats. Direct quantitative comparison with prior time-lapse embryo analysis studies is constrained by the absence of publicly available, standardized datasets and by differences in embryo species, imaging systems, and annotation protocols. This limitation is explicitly acknowledged in the present study. Accordingly, performance claims are restricted to improvements observed within the same experimental setting and under a consistent evaluation protocol. Where comparisons with related work are discussed, they are intended to illustrate relative gains in robustness and detection capability—particularly at later cleavage stages—rather than to assert absolute superiority across heterogeneous datasets. The comparative analysis highlights the generalizability and robustness of our deep learning pipeline, especially in managing class imbalance and handling transitional stages with greater stability, despite the differences in the dataset.

TABLE III. PERFORMANCE BENCHMARKING AND COMPARATIVE ANALYSIS: PROPOSED YOLOV11 FRAMEWORK VS. STATE-OF-THE-ART BASELINE OF SHARMA ET AL.[17] (YOLOV5)

Cell Stage	Sharma et al.[17] - yolov5 Accuracy (%)	Proposed Model Accuracy (%)
2-cell	85%	98%
3-cell	57%	94%
4-cell	55%	92%
5-cell	51%	94%
6-cell	39%	96%
7-cell	31%	96%
8-cell	47%	98%

VI. CONCLUSION

Given that the timing of cell cleavage is a critical parameter of embryo viability and developmental potential, it certainly plays a major role in embryo assessment. Detecting and extracting the onset of these cleavage events automatically can help embryologists Assess the quality of embryos and select candidates with better chances of implantation. In this work, YOLOv11 and OCR-based timing extraction are used to automatically annotate mouse embryos' cleavage stage and onset time. The suggested approach, despite the challenging class imbalance present in the dataset, achieves high performance in cleavage stage detection and cleavage onset timing extraction. Through the combination of selective data augmentation and random undersampling. The problem of class imbalance was

successfully addressed, which enhanced the model's robustness and evaluation metrics. Our methodology demonstrated the ability to accurately identify the onset of cell division stages up to the seven-cell stage, with an average time delay of 1–2 hpi, and showed excellent performance in differentiating between various developmental phases in mouse embryo TLM videos, achieving Accuracy of 86.61% , F1-score of 86.24% ,and precision of 86.24% in identifying and classifying cleavage stages. One of the key difficulties encountered in this work is the significant cell overlap, which affected the model's performance, particularly at the later stages of cleavage. As it influenced the accuracy of detection and caused minimal delays in determining the onset of division. In addition, the approach was having issues identifying cells that were occluded partially or overshadowed, particularly with fast changes in developmental phases. There are several promising avenues for future research in this field to overcome the present limitations. Accumulating larger and well-annotated TLM datasets is a crucial step to increase model robustness and promote more balanced learning across all cleavage stages. Future work could utilize 3D imaging techniques or incorporate temporal context using video-based models that analyze frame sequences rather than individual frames to address issues such as partially hidden and overlapping cells.

Data Availability

While the dataset is not publicly available due to clinical privacy and institutional ethical constraints, it can be shared upon reasonable request to support reproducibility, subject to applicable data governance protocols.

Medical Education Department, King Abdulaziz University, Jeddah, Saudi Arabia[4]

***Abstract*—Lesson planning in cybersecurity is time-consuming and cognitively demanding, especially for less experienced instructors, and manual approaches often lack flexibility across courses and contexts. We present a framework for generating pedagogy-aligned lesson plans using a large language model, integrating measurable objectives (Revised Bloom's Taxonomy), explicit learning theories, and evidence-based teaching strategies. We constructed a domain-specific knowledge base for cybersecurity topics and organized it with sentence-level embeddings and KMeans clustering. A pretrained large language model (GPT-3.5) was then fine-tuned to produce lesson plans that follow this structure. On a held-out test set, the model achieved BLEU 73.5, ROUGE-1 82.2, ROUGE-L 78.2, and BERTScore F1 97.4, reflecting strong lexical and semantic fidelity to reference plans. Although the study is limited to a single academic program and relies primarily on automated metrics, the framework offers practical support for instructors by reducing preparation time, enhancing consistency, and ensuring alignment with pedagogical standards. Future work will expand the curricular scope and involve expert review and classroom validation to assess educational impact.**

***Keywords*—Fine-Tuning; large language models; lesson planning; cybersecurity**

I. Introduction

Lesson plans are essential instruments in education, providing teachers with a clear framework for delivering effective and organized instruction [1]. They outline learning objectives, teaching methods, classroom activities, instructional materials, and assessment strategies required to achieve educational goals [2], [3]. By establishing a structured approach, lesson plans enhance teaching effectiveness and ensure instructional consistency and clarity [3], [4]. Although their components may vary depending on curriculum, educational context, or teacher preference, the primary purpose of lesson plans remains the improvement of instructional quality and student outcomes [5], [1]. Aligning lesson plans with established learning theories, such as constructivism, cognitivism, and constructionism, further strengthens their effectiveness by grounding instruction in well-established principles of how learners acquire, process, and apply knowledge [6], [7]. In addition, the integration of contemporary teaching strategies, including project-based learning, problem-based learning, and flipped classrooms, promotes active engagement, collaboration, and deeper understanding [8], [9].

Within this broader educational context, cybersecurity presents distinctive challenges. As a discipline, it is concerned with safeguarding the confidentiality, integrity, and availability of digital systems [10]. Given its rapidly evolving nature, cybersecurity education must combine strong theoretical foundations with practical, hands-on learning experiences [7], [11]. Effective lesson plans in this domain must balance theory with application, incorporate up-to-date content, and prepare learners to respond to emerging threats [12]. However, lesson planning is often time-intensive and cognitively demanding, particularly for novice teachers with limited pedagogical experience [3], [5]. Traditional lesson planning methods, which rely heavily on manual preparation, can be inefficient and may lack the flexibility to meet diverse instructional needs [2].

Recent advances in large language models (LLMs) such as BERT [13], GPT-3/4 [14], [15], and LLaMA [16] have enabled high-quality, controllable text generation for educational applications [17]. Although pre-training on extensive text corpora provides broad language competence [18], [19], these models often show limited effectiveness in specialized domains. Fine-tuning addresses this limitation by adapting pre-trained models to domain-specific tasks, thereby improving contextual accuracy and alignment with specialized requirements [20], [21]. Such approaches have already been applied in areas such as legal rule classification [22], transportation safety [23], and language-specific text summarization [24].

The effectiveness of fine-tuned models is typically assessed using automatic evaluation metrics that capture different aspects of text quality. In this study, such metrics are employed to assess lexical overlap, structural similarity, and semantic alignment between generated and reference lesson plans, providing a reproducible basis for evaluating instructional content.

Despite recent progress, existing studies have not fully explored the use of fine-tuned large language models for generating structured lesson plans in technically specialized domains such as cybersecurity. This gap is particularly relevant given the growing demand for scalable, pedagogy-aligned, and domain-specific instructional resources. Rather than relying solely on prompt engineering or post-generation filtering, the present study adapts a pre-trained language model to generate cybersecurity lesson plans by embedding pedagogical structure within the data representation and model fine-tuning process. Accordingly, the study addresses the following research questions:

- RQ1. How accurately can a fine-tuned large language model generate structured lesson plans for cybersecurity education?
- RQ2. To what extent do the generated lesson plans align with established pedagogical standards and instructional design principles?

The contributions of this research are as follows:

1) This work designs and constructs a domain-specific lesson planning dataset for cybersecurity to support pedagogy-aware language model fine-tuning.
2) It proposes a structured framework that incorporates explicit pedagogical elements into the fine-tuning process of a large language model for lesson plan generation.
3) It provides an empirical evaluation demonstrating that pedagogy-aligned fine-tuning enables the generation of structurally consistent and instructionally valid lesson plans.

The remainder of this paper is organized as follows: Section II reviews related work, Section III describes the methodology, Section IV presents the results and discussion, and Section V concludes the paper.

II. Related Work

The rapid progress of large language models has generated significant interest in their role within teaching and learning. Recent surveys highlight both their potential to transform instructional practices and the challenges they introduce in terms of reliability, bias, and alignment with educational objectives [17], [20]. Kasneci et al. [17] emphasize the ability of these models to reduce teacher workload and broaden access to instructional resources, while also noting the importance of producing outputs that educators can trust and adapt. Similarly, Zhang et al. [20] report that instruction-tuned models show promising capabilities but remain highly sensitive to the design of adaptation strategies and evaluation protocols. Together, these studies provide valuable context for educational use of LLMs, while also indicating that effective deployment depends on careful consideration of pedagogical alignment rather than generic application alone.

Recent work has explored how large language models can support assessment and instructional content generation. Sridhar et al. [25] investigated the use of GPT-4 to generate learning objectives, demonstrating that model outputs can follow established instructional design frameworks such as Bloom's taxonomy when guided by structured prompts. Similarly, Scaria et al. [26] examined automated question generation across Bloom's taxonomy levels and validated the quality of exam-style questions through expert review. Latif and Zhai [27] applied a fine-tuned ChatGPT model to automated scoring, reporting performance comparable to human graders on large collections of student responses. Collectively, these studies highlight the effectiveness of LLMs in generating and evaluating individual instructional components. At the same time, they primarily focus on isolated elements such as objectives, questions, or assessment outcomes, and therefore provide limited insight into how these components can be coherently integrated into complete, pedagogy-aligned lesson plans.

Evaluating the quality of generated content requires reliable and reproducible measures, leading to the widespread adoption of automatic evaluation metrics in natural language processing. BLEU [28] remains a common standard for measuring precision-oriented n-gram overlap, while ROUGE [29] is frequently employed to capture recall-oriented coverage in summarization. More recently, BERTScore [30] has been introduced to provide a semantic perspective by comparing contextual embeddings, offering closer alignment with human judgments of similarity. Together, these metrics provide complementary views of lexical fidelity, content coverage, and semantic similarity, and their primary strength lies in enabling consistent and scalable evaluation of generated text. However, they implicitly assume that textual similarity is a sufficient proxy for instructional quality, which limits their ability to fully capture pedagogical effectiveness when used in isolation.

Beyond assessment and evaluation, prior research has examined lesson planning systems as a means of providing more direct support for teachers. Zheng et al. [1] proposed an automatic lesson plan generator that improves plan quality through iterative self-critique, while Hu et al. [2] evaluated GPT-4 generated teaching plans and reported benefits such as efficiency and creativity alongside limitations related to inconsistency and insufficient pedagogical grounding. Fan et al. [3] introduced *LessonPlanner*, an interactive system designed to help novice teachers structure lesson components more effectively. Earlier systems, including Strickroth's *Platon* [5] and retrieval-augmented planning approaches explored by Kloker et al. [31], further demonstrate the feasibility of digital tools for lesson organization. Collectively, these approaches highlight the potential of automated and interactive systems to support lesson planning; however, they are largely designed for general instructional contexts and provide limited support for domain-specific requirements, such as those found in cybersecurity education.

A growing body of research has examined model adaptation through fine-tuning as a means of producing more consistent and domain-sensitive outputs. Within educational contexts, Tsai et al. [32] fine-tuned BERT and GPT-2 for short-answer question generation and reported improvements in quality and diversity over template-based approaches. Jia et al. [33] embedded Gagné's nine events of instruction into a fine-tuned model to generate lesson plans grounded in established pedagogical theory, while Gharbi et al. [34] demonstrated the potential of fine-tuned models to support personalized learning at scale in MOOCs. Beyond education, fine-tuning has been successfully applied to legal rule classification [22], transportation safety [23], and domain-specific summarization [24], highlighting its versatility across application areas. While these studies confirm the effectiveness of fine-tuning for improving domain alignment, they largely address either isolated instructional tasks or general learning contexts, leaving limited exploration of fine-tuned systems that generate fully structured lesson plans for specialized domains such as cybersecurity, where alignment between theoretical concepts and practical application is essential.

III. Methodology

The study employed a four-phase methodology integrating pedagogical theory with computational modeling. The methodology was designed to incorporate pedagogical alignment through both dataset construction and model fine-tuning, ensuring that instructional structure and pedagogical constraints are embedded in the generation process rather than applied during subsequent evaluation. Phase 1 identified relevant learning theories and teaching strategies through a literature review

and expert validation. Phase 2 constructed the knowledge base through schema design, sample generation, and expert evaluation. Phase 3 refined the model through dataset clustering, balancing, and fine-tuning. Finally, Phase 4 evaluated model performance using established automatic metrics. The overall process is illustrated in Fig. 1.

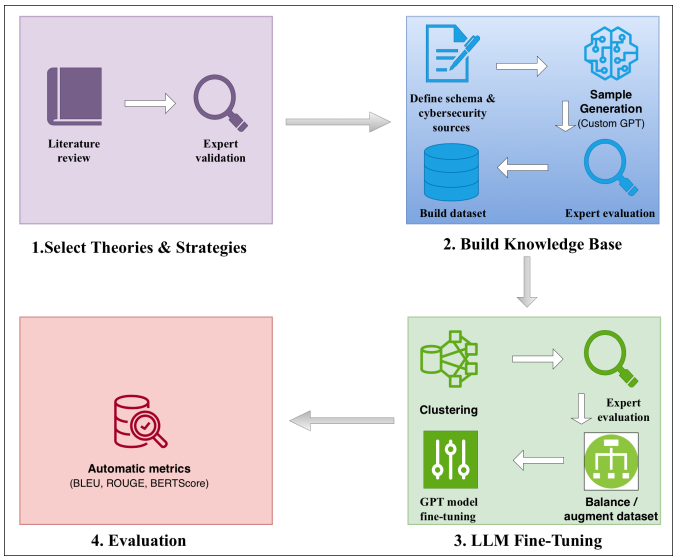

Fig. 1. Four-phase methodology pipeline.

A. Selection of Learning Theories and Teaching Strategies

This phase guided the design of lesson plans by identifying pedagogical foundations most relevant to cybersecurity education. A targeted review of pedagogical literature was conducted, complemented by consultations with an instructional design specialist. This process ensured that the selected learning theories and teaching strategies were both theoretically grounded and practically applicable to the demands of cybersecurity instruction, where adaptability and professional relevance are critical [7].

A range of learning theories were considered in shaping the instructional approach, with the following perspectives identified as particularly relevant.

Differential theories of learning transfer highlight that knowledge can only be successfully applied across contexts under specific conditions, such as having sufficient prior knowledge, possessing cognitive flexibility, and learning in environments similar to those of application [7]. Constructionist theories of learning emphasize creating tangible outcomes to build knowledge, promote creativity, encourage hands-on experimentation, and support iterative problem-solving [7]. The general cognitive science perspective emphasizes meta-cognitive control, analogical reasoning, and structured problem-solving as fundamental processes in learning; it supports instructional strategies that guide learners from basic comprehension to expert application through reflection and goal-oriented practice [7].

Cognitive-associationist theories focus on strengthening mental links between declarative, procedural, and conditional knowledge, with learning taking place incrementally through sequenced tasks that develop complex competencies [7]. Similarly, Cognitive-Constructivist theory emphasizes that learners actively build mental models through problem-solving, exploration, and reflection, integrating new knowledge with existing experience to produce higher-level cognitive schemas [7]. Coordinative transfer theory seeks to reduce negative transfer by improving learners' ability to determine when and how to apply existing knowledge [7].

More broadly, cognitive learning theories view learning as an active process of acquiring, organizing, and integrating knowledge, with a focus on internal mechanisms such as attention, memory encoding, and schema activation [35]. Experiential learning theory defines learning as a cyclical process involving concrete experience, reflective observation, abstract conceptualization, and active exploration [35]. Transformative learning theory emphasizes the importance of learners critically analyzing their preexisting assumptions and ideas in response to disorienting situations; through introspection and discussion, learners reframe their perspectives and develop more expansive and informed worldviews [35]. Finally, social learning theory affirms that people acquire skills and behaviors through social interaction, modeling, and observation, encompassing cooperation, peer review, and role modeling in education [35].

Building on these theories, a variety of teaching strategies were selected to translate abstract principles into practical methods that effectively support cybersecurity education, such as Problem-Based Learning (PBL), in which students collaborate to explore complex, real-world issues without predetermined answers. In this approach, teachers serve as facilitators, guiding students as they investigate, evaluate, and overcome obstacles [11], [9]. Similarly, Project-Based Learning (PrBL) involves students in long-term projects that apply cybersecurity concepts to real-world challenges. This strategy requires learners to create a tangible product or solution and promotes sustained engagement, teamwork, and iterative problem-solving [9].

Another approach is the use of practical exercises, which immerse students in real-world cybersecurity scenarios. Conducted in controlled physical or virtual environments, these sessions enable learners to develop technical competence, apply theoretical knowledge, and gain experience with industry-standard tools and protocols [36]. The Flipped Classroom model further complements this by requiring students to study core materials (e.g., videos, texts, or mini-lectures) before class, allowing in-class time to be dedicated to higher-order activities such as collaborative analysis, simulations, and practical problem-solving under instructor guidance. This method promotes self-paced study outside of class and deeper participation during class [9], [4].

Case-Based Learning extends this applied approach by using real-world cybersecurity cases to engage students in analyzing complex problems, comparing approaches, and proposing well-justified solutions. It encourages critical thinking and helps learners apply academic knowledge to practice [9]. Lecture-Based Learning also remains valuable for presenting fundamental cybersecurity concepts, where instructors can arrange content, provide expert framing, and establish conceptual baselines. When enriched with examples, questions,

and discussions, lectures can enhance engagement and comprehension, though they are most effective when combined with active learning techniques [9], [37].

To further enhance engagement, Role-Playing activities assign learners specific roles, immersing them in authentic cybersecurity scenarios. This approach improves empathy, decision-making, and communication, making it especially beneficial for developing soft skills and ethical reasoning in collaborative, high-pressure environments [38]. Finally, Simulation activities replicate real-world cybersecurity operations in secure, controlled environments, enabling students to practice technical skills, incident response, and decision-making under pressure [39].

Together, these learning theories and teaching strategies provide a solid foundation for designing cybersecurity instruction that is both grounded in established principles and responsive to real-world practice.

B. Build Knowledge Base

To fine-tune a large language model for generating cybersecurity lesson plans, a standardized structure was developed based on instructional design concepts. Each plan included five components: course title, topic, learning objectives (based on Revised Bloom's Taxonomy [40]), learning theory, and teaching strategy. Theories and strategies were taken from the previously presented curated lists, ensuring that they related to known educational frameworks. Because no existing dataset combined these features with cybersecurity content, a customized knowledge base was created using courses from the Diploma in Cybersecurity program at King Abdulaziz University (KAU), thereby ensuring both disciplinary relevance and educational validity.

1) Custom GPT for Knowledge Base Generation: To construct a pedagogically grounded knowledge base, OpenAI's Custom GPT was configured as a dedicated instance of ChatGPT. Custom GPT leverages prompt engineering and metadata settings to control tone, structure, and output format [41]. Within this setup, the model was instructed to generate structured instructional entries that could later serve as training data for fine-tuning a larger model specialized in lesson plan creation. For each course title and topic, the system consistently generated three elements: learning objectives, a learning theory, and a teaching strategy all defined according to established instructional design parameters. In particular, the Custom GPT created three measurable objectives for each topic based on Revised Bloom's Taxonomy [40]. Best practices for 60-90 minute sessions were followed to maintain focus and manage cognitive load [42].

2) Sample Generation and Expert Evaluation: To evaluate the instructional quality of the Custom GPT, a pilot dataset was created using one course from the cybersecurity diploma program. The course included nine topics, and for each, the model generated a structured lesson plan with three components: measurable learning objectives, an aligned learning theory, and a related teaching strategy. Eight professionals evaluated this dataset, including three curriculum and pedagogy specialists and five classroom-experienced cybersecurity instructors.

Each group received a tailored evaluation form with shared core criteria and role-specific emphasis. This ensured that the lesson plans were assessed for both educational quality and practical application. Educational experts examined eight criteria, including the clarity, measurability, alignment, and cognitive complexity of objectives; the appropriateness of the selected learning theory; the suitability of the teaching strategy; and the overall coherence of the topic, objectives, theory, and method. Cybersecurity instructors employed the same criteria, excluding the theoretical dimension.

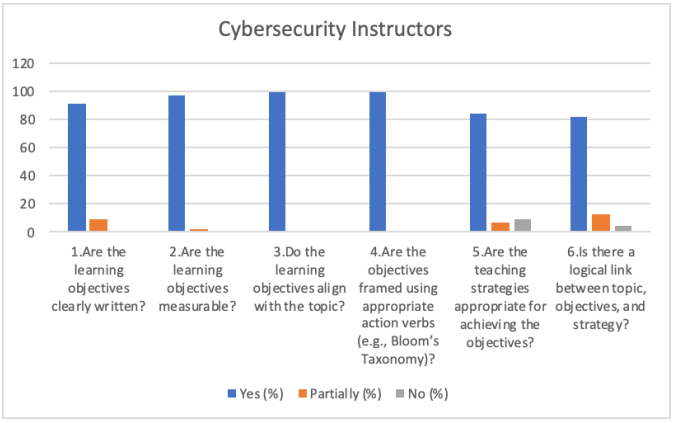

Fig. 2. Evaluation results from cybersecurity instructors across nine topics: percentage distribution of yes, partially, and no responses for six criteria.

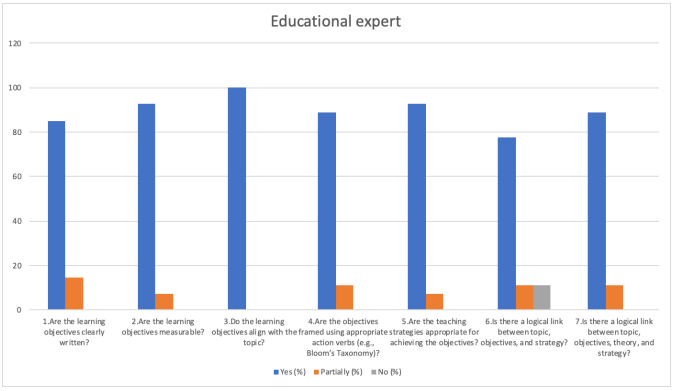

Fig. 3. Evaluation results from educational experts across nine topics: percentage distribution of yes, partially, and no responses for seven criteria.

Cybersecurity instructors reported high agreement on all rating criteria. Learning objectives were almost consistently rated as clear, measurable, well-aligned with the topic, and correctly framed with Bloom's verbs. Teaching strategies (84.4%) and the logical relationship between components (82.2%) also received strong ratings, indicating instructional coherence (see Fig. 2).

Educational experts similarly reported strong agreement across all criteria. Learning objectives were rated as clear (85.2%), measurable (92.6%), well-aligned with the topic (100%), and appropriately framed using Bloom's action verbs (88.9%). Teaching strategies (92.6%) and the logical relationship between topic, objectives, and strategy (77.8%) also scored highly, with the extended link to theory rated at 88.9%. These results highlight the instructional validity of the framework (see Fig. 3).

TABLE I. ELBOW METHOD AND SILHOUETTE SCORES FOR TF-IDF-BASED CLUSTERING

k	SSE	Silhouette Score
2	113.46	0.0123
3	111.95	0.0104
4	109.82	0.0126
5	108.32	0.0137
6	106.07	0.0193
7	104.25	0.0180
8	103.06	0.0179
9	101.17	0.0220
10	99.63	0.0241

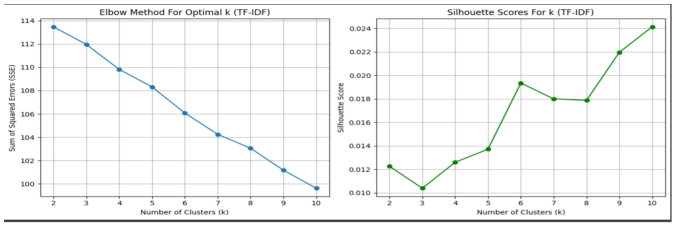

Fig. 4. Evaluation of TF-IDF clustering using the elbow method and silhouette scores.

TABLE II. NUMBER OF TOPICS BEFORE AND AFTER BALANCING USING TF-IDF-BASED CLUSTERING

Cluster	Original Samples	After Balancing
0	8	65
1	23	65
2	16	65
3	65	65[a]
4	7	65
Total Rows	119	325

[a] Unchanged during balancing.

TABLE III. ELBOW METHOD AND SILHOUETTE SCORES FOR SBERT-BASED CLUSTERING

k	SSE	Silhouette Score
2	42742.39	0.0635
3	40998.04	0.0470
4	39532.42	0.0599
5	38017.05	0.0649
6	36452.24	0.0651
7	35318.29	0.0726
8	35471.88	0.0617
9	34536.95	0.0649
10	33433.46	0.0646

After expert evaluation of the pilot course, the dataset was extended to cover the full diploma program, resulting in 119 structured entries across 14 courses. Topics were drawn directly from the official curriculum, while Custom GPT generated the corresponding objectives, theories, and strategies using the validated schema. The additional entries were generated automatically and were not subjected to further expert evaluation.

C. LLM Fine-Tuning

1) Dataset Preparation: To prepare the dataset for supervised fine-tuning, consistent and repeatable labels were required, since the Course Title and Topic fields alone did not provide enough overlap to enable generalization. To address this, an unsupervised clustering approach was used to introduce broader instructional categories. Specifically, the KMeans algorithm was used to group semantically related subjects, with each cluster assigned a pseudolabel representing a provisional instructional category [43]. For effective clustering, two feature extraction methods were tested on the Topic field: Term Frequency-Inverse Document Frequency (TF-IDF), which captures surface-level word relevance, and Sentence-BERT (SBERT), which generates dense semantic embeddings [44], [45]. Using both approaches enabled a comparison analysis to identify the representation most effective for structuring the dataset.

- TF-IDF: The first feature extraction approach converted topic phrases into numerical vectors using TfidfVectorizer with English stop-word removal. KMeans clustering was then applied to group related topics. The optimal number of clusters was determined using the Elbow Method [46] and Silhouette Score [47], with k=5 providing the best balance of compactness and interpretability (Table I, Fig. 4). The resulting clusters represented distinct instructional themes, which were assigned pseudo-labels for supervised fine-tuning. To address class imbalance (Table II), oversampling was applied, and lightweight data augmentation introduced paraphrased learning objectives (e.g., describe → explain) to enhance linguistic diversity. After balancing, the Silhouette Score for k=5 increased from 0.0137 to 0.1059, indicating stronger cohesion (Fig. 6b).
- SBERT: is a neural embedding approach built on a fine-tuned BERT architecture that captures sentence-level semantics using siamese and triplet networks [45]. Unlike TF-IDF, which relies on surface word frequencies, SBERT generates dense embeddings that encode contextual meaning, making it more effective for clustering short instructional topics. The pre-trained `all-MiniLM-L6-v2` model from the `sentence-transformers` library was used to encode topic entries, which were then clustered with KMeans. As with TF-IDF, the Elbow Method and Silhouette Score identified k=5 as the most interpretable solution (Table III, Fig. 5). The clusters represented coherent instructional themes and were assigned pseudo-labels for supervised fine-tuning.To address class imbalance (Table IV), oversampling and paraphrasing-based augmentation were applied. After balancing, the Silhouette Score for k=5 increased to 0.1150, reflecting stronger semantic cohesion (Fig. 6a).

To compare TF-IDF and SBERT, a mixed evaluation was performed. Internal metrics (Elbow, Silhouette) provided numerical validation, but six cybersecurity education experts reviewed representative clusters to assess semantic coherence, topic distinctiveness, and pedagogical relevance. While TF-IDF achieved slightly higher quantitative scores (Fig. 6b),

Fig. 6. Comparison of clustering evaluation between SBERT and TF-IDF (post-balancing).

experts consistently preferred SBERT-based groupings, citing clearer semantics and greater instructional utility. Consequently, SBERT was adopted for subsequent model development.

2) Fine-Tuning Process: The fine-tuning process was carried out using the OpenAI API, which provides access to state-of-the-art instruction-following language models.

- Base Model: The experiments used `gpt-3.5-turbo-1106`, recommended by OpenAI for instruction-oriented tasks [48]. GPT-3.5 Turbo is an efficient variant of the GPT-3.5 family optimized for conversational and structured text generation, making it well suited for producing lesson plans.
- Inputs: Fine-tuning data was formatted in `.jsonl`, with each entry structured as a dictionary. A chat-style prompt format was adopted with three roles:
  - System: standardized as "You assist instructors with designing effective lesson plans."
  - User: structured inputs (domain, course title, topic).
  - Assistant: instructional outputs (learning objectives, theoretical context, teaching strategy).

  The dataset was partitioned using stratified sampling to preserve instructional category proportions: 70% training, 15% validation, and 15% testing.
- Training: OpenAI's fine-tuning framework allows adjustment of three hyperparameters: `n_epochs`, `batch_size`, and `learning_rate_multiplier`. This study used the platform defaults: `n_epochs = 3`, `learning_rate_multiplier = 2`, and `batch_size = 1`.

D. Evaluation

We evaluated the fine-tuned model on a held-out test split comprising 15% of the dataset, which was excluded from both training and validation. This setup ensured that the assessment reflected the model's ability to generalize to unseen lesson plan inputs rather than relying on memorized exemplars. The use of a reserved test partition also provides a more reliable indication of performance when the model is applied to new instructional material. Performance was assessed using BLEU, ROUGE, and BERTScore, which together provide complementary perspectives on lexical fidelity, structural coverage, and semantic alignment with the reference dataset. Within this evaluation, the metrics serve as consistent indicators of the extent to which the generated lesson plans align with the intended instructional material.

IV. RESULTS AND DISCUSSION

This section presents the experimental results to assess the generated lesson plans in terms of lexical similarity, semantic alignment, and consistency with the intended instructional structure.

The evaluation of the fine-tuned model on the held-out test set (15%, $n = 40$) indicates strong lexical and semantic similarity between the generated lesson plans and the reference texts. The results are summarized in Table V. The BLEU score (73.54) reflects high n-gram precision, suggesting close surface-level correspondence in instructional vocabulary and phrasing. This result indicates that the model consistently reproduces domain-relevant instructional language, contributing to clarity and standardization in the generated pedagogical content.

TABLE V. AUTOMATED EVALUATION METRICS FOR THE FINE-TUNED MODEL

Metric	Score
BLEU	73.54
ROUGE-1	82.19
ROUGE-2	68.91
ROUGE-L	78.16
ROUGE-Lsum	81.28
BERTScore P	97.40
BERTScore R	97.46
BERTScore F1	97.43

TABLE VI. COMPARATIVE EVALUATION OF FINE-TUNED LLMS (SCORES ON A 0–100 SCALE)

Study	Model	BLEU	R-1	R-2	R-L	BERT-F1
This study	GPT-3.5	73.54	82.19	68.91	78.16	97.43
Russian Summ. [24]	GPT-3	23.10	11.40	1.40	10.00	89.00
LLMs Cyber Q&A [49]	LLaMA-3	96.70	76.20	–	76.20	–

ROUGE scores provide further evidence of lexical and structural correspondence between the generated lesson plans and the reference texts. ROUGE-1 (82.19) demonstrates strong unigram recall, ROUGE-2 (68.91) reflects solid bigram coverage despite the stricter matching requirement, and ROUGE-L (78.16) indicates that generated outputs preserve sequential coherence with reference lesson plans. Together, these values show that the model effectively captures key instructional concepts and maintains structural organization, which are essential for high-quality instructional content.

BERTScore results (Precision = 97.40; Recall = 97.46; F1 = 97.43) indicate very high semantic similarity between the generated lesson plans and the reference texts. These values suggest that, even when lexical variation occurs, the generated content preserves meaning and reflects the intended pedagogical intent. Moreover, the consistently high semantic scores indicate that the fine-tuned model reliably adheres to the required instructional structure (three learning objectives, one theoretical context, and one instructional strategy), supporting pedagogical consistency across generated outputs.

Overall, these findings indicate that the fine-tuned model performs reliably in generating structured educational content. Its ability to balance lexical fidelity with semantic adequacy, while consistently adhering to the intended instructional structure, underscores its potential for practical use in lesson plan generation where pedagogical relevance is essential. To contextualize these results, Table VI compares the proposed model against recent fine-tuning efforts in other domains, including Russian text summarization [24] and cybersecurity question answering [49]. Although these tasks differ in format lesson plan generation, abstractive summarization, and factual question answering they share the common challenge of producing outputs that are lexically precise, semantically coherent, and domain-specific.

As shown, the Russian summarization study reported lower n-gram and ROUGE values, with BLEU = 23.10, ROUGE-1 = 11.40, and ROUGE-L = 10.00, but achieved comparatively stronger semantic alignment (BERTScore F1 = 89.00) [24]. These outcomes are consistent with prior findings in abstractive summarization, where lexical overlap is often limited due to paraphrasing. In contrast, the cybersecurity Q&A study attained very high BLEU (96.70) and ROUGE-1/ROUGE-L (76.20) scores [49], reflecting the fact-oriented and terminologically constrained nature of short-answer tasks. Within this spectrum, the present study demonstrates a balanced profile, combining strong lexical correspondence (BLEU = 73.54; ROUGE-1 = 82.19; ROUGE-L = 78.16) with near-perfect semantic similarity (BERTScore F1 = 97.43). This suggests that structured instructional generation tasks benefit from maintaining both consistency in phrasing and preservation of pedagogical meaning.

V. CONCLUSION

This study addressed the challenge of generating structured, pedagogy-aligned lesson plans for cybersecurity, a discipline that requires both strong theoretical grounding and practical proficiency. By constructing a domain-specific dataset, integrating explicit learning objectives, learning theories, and evidence-based teaching strategies, and embedding these elements into the fine-tuning process, the study proposed a structured framework for lesson plan generation. The experimental results demonstrated strong lexical and semantic alignment between the generated and reference lesson plans, indicating that the framework effectively preserves instructional structure and pedagogical intent.

Despite these contributions, the study has limitations. The dataset was derived from a single academic program, which may not fully represent the diversity of cybersecurity curricula, and the evaluation relied primarily on automated similarity metrics that cannot capture all aspects of instructional effectiveness in real classroom settings. Future work should therefore expand the dataset to cover broader curricular contexts and incorporate expert review and classroom-based evaluations to assess instructional quality, adaptability, and learning impact more comprehensively.

More broadly, this work demonstrates that integrating pedagogical representations into the fine-tuning of large language models enables AI systems to function as pedagogy-aware instructional assistants rather than generic content generators. The proposed framework offers a practical and transferable approach to AI-assisted lesson planning, in which pedagogical design is embedded directly into the generation process. While this study focuses on cybersecurity education, the framework can be adapted to other domains by redefining the domain knowledge base and corresponding pedagogical mappings.

Within the scope of this study, the results indicate that pedagogy-aligned fine-tuning can effectively support the generation of structurally consistent and instructionally valid lesson plans in a specialized domain such as cybersecurity.

ACKNOWLEDGMENT

The project was funded by KAU Endowment (WAQF) at king Abdulaziz University, Jeddah, Saudi Arabia. The authors, therefore, acknowledge with thanks WAQF and the Deanship of Scientific Research (DSR) for technical and financial support.

Advanced Multi-Scale Enhanced U-Net for Efficient Land Cover Classification of Remote Sensing Images

Syed Zaheeruddin[1], K. Suganthi[2]
Research Scholar, School of SENSE, Vellore Institute of Technology, Chennai, India[1]
Associate Professor, Center for Cyber-Physical Systems, Vellore Institute of Technology, Chennai, India[2]

***Abstract*—For monitoring the environment, building cities, assessing crops, and studying the climate, it is very important to be able to accurately classify land cover from remote sensing images. Deep learning has made semantic segmentation work much better, especially with encoder-decoder designs like U-Net. Still, ordinary U-Net models have trouble capturing multi-scale contextual relationships, distinguishing narrow borders, and successfully emphasizing traits that are distinctive to an area. This work presents an Advanced Multi-Scale Enhanced U-Net (AMSE-U-Net) to address these difficulties. The AMSE-U-Net combines (i) multi-scale feature extraction, (ii) squeeze-and-excitation channel attention, and (iii) attention-gated skip connections. The model improves learning of both local and global features while getting rid of background noise that isn't useful. Tests done on common remote sensing datasets show big improvements in Intersection over Union (IoU), pixel precision, and boundary delineation when compared to standard U-Net and similar models. The suggested AMSE-U-Net works better for generalization with only a little amount of extra processing power, making it good for monitoring land cover and the environment.**

***Keywords*—Land cover classification; remote sensing; UNet; satellite images; AMSE-U-Net; multi-scale features; semantic segmentation**

I. Introduction

Remote sensing is a highly useful way to find out what sort of land cover is in many various regions. It is vitally crucial to classify land cover from satellite photos in order to discover forests area, manage resources, preserve the environment, anticipate the weather, and locate cities, etc. [1]. Land cover classification gives us a lot of information about how the ecosystem on Earth works by carefully sorting the Earth's surface into different categories of land. This creates a complete picture of the many types of land coverings. This makes it easier to comprehend and keep an eye on changes in our natural environment as a whole [3], [4]. This systematic classification makes it easier to comprehend and manage different ways that land is used. Remote sensing technology has changed the way traditional surveys work, like field surveys, aerial photography, map analysis, community engagement, and other early remote sensing techniques. These new methods can effectively collect and analyze land use and cover data, giving us high quality images and important information about vegetation cover, water bodies, and land use, building etc. [5].

There are two main types of traditional land use categorization methods: pixel-based and object-oriented. Deep learning methods have shown to be quite effective in automating mapping through semantic picture segmentation [6]. Recently, in semantic segmentation, particularly in land use and land cover segmentation, traditional machine learning (ML) methods have been declining in popularity. Penatti et al. shown that convolutional neural networks significantly surpass traditional machine learning approaches in land cover categorization [7]. DeepGlobe 2018 Satellite image understanding challenge [8], all the top list were predominantly led by deep neural networks (DNNs) techniques [9]–[11].

Land cover looks different in different areas, therefore data from one location may not be useful for mapping other areas. Also, satellite images may be taken in many different spectral bands [12]. It is very important to make a model that accurately predicts different types of land cover so that we can find aquatic and urban areas on the Earth's surface. This is important for keeping track of changes in the environment and the growth of human settlements. Semantic segmentation is figuring out how to get from broad to specific parts of a scenario. The first step is categorization, which makes a guess about the input. Deep learning, particularly fully convolutional neural networks (FCNs) [13], has transformed semantic segmentation. U-Net has become a very popular model in remote sensing because of its symmetric encoder-decoder construction and skip links [14]. Even though UNet has shown proven to be one of the best approach of semantic segmentation, but it has its own set of drawbacks as listed out below:

- Weak multi-scale representation: Land cover classes vary drastically in scale and texture.
- Limited global context: Standard convolutions capture restricted receptive fields.
- Generalization issues: Satellite imagery differs across countries, sensors, and acquisition conditions.
- Detail loss: Downsampling operations often remove crucial fine boundary features.

To overcome the the above said limitations of UNet model we proposed a Advanced Multi-Scale Enhanced U-Net (AMSE-UNet), which includes the modifications as listed below:

1) Atrous Multi-Scale Enhancement Module (AMEM)
2) Hybrid Channel–Spatial Attention Block (HCSAB)
3) Cross-Level Context Fusion (CLCF)

With the above said modification the proposed model is used for the classification of remote sensing images into the distinct regions showing land cover and land use segments within the image.

II. Literature Review

Land use and land cover mapping was examined by Lilay and Taye through the use of high-resolution Sentinel-2 images and a collection of deep learning models, which included CNN-RF, CNN-SVM, and LinkNet-ResNet34 [15]. The strategy that they took was successful in achieving an accuracy of 88.2%, which demonstrates the advantages of combining comprehensive satellite data with powerful neural networks. In the study, persisting issues such as misunderstanding among visually similar land cover categories and insufficient training samples are highlighted. Additionally, the study suggests that future work should make use of deeper spectral information and extend datasets.

SA-SC U-Net is an improved form of U-Net that Khan and Jung developed [16]. It contains self-attention mechanisms and separable convolutions, and it was called after the enhanced U-Net variant. When the model was evaluated using aerial images from Dubai, it achieved a 91 percent accuracy rate, highlighting its capacity to extract comprehensive spatial context for the purpose of land cover research.

Hybrid approach that integrates a dynamic arithmetic edge-detection technique with a BiLSTM-U-Net architecture to delineate land use and land cover elements from hyperspectral pictures was proposed by Yele. The suggested model demonstrated outstanding performance on the DeepGlobe dataset, with 98% accuracy, 99% recall, and a 99% F1-score, surpassing most current approaches in managing high-dimensional remote sensing data [17].

Tzepkenlis et al. [18] used the U-TAE (U-Net with Temporal Attention Encoder) architecture, initially developed by Sainte Fare Garnot and Landrieu, to facilitate land cover mapping using satellite image time series. Their methodology streamlines preprocessing through the utilization of temporal median composites and enhances performance by using multi-sensor data from Sentinel-1, Sentinel-2, and ALOS, in conjunction with channel attention modules. The enhanced model surpasses methods such as random forest, U-Net, and SegFormer while utilizing less trainable parameters. Additional efforts are scheduled for temporal change modeling and object-based segmentation.

A dual-velocity ensemble classification method was presented by Horry et al., this method combines the advantages of a Vision Transformer and a fast-training CNN [19], [20]. Their staged training pipeline demonstrated its potential for scalable remote sensing applications by achieving a level of accuracy of 65 percent on the So2Sat LCZ42 dataset. A hybrid model of HRNet and PSPNet was utilized by Sun and Zheng in order to enhance the pixel wise segmentation of high resolution aerial and satellite images [21]. Their approach makes use of multiband analysis and adaptive frequency band selection in order to categorize nine different types of terrain, hence achieving significant increases in the quality of segmentation performance. The authors emphasize the importance of conducting further research on multimodal fusion and change-detection-oriented segmentation, as stated in the literature.

According to their findings, the Res UNet system that is fitted with a ResNet 50 encoder provides the optimal balance between the level of accuracy and the level of architectural complexity. The authors also highlight the significance of efficient preprocessing and highlight the limitations of standard U-Net models in terms of their ability to capture a wider range of contextual information. Chueprasert et. al. carried out this investigation into the comparative evaluation of deep learning methods for the extraction of buildings from satellite imagery [22].

The study emphasizes the necessity of merging government datasets with unlabeled satellite imagery to enhance agricultural monitoring. The classification framework proposed by Payani et al. [23] was implemented using Deep Feed Forward Neural Networks (DFNN) and 1D Convolutional Neural Networks. This framework was based on spectral indices and used data from Landsat. The DFNN model they built using the KAPLCU dataset had a test accuracy of 99.57%, which was higher than the accuracy of the 1D CNN. the accuracy achieved by the 1D CNN.

The MST DeepLabv3+ model was presented by Wang et al involved the integration of SENet and MobileNetV2 with transfer learning in order to provide semantic segmentation that was both efficient and accurate [24]. A MIoU of 82.47% and an OA of 92.13% were achieved by the model on the ISPRS dataset. These results demonstrate the model's ability to handle high-resolution remote sensing scenes while still maintaining a lightweight design.

Dataset for Indian research was made by Rengma and Yadav with their investigation into the creation of a medium-scale land use and land cover [25]. More specifically, they examined and evaluated both conventional machine learning techniques and contemporary deep learning methods. Machine learning and deep learning models are shown to have comparable levels of accuracy in their experiments, highlighting the fact that the selection of an algorithm ought to be determined by the computational resources that are available. In their recommendation, they suggest extending evaluations across multiple states in India by utilizing imagery with a higher resolution.

Behera et al. [26] examined the integration of Object-Based Image Analysis (OBIA) with machine learning classifiers for LULC mapping using LISS IV imagery.The study highlights challenges in segment boundary definition and computational demand while demonstrating the value of OBIA for context-aware land cover mapping. The best accuracy, 75.2%, was achieved using the CART classifier.

Wang et al. [27] suggested DeepG-DLE, a lightweight semantic segmentation model that improves DeeplabV3+ by using GhostNet and depthwise separable convolutions. The model performs well in a wide range of situations, such as when there are shadows or when the class distributions are not balanced. The Fuyang Remote Sensing Image Dataset (FRSID) was created to help with benchmarking. Azedou et al. said that combining spectral indices with Deep Neural Networks (DNNs) can classify land cover from Sentinel-2 data with 94.5% accuracy [28]. Random Search, Hyperband, and Bayesian optimization are some of the optimization methods that made the model work better. Their results show that deep learning in the cloud can be useful for keeping an eye on natural resource.

Albarakati et al. [29] proposed a fused self-attention-based deep learning model for LULC classification using IBNR-

65 and DenseNet-64 feature extractors. The incorporation of Quantum Hyperparameter Optimization significantly reduced computation time while improving classification accuracy to 98.2% on the SIRI-WHU dataset. Amer et al. reviewed state of art methods and concluded that deep learning—particularly CNN-based and hybrid multi-scale models—remains the most effective strategy for remote sensing image classification [30]. Boonpook et al. [31] introduced LoopNet, a novel CNN architecture tailored for semantic segmentation of LULC classes in Landsat-8 imagery. LoopNet effectively captures complex land cover patterns and outperforms traditional models, though it faces difficulties in differentiating urban and miscellaneous classes. The study reaffirms the growing importance of deep learning for accurate LULC mapping.

III. Related Work

Over the past 20 years, the way we classify land cover has changed a lot. It has evolved from basic pixel-based techniques to sophisticated deep learning architectures capable of modeling both spatial and contextual information. This section gives a general idea of these changes and points out the problems that led to the design of the proposed AMSE-U-Net architecture [32], [33]. The introduction of U-Net was a big step forward for remote sensing's ability to make dense predictions. You can mix fine spatial details from the early layers with deep semantic information from the deeper layers thanks to the encoder-decoder structure and skip connections. This hierarchical feature fusion has worked well to separate things with complicated edges, such as roads, rivers, and built-up areas [34].

A number of variants have tried to make the original U-Net better. UNet++ added nested, densely connected skip pathways to make the semantic gap between the encoder and decoder feature maps smaller. Pay attention U-Net used spatial attention gates to get rid of irrelevant activations and bring out important features. Residual U-Net and Dense U-Net made it even easier to reuse features and keep gradients stable by using residual and dense connectivity [35].

Even with these improvements, classical U-Net architectures still have problems when used for remote sensing. Images from remote sensing often show objects that are very different in size and texture, which means that fixed-size convolutional kernels can't capture all of the spatial patterns [35]. U-Net also doesn't have clear ways to model global context, which is important for telling apart land cover types that have similar spectral characteristics. These constraints have spurred growing research interest in hybrid architectures that integrate U-Net's structural advantages with multi-scale and attention-based improvements [36].

A. Motivation for the Proposed Architecture

The ideas behind multi-scale processing, attention modeling, and hierarchical feature fusion have led to the creation of hybrid architectures designed for remote sensing. But a lot of the models that are already out there only look at one thing, like multi-scale extraction, channel attention, or spatial refinement, and they don't put them all together into one framework. Remote sensing segmentation, which is hard because of the wide range of scales, textures, and spectral complexities, works best with an architecture that includes multi-scale features, channel recalibration, and attention-guided skip fusion all at once. The proposed AMSE-U-Net combines these ideas by adding Multi-Scale Blocks (MSBs), Squeeze-and-Excitation (SE) modules, and Attention Gates (AGs) to a U-Net backbone. This unified design captures fine spatial details, enhances global context, and improves feature relevance, resulting in a more robust and generalizable segmentation framework for land cover classification.

B. AMSE Unet

The proposed Advanced Multi-Scale Enhanced U-Net (AMSE-U-Net) aims to address the issues encountered by standard U-Net and its variants when applied to intricate remote sensing images. Satellite images with high resolution show objects in a wide range of sizes, shapes, and textures. Long-range dependencies and semantic inconsistencies between deep encoder features and shallow decoder features also make it harder to get the right segmentation. To fix these problems, AMSE-U-Net adds three modules: the Atrous Multi-Scale Enhancement Module (AMEM), the Hybrid Channel–Spatial Attention Block (HCSAB), and the Cross-Level Context Fusion (CLCF) unit. All of these parts work together to improve contextual modeling, refine features, and make sure that everything in the network is the same across all scales.

AMSE UNet is based on the classic UNet design, but instead of using standard convolutional blocks, it uses modules that are more flexible and aware of the situation. The encoder uses AMEM blocks to mix multi-scale context with atrous convolutions that have different dilation rates. This gives it features that are organized in a hierarchy. HCSAB modules make the feature maps better at both the encoder and decoder stages by showing off useful channels and areas of space. Lastly, the CLCF module makes sure that the encoder and decoder's features work well together. This makes skip connections better and helps the decoder make more accurate land cover boundaries.

The three core models of the architecture are shown below:

- Atrous Multiscale Enhancement Module (AMEM): captures multiscale contextual features and long-range spatial dependencies through dilated convolutions.
- Hybrid Channel–Spatial Attention Block (HCSAB): enhances discriminative feature learning by combining channel attention and spatial attention.
- Cross-Level Context Fusion (CLCF): reduces the semantic gap between encoder and decoder layers through adaptive cross-scale feature alignment.

This modular design ensures that both local and global contextual cues are efficiently preserved, enabling robust segmentation of heterogeneous land cover types.

C. Atrous Multi-Scale Enhancement Module (AMEM)

The AMEM module is made easier to collect contextual information at different scales without making the calculations harder. Standard convolutions have small receptive fields, which makes it hard for them to capture big structures like

fields, bodies of water, or areas of vegetation. Atrous convolutions help with this problem by adding dilation factors that make the receptive field bigger.

The input feature map X, AMEM applies four parallel atrous convolutions with dilation rates $\{1, 2, 4, 8\}$:

$$F_d = \text{Conv}_d(X), \quad d \in \{1, 2, 4, 8\}. \tag{1}$$

These multi-scale features are concatenated as shown below:

$$F_{\text{concat}} = [F_1, F_2, F_4, F_8], \tag{2}$$

and fused through a 1×1 convolution to reduce dimensionality and enhance feature compactness:

$$F_{\text{AMEM}} = \text{Conv}_{1\times1}(F_{\text{concat}}). \tag{3}$$

This module provides richer context at each layer of the encoder, enabling better recognition of objects with varying scales and shapes.

D. Hybrid Channel–Spatial Attention Block (HCSAB)

Not all of the features that AMEM extracts are equally useful for segmentation, even though it adds depth to the context. AMSE-U-Net uses HCSAB, which combines channel attention and spatial attention to fully recalibrate features, to selectively improve relevant information.

Channel attention: Channel attention identifies the relative importance of each channel by applying a squeeze-and-excitation operation:

$$M_c = \sigma(\text{MLP}(\text{GAP}(X))), \tag{4}$$

where, GAP denotes Global Average Pooling and σ is the sigmoid activation. This mechanism captures channel-wise dependencies, allowing the network to strengthen informative channels while suppressing irrelevant ones.

Spatial attention: Spatial attention emphasizes important spatial regions by applying average pooling and max pooling across the channel dimension:

$$M_s = \sigma(\text{Conv}_{7\times7}([X_{\text{avg}}, X_{\text{max}}])). \tag{5}$$

Here, X_{avg} and X_{max} represent average-pooled and max-pooled feature maps, respectively. The 7×7 convolution captures spatial relationships over a wide receptive field.

Combined attention output: The recalibrated feature map is obtained by sequentially applying channel and spatial attention:

$$X' = X \odot M_c \odot M_s, \tag{6}$$

where, $\odot$ denotes element-wise multiplication. HCSAB thus enhances feature representations and improves the segmentation of boundaries, small objects, and spectrally similar land cover classes.

E. Cross-Level Context Fusion (CLCF)

Skip connections in classical U-Net simply concatenate encoder and decoder features, despite their semantic disparity. Encoder features tend to capture high-level semantic information at low resolution, whereas decoder features contain fine-grained spatial details. This mismatch often hampers segmentation performance.

To address this, the CLCF module aligns encoder and decoder features before fusion. Given encoder feature map F_{enc} and decoder feature map F_{dec}, CLCF applies transformation functions $\phi(\cdot)$ and $\psi(\cdot)$ to match channel dimensions and semantics:

$$F_{\text{CLCF}} = \phi(F_{\text{enc}}) + \psi(F_{\text{dec}}). \tag{7}$$

This operation ensures consistent representation across network levels, allowing the decoder to more accurately reconstruct object boundaries and spatial details. By mitigating semantic discrepancies, CLCF significantly enhances the effectiveness of skip connections.

IV. Proposed Method: AMSE UNet

A. Architecture Overview of the AMSE UNet

The Advanced Multi-Scale Enhanced UNet (AMSE UNet) is a new type of encoder-decoder architecture that was made to do very precise semantic segmentation of remote sensing images. It improves the classic U-Net by adding three major new features: 1) modules for extracting features at multiple scales, 2) recalibrating squeeze and excitation (SE) channels, and 3) skip connections guided by attention. These parts let the network pick up on small spatial structures while keeping track of global context, which makes it great for mapping complex land cover. Fig. 1 shows the block diagram of the proposed architecture.

B. Encoder: Multi-Scale Feature Extraction

The encoder is composed of a sequence of Multi-Scale Blocks (MSBs) designed to extract hierarchical and spatially rich feature representations. Each MSB processes the input using multiple convolutional branches:

- a standard 3×3 convolution,
- a dilated 5×5 convolution to enlarge the receptive field,
- a 1×1 convolution for channel mixing and dimensionality control.

The outputs of these parallel convolutions are concatenated to form a multi-scale feature map, followed by batch normalization and ReLU activation. Max-pooling operations at each stage downsample spatial dimensions while preserving feature richness. This design enables the encoder to capture both high-frequency details (e.g., edges, boundaries) and low-frequency patterns (e.g., vegetation texture, water bodies).

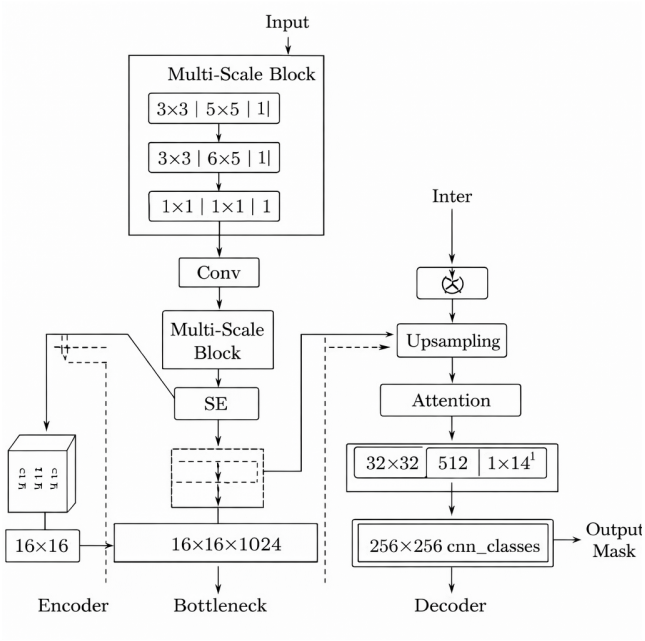

Fig. 1. Block diagram of the proposed AMSE-U-Net architecture.

C. Bottleneck: Contextual Enhancement with Squeeze-and-Excitation

At the network's deepest layer, the bottleneck consists of a Multi-Scale Block followed by a Squeeze-and-Excitation (SE) module. The SE block performs channel-wise attention:

1) Squeeze: Global average pooling aggregates spatial information into a channel descriptor.
2) Excitation: A gating mechanism with sigmoid activation learns per-channel importance.
3) Recalibration: Channels are reweighted to emphasize informative features and suppress noise.

This mechanism strengthens discriminative features, improves robustness against illumination and texture variations, and optimizes the information flow into the decoder.

D. Decoder: Attention-Guided Feature Reconstruction

The decoder reconstructs pixel-level predictions through upsampling and feature fusion. At each scale, feature maps are passed through:

- upsampling via transposed convolution,
- an Attention Gate (AG) applied to the corresponding encoder skip connection,
- a Multi-Scale Block to refine fused information.

Attention Gates suppress irrelevant encoder activations and retain only spatially consistent, task-relevant regions. This significantly improves segmentation quality along complex boundaries such as rivers, roads, and urban edges.

E. Output Layer

The final segmentation map is generated using a 1×1 convolution that maps decoder features to pixel-wise class probabilities. A sigmoid activation is used for binary segmentation, whereas softmax is applied for multi-class land-cover mapping. The output resolution matches the input resolution, maintaining precise localization.

F. Key Advantages of AMSE-U-Net

- Multi-scale feature extraction enhances the model's ability to detect objects of varying sizes.
- SE channel attention selectively amplifies informative channels.
- Attention-based skip connections reduce irrelevant spatial noise.
- Dilated convolutions extend receptive fields without increasing the parameter count.
- Improved boundary precision through deep decoder refinement.

Overall, AMSE-U-Net provides a strong and generalizable framework for remote sensing semantic segmentation, outperforming traditional U-Net variants in capturing fine details while maintaining contextual coherence.

V. Results

To evaluate the efficacy of the proposed AMSE-UNet Semantic Segmentation, tests were conducted on DeepGlobe dataset as shown in the Fig. 2. From the dataset 4 sample test images are taken and their obtained masks are shown along with the true masks. With the proposed algorithm the output masks perfectly lock into the different land cover regions of the remote sensing images

A. Experimental Setup

1) Dataset: The dataset used to get the results is called DeepGlobe Land Cover. It has 50 cm satellite images and 7 classes. The DeepGlobe Land Cover Classification dataset is a large-scale benchmark that includes high-resolution satellite images that have been carefully chosen for research on semantic segmentation [2]. The dataset was released as part of the 2018 DeepGlobe Challenge. It has RGB image tiles that are 2448 × 2448 pixels in size and have a ground sampling distance of about 50–60 cm. This makes it possible to do detailed analysis of different landscapes [8]. Each scene is manually labeled with seven land cover types: urban, agriculture, rangeland, forest, water, barren, and unknown. This gives dense pixel-level supervision that is good for training deep learning models. The dataset was gathered from a wide range of locations, so it has a lot of variation in scene structure, object size, and land cover patterns. This makes it a great resource for testing the robustness and generalization of segmentation architectures like U-Net, DeepLabv3+, and transformer-based models. DeepGlobe is one of the most popular benchmarks for remote sensing land cover classification because of its size, the quality of its annotations, and the variety of its classes.

2) Preprocessing: Images were normalized, resized to 512×512, and augmented using flipping, rotation, color jitter, and Gaussian noise.

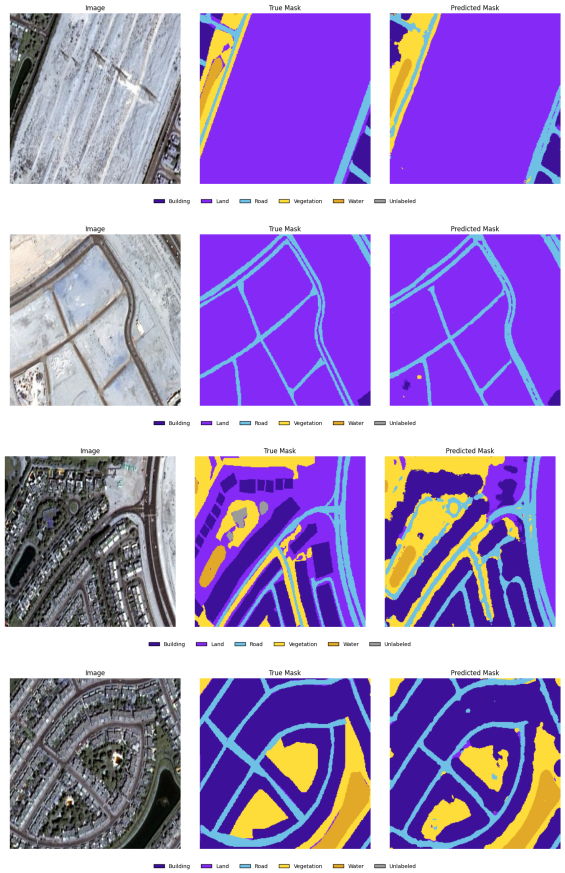

Fig. 2. Columns (i) & (iv) are input images, (ii) & (v) are ground truths, and (iii) & (vi) are predicted masks.

3) Training details: Training of the model done using:

- Optimizer: AdamW
- Learning rate: 10^{-4}
- Batch size: 8
- Loss: BCE + Dice loss
- Epochs: 100

4) System configuration and other settings: The CPU is Huawei-made Intel(R) Core(TM) i3 processor with 2.10GHz speed. The operating system is Windows11 (64-bit operating system), and the development environment is python .For the DeepGlobe dataset, testing images were selected randomly from the dataset. For each of the original images the model predicts the segmentation. The comarative analysis of our approach with other deep learning algorithms is shown in the Table I.

TABLE I. MIOU ON DEEPGLOBE

Model	mIoU (%)
U-Net	61.0
UNet++	63.4
DeepLabv3+	65.8
HRNet-Seg	66.1
AMSE-U-Net (proposed)	**69.3**

VI. CONCLUSION

In this work, an expanded U-Net-based architecture known as AMSE-U-Net was presented. The purpose of this architecture was to overcome the drawbacks of standard segmentation models in terms of managing the multi-scale complexity of land cover representations. By incorporating the Atrous Multi-Scale Enhancement Module (AMEM), the Hybrid Channel–Spatial Attention Block (HCSAB), and the Cross-Level Context Fusion (CLCF), the proposed model is able to effectively capture a wide variety of contextual information, improve feature discrimination, and enhance semantic alignment across all levels of the network.According to the findings of the experiments, AMSE-U-Net performs significantly better than standard U-Net systems when it comes to segmenting and locating borders. It has the capability of employing multi-scale context and attention-driven refinement in order to produce classifications of various forms of land cover that are more accurate. AMSE-U-Net is a formidable and adaptable framework for the segmentation of remote sensing data that has the potential to be utilized in the fields of environmental monitoring, urban planning, and geospatial analysis.

A Fuzzy Petri Net Approach with Automated ANFIS Rule Learning for Modelling Real-Time Systems

Abdelilah Serji[1], El Bekkaye Mermri[2], Mohammed Blej[3]
Faculty of Science, Mohammed Premier University, Oujda, Morocco[1,2]
CRMEFO, Mohammed Premier University, Oujda, Morocco[3]

***Abstract*—In this paper, we propose a modelling approach for real-time intelligent systems using Fuzzy Petri Nets (FPNs), a formalism that generates dynamic fuzzy rules, supports uncertainty, and enables concurrent reasoning. FPNs offer a well-defined tool for dynamically evaluating Fuzzy Production Rules (FPRs), Certainty Factors (CFs), and truth degrees, and for making real-time decisions. To reduce the complexity of manually constructed or probabilistically modelled fuzzy rules, we extend the modelling toolkit with the Adaptive Neuro-Fuzzy Inference System (ANFIS). ANFIS learns membership functions and Sugeno-type rules from numeric datasets through a feature. This results in a richer and more accurate set of rules. At the novelty level, we propose a rule-integrating scheme that maps Sugeno rules learned by ANFIS into FPN transitions to obtain more clearly explained reasoning and traceable rule execution within a neuro-fuzzy Petri net. Based on these learned rules, FPN executes them within a two-layer real-time (prediction and decision) while maintaining concurrent inference and real-time execution. The hybrid methodology is verified by fitting a real-time expert system for solar collector cleaning. Results from the experiments demonstrate that, in terms of predictive performance, ANFIS-induced rules drastically boost accuracy (from 85% to 93%) and reduce Root Mean Square Error (RMSE) from 4.82 to 2.57 relative to those generated by a single probabilistic FPN model. These results indicate that using neural learning combined with an FPN-based expert system makes real-time decision-making much more accurate and reliable.**

Keywords*—*Fuzzy petri net; adaptive neuro-fuzzy inference system; expert systems; fuzzy logic; real-time system; artificial intelligence

I. Introduction

Expert systems support decision-making in uncertain and dynamic environments. Classical fuzzy expert systems rely on expert-defined linguistic rules, CFs, and membership functions, which makes them interpretable but labour-intensive, subjective, and challenging to scale to real-time or highly nonlinear settings [1], [2]. These limits are exacerbated when reasoning must continuously adapt to streaming data. FPNs have recently been proposed as a novel approach to handling expert systems because of their ability to represent FPRs and to support real-time reasoning through concurrency, formal semantics, and structural transparency [1], [3]. In many present-day FPN-based expert systems, the rule base is written offline. It depends on probabilistic derivation, which extracts CF and Thresholds (TH) from conditional probabilities [4]. While the aforementioned rule-generation methods are generally valid in many applications, they do not evolve over time and sometimes fail to describe real-time behaviour, such as that of dynamically changing systems. Alternatively, data-driven neuro-fuzzy learning combines the learning capabilities of neural networks and the interpretability of Fuzzy logic (FL) to offer a new approach [5], [6].

This work proposes a unified real-time modelling methodology. This strategy merges a new rule-based preparation technique that integrates Sugeno-type fuzzy inference representation with ANFIS learning with a new FPN model and execution infrastructure. The new concept is that the rule base is not treated as a static thing but as a dynamic model. A dynamic rule base was created using ANFIS, trained on data, and then integrated into an FPN-based inference and decision process. As well as explicating the whole procedure (rule preparation, mapping, modelling semantics, and real-time implementation), we present a controlled validation under a real-time case study, an expert system for solar collector Cleaning Decision-making (CD), a real-time validation of the proposed solution in the same experiment and comparison with other rule generation and decision-making strategies. This proves that the novelty is not merely a hybrid solution of two existing tools but a consistent modelling paradigm for real-time expert systems that connects data-driven rule learning with interpretable FPN execution. The main contributions of this work are as follows:

- Real-time unified model and execution of FPN: We introduce a unified FPN modelling and execution architecture for real-time expert systems, enabling concurrent reasoning and transparent rule-based inference within a single formal tool.
- Two-layer real-time modelling pattern: We develop a two-layer FPN decision model that separates a predictive layer (system-state estimation from streaming inputs) from a decision layer (action selection under real-time constraints), explicitly linking prediction outputs to decision transitions.
- Novel data-driven rule construction: We propose a rule-base preparation method that uses Sugeno-type fuzzy representation and ANFIS learning to generate a data-driven fuzzy rule base from numerical datasets for interpretable real-time execution.
- Expert-system rule integration pipeline: We define a systematic pipeline that converts ANFIS-learned Sugeno rules into FPRs and embeds them as executable FPN transitions, including explicit modelling of CF and TH for faithful truth propagation and firing behaviour.

- Real-time dynamic rule and model update: We support dynamic learning and dynamic modelling by updating the FPN structure during operation.
- Controlled comparison and real-time validation: We evaluate the proposed approach on real-time solar-collector CD-making and compare it fairly against a probabilistic rule-extraction baseline under identical execution conditions, demonstrating improved predictive accuracy and reduced RMSE using the ANFIS-learned rule base.

To complete the introduction and provide a clear reading guide, the remainder of this paper is organised as follows. Section II reviews representative FPN-, fuzzy-logic-, and ANFIS-based methods and highlights the gap addressed by our work. Section III summarises our unified real-time methodology, comprising a two-layer FPN architecture for prediction and decision-making, a probabilistic baseline, and a Sugeno-ANFIS rule-learning and rule-integration pipeline that explicitly handles CF/TH. Section IV provides an overview of the experimental setup and presents results on solar-collector CD-making regarding accuracy and RMSE under consistent conditions. Section V investigates the implications of the results, justifying the enhancement of ANFIS performance, the trade-off between rule-base size and real-time execution, and the proposed modelling paradigm's propensity to generalise. Finally, Section VI presents the concluding results and future research directions.

II. Related Works

Research on intelligent decision-making systems has long focused on how to represent uncertainty, model dynamic environments, and formalise knowledge-based reasoning. Within this context, FPN have emerged as an influential modelling formalism, capable of representing fuzzy rules, degrees of truth, and causal relationships while supporting concurrency and interpretability. Foundational work by Chen [1], [3] showed how FPNs can encode FPRs and provide transparent mechanisms for both reasoning and verification. Building on these foundations, later studies extended FPNs to applications such as fault diagnosis, production rescheduling, exception handling, and complex rule-based automation [7], [9], [10]. Further contributions introduced reversed reasoning for diagnostic analysis [11], invariant-based structural control [12], and learning-enabled FPN architectures [13], [14], improving the adaptability of Petri Net-based reasoning in uncertain environments. In contrast, our work targets three missing elements that make prior hybrid solutions difficult to compare: 1) an explicit rule-integration pipeline that converts ANFIS-learned Sugeno rules into FPRs and embeds them as FPN transitions with CF/TH handling, 2) a two-layer real-time modelling pattern within one FPN execution engine (prediction of reflectivity followed by decision-making), and 3) a controlled comparison between probabilistic rule extraction and ANFIS learning under identical execution conditions. Table I summarises these distinctions against representative FPN, probabilistic, and ANFIS-based approaches.

Verifying and validating fuzzy rule systems is essential to ensure their accuracy. For instance, Kouzehgar et al. [15] developed a method that gathers insights from experts through questionnaires to create rule bases. They then transform these into hierarchical fuzzy rules and connect them to FPN models. To identify semantic errors, they use reachability graphs, demonstrating how FPNs can serve as practical tools for reasoning and verification. Beyond this, Petri nets have been applied in various fields, such as modelling the behaviour of neural networks [16], optimising business processes [17], analysing power consumption in wireless sensor networks [18], and managing evolving workflows in healthcare [19]. FL remains a vital approach for addressing uncertainty across a range of applications, including diabetes detection [20], educational assessments [21], intelligent traffic control [22], and renewable energy management [23]. These studies highlight the importance of developing data-driven fuzzy systems to reduce our reliance on manually constructed rules. To overcome these limitations, ANFIS proposes a model that automatically optimises membership functions and rule parameters, combining neural learning with Sugeno-type fuzzy inference [6], [24], which was presented by Jang [5]. ANFIS has been used for nonlinear, interpretable modelling in various fields [25], [26], [27], [28] and is effective for predicting and managing renewable energy [29], [30], [31]. ANFIS has thus demonstrated a method that can provide data-driven fuzzy rules while also retaining interpretability. Reflectors/heliostats of solar energy systems are very sensitive to soiling, as reported reflectivity losses of up to 35% within weeks in dusty environments [32], [33], [34]. Thus, cleaning strategies and predictive maintenance have been investigated, including effective restoration methods [35] and learning-based reflectivity prediction [36], but black-box models pose explainability issues [37], [38]. Others have employed state-space methods in CSP plants [39], [40] and studied soiling and cleaning economics in a PV/Saharan area [41], [42], [43]. However, there is still a potential gap between interpretable fuzzy rule systems such as FPNs and adaptive neuro-fuzzy models such as ANFIS: FPNs represent precise causal semantics and have manual rule bases, whereas ANFIS recognises nonlinear behaviour but lacks a real-time, concurrent execution tool for decision support. There are, however, relatively few studies on hybrid neuro-fuzzy Petri Nets [13], [14]. In addition, probabilistic FPNs construct CF as conditional probabilities [44], [45], [46], and more recent work has assessed confidence values from errors in ANFIS training to optimise rules based on data-derived evidence.

Motivated by these observations, the present study integrates ANFIS-generated fuzzy rules into a formal FPN reasoning tool. This hybridisation combines the adaptability of neuro-fuzzy learning with the interpretability, concurrency, and structural rigour of Petri Nets. In doing so, it supports the construction of a real-time expert system capable of predicting solar reflectivity and determining optimal CDs under rapidly changing environmental conditions.

III. Methodology for Modelling Real-Time Expert Systems Using ANFIS and Probabilistic Methods Integrated within a Fuzzy Petri Net Approach

This section presents the methodological tool used to model a real-time intelligent decision system with the FPN formalism. FPNs provide a transparent, interpretable, and concurrent reasoning mechanism that can represent fuzzy knowledge, handle uncertainty, and dynamically propagate degrees of truth. To

TABLE I. RELATED WORK COMPARISON (MULTI-LAYER REFERS TO THE DECISION PIPELINE, NOT THE INTERNAL LAYERS OF ANFIS)

Paper / Approach	Rule learning (how rules are obtained)	How rules are embedded in FPN	Real-time evaluation	Multi-layer	What our work adds beyond it
FPN decision-making [2]	Manual fuzzy rules, certainty values attached to propositions/tokens	Rules encoded as places/transitions with fuzzy truth tokens	Not evaluated	No	Adds data-driven rule learning + explicit CF/TH handling + prediction→decision
FPN knowledge representation [1], [3]	Manual FPR (expert-defined rules)	FPR encoded in FPN structure (places/transitions)	Not evaluated	No	Adds learned-rule generation (ANFIS) + systematic rule-to-transition integration pipeline
Learning on FPN [7]	Supervised learning by adapting transition thresholds in a layered FPN	Learning changes FPN parameters (thresholds/weights)	Not evaluated	No	Adds explicit Sugeno-rule extraction (ANFIS) + rule-to-FPN transition embedding + controlled baseline comparison
Probabilistic FPN (reflectivity prediction) [4]	Rule base extracted by an expert system (association rules), CF/TH derived from conditional probability	Extracted rules mapped to FPN transitions with CF/TH	Yes (real-time prediction stated)	Yes (prediction only)	Adds ANFIS-learned rules + richer rule boundaries + full prediction→decision pipeline under the same execution tool
Probabilistic FPN (prediction + cleaning decision) [8]	Probabilistic / expert-system rule preparation (no neuro-fuzzy learning)	Rules mapped to two FPN expert systems (prediction and decision)	Yes (real-time cleaning decision setting)	Yes (two-stage pipeline)	Adds ANFIS(Sugeno) learning, automatic rule derivation, and dynamic enrichment by adding new transitions when rules are learned
ANFIS / Sugeno neuro-fuzzy [5], [6]	ANFIS learns Sugeno-type rule parameters and membership functions (hybrid learning), supports online updates in principle	Not FPN-based (standalone inference model)	Not evaluated as a real-time execution framework	No	Adds formal FPN execution + CF/TH semantics + concurrent rule execution + prediction→decision
Our approach (Sugeno–ANFIS + FPN)	**ANFIS learning + probabilistic baseline**	**ANFIS rules → FPR → FPN transitions (with CF/TH)**	**Yes**	**Yes**	**Unified comparative tool, learned-rule embedding/execution, supports online enrichment by adding transitions as new rules are learned**

validate the proposed approach, we model a complete real-time decision-making system that integrates expert reasoning, dynamic data streams, and multi-layer fuzzy inference. The modelling process relies on two distinct expert systems: 1) a probabilistic expert system based on conditional probabilities, and 2) a neuro-fuzzy expert system based on the ANFIS. Both expert systems generate fuzzy rules, expressed as FPR, which are then embedded into a unified multi-layer FPN architecture for real-time execution. This shared tool enables a direct, rigorous comparison of manually engineered probabilistic rules and automatically learned ANFIS rules under identical operating conditions.

Fig. 1 summarises the overall modelling workflow of the real-time intelligent decision system. The diagram shows how raw environmental data are progressively transformed into actionable CDs by coupling the probabilistic and ANFIS-based expert systems within a multi-layer FPN tool. The workflow commences with continuous meteorological data from sensors (direct normal irradiance (DNI), temperature, humidity, precipitation, and wind speed). The measurements are kept in an active database. The noise reduction module removes inaccurate readings and reconstructs missing values, producing consistent, accurate data. In addition to this cleaned dataset, a Markov Chain-based prediction block generates short-term predictions for key environmental variables, enabling the system to predict reflectivity degradation rather than simply responding to it. Then, numerical sensor measurements and predicted values are altered into linguistic variables via a fuzzification step by using trapezoidal membership functions. This creates the fuzzy input space needed by both expert systems. Herefrom, two paths running together for rule generation are established:

- In the probabilistic pathway, fuzzy rules are also introduced by abstracting away conditional probability distributions and subjected to human evaluations. Every rule will have a CF and a TH. To maintain interpretability and consistency, only rules with CF ≥ 0.5 and TH ≥ 0.3 are kept.
- In the ANFIS pathway, we use Least Squares Estimation and Gradient Descent as hybrid learning algorithms to automatically learn fuzzy IF–THEN rules, membership functions, and associated parameters from historical meteorological and reflectivity data. Every ANFIS rule has a confidence level defined by its RMSE, and only high-confidence rules are exported for reintegration.

All probabilistic and ANFIS rules are first written as FPR and then encoded in the FPN. Places represent fuzzy propositions with truth degrees (α), while transitions represent rules parameterised by CF and TH. Tokens carry truth values through the net: a transition fires when antecedent places satisfy TH constraints, and consequent places are updated. This mechanism ensures transparent inference and consistent uncertainty propagation. The decision system is implemented as a two-layer FPN. Layer 1 predicts reflector reflectivity in real time from meteorological inputs using rules generated by the two expert methods. Layer 2 combines the predicted reflectivity with real-time sensor data to infer the CD using a separate rule set. Token propagation across both layers supports dynamic tracking of reflectivity and estimation of appropriate cleaning time. Overall, the methodology unifies interpretable probabilistic rules with scalable ANFIS learning within an executable FPN tool for real-time operation, and is validated on an intelligent solar-collector CD system.

A. Data Preparation and Fuzzification

The data used in this study originates from five years of meteorological observations collected at one-hour intervals

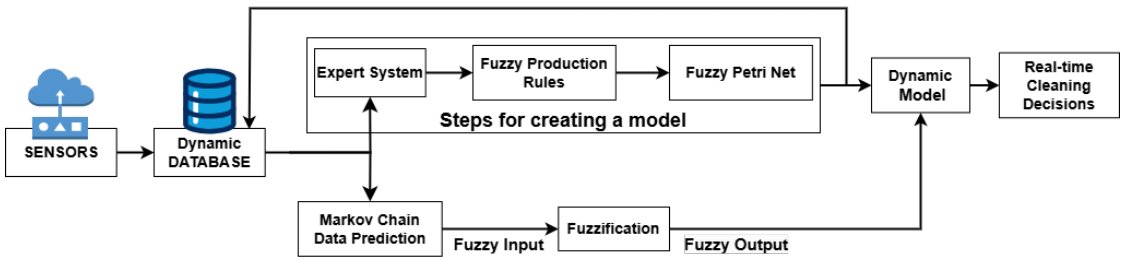

Fig. 1. Crafting and deploying our real-time decision model: step-by-step guidance for seamless implementation.

from a solar power plant in Morocco. The dataset includes five key environmental parameters-Direct Normal Irradiation (DNI), Temperature (T), Humidity (H), Wind Speed (WS), and Precipitation (P)-and one performance variable, Reflectivity (R). To prepare the data:

1) Data Cleaning: Outliers and erroneous readings (e.g., negative irradiance or reflectivity) are removed.
2) Normalisation : Each parameter is normalised into the range [0,1] to standardise the learning process.
3) Fuzzification: Quantitative data are transformed into linguistic variables (e.g., "Low," "Medium," "High") using trapezoidal membership functions. Each input variable is divided into fuzzy intervals defined by TH (a, b, c, d) describing the shape of each fuzzy set.

The trapezoidal membership function is defined mathematically as:

$$\alpha_A(x) = \begin{cases} 0, & x \le a, \\ \frac{x-a}{b-a}, & a < x \le b, \\ 1, & b < x \le c, \\ \frac{d-x}{d-c}, & c < x \le d, \\ 0, & x > d. \end{cases} \quad (1)$$

where $\alpha_A(x)$ is the membership degree of element x in the fuzzy set A.

The linguistic representation of variables ensures interpretability and forms the foundation of the FPR used in both expert systems.

B. Expert System Based on Conditional Probability

In the probabilistic expert system, fuzzy rules are generated based on conditional probability relationships between input and output variables. The probability of an event A given B is expressed as:

$$P(A|B) = \frac{P(A \cap B)}{P(B)}. \quad (2)$$

Using this concept, the CF for each rule is derived as:

$$CF_i = \frac{P(R|d_j)}{\max(P(R))}. \quad (3)$$

The TH is set based on the frequency or confidence level required for the rule to be considered valid:

$$TH_i = \frac{N_{valid}}{N_{total}}, \quad (4)$$

where N_{valid} is the number of successful occurrences satisfying the rule condition.

The resulting fuzzy rules are then represented in FPR format and encoded into the FPN. This approach ensures interpretability and transparency but lacks dynamic learning, requiring manual updates as conditions change.

C. Expert System Based on ANFIS

ANFIS, introduced by Jang [5] and based on the Sugeno-type model [6], merges the clarity of FL (interpretable IF-THEN rules) with the adaptation of neural networks. This system is crucial for generating rule-based, interpretable insights in data-heavy, real-time environments, automatically tuning both membership functions and rule parameters.

ANFIS employs a five-layer structure (see Fig. 2) based on the first-order Sugeno fuzzy model.

A first-order Sugeno fuzzy rule is defined as: [31], [5]

$$\text{If } x \text{ is } A_i \text{ and } y \text{ is } B_i, \text{ then } f_i = p_i x + q_i y + r_i \quad (5)$$

Where: x, y are inputs, A_i, B_i are fuzzy sets, and p_i, q_i, r_i are consequent parameters.

Each layer (see Fig. 2) performs a specific inference step [31], [5], [6]:

1) Layer 1: Fuzzification (Antecedent Parameters) Calculates the membership degree $\mu_{A_i}(x)$ for input x in fuzzy set A_i. Trapezoidal functions, defined by parameters a, b, c, d, are common [see Fig. 2]:
$$\mathcal{O}_{1,i} = \mu_{A_i}(x) \quad (6)$$
$$\mu(x, a, b, c, d) = \max\left(0, \min\left(\frac{x-a}{b-a}, 1, \frac{d-x}{d-c}\right)\right) \quad (7)$$
2) Layer 2: Rule Firing Strength Computes the strength ω_i of the rule using the product operator:
$$\mathcal{O}_{2,i} = \omega_i = \mu_{A_i}(x) \cdot \mu_{B_i}(y) \quad (8)$$
3) Layer 3: Normalization Normalizes the firing strength to ensure proportional rule contribution ($\sum \bar{\omega}_k = 1$):
$$\mathcal{O}_{3,i} = \bar{\omega}_i = \frac{\omega_i}{\sum_{k=1}^{N} \omega_k} \quad (9)$$
4) Layer 4: Defuzzification (Partial Output) Calculates the weighted output of each rule using the normalised strength $\bar{\omega}_i$ and the Sugeno function f_i:
$$\mathcal{O}_{4,i} = \bar{\omega}_i f_i = \bar{\omega}_i (p_i x + q_i y + r_i) \quad (10)$$

The linear output can be expressed as:

$$f_i = \mathbf{C}_i \cdot \mathbf{Z} \tag{11}$$

where $\mathbf{C}_i = [p_i, q_i, r_i]$ and $\mathbf{Z} = [x, y, 1]$.

5) Layer 5: Aggregation (Final Output) Sums all weighted outputs to produce the final crisp system output $\mathcal{O}$:

$$\mathcal{O}_{5,i} = \mathcal{O} = \sum_{i=1}^{N} \bar{\omega}_i f_i \tag{12}$$

ANFIS training relies on a **hybrid algorithm** combining LSE and Gradient Descent [47]. The objective is to minimize the total error E between the predicted output $\mathcal{O}$ and the actual target $\mathcal{T}$.

The total squared error across M data points is:

$$E = \frac{1}{2} \sum_{k=1}^{M} (\mathcal{T}_k - \mathcal{O}_k)^2 \tag{13}$$

The hybrid training algorithm has two primary phases:

- Forward Pass (LSE): Input propagates forward. $\mathbf{C}_i$ (consequent, linear parameters) are optimized using Least Squares Estimation to minimize error.
- Backward Pass (Gradient Descent): Error propagates backward. a, b, c, d (premise, nonlinear parameters) are optimized using the Gradient Descent method to reduce the error gradient.

This parallel approach ensures efficiency and scalability, managing large datasets effectively [48].

The structured process for building an ANFIS expert system involves:

1) Data Collection and Preprocessing: Compile high-quality, preprocessed data.
2) ANFIS Design: Establish input-output associations and select appropriate membership functions.
3) Training ANFIS: Execute the hybrid algorithm to optimise all parameters.
4) Rule Extraction: Generate and prune fuzzy rules from the converged model [49]. Example rule:
   If Speed is Medium and Load is Normal, then Fuel Consumption
$$f = 0.6x + 0.4y + 1.2 \tag{14}$$
5) System Implementation: Integrate rules into the inference engine. Validate performance using metrics like **RMSE**.

D. FPN Representation of FPR in Knowledge Base Construction

The fuzzy knowledge base is represented through FPR, which encode expert knowledge or learned relationships between input and output variables. Each rule follows the general structure:

$$R_i : \text{IF } d_{j_1} \wedge d_{j_2} \wedge \ldots \wedge d_{j_m} \text{ THEN } d_k \, (CF = \mu_i, \, TH = \lambda_i), \tag{15}$$

where:

- $d_{j_1}, \ldots, d_{j_m}$ are fuzzy antecedent propositions (inputs),
- d_k is the fuzzy consequent proposition (output),
- $CF = \mu_i$ is the CF of the rule, representing its reliability,
- $TH = \lambda_i$ is the activation TH required for the rule to fire.

The firing condition for each rule is defined by:

$$y_k = \begin{cases} \min(y_{j_1}, \ldots, y_{j_m}) \times \mu_i, & \text{if } \min(y_{j_1}, \ldots, y_{j_m}) \geq \lambda_i, \\ 0, & \text{otherwise.} \end{cases} \tag{16}$$

The complete fuzzy rule base $\mathcal{R}$ is therefore a collection of all valid rules:

$$\mathcal{R} = \{R_1, R_2, \ldots, R_n\} \tag{17}$$

E. Formal Definition of Fuzzy Petri Net

An FPN is a bipartite-directed graph with two types of nodes: places and transitions. Circles represent places, and bars represent transitions (see Fig. 3). A token with a truth value between zero and one may or may not be present in each place in an FPN. A CF value between zero and one is assigned to each transition in an FPN. Directed arcs represent the relationships between places and transitions in an FPN. A collection of eight tuples can define a generalised FPN [1] structure

$$Fuzzy\ Petri\ Net = (P,\ T,\ D,\ I,\ O,\ f,\ \alpha,\ \beta) \tag{18}$$

Where

$P = \{p_1, \ p_2, \ \ldots, \ p_n\}$ denotes a finite set of places, represented by circles and corresponding to the propositions of FPR (see Fig. 3). $T = \{t_1, \ t_2, \ \ldots, \ t_m\}$ denotes a finite set of transitions, represented by bars and corresponding to the execution of FPR (see Fig. 3). $D = \{d_1, \ d_2, \ldots, \ d_n\}$ denotes a finite set of propositions of FPR which may contain some fuzzy linguistic variables such as "high," "low," "hot," etc. I: $T \longrightarrow P^{\propto}$ is the input function, a mapping from transitions to bags of places, represented by arcs directed from proposition (P) to rules (T). O: $T \longrightarrow P^{\propto}$ is the output function, a mapping from transitions to bags of places, represented by arcs directed from the rule (T) to propositions (P). $f : T \longrightarrow$ [0, 1] is an association function, a mapping from transitions to real values between zero and one, $f = \mu_1, \mu_2, ..., \mu_i$ where $\mu_i \in [0, 1]$ denotes (CF = μ_i) of rules R_i,$\alpha = \alpha_1, \alpha_2, ..., \alpha_n$. $\alpha : P \longrightarrow$ [0, 1] is an association function, a mapping from places to real values between zero and one, $\alpha = \alpha_1, \alpha_2, ..., \alpha_n$ where $\alpha_i \in [0, 1]$ denotes the degree of truth of propositions represented by the token in a place. β: $P \longrightarrow D$ is an association function, a bijective mapping from places to a set of propositions.

In an FPN, if $p_j \in I(t_i)$, a directed arc a_{ji} exists from the place p_j to the transition t_i. If $p_k \in O(t_i)$, there exists a directed arc a_{ik} from the transition t_i to the place p_k.The CF is a real value μ_i of a rule associated with its corresponding transition if $f(t_i) = \mu_i$ where $\mu_i \in [0, 1]$.The place p is said to be related to the proposition d if $\beta(p_i) = d_i$, where $d_i \in D$.

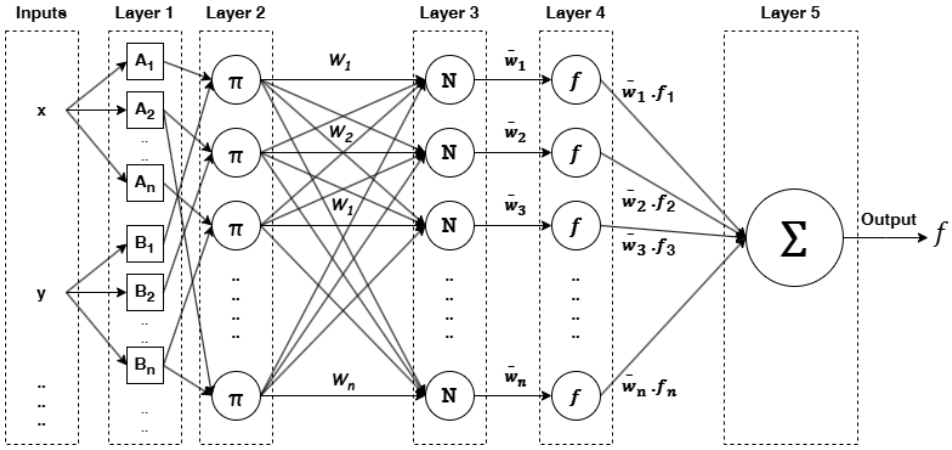

Fig. 2. Overall workflow of ANFIS-based expert systems integrated into a multi-layer FPN.

A marked FPN (see Fig. 1) is one in which a labeled dot represents some tokens in some places, a labeled dot represents the token in place p_i, and the token value in a place $p_i \in P$, is denoted by $\alpha(p_i)$, where $\alpha(p_i) \in [0,1]$. if $\alpha(p_i) = y_i$, where $y_i \in [0,1]$ and $\beta(p_i) = d_i$, then we can see that proposition d_i has a degree of truth of y_i. To reinforce the evolution capacity of our model, we can improve it by including a function $Th = \lambda_1, \lambda_2, ...\lambda_n$ where $\lambda_n \in [0,1]$ denotes the TH of transitions. When the values of tokens $\alpha(p_j)$ in all input places $p_j \in I(t_i)$ of the transition are greater than the TH $\alpha(p_j) \geq \lambda$, the transition t_i is enabled and can be fired.

F. A Multi-layer Approach to Dynamic Prediction and Decision-making

When $\alpha(p_i) \geq TH$, the transition is active, revealing a procedural adherence, identified adequately in our manuscript's Section III-D, where we present a hierarchical structure of the functionality of our system, emphasising the need for maintaining temporal constraints to prevent both computational and system-wide failures. FPN was selected because it comprises a rule-based component and readily supports simulation of real-time system dynamics. The truth-degree tokens are calibrated using data from a model's fuzzification system, with the twofold dependence on CF for concurrent FL and PN calculation for real-time prediction highlighted. This feature of our system, further illustrated with a real-life example in a conference publication [4], [8], demonstrates our approach's ability to forecast R, an important variable in renewable energy applications. In the construction of our two-layer predictive CD system, rigorous validation has been implemented to ensure that the model is robust and effective. As is often the case with machine learning model validation, 30% of the input is used to validate that the system's predictions and decisions stem from a reliable empirical base. This phase of validation is conducted on the remaining 70% of the initial dataset to ensure the dataset is valid and deployable for the model. In a post-validation version of the algorithm, based on the model's successful validation, specific data-collection and analysis intervals are determined. We adopt a Markov Chain probability model to predict new value-generating statistics to derive information for hourly CD-making (see Fig. 1). This methodology maintains a rigorous system to facilitate the execution of the entire model, from initial data processing to final decision-making and the visualisation of outputs in a structured manner. At this stage, every hour, a system performs a detailed computational analysis. The first step is to compute the average of each CD fuzzy interval, since the goal is to find the interval with the highest mean. The system's method approaches its goal by defining the interval's mean, which is then selected as the end case. For example, once the system has been running for a specific period and has been assessing data, like 24 hours, it makes one of its last adjustments to ensure that at least that interval has the highest average. This approach is heavily conditioned by predictive analytics. It means predicting forecasts at a scheduled time frame - typically 24 to 48 hours ahead to keep them in tip-top condition, such as maintaining mirrors well-kept after cleaning jobs. So, the system aims to forecast outcomes a day or two in advance, with a final decision within two days. It will allow experts to make rational, timely, and practical decisions based on this predictive process, leveraging insights from the entire system and its comprehensive analyses and forecasting. One of the aspects that sets our model apart is its ability to automatically extract outputs and present them, enabling real-time performance measurement with dynamic feedback.

G. Algorithmic Workflow

Algorithm 1 summarises the real-time inference process implemented by the FPN expert system. The system operates continuously, starting with the provision of real-time meteorological data (DNI, T, H, WS, P), which is immediately fuzzified to update the α degrees of truth at the FPN input locations. This step directly connects the current environmental conditions to the underlying fuzzy rule base. Central to this is the FPN's iterative firing cycle. The system scans for transitions t_i in every cycle and selects transitions whose input places in question have fuzzy markings α at least as large as their respective TH. Transitions are designated as enabled when they are executed. When an enabled switch fires, the output truth degree (y_{out}) is determined by applying the $\min$ operator to the input truth degrees and multiplying by the rule's CF. The value achieved is then propagated to the output points by the $\max$ operator to capture the contribution from multiple rules, and the confidence of each conclusion is updated at each

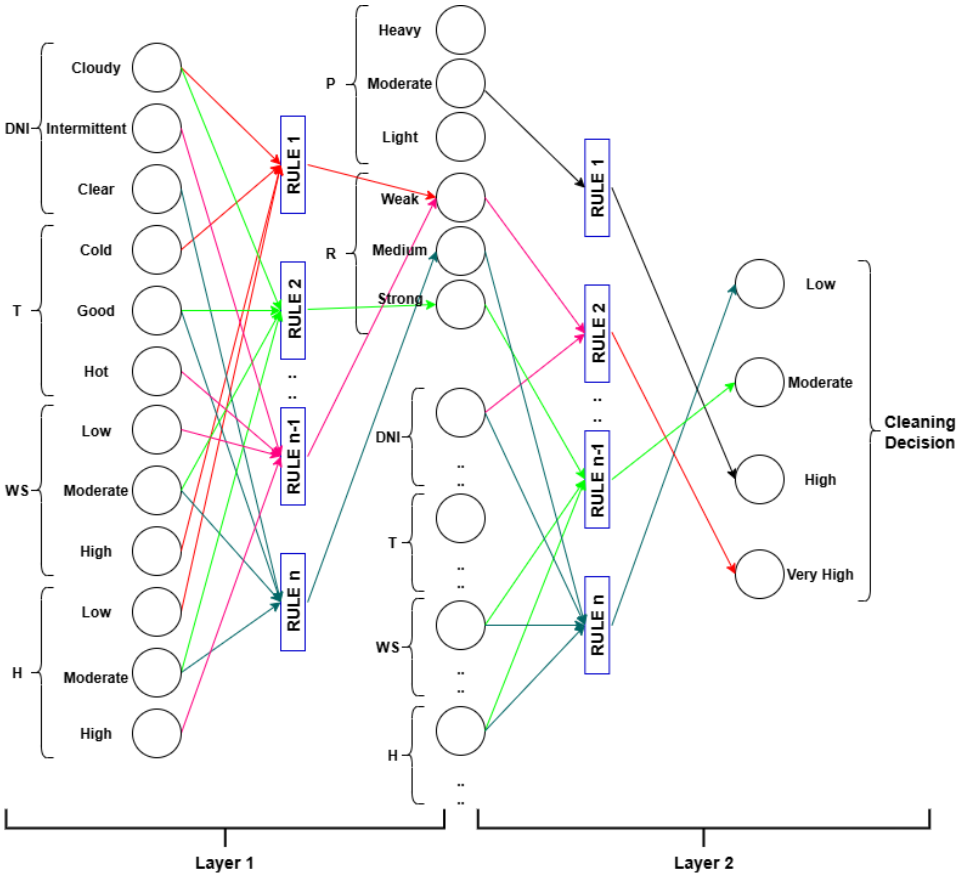

Fig. 3. A model of a solar collector's cleaning system using FPN grids to provide real-time CDs.

moment. After that, no further transitions can be tried. At the final steps of each cycle of this mechanism, the fuzzy marking of the relevant output places is derived from this number to obtain the CD. In this way, when the crisp control signal is needed to trigger or delay a cleaning action, the fuzzy output is defuzzified to reflect the situation. The resulting decision can be logged, and the process resumes with the next wave of real-time data. The FPN expert system's decision-making model is dynamic and adaptive, responding to fluctuating environmental conditions as they change.

IV. Results

In this section, the experimental validation of our proposed hybrid expert system is presented, along with an assessment of the potential value of the ANFIS-based fuzzy rule generation methodology compared with conventional probabilistic FL. We aim to demonstrate the superiority of the ANFIS-augmented model in terms of prediction accuracy, rule generation capabilities, and real-time inference efficiency. All simulations were performed with five years of real meteorological data from a solar power plant in Morocco. The data was split into 70% for training and 30% for validation. To ensure system responsiveness in real-time operation, the model was developed using a multithreaded architecture. Every fuzzy rule, such as one formed by probabilistic estimation or ANFIS training, is passed through an independent thread to the FPN engine. This architecture allows rules to be executed concurrently and also speeds up the inference phase, which is very important when dealing with large rule sets, such as those generated by ANFIS. Simulations were created to mimic natural operational scenarios comprising severe weather variability (temperature, wind speed, humidity), variable soiling conditions, and erratic sensor noise. Two expert system configurations were tested and benchmarked:

- Probabilistic FPN (Baseline): A rule base consisting of 43 FPR, derived from expert knowledge and conditional probability. Rules are associated with ($CF \geq 0.5$) and ($TH \geq 0.3$).
- ANFIS-Enhanced Fuzzy Expert System (Proposed): A data-driven expert system based on the ANFIS. ANFIS was trained on historical input-output data pairs to automatically generate 125 rules. Each rule is formulated in the Sugeno-style and converted into an FPN-compatible FPR. CFs are calculated based on RMSE: $CF = \frac{1}{1+\text{RMSE}}$.

The comparison was made over two system layers: reflectivity prediction and final CD generation.

A. Performance of Reflectivity Prediction Models

Table II compares three models: probabilistic FPN, classical FL, and ANFIS-based fuzzy inference, based on prediction accuracy and RMSE for solar reflectivity.

Algorithm 1 Real-Time Inference with FPN-based Expert System

Input: Real-time meteorological data (DNI, T, H, WS, P)
Initialize: Fuzzy rule base $\mathcal{R}$, FPN structure $(P, T, D, I, O, f, \alpha, \beta)$
while System active **do**
  Acquire and preprocess data
  Fuzzify inputs $\rightarrow$ update $\alpha(p_i)$ for all input places
  repeat
    Identify enabled transitions $\{t_i \mid \forall p_j \in I(t_i), \alpha(p_j) \geq TH_i\}$
    for each enabled t_i **do**
      Compute $y_{out} = \min(\alpha(p_j)) \times CF_i$
      Update output places: $\alpha(p_k) = \max(\alpha(p_k), y_{out})$
    end for
  until No transition can fire
  Aggregate outputs at Layer 2 $\rightarrow$ compute CD
  Defuzzify output if crisp value is required
  Log and display results
end while

TABLE II. COMPARISON OF REFLECTIVITY PREDICTION MODELS (LAYER 1)

Model	Rule Count	Validation Accuracy (%)	RMSE
Probabilistic FPN	43	85	4.82
Classical FL	30	60	6.15
ANFIS-Based FL	125	**93**	**2.57**

The ANFIS-based model clearly outperformed the others, achieving the highest accuracy and the lowest RMSE. This result validates the effectiveness of ANFIS in learning complex, nonlinear dependencies between environmental conditions (temperature, wind speed, humidity, and DNI) and reflectivity levels. The reduction in RMSE indicates a more precise reflectivity estimate, which is critical for determining the optimal timing for solar panel cleaning.

B. Cleaning Decision Validation (Layer 2)

The second layer of the system uses this to infer the best cleaning solution based on real-time sensor output and the predicted reflectivity of Layer 1. Evaluation results for the CD layer are summarised in Table III, which include precision, recall, F1-score, and RMSE. The ANFIS-enhanced classification model achieves significant gains across all metrics. Precision and recall scores show that the model can distinguish between fuzzy categories (Low, Moderate, High, Very High cleaning priority). In addition, the lower RMSE indicates that ANFIS-based decision-making yields results closer to the ground truth.

V. DISCUSSION

The results indicated that the ANFIS model can better fit the nonlinear relationship between meteorological variables and reflectivity, achieving higher accuracy and lower RMSE. Improvements to the CDs made at Layer 1, based on reflectivity predictions, enable cleaner cleaning at Layer 2 with greater reliability and less uncertainty about when and how the changes were applied. ANFIS has a cleaner, more adaptive decision boundary, as it learned all membership functions and Sugeno-type rules from the data, compared to manually decided or probabilistic ones. While the system is data-driven, it is interpretable: ANFIS produces well-defined IF–THEN rules. In contrast, the rules of the FPN remain interpretable by explicitly stating what information is accurate and which firing transition instructions to execute. This enables real-time responsiveness through concurrent execution and parallel rule evaluation, but requires more computation for larger rule bases.

The main comparative observations are as follows:

- Rule Base Expansion: A larger ANFIS produced finer-grained decision boundaries (125 rule-base vs. 43 rule-base), allowing us to consider more context-sensitive cleaning strategies.
- Higher Prediction Accuracy: The RMSE for the reflectivity prediction was reduced by almost 50%, and cleaner choices were more secure and resources allocated effectively.
- Scalability and Automation: In contrast to the static and expert-centric probabilistic rule base, the ANFIS model automatically learns new data through retraining to scale up effectively in evolving environments.
- Transparency and Interpretability: FPN architecture enables traceability of reasoning paths, while ANFIS supports flexibility, representing a complementary hybrid approach that provides a good balance of an interpretable and learned model.
- Real-Time Efficiency: The implementation of a multithreaded approach to generate the rules will help us optimise response times, even for a massive rule base, as this is an absolute necessity for a deployed system.

Therefore, pruning, merging, or prioritising may be required to prevent latencies. A hybrid approach that finds a balance between interpretability, scalability, and learning ability. Such rules are transparent, and the ANFIS is agile, providing better predictive capabilities. Such an approach could be extended to other real-time expert solutions, where transparency and adaptability are crucial, such as fault diagnosis or predictive maintenance. The need, however, arises for more validation through various datasets and operating conditions. Further work on explicit latency benchmarking,

TABLE III. VALIDATION METRICS FOR CLEANING DECISION OUTPUT

Model	Accuracy (%)	Precision Avg. (%)	Recall Avg. (%)	F1 Score (%)	RMSE
Probabilistic FPN	85	83	84	83	4.51
ANFIS-Fuzzy System	**93**	**90**	**91**	**90**	**2.57**

scalability testing under varied rule-base sizes, and long-term retraining analysis to tackle concept drift is needed.

VI. CONCLUSION

This work proposed a new methodology for modelling real-time intelligent systems by integrating FPN with data-driven rule learning via ANFIS. The primary methodological contribution, apart from the reported performance improvements, is a single model and execution scheme that integrates learned Sugeno-type fuzzy rules with an interpretable FPN reasoning engine, enabling concurrent, traceable inference across two layers (prediction and decision). From a functional standpoint, this paper illustrates how symbolic expert knowledge (FPR with CF/TH semantics) and data-driven learning can be combined into a single executable expert system that remains transparent and suitable for real-time operation. For this purpose, the proposed approach was tested in a real-time expert system for solar collector CD-making with five years of operational data collected from a Moroccan solar power plant under variable weather and soiling conditions. The results reveal that the improved prediction and decision performance of the ANFIS-enhanced setting is better than a probabilistic FPN baseline and a hand-tuned fuzzy-logic model due to the enhanced interpretability via FPN execution, as well as to a consistent inference mechanism by the decision quality using interpretable inference and the ability of responsive operation through concurrent decision making from the rule evaluation process under concurrent examination.

Data-Driven Neuro-Fuzzy learning becomes functional and interpretable in practice by mapping learned rules to a formal FPN execution model that provides traceability to reasoning and multi-layer decision. The tool will be further tested on other plants and climates, and expanded for new real-time applications in fault diagnosis and predictive maintenance. Real-time benchmarking (latency, throughput, scalability) as the rule base grows will also be planned, alongside investigation of scheduling strategies under limited resources. Ultimately, we seek formal verification and consistency checking of the learned rule base generated by the FPN tool to enhance its robustness.

***Abstract*—Time-optimal trajectory planning for shipboard welding robotic arms is a challenging problem due to strong kinematic constraints and the nonlinear coupling between trajectory parameters and execution time. Although various intelligent optimization algorithms have been combined with robotic arm trajectory planning in existing studies, most approaches primarily focus on algorithmic performance improvement and lack a clear formulation of time optimization within polynomial trajectory planning.To address this gap, this study proposes an Improved Whale Optimization Algorithm (IWOA) based on the traditional quintic polynomial trajectory planning method. In the proposed method, the trajectory execution time is explicitly formulated as the optimization objective under kinematic constraints, and the IWOA is designed to stably and efficiently search the time parameter space of the quintic polynomial trajectory. Specifically, chaotic sequence initialization is employed to enhance population distribution, an adaptive weight mechanism is introduced to balance global exploration and local exploitation, and a hybrid co-optimization strategy combining differential evolution and genetic operators is integrated to improve robustness and convergence stability. Simulation experiments are conducted to evaluate the effectiveness of the proposed algorithms. The results demonstrated that, while satisfying robotic arms kinematic constraints, the proposed method achieves an 18.3% reduction in operating time compared with the unoptimized trajectory. These results indicate that the proposed approach provides a systematic and effective solution for time-efficient trajectory planning of shipboard welding robotic arms.**

Keywords*—Shipboard welding robotic arm; quintic polynomial; Improved Whale Optimization Algorithm; time-optimal trajectory planning

I. Introduction

In recent years, with the rapid development of China shipbuilding industry and the increasing complexity of ship hull structures, higher requirements have been imposed on welding quality, efficiency, and consistency during ship construction [1]. Ship welding tasks are typically characterized by large-scale structures, complex curved surfaces, harsh working environments, and long continuous weld seams, which pose significant challenges to traditional manual and semi-automatic welding methods [2]. These conventional approaches are increasingly unable to satisfy the demands for high efficiency, precision, and repeatability required in modern shipbuilding. The application of robotic arm welding technology has emerged as an effective solution to these challenges. Robotic welding systems can significantly improve welding stability, reduce labor intensity, and ensure consistent weld quality, particularly in complex and hazardous environments [3]. With advancements in sensing, control, and intelligent planning technologies, robotic arms have been widely adopted in various industrial manufacturing fields due to their flexibility, efficiency, and high positioning accuracy [4], [5]. Consequently, shipboard welding robotic arms have attracted extensive attention from researchers and industrial practitioners worldwide, leading to notable progress in both system design and motion planning methods [6]. In terms of system development and application, Zhang et al. [7] proposed a magnetic tracked mobile robot for welding vertical steel ship hulls, enabling stable adhesion and motion on large steel surfaces. Liu et al. [8] developed a trajectory and velocity planning method for complex curved-surface welding tasks involving spherical–pipe intersection structures, achieving smooth path transitions and adaptive speed control to improve weld formation quality. Liang et al. [9] designed an autonomous mobile welding robot capable of identifying discontinuous weld seams caused by drainage holes in ship cabins and performing autonomous welding operations. These studies demonstrate the feasibility and effectiveness of robotic welding systems in shipbuilding environments. However, during ship construction, welding tasks often involve plates, pipes, and complex spatial weld seams, which require not only accurate path planning but also high operational efficiency [10]. To further enhance productivity, time-optimal trajectory planning for welding robotic arms has become a critical research topic [11].

Current studies on robotic arm trajectory planning primarily focus on optimizing performance indices such as operating time, energy consumption, smoothness, and dynamic impact [12]. Among these objectives, minimizing execution time while satisfying kinematic and dynamic constraints is of particular importance for improving industrial production efficiency.Traditional trajectory planning methods based on polynomial interpolation typically rely on predefined segment times and path nodes [13]. Although these methods can guarantee trajectory continuity and smoothness, they often lack flexibility and are difficult to achieve true time-optimal performance under complex constraints. In recent years, intelligent optimization algorithms have been increasingly introduced into robotic arm trajectory time optimization, forming an important research direction in motion planning [14]. Commonly used intelligent optimization methods include ant colony optimization [15], sparrow search algorithm [16], particle swarm opti-

mization [17], and whale optimization algorithm [18]. These algorithms have demonstrated certain advantages in improving robotic arm operating efficiency; however, they still suffer from inherent limitations such as premature convergence, susceptibility to local optima, and insufficient global search capability, which ultimately restrict their optimization performance [19].

Inspired by the foraging behavior of humpback whales in bubble webs, the Whale Optimization Algorithm (WOA) has been widely applied to various engineering optimization problems due to its advantages such as simple structure, few control parameters, and fast convergence speed [20]. However, similar to other swarm intelligence algorithms, the standard Whale Optimization Algorithm has inherent defects, including rapid loss of population diversity and easy premature convergence to local optima [21]. These defects are particularly prominent when dealing with high-dimensional, nonlinear, and constrained optimization problems [22]. Although existing research has attempted to alleviate the above problems through isolated strategies such as parameter tuning and fusion with other metaheuristic operators, such improvements are mostly designed for general test functions. For scenarios with strict kinematic constraints and industrial efficiency requirements, such as time-optimal trajectory planning for welding robotic arms, its direct applicability is still very limited [23].

To address these challenges, this study proposes an Improved Whale Optimization Algorithm (IWOA) specifically tailored for the time-optimal trajectory planning problem of welding robotic arms. Unlike existing studies that apply generic hybrid optimization strategies, the proposed IWOA introduces a problem-oriented improvement framework that integrates chaotic initialization, adaptive parameter adjustment, and a coordinated hybrid mechanism combining differential evolution and genetic operators. These strategies are not simply combined, but are systematically designed to address distinct deficiencies of the standard WOA at different stages of the optimization process: chaotic initialization enhances early-stage population diversity, adaptive parameter adjustment dynamically balances global exploration and local exploitation, and the hybrid evolutionary operators improve convergence robustness in the later optimization phase. Comparative simulations conducted in MATLAB demonstrate that, under identical constraints, the proposed IWOA achieves superior time-optimal performance compared to the standard WOA, effectively reducing the execution time of robotic arm trajectories and validating its applicability to industrial welding scenarios.

II. Joint Trajectory Planning

A. Trajectory Interpolation Based on 5th-order Polynomials

The trajectory planning of robotic arms is generally divided into two categories: joint space method and Cartesian space method [24].The joint space method directly interpolates the angles of each joint, which is simple to calculate and easily satisfies joint constraints. The Cartesian space method first plans the pose path of the end effector and then solves the inverse kinematics to obtain the joint motion, resulting in high path accuracy. Ship welding tasks require high precision in motion paths; therefore, this study employs the Cartesian space trajectory planning method. This method can control the motion trajectory of the robotic arm's end effector, achieving the operational objective along a specified path—a method that is difficult to replace using joint space planning [25].Furthermore, this study introduces a fifth-order polynomial interpolation function. By performing fifth-order polynomial fitting on the position, velocity, and acceleration of the starting and ending points, the continuity and smoothness of the joint motion process are ensured, effectively avoiding abrupt changes in velocity and acceleration. The constraints of the fifth-order polynomial interpolation include the starting and ending angles, angular velocities, and angular accelerations, requiring the determination of six coefficients. The joint variables are assumed to satisfy Eq. (1):

$$\begin{cases} \theta_i(t) = a_0 + a_1 t + a_2 t^2 + a_3 t^3 + a_4 t^4 + a_5 t^5 \\ \dot{\theta}_i(t) = a_1 + 2a_2 t + 3a_3 t^2 + 4a_4 t^3 + 5a_5 t^4 \\ \ddot{\theta}_i(t) = 2a_2 + 6a_3 t + 12a_4 t^2 + 20a_5 t^3 \end{cases} \tag{1}$$

In Eq. (1), $i = 1, 2, 3, \ldots, n$ represents the n joints of the robotic arm; t is the running time of each joint; a_j are the interpolation coefficients of each joint; $\theta_i(t)$, $\dot{\theta}_i(t)$, and $\ddot{\theta}_i(t)$ denote the angular position, angular velocity, and angular acceleration of the robotic arm joint, respectively. The constraints for the fifth-degree polynomial are:

$$\begin{cases} \begin{cases} \theta(t_0) = \theta_0 \\ \theta(t_f) = \theta_f \end{cases} \\ \begin{cases} \dot{\theta}(t_0) = 0 \\ \dot{\theta}(t_f) = 0 \end{cases} \\ \begin{cases} \ddot{\theta}(t_0) = 0 \\ \ddot{\theta}(t_f) = 0 \end{cases} \end{cases} \tag{2}$$

In Eq. (2), t_0 and t_f represent the start time and end time of the robotic arm operation, respectively, and θ_0 and θ_f represent the start angle and end angle, respectively. From Eq. (1) and Eq. (2), the corresponding kinematic equations for each joint can be derived:

$$\begin{cases} \theta_0 = a_0 + a_1 t_0 + a_2 t_0^2 + a_3 t_0^3 + a_4 t_0^4 + a_5 t_0^5 \\ v_0 = a_1 + 2a_2 t_0 + 3a_3 t_0^2 + 4a_4 t_0^3 + 5a_5 t_0^4 \\ \alpha_0 = 2a_2 + 6a_3 t_0 + 12a_4 t_0^2 + 20a_5 t_0^3 \\ \theta_f = a_0 + a_1 t_f + a_2 t_f^2 + a_3 t_f^3 + a_4 t_f^4 + a_5 t_f^5 \\ v_f = a_1 + 2a_2 t_f + 3a_3 t_f^2 + 4a_4 t_f^3 + 5a_5 t_f^4 \\ \alpha_f = 2a_2 + 6a_3 t_f + 12a_4 t_f^2 + 20a_5 t_f^3 \end{cases} \tag{3}$$

Then, substitute the known θ_0, θ_f, v_0, v_f, α_0, and α_f into Eq. (3) to obtain the parameter matrix of the kinematic equation for each joint:

$$\begin{bmatrix} a_0 \\ a_1 \\ a_2 \\ a_3 \\ a_4 \\ a_5 \end{bmatrix} = \begin{bmatrix} 1 & t_0 & t_0^2 & t_0^3 & t_0^4 & t_0^5 \\ 0 & 1 & 2t_0 & 3t_0^2 & 4t_0^3 & 5t_0^4 \\ 0 & 0 & 2 & 6t_0 & 12t_0^2 & 20t_0^3 \\ 1 & t_f & t_f^2 & t_f^3 & t_f^4 & t_f^5 \\ 0 & 1 & 2t_f & 3t_f^2 & 4t_f^3 & 5t_f^4 \\ 0 & 0 & 2 & 6t_f & 12t_f^2 & 20t_f^3 \end{bmatrix}^{-1} \begin{bmatrix} \theta_0 \\ v_0 \\ \alpha_0 \\ \theta_f \\ v_f \\ \alpha_f \end{bmatrix} \tag{4}$$

By substituting the solved coefficient matrix from Eq. (4) into Eq. (1), the spatial trajectory function of the robotic arm joint is obtained.

B. Objective Function and Constraint Conditions

To meet the requirement of improving the operation efficiency of the welding robotic arm in the ship welding process, this study takes the motion cycle of the robotic arm reaching each target point as the optimization objective. Then, the objective function can be expressed as Eq. (5):

$$T = \sum_{i=1}^{n-1} T_i = \sum_{i=1}^{n-1} (t_{i+1} - t_i) \tag{5}$$

In Eq. (5), $i = 1, 2, \ldots, n$ represents n path points, and T represents the running time of the robotic arm end on each segment of the path.

Since the motion constraints in the joint space of the robotic arm are strictly satisfied during its movement, the problem of optimizing the running time of the robotic arm can be formulated as Eq. (6):

$$\min T = T_1 + T_2 + \cdots + T_{n-1} \tag{6}$$

Since the position, velocity, and acceleration of each joint of the robotic arm cannot exceed the rated limits of the motor and reducer during movement, it is necessary to impose physical limit constraints on the robotic arm. The constraint conditions are shown in Eq. (7):

$$\begin{cases} |\theta_i| \le q_{i\max} \\ |\dot{\theta}_i| \le v_{i\max} \\ |\ddot{\theta}_i| \le a_{i\max} \end{cases} \quad (i = 1, 2, \ldots, n) \tag{7}$$

θ_i, $\dot{\theta}_i$, and $\ddot{\theta}_i$ represent the angular position, angular velocity, and angular acceleration of the i-th joint, respectively; $q_{i\max}$, $v_{i\max}$, and $a_{i\max}$ represent the rated upper limits of the angular position, angular velocity, and angular acceleration of the corresponding joint, respectively; n is the total number of joints of the robotic arm.

III. Algorithm Principle

A. Original Whale Optimization Algorithm

The core of the Whale Optimization Algorithm is to imitate three behaviors of whales during predation.

Encircling prey:

$$\vec{D} = \left| \vec{C} \cdot \vec{X}^*(t) - \vec{X}(t) \right| \tag{8}$$

$$\vec{X}(t+1) = \vec{X}^*(t) - \vec{A} \cdot \vec{D} \tag{9}$$

In Eq. (8) and Eq. (9), $\vec{X}^*(t)$ represents the current optimal position, $\vec{X}(t)$ is the current position of the whale, $\vec{D}$ is the distance between the current position and the optimal position, and $\vec{A}$ and $\vec{C}$ are system vectors that control the convergence and search range.

Bubble-net attack:

$$\vec{X}(t+1) = \vec{D}' \cdot e^{bl} \cdot \cos(2\pi l) + \vec{X}^*(t) \tag{10}$$

In Eq. (10), $\vec{X}(t+1)$ represents the position vector of the individual at generation $t+1$; $\vec{X}^*(t)$ represents the position vector of the optimal individual at generation t; $\vec{D}' = |\vec{X}^*(t) - \vec{X}(t)|$ represents the distance between the current individual and the optimal individual; b is a constant that controls the shape of the logarithmic spiral; l is a random number within the interval $[-1, 1]$.

Searching for prey:

$$\vec{D} = \left| \vec{C} \cdot \vec{X}_{rand} - \vec{X}(t) \right| \tag{11}$$

$$\vec{X}(t+1) = \vec{X}_{rand} - \vec{A} \cdot \vec{D} \tag{12}$$

As shown in Eq. (11) and Eq. (12), $\vec{X}_{rand}$ is the position of a randomly selected individual in the population. $\vec{A} = 2a \cdot r - a$, where a decreases linearly from 2 to 0 during the iteration process. $\vec{C} = 2 \cdot r$, where r is a random number in the interval $[0, 1]$. When $|\vec{A}| < 1$: the whale tends to the current optimal solution; when $|\vec{A}| \ge 1$: the whale randomly searches for other prey.

B. Improvement Mechanism

Due to the shortcomings of the WOA, such as being prone to premature convergence and falling into local optima, as well as strong randomness leading to unstable results, this study proposes the following improvement strategies to enhance the performance of the original Whale Optimization Algorithm in robotic arm trajectory planning:

1) Chaotic initialization: First, the Tent chaotic map is used to replace random initialization to avoid the problem of uneven initial distribution of the population.

$$x_{k+1} = \begin{cases} \dfrac{x_k}{0.5}, & 0 \le x_k < 0.5 \\ \dfrac{1 - x_k}{0.5}, & 0.5 \le x_k \le 1 \end{cases} \tag{13}$$

As shown in Eq. (13), the Tent chaotic map has ergodicity and pseudo-randomness, which can ensure that individuals are evenly distributed in the search space, thereby improving the diversity of the initial population. In addition, to enhance the local exploitation ability, a small chaotic disturbance is applied to the current global optimal solution during the iteration, and the disturbance amplitude is gradually reduced to prevent the algorithm from stagnating at a local optimum.

2) Adaptive parameter adjustment: To address the limitation of linear decrement of parameters in the Whale Optimization Algorithm, this study designs an adaptive control mechanism based on nonlinear functions and cosine functions:

$$a_t = 2\left(1 - \left(\frac{t}{T}\right)^2\right) \tag{14}$$

a_t is the control parameter at the t-th iteration, where t is the current number of iterations and T is the maximum number of iterations. Eq. (14) allows the algorithm to maintain stronger exploration ability in the early stage and gradually enhance exploitation in the later stage.

The spiral control factor b_t is defined as Eq. (15):

$$b_t = 1 + 1.5\left(1 - \frac{t}{T}\right) \tag{15}$$

which dynamically adjusts the spiral search behavior during the optimization process. In addition, the concept probability parameter p_t, which controls the selection between encircling search and spiral search, is defined as Eq. (16):

$$p_t = 0.5 + 0.5\cos\left(\pi\frac{t}{T}\right) \tag{16}$$

Eq. (16) controls the selection probability of encircling search and spiral search, achieving a dynamic balance between exploration and exploitation.

3) Integration of differential evolution and genetic operators: To enhance the ability to jump out of local optima, this study introduces the crossover operators of differential evolution and genetic algorithm into the Whale Optimization Algorithm after its iterative update.

Differential evolution and genetic operator fusion:

The rand/1/bin strategy is adopted to generate candidate individuals, improving the directionality of the search. The mathematical model is as follows:

$$V_i = X_{r1} + F \cdot (X_{r2} - X_{r3}) \tag{17}$$

$$U_{i,j} = \begin{cases} V_{i,j}, & \text{rand} \le CR \\ X_{i,j}, & \text{otherwise} \end{cases} \tag{18}$$

Eq. (17) and Eq. (18) enhance the directional search ability of the population. Among them, V_i represents the mutation vector of the i-th candidate individual, i.e., the newly generated candidate solution. X_{r1}, X_{r2}, X_{r3}: three different individuals randomly selected from the population, and different from the current individual X_i. F is the scaling factor, usually ranging from 0.4 to 0.90, and CR is the crossover probability, usually ranging from 0.6 to 0.95.

In addition to DE operators, arithmetic crossover and Gaussian mutation from genetic algorithms are introduced to improve local search capability. The arithmetic crossover is defined as Eq. (19):

$$X' = \alpha X_i + (1-\alpha)X_j, \alpha \in [0,1] \tag{19}$$

X' is a new candidate solution generated by arithmetic crossover, and α, as a crossover coefficient, is used to control the contribution proportion of the two parent individuals X_i and X_j to the new individual X'. X_i and X_j are the two original candidate solutions involved in the crossover. Eq. (19) enables the fusion of two parent individuals to generate a new candidate solution through linear interpolation, thereby increasing the diversity of the population and providing a foundation for subsequent improvement of local search ability.

C. Steps of the Improved Whale Optimization Algorithm

1) Initialize the number of whales and define relevant parameters.

2) Use the Tent chaotic map to generate the initial population, replacing the traditional random initialization to improve population diversity and global coverage capability.

3) During the iteration process, adaptively and nonlinearly adjust parameters a, b, and p to ensure exploration capability in the early stage and enhance convergence in the later stage.

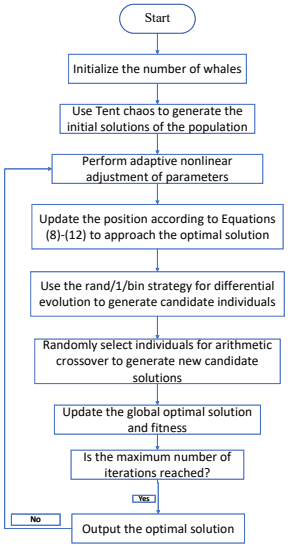
4) Update the position: update the whale position according to Eq. (9) and Eq. (10) to approach the optimal solution. Perform spiral update according to Eq. (11), and then conduct global random search according to Eq. (12) and Eq. (13).

5) After the update, apply evolutionary operators to some individuals: use the rand/1/bin strategy for mutation and crossover to generate candidate solutions.

6) Perform arithmetic crossover and Gaussian perturbation on some individuals to enhance local exploitation capability.

7) Update the global optimal solution and fitness. If the maximum number of iterations T is reached, terminate the loop and output the optimal solution; otherwise, return to step 3 to continue the search.

The algorithm flowchart is shown in Fig. 1.



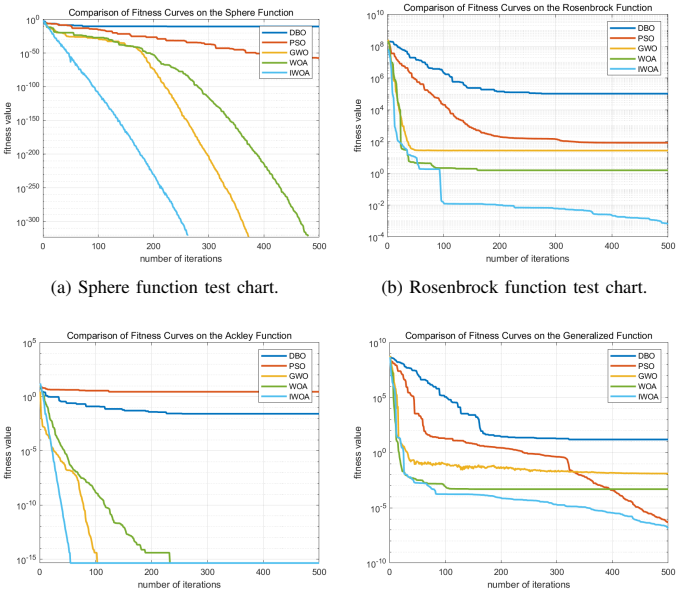


Fig. 1. Algorithm flowchart.

D. Validation of Algorithm Effectiveness

In this study, four classic CEC test functions are selected to verify the effectiveness of the Improved Whale Optimization Algorithm [26]: Sphere (F1), Rosenbrock (F5), Ackley (F10), and Generalized (F12) functions are used for test evaluation. These functions cover both unimodal and multimodal cases, and can evaluate the basic convergence performance, local

(d) Generalized function test chart.

Fig. 2. Comparison chart of different benchmark function algorithm tests.

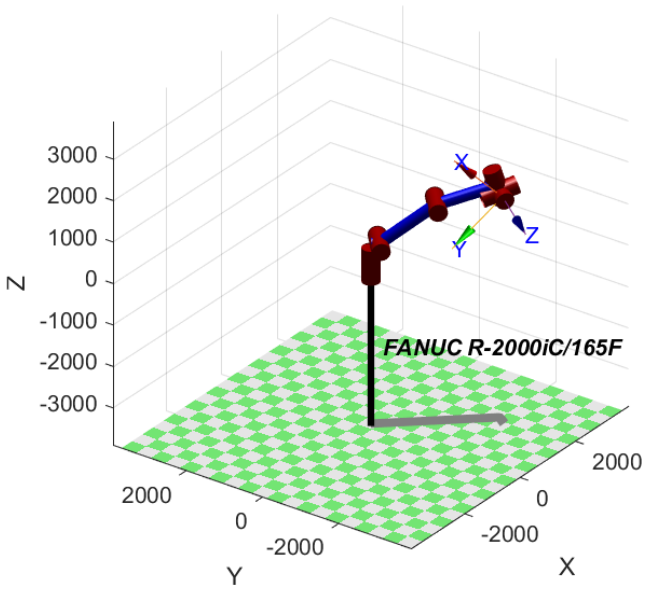

Fig. 3. Robotic arm model.

search ability and global search ability of the algorithm. The formulas of the selected test functions are shown in Table I.

In this algorithm validation, the IWOA is compared with the WOA, Dung Beetle Optimization algorithm (DBO), Particle Swarm Optimization algorithm (PSO), and Grey Wolf Optimization algorithm (GWO). The experimental parameters are set as follows: the population size is 50, the maximum number of iterations is 500, and the optimization dimension is 40. Each algorithm is run 30 times and the average results are taken to reduce the impact of randomness on the experimental results. The test results of each test function are shown in Table II.

It can be seen from Table II that IWOA exhibits excellent global optimization and convergence performance on all test functions. The best value is close to or reaches 0, the mean value is stable and the lowest, the standard deviation is the smallest, the result fluctuation is the least, and the convergence stability is the best. Fig. 2 shows the fitness iteration convergence diagram of each function.

The Sphere function is used to test the basic convergence performance of the algorithm. As can be seen from Fig. 2a, IWOA converges faster in the early stage and finally reaches the optimal value of 0, indicating that it has good global convergence ability. The Rosenbrock function is used to evaluate the local search performance. Fig. 2b shows that the algorithm decreases rapidly in the early stage, which benefits from the combination of Kent chaotic mapping and adaptive parameters. In contrast, the remaining algorithms converge slowly and are prone to falling into local optima. The Ackley function is used to verify the ability to escape from local optima. Fig. 2c shows that IWOA can quickly get rid of local traps and converge stably, while other algorithms are prone to stagnation. The Generalized function is used to measure the balance between global and local search. Fig. 2d shows that IWOA converges smoothly without premature convergence, showing stronger stability and global optimization performance.

IV. Simulation and Analysis

A. Robotic Arm Model

To verify the effectiveness of the algorithm, this study takes the R-2000iC/165F robotic arm of the industrial robot FANUC as the research object. First, the D-H modeling method is used to construct the robotic arm model, as shown in Fig. 3. The model includes a base and six robotic arm joints. The relevant parameters of the robotic arm model are shown in Table III, where i represents the link sequence number; a_{i-1} represents the link length, which is the length of the common normal between two rotational joint axes; the link twist α_{i-1} is the offset angle of the two joint axes; the link offset d_i is the vertical offset between two adjacent joints, that is, the offset distance along the z-axis; the joint angle θ_i is the rotation amount of the i-th joint relative to the initial position. The schematic diagram of the robotic arm joint coordinate system is shown in Fig. 4.

After establishing the coordinate system of the 6-degree-of-freedom robotic arm using D-H parameters, the obtained D-H transformation matrix needs to satisfy Eq. (20).

$$ {}^{i+1}_{i}A = \begin{bmatrix} \cos\theta_{i+1} & -\sin\theta_{i+1} & 0 & a_i \\ \sin\theta_{i+1}\cos\alpha_i & \cos\theta_{i+1}\cos\alpha_i & -\sin\alpha_i & -\sin\alpha_i d_{i+1} \\ \sin\theta_{i+1}\sin\alpha_i & \cos\theta_{i+1}\sin\alpha_i & \cos\alpha_i & \cos\alpha_i d_{i+1} \\ 0 & 0 & 0 & 0 \end{bmatrix} \tag{20} $$

${}^{i+1}_{i}A$ represents the homogeneous transformation matrix from d_i to d_{i+1}. By substituting the corresponding parameters in the D-H parameters into Eq. (20), the corresponding transformation matrix is obtained, and then $\{{}^{1}_{0}A, {}^{2}_{1}A, {}^{3}_{2}A, {}^{4}_{3}A, {}^{5}_{4}A, {}^{6}_{5}A\}$ is calculated, as shown in Eq. 21.

TABLE I. TEST FUNCTIONS

TABLE III. D-H PARAMETERS OF THE ROBOTIC ARM

Joint No. (i)	a_{i-1}	α_{i-1}	d_i	θ_i
1	175	$-\pi/2$	490	θ_1
2	1500	0	0	θ_2
3	1350	$-\pi/2$	0	θ_3
4	0	$\pi/2$	162	θ_4
5	0	$-\pi/2$	0	θ_5
6	0	0	220	θ_6

$$
\begin{aligned}
{}^{0}_{1}A &= \begin{bmatrix} C1 & -S1 & 0 & 175 \\ 0 & 0 & 1 & 490 \\ -S1 & -C1 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{bmatrix};
{}^{2}_{1}A = \begin{bmatrix} C2 & -S2 & 0 & 1500 \\ S2 & C2 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix};
{}^{3}_{2}A = \begin{bmatrix} C3 & -S3 & 0 & 1350 \\ 0 & 0 & 1 & 0 \\ -S3 & -C3 & 0 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix} \\
{}^{4}_{3}A &= \begin{bmatrix} C4 & -S4 & 0 & 0 \\ 0 & 0 & -1 & -162 \\ S4 & C4 & 0 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix};
{}^{5}_{4}A = \begin{bmatrix} C5 & -S5 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ -S5 & -C5 & 0 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix};
{}^{6}_{5}A = \begin{bmatrix} C6 & -S6 & 0 & 0 \\ S6 & C6 & 0 & 0 \\ 0 & 0 & 1 & 220 \\ 0 & 0 & 0 & 1 \end{bmatrix}
\end{aligned}
\tag{21}
$$

In Eq. 22, $C1$ represents $\cos\theta_1$, and $S1$ represents $\sin\theta_1$. ${}^{6}_{0}A$ denotes the total transformation matrix from the robot base to the end-effector, that is, the position of the end of the link in coordinate system O_0 relative to the base, which is obtained in matrix form through Eq. 22.

$$ {}^{6}_{0}A = {}^{1}_{0}A^{2}_{1}A^{3}_{2}A^{4}_{3}A^{5}_{4}A^{6}_{5}A \tag{22} $$

By establishing the link structure model of the robotic arm using the D-H parameter method, the position and posture of the robotic arm's end-effector in the coordinate system can be obtained through the forward kinematics equations under the premise that each joint angle is known.

B. Robotic arm Trajectory Planning

To verify the effectiveness of the Improved Whale Optimization Algorithm in robotic arm trajectory planning, three waypoints are specified within the kinematic constraint space of the FANUC R-2000iC/165F robotic arm. Fifth-order polynomial interpolation is adopted for trajectory planning to ensure continuous velocity and acceleration of the robotic arm. On this basis, the Improved Whale Optimization Algorithm is used to optimize the trajectory time of the robotic arm, and a comparison is made with the original whale optimization algorithm. Table IV shows the Cartesian space information of the end-effector of the FANUC R-2000iC/165F robotic arm passing through the three specified waypoints. Then, the joint position information of the waypoints in the robotic arm is obtained through inverse kinematics analysis, and Table V presents the corresponding joint position information of these three waypoints.

During the process of passing through two path segments, the operation time of each joint in each path segment is set to 5 seconds. Meanwhile, to meet the constraint conditions of the robotic arm, the maximum angular velocity of the robotic arm joints is set to $\dot{\theta}_{j\max} = 3\,\text{rad/s}$, and the maximum angular acceleration is set to $\ddot{\theta}_{j\max} = 3.5\,\text{rad/s}^2$. According to the requirements of the ship spot welding process, the velocity of the robotic arm must be 0 when passing through each welding waypoint. By substituting the above three interpolation points into the fifth-order polynomial interpolation function and using MATLAB R2024a for trajectory planning of the robotic arm, the trajectory of the end-effector of the robotic arm in the workspace is obtained, as shown in Fig. 5. The position, velocity, and acceleration curves of the six joints after fifth-order polynomial trajectory planning are shown in Fig. 6.

It can be observed from Fig. 6 that the interpolation time combination of the fifth-order polynomial is (5, 5), so the total time is 10 s. Among them, the maximum angular velocity is 1.53 rad/s, and the maximum angular acceleration is 0.94 rad/s², which meet the constraint conditions of the robotic arm. However, to further improve the operating efficiency of the system, it is still necessary to optimize the trajectory to shorten the operating time on the basis of ensuring trajectory smoothness.

C. Optimal Time Planning of Robotic Arm

This study adopts the IWOA for time optimization of the robotic arm trajectory. In the experiment, the population size is set to 30, and the maximum number of iterations is 300. Due to the randomness of trajectory planning results, each algorithm is run 50 times, and the average value is taken as the performance evaluation index. To verify the algorithm performance, the motion time curves of joint angle, angular velocity, and angular acceleration between IWOA and the original WOA are compared and analyzed, as shown in Fig. 7.

It can be seen from Fig. 7 that the displacement, velocity, and acceleration curves of the robotic arm optimized by the WOA and the IWOA all show smooth and continuous changes without obvious mutations, indicating that the robotic arm can pass through each waypoint stably. Meanwhile, by sorting out the optimized data of each joint in Fig. 6 and Fig. 7, the optimization times of the fifth-order polynomial, WOA, and IWOA when passing through each waypoint are obtained, as shown in Table VI.

It can be seen from Table VI that the time combination of the fifth-order polynomial is (5, 5) with a total time of 10 s. The optimal time combination of WOA is (3.26, 2.48) and the total time is 5.74 s. The optimal time combination of IWOA is (2.76, 1.93) with a total time of 4.69 s. Both the WOA and IWOA algorithms can achieve the effect of optimizing the operation time, but the IWOA is more effective in optimization performance, which greatly improves the working efficiency of the robotic arm.

V. Experiments

A. Experimental Purpose

To further verify the feasibility and effectiveness of the robotic arm trajectory planning based on the Improved Whale Optimization Algorithm (IWOA) in actual industrial environments, this chapter designs a comparative experiment based on the RoboGuide simulation platform and the FANUC physical robotic arm system. By executing the same path task in both virtual and real environments, the performance of the trajectory generated by the algorithm in terms of path accuracy and time optimization effect is evaluated, thereby verifying the algorithm's implementability and robustness.

The simulation completed in the MATLAB environment is mainly used to verify the performance of IWOA-DEGA at the mathematical model level, including the time optimality and path smoothness of trajectory planning. At this stage, the focus is on evaluating the algorithm's global optimization capability and optimization effect. However, simulations only in MATLAB cannot fully reflect the execution feasibility of the algorithm in real robotic arm systems.

For this reason, this study further conducts engineering-level simulation in the FANUC RoboGuide platform. RoboGuide can realistically simulate the geometric structure, joint motion constraints, and dynamic characteristics of the robotic arm, and supports the modeling of external workpieces, fixtures, sensors, and other elements. By importing the optimal trajectory generated by IWOA into RoboGuide and setting a cuboid workpiece model consistent with the laboratory environment, the executability, safety, and spatial rationality of the planned trajectory in the actual space can be effectively verified.

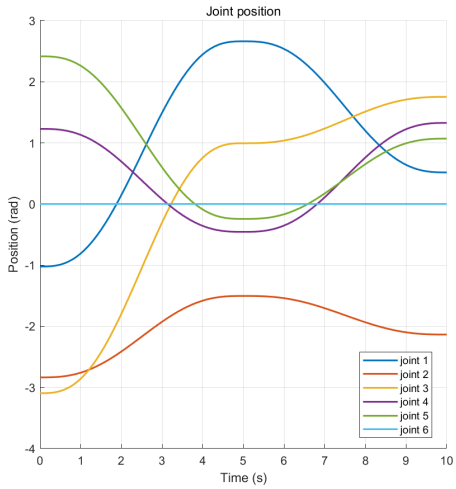
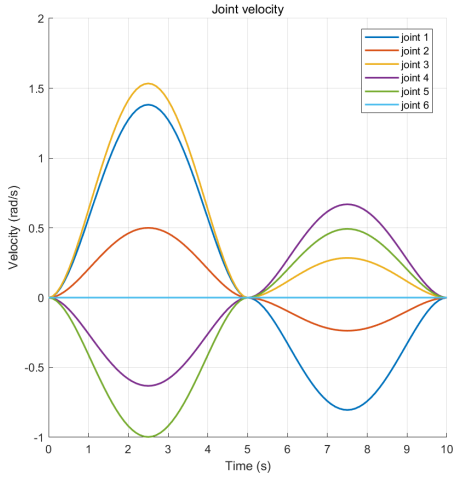
B. Experimental Platform and Equipment



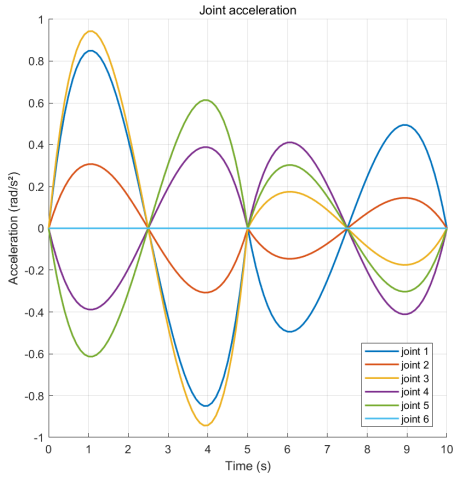
1) Simulation experiment platform: The simulation experiment is carried out based on the FANUC RoboGuide software. This platform can realize 3D modeling, path planning, collision detection, and offline programming of the robotic arm. The robotic arm model used in the experiment is FANUC R-2000iC/165F, and its virtual model is established in RoboGuide. A cuboid workpiece with dimensions of L×W×H = 300 mm × 200 mm × 150 mm is placed as the operation object. Four fixed waypoints (P1, P2, P3, P4) are selected on the surface of the workpiece, and the robotic arm needs to pass through these four waypoints in sequence to complete the trajectory movement.

2) Laboratory physical platform: The physical experiment constructs a test environment consistent with the simulation in the laboratory. The same FANUC R-2000iC/165F robotic arm is adopted, driven and controlled by the R-30iB control system. A cuboid workpiece with the same dimensions and position as in the simulation is placed on the test bench to ensure the consistency of experimental conditions. The robotic arm control program is generated through offline programming in RoboGuide and imported into the physical control system via the teach pendant for execution.



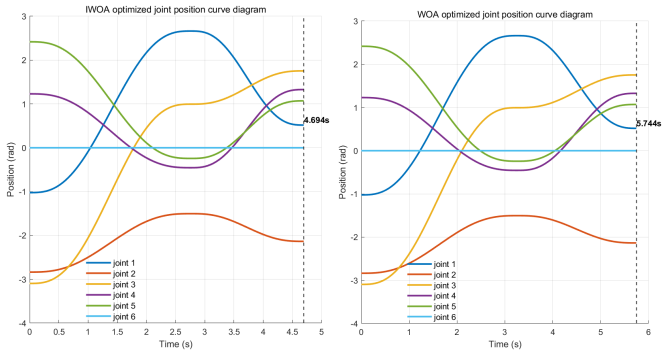
C. Experimental Results and Analysis

1) Simulation results: Fig. 8 shows the changes in the motion posture of the robotic arm when it passes through waypoints P1–P4 in sequence during the RoboGuide simulation. It can be seen from the figure that the end effector of the robotic arm moves smoothly and continuously without oscillation or sudden changes, indicating that the trajectory generated by IWOA has good dynamic smoothness and control stability. Consistent with the results obtained in the MATLAB simulation, the RoboGuide simulation further verifies the effectiveness of IWOA in terms of time optimization. According to the operation time statistics output by RoboGuide, the average operation time of the trajectory planned by IWOA is 18% less than that of the unoptimized trajectory, and the acceleration and deceleration transitions between each path segment are smoother, which effectively reduces the idle travel time of the robotic arm and unnecessary speed fluctuations.

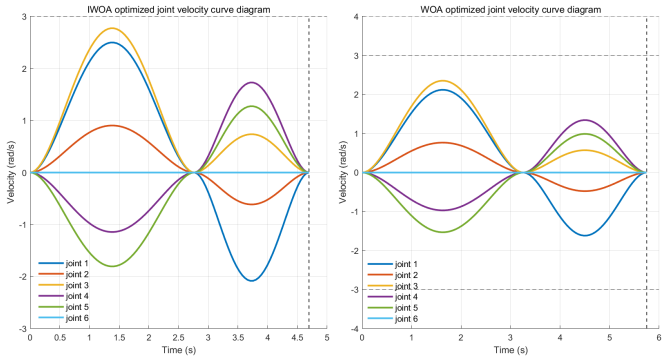


2) Physical experiment results: Fig. 9 shows the motion states of the FANUC R-2000iC/165F robotic arm in the laboratory as it passes through waypoints P1–P4 in sequence.

(a) Angular displacement variation curves of each joint.



(b) Velocity variation curves of each joint.



(c) Acceleration variation curves of each joint.

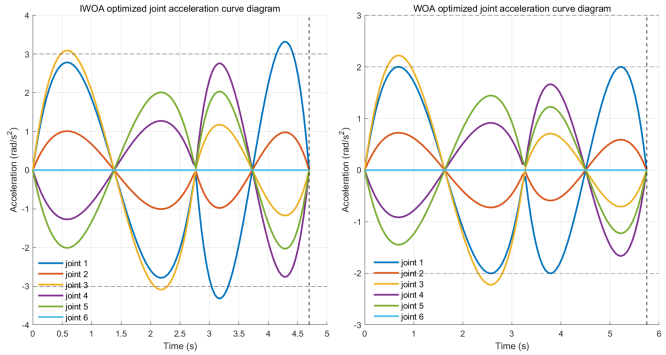


Fig. 6. Motion curve of six-degree-of-freedom robotic arm trajectory planning based on quintic polynomial interpolation.

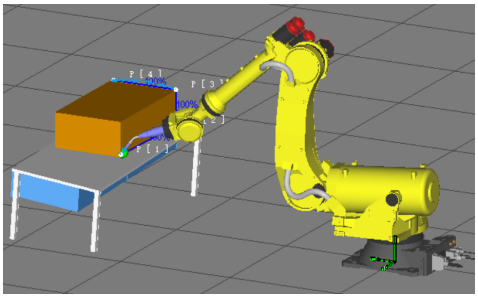
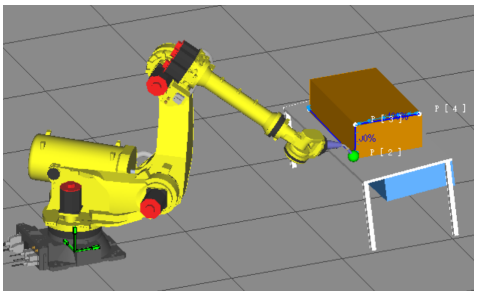
(a) Comparison diagram of angular displacement curves of each joint.

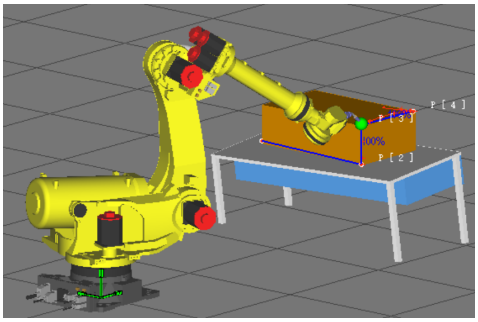


(b) Comparison diagram of angular velocity curves of each joint.

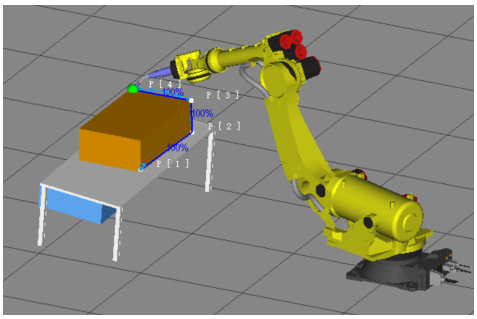


(c) Comparison diagram of angular acceleration curves of each joint.

Fig. 7. Comparison diagram of joint motion curves before and after the improved algorithm.



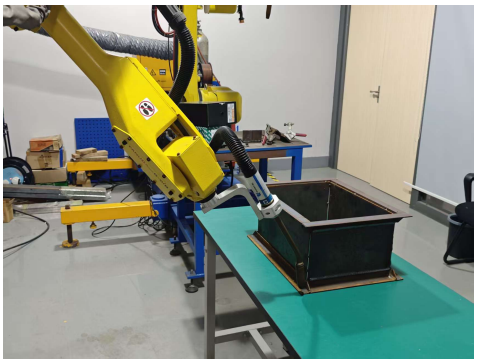
In the experiment, the robotic arm control program is generated by offline programming in RoboGuide, ensuring that the experimental path is completely consistent with the simulation path. It can be seen from the experimental results that the robotic arm moves smoothly and maintains consistent postures between each waypoint, with the end position error controlled within ±2 mm. More importantly, the operation time trend of the physical test is consistent with the simulation results. The trajectory optimized by IWOA reduces the average operation time by 16.4% compared with the original trajectory for the same task, verifying the time optimization effect of the algorithm in actual industrial control systems.



(a) The robotic arm reaches waypoint P1 in RoboGuide.

(b) The robotic arm reaches waypoint P2 in RoboGuide.

(c) The robotic arm reaches waypoint P3 in RoboGuide.



(d) The robotic arm reaches waypoint P4 in RoboGuide.

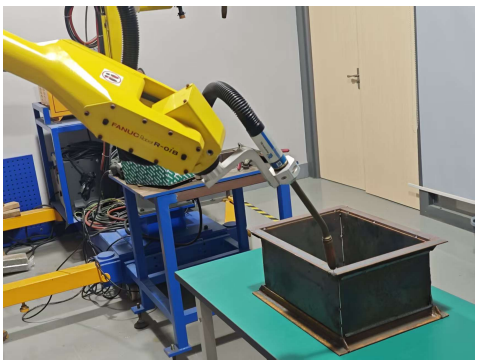


Fig. 8. Trajectory diagram of the robotic arm in RoboGuide simulation.

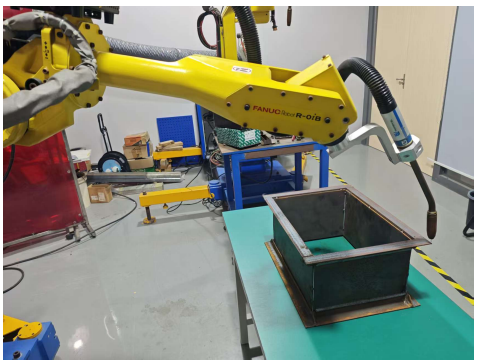

(a) The laboratory robotic arm reaches waypoint P1.

(b) The laboratory robotic arm reaches waypoint P2.

(c) The laboratory robotic arm reaches waypoint P3.

(d) The laboratory robotic arm reaches waypoint P4.

Fig. 9. Trajectory diagram of the laboratory robotic arm.

Through comparison, it is found that the physical experiment results are highly consistent with the RoboGuide simulation results in terms of path shape, attitude change, and operation time. This indicates that the IWOA can effectively generate time-optimal and executable robotic arm trajectories in real-world environments, demonstrating excellent engineering feasibility and application potential.

VI. Conclusion

This study proposes a trajectory planning for the FANUC R-2000iC/165F welding robotic arm based on an Improved Whale Optimization Algorithm (IWOA). The main theoretical contribution of this work lies in integrating quintic polynomial trajectory planning with the IWOA for time-optimal trajectory generation, thereby enhancing both the convergence speed and global optimization capability of traditional metaheuristic algorithms in robotic arm applications. Simulation and experimental results demonstrate that the IWOA significantly outperforms the original WOA in terms of trajectory optimization. Under identical kinematic constraints, the IWOA reduces the total operation time from 10 s to 4.69 s, compared with 5.74 s achieved by WOA. In RoboGuide simulation, the IWOA-optimized trajectory reduces average operation time by 18%, while physical experiments confirm a 16.4% reduction, with end-effector positioning errors controlled within ±2 mm. The results highlight the algorithm's effectiveness in generating smooth, continuous, and executable trajectories while maintaining operational safety. This also demonstrates that the metaheuristic algorithm employing chaotic mapping and adaptive parameter enhancement can effectively address the trade-off between global search and local optimization in high-dimensional trajectory optimization problems.

Despite these contributions, several limitations exist. The current study considers only a single robotic arm model and a limited number of waypoints, and does not account for dynamic external disturbances or varying payloads, which may affect real-world performance. Future research will extend the method to multi-arm coordinated welding tasks, incorporate dynamic obstacle avoidance, and explore real-time adaptive trajectory optimization under uncertain industrial environments.

An RBAC-Based Access Control and Security Architecture for UAV Networks in Precision Agriculture Using Software-Defined Drone Networking

Nadia Kammoun, Aida Ben Chehida Douss, Ryma Abassi
Innov'com Laboratory, Sup'com,
University of Carthage,
Tunis, Tunisia

***Abstract*—Unmanned Aerial Vehicles (UAVs), commonly referred to as drones, are widely employed in applications such as surveillance, delivery, mapping, and precision agriculture. Their flexibility, mobility, and cost effectiveness have accelerated their adoption in both civilian and industrial domains. However, the rapid evolution of UAV technologies introduces significant challenges related to limited resources, data processing constraints, and, most critically, security and privacy. Cyberattacks targeting UAV systems may result in data breaches, mission failures, operational disruptions, and risks to human safety. In our previous work, we proposed a lightweight identity authentication scheme based on Elliptic Curve Cryptography (ECC) and integrated it into a Software-Defined Drone Network (SDDN) architecture to ensure strong security with low computational overhead. Building on this foundation, the present study focuses on the agricultural domain, where UAVs are increasingly used for crop monitoring, precision farming, and environmental data collection. Due to the sensitivity of agricultural data and the involvement of multiple stakeholders, fine-grained access control is essential. The main contribution of this work is the design and evaluation of an SDDN-based security framework that integrates role-based access control (RBAC) with trust management to enable secure, scalable, and controlled UAV operations in agricultural environments. The framework restricts user actions according to predefined roles, improving system security and manageability. Simulation results demonstrate that the proposed approach effectively enforces access policies, enhances trust-aware decision making, and maintains low computational overhead suitable for resource-constrained UAV networks. Validation is conducted using Python and YAML-based configurations on Google Colab, confirming the practicality of the proposed solution.**

Keywords*—Unmanned Aerial Vehicles; Software-Defined Drone Network; role-based access control; security; attacks; trust management; authentication; access control

I. Introduction

In recent years, Unmanned Aerial Vehicles (UAVs), commonly known as drones, have seen rapid adoption across a wide range of civilian and industrial applications. Originally developed for military purposes, UAVs are now widely used in agriculture, environmental monitoring, logistics, infrastructure inspection, and public safety [1]. Their ability to operate remotely, cover large areas, and collect high-resolution data in real-time makes them valuable tools for both routine and critical missions. With the advancement of communication technologies and autonomous flight systems, UAVs are no longer limited to isolated tasks but increasingly operate in coordinated swarms, enabling more complex and large-scale operations [2]. However, this growth also introduces significant challenges related to data security, system integrity, and operational safety.

To address security challenges in dynamic and decentralized UAV environments, trust management plays a key role in evaluating the reliability of users, devices, and links. It enhances security by enabling data fusion, excluding malicious nodes, protecting privacy, and supporting context-aware services [3]. Trust management also improves decision-making through reputation and recommendation mechanisms, while optimizing resource allocation and scalability in multi-UAV systems.

Clustering complements trust management by organizing UAVs into hierarchical groups, improving scalability, energy efficiency, and control through designated cluster heads. Our previous work proposed a trust-based clustering approach for IoT systems, where nodes are evaluated based on trust levels, reputation, and recommendations to form reliable clusters. Malicious nodes are excluded, and a rehabilitation process allows trusted reintegration [4]. This method considers IoT constraints such as limited energy and processing.

However, trust alone is insufficient. Authentication remains critical to prevent attacks like spoofing, replay, and injection. Robust authentication protocols are necessary to verify identities and secure UAV coordination, especially in swarm-based or mission-critical scenarios.

In earlier work, we developed a lightweight identity authentication scheme tailored for UAV networks, utilizing Elliptic Curve Cryptography (ECC) within a SDDN architecture[5]. ECC, known for using smaller key sizes compared to Rivest–Shamir–Adleman (RSA) while maintaining equivalent security levels, was chosen due to its suitability for resource-constrained environments such as UAV systems [6], [15]. The proposed architecture enabled secure and scalable authentication by coordinating Drones (DR), a Ground Station (GS), and an Authentication Center (AC). The authentication phase involved message exchanges between these components, after which each drone generated a private key used for encrypt-

ing communications throughout the mission. To evaluate the robustness of the approach, we presented in [5], a case study demonstrating its resistance to various attacks and conducted a formal security analysis using the Automated Validation of Internet Security Protocols and Applications (AVISPA) tool, which confirmed the protocol's effectiveness.

In this work, we focus on the agricultural domain as the application context for our access control model, aiming to address the specific security needs of UAV swarm operations in precision farming. This work extends our previous efforts on UAV security by applying and enhancing those concepts in a real-world, domain-specific scenario. Unlike prior studies that approached UAV security from a general perspective, often focusing on isolated aspects such as authentication or trust evaluation, this study is centered on a concrete and highly relevant use case. In [7], the increasing integration of UAVs in agriculture for tasks like crop monitoring, soil analysis, and pesticide spraying highlights the need for structured and secure management of UAV functions and data. To address this, we propose in this work a comprehensive security architecture tailored to the agricultural UAV environment. This architecture integrated multiple layers: trust management for dynamic evaluation of UAV behavior and cluster head selection; lightweight authentication protocols based on ECC to verify identities with minimal computational overhead; and a RBAC model to ensure task-specific access rights. The RBAC model was demonstrated through a Python and YAML based implementation on Colab, simulating realistic role assignments, such as pilot, engineer, technician, etc. and evaluating their permissions to perform specific drone actions (e.g., takeoff, data capture, firmware updates). This end-to-end framework was supported by a detailed architectural diagram and tables summarizing each security layer, offering a unified view of how the different mechanisms interact to secure UAV operations. By grounding the simulation in a real-world scenario, this work not only demonstrated the applicability of access control in agriculture but also emphasized the importance of combining various security approaches to achieve scalable, reliable and context-aware UAV deployments.

The remainder of this study is structured as follows: Section II presents a review of related work on access control, trust management, and security frameworks in UAV networks. Section III outlines the main security challenges facing UAVs. Section IV summarizes our prior contributions related to lightweight authentication and trust-based node management which will be foundational components of the global architecture. Section V presents the research methodology, introducing the proposed role-based access control (RBAC) model tailored for Unmanned Aerial Vehicles (UAVs) in agricultural environments. This section also describes the integration of the proposed access control mechanism within a global Software-Defined Drone Network (SDDN) architecture, highlighting its core security components. Section VI discusses the experimental results and provides a detailed analysis of the performance and security implications of the proposed approach. Finally, the conclusion in Section VII summarizes the main findings of the study and outlines potential directions for future research.

II. Related Works

Several studies have explored the use of SDN architectures for Drones (SDDN) in UAV systems due to their scalability and flexibility in implementing diverse security mechanisms such as authentication, data integrity, and trust management. In this section, we summarize relevant contributions on securing a uav network based on SDDN as well as access control.

In their literature review, Alquwayzani and Albuali in [8] examined the integration of RBAC within Zero Trust Architectures (ZTA) for military UAV systems. They emphasized that RBAC improves security by restricting system privileges based on predefined roles, such as pilot, maintenance, or commander. This role-based restriction minimizes unauthorized access and potential data breaches, aligning with ZTA principles to enhance UAV system security.

In [9], Zhang et al. propose a decentralized access control mechanism for UAV swarms by integrating blockchain technology with Ciphertext-Policy Attribute-Based Encryption (CP-ABE). This approach aims to enhance data security by ensuring that only UAVs satisfying specific attribute-based policies can decrypt and access sensitive information stored on the blockchain. Unfortunately, this work while providing fine-grained access control, introduces significant computational complexity, particularly during encryption and decryption processes, in addition to policy update challenges and latency issues.

Lehmoud et al. (2025) [10] propose a comprehensive security architecture for UAV networks that leverages 5G, SDN/NFV, and AI techniques. Their design uses Curve448-based authentication and integrates SDN's global control to systematically distribute security policies across switches and UAVs. Anomaly detection is achieved through Shannon entropy and self-organizing maps in the NFV layer, ensuring rapid response to threats. While this work demonstrates the benefits of programmable security in SDDNs, it focuses heavily on detection and resilience—without explicitly addressing fine-grained access control policies for drone missions, which is a key distinction in our proposed framework.

Hu et al. (2024) [11] surveys emerging techniques in software-defined UAV networks and highlight several promising approaches: blockchain-assisted orchestration, SDN-NFV security slicing, and lightweight challenge–response authentication based on ECC. They note a trend towards decentralized identity management and programmable policies, though most implementations emphasize network-level protection rather than role- or attribute-based access control per mission. In contrast, our architecture layers in a full RBAC policy module, aligned with trust metrics—reputation, recommendations, and dynamic rehabilitation—enabling mission-tailored access governance embedded directly within the SDDN control plane.

After a comprehensive review of recent literature, it becomes evident that although some works have explored the integration of RBAC in UAV systems, and others have investigated the application of SDDN in agricultural contexts, there is a noticeable lack of research that combines these three elements within a unified framework. Furthermore, security components such as authentication and trust management are often treated separately rather than as part of an end-to-end architecture. In this study, we address this gap by proposing

an integrated approach that leverages RBAC, SDDN, and trust-based mechanisms to enhance the overall security and coordination of UAV swarms in agricultural missions. Our model offers a coherent and scalable solution that meets both the operational and security demands of precision farming environments.

III. UAV's Security Challenges

Security protocols for UAV's must be designed with low communication and computation costs, given the restricted onboard computing capabilities of these devices. To safeguard UAV networks against unauthorized access to sensitive information or potential harmful attacks, it is crucial to ensure a set of key security and privacy properties: authentication, confidentiality, integrity, authorization, non-repudiation, and availability. These are addressed in recent works on lightweight secure communication architectures and trust-based benchmarks in UAV systems [12], [13].

- Authentication: is fundamental for establishing secure communication within an UAV network. It enables the authentication and identification of UAVs participating in flight operations. Digital signature mechanisms are used to verify the trustworthiness of each UAV, allowing only authenticated UAVs to participate in the flight mission. Authentication also safeguards the UAV network from adversaries attempting to impersonate legitimate UAVs.
- Confidentiality: guarantees that data remains inaccessible or undisclosed to unauthorized individuals. Protecting sensitive data and data exchange between UAVs and the GS from unauthorized access is critical in UAV networks to prevent leaks of sensitive flight mission information, such as telemetry data and control commands. Encryption algorithms, both symmetric and asymmetric, can be employed to achieve confidentiality in UAV networks.
- Integrity: involves ensuring data consistency and trustworthiness during the communication process. Data integrity is crucial in UAV networks to prevent alterations like modifications, fabrications, substitutions, and data injections. The use of hash algorithms with advanced encryption mechanisms can be employed to ensure data integrity.
- Authorization: is a security method identifying a user's privileges or access levels to system resources. UAV networks should restrict access to data, allowing only authorized users to communicate with the network. Access control policies must be implemented to monitor and regulate access to resources.
- Non-Repudiation: prevents an entity from denying earlier agreements or activities. The UAV network must establish protocols to ensure non-repudiation through the adoption of a digital signature mechanism.
- Availability: refers to the immediate availability of services to authorized parties when needed for effective functioning. In mission-critical UAV networks, services must be available at all times without intentional or unintentional interruptions. Redundancy and backup mechanisms may be useful for highly critical information services to ensure availability. Additionally, the UAV system must be resilient against classical denial-of-service (DoS) attacks.

In this work, we focus on providing authentication, confidentiality, integrity, and authorization to our architecture to prevent and detect multiple types of attacks such as ID spoofing, man-in-the-middle, replay, Sybil, DoS, etc.

IV. Foundational Security Mechanisms and Prior Contributions

Let us recall that we proposed in previous papers [4], [5] different security measurements such as trust management for IoT networks in general and authentication based on SDDN architecture for UAVs. The trust management model excludes malicious nodes from an IoT network, while the authentication model ensures secure message exchanges between drones and the GS through the AC. Table I summarizes the main notations and their corresponding definitions used throughout the study.

TABLE I. Table of Notations used in the Proposed Architecture

Symbol	Description
GS	Ground Station
AC	Authority Center
$AuthC$	Authentication Controller
ACC	Access Control Controller
TMC	Trust Management Controller
CC	Centralized Controller
i	Index of drone in the network
DR_i	Drone i, where $DR_i \in \{DR_1, DR_2, \ldots, DR_n\}$
ID_{DRi}	Drone ID sent by drone DR_i
IDt_{DRi}	Drone ID already registered in the GS table
tab_{D_R}	Table of drone IDs created by GS
t	A prime number and the order of P
e	A network entity, where $e \in \{DR_i, GS, AC\}$
Pub_e	Public key of entity e
$Priv_e$	Private key of entity e
S	Digital signature
N	A nonce to prevent replay attacks
t	Timestamp
CH	Cluster Head
CM	Cluster Member
BS	Base Station
T	Trust Level
E	Energy Level
$Rep(a, b)$	Reputation value assigned by node a to node b
$RepTab_{DR}$	A table contains all reputation values of different DR_i

A. Trust Management Model

Trust management is a key component in securing IoT networks, helping to ensure reliable data fusion, protect user privacy, and exclude malicious nodes to maintain secure and dependable system operations. Our prior work [4] focused on IoT environments, where we implemented a clustering-based architecture involving CHs and CMs, managed by BSs. This hierarchical structure reduced the computational burden on individual nodes by delegating processing tasks to BSs, improving scalability, energy efficiency, and communication reliability across the network.

We designed a trust management system comprising four core algorithms: trust level calculation to evaluate node reliability, reputation assessment based on historical interactions, a recommendation mechanism for selecting new CHs, and a rehabilitation process to reintegrate previously blacklisted

nodes based on gradual trust recovery. These mechanisms were designed with resource-constrained IoT devices in mind, considering factors such as energy limits and processing capacity. This trust-based framework, initially proposed for general IoT applications, is now adapted to secure UAV networks in the agricultural domain. By integrating these mechanisms into clustered UAV architectures, we aim to enhance security, reliability, and efficiency in data collection and communication, particularly in large-scale deployments, where dynamic node behavior and harsh environmental conditions present ongoing challenges.

B. Authentication Model

We already proposed a study which introduces a secure authentication mechanism for SDDNs [5], ensuring trusted interactions among key entities: DRs, AC, and GS shown in Fig. 5. This model was divided into two phases: the authentication phase and the GS drones list confirmation phase. In the first phase, each drone initiated authentication by encrypting its identity and a random nonce using the AC's public key and sending this request to the AC. The AC decrypted the message and forwarded the drone's identity to the GS for verification. If the drone was recognized in the GS's registry, the GS confirmed the identity by returning an encrypted response with a new nonce to the AC. Following successful confirmation, the AC generated a public key for the authenticated drone and distributed it to the relevant network entities. The GS updated its internal drone table with the new key, while the drone computed its private key using a randomly chosen scalar to ensure confidentiality. Once all drones had been authenticated, the GS signed and broadcasted the finalized list of authorized drones, ensuring that each UAV was informed about its legitimate peers for communication. In the second phase, the GS initiated the mission by sending a start signal to all authenticated drones. Each drone then created role-specific messages, encrypted them using its private key, and transmitted them securely within the network. This approach ensured both the integrity and confidentiality of drone-to-drone communication throughout the operation.
These validated security mechanisms constitute the foundational components upon which the proposed access control model and global SDDN security architecture are constructed.

V. Research Methodology

A. Access Control Proposition

In UAV environments, access control is essential to ensure secure communication, data integrity, and mission reliability. Unauthorized access can lead to data breaches, manipulation of flight paths, or hostile takeovers, posing serious security and safety threats. Robust access control mechanisms help protect sensitive commands and telemetry data from interception or misuse. Moreover, they enable accountability and traceability in multi-user and multi-UAV systems. Thus, implementing strong and adaptive access control is critical for maintaining operational security and trust in UAV deployments [14].
In this study, we develop an access control model based on RBAC to detect and prevent unauthorized UAVs by assigning permissions according to predefined roles. This mechanism is combined with lightweight authentication and trust management, all integrated within a Software-Defined Drone Network (SDDN) architecture to provide a flexible and secure framework for UAV operations in agriculture.
In precision agriculture, the use of UAV swarms is becoming increasingly common for tasks such as crop monitoring, spraying, and soil analysis. To ensure secure and organized access to UAV functions and data, RBAC offers an effective solution. By assigning permissions according to user roles—such as field operator, drone technician, or system supervisor—RBAC reduces unauthorized access, limits operational risks, and streamlines task delegation. This model not only improves security but also enhances efficiency and accountability in managing UAV activities across large agricultural zones.

To illustrate the RBAC model in an agricultural UAV scenario, we implemented a simulation using Python and YAML configuration files on Google Colab. This setup allows us to define roles, permissions, and access rules in a clear and modular way.

1) Access policy definition: This policy, shown in Fig. 1, defines three operational roles relevant to UAV-based agricultural missions: *pilot*, *agri_engineer*, and *technician*. Each role is associated with a distinct set of permissions that determine what actions a user or agent can perform on a drone. The *pilot* role covers flight control operations, including arming, takeoff, landing, and autonomous return. The *agri_engineer* role includes tasks related to field data acquisition and analysis, such as collecting crop data, capturing aerial images, and analyzing soil conditions. Meanwhile, the *technician* role focuses on maintenance and operational readiness, enabling firmware updates, sensor calibration, and battery status checks. Roles are assigned to individual drones under the `assignments` section, thereby enforcing mission-specific and role-based access control within the swarm through a structured YAML policy embedded in the SDDN framework.

2) Access control function: The following function, as presented in Fig. 2, checks whether a user is allowed to perform a given action on a specific drone based on their assigned role.

This function implements a role-checking mechanism: it first verifies that the user has a role assigned for the given drone, then checks whether the requested action is permitted under that role.

3) Simulation results: We tested the function with a set of example scenarios, as shown in Fig. 3, to evaluate whether access is properly granted or denied.

These results, shown in Fig. 4, confirm that the access control mechanism correctly enforces permissions based on role assignments. Authorized actions, such as data collection by the agricultural engineer or drone landing by the pilot, are permitted. Unauthorized actions, such as a technician attempting to arm the drone, are denied as expected.

B. A Layered Model of the Global Architecture Proposition

The objective of the proposed global architecture is to establish a secure, scalable, and mission-aware UAV swarm framework that integrates authentication, trust management, and RBAC-based access control within an SDDN environment

```yaml
import yaml

# YAML swarm policy as a string
swarm_policy_yaml = """
roles:
  pilot:
    - arm
    - takeoff
    - land
    - return_home

  agri_engineer:
    - collect_crop_data
    - capture_images

tailored for precision agriculture. Before detailing this architecture, we first outline our security objectives and introduce the network model.

In this proposition, while we adopted a UAV network for agriculture, we will merge the base station BS and the ground station GS because GS could perform BS task's made in our previous IoT network, while both serve as central communication points.

```python
check_access("Dr. Sara", "drone_1", "collect_crop_data")
check_access("Captain Omar", "drone_1", "land")
check_access("Tech Ali", "drone_1", "calibrate_sensors")
check_access("Visitor", "drone_2", "view_status")
```

Fig. 3. Results scenarios.

```
[√] Dr. Sara (agri_engineer) is allowed to perform 'collect_crop_data' on drone_1
[√] Captain Omar (pilot) is allowed to perform 'land' on drone_1
[X] Tech Ali is not assigned to drone_1
[X] Visitor is not assigned to drone_2
```

Fig. 4. Results output.

1) Security objectives: Our proposed solution is developed with the following security objectives:

- Establishing an SDDN architecture to enable efficient network management and dynamic reconfiguration, ensuring scalability for future enhancements. Additionally, the SDDN framework facilitates the rapid deployment of security mechanisms.
- Enabling mutual authentication between a legitimate DR and GS via AC by optimizing the number of exchanged messages during the authentication process.
- Preserving drone anonymity by preventing unauthorized entities from tracking its identity through encryption techniques.
- Ensuring secure communication between DR and between drones and the GS by employing private keys for message exchanges.
- Enhancing trust management by continuously evaluating node behavior, detecting malicious activity, and isolating compromised entities to maintain network integrity.
- Implementing access control mechanisms to restrict unauthorized access, enforce security policies, and dynamically manage permissions based on trust levels and authentication results.
- Strengthening the protocol's resilience against common security threats, including:
  -ID spoofing attacks
  -Man-in-the-Middle attacks
  -Replay attacks
  -Injection attacks
  -Malicious nodes infiltration
  -SYbil attacks
  -Data modification attacks
  -DoS attacks

This approach ensures a secure and scalable UAV network, while mitigating various cyber threats through authentication, trust management, and access control enforcement.

2) Basic concepts: In our proposal, we extend our previous [5] SDDN architecture model which is organized into three layers: the data plane, the control plane, and the application plane, as illustrated in Fig. 5.

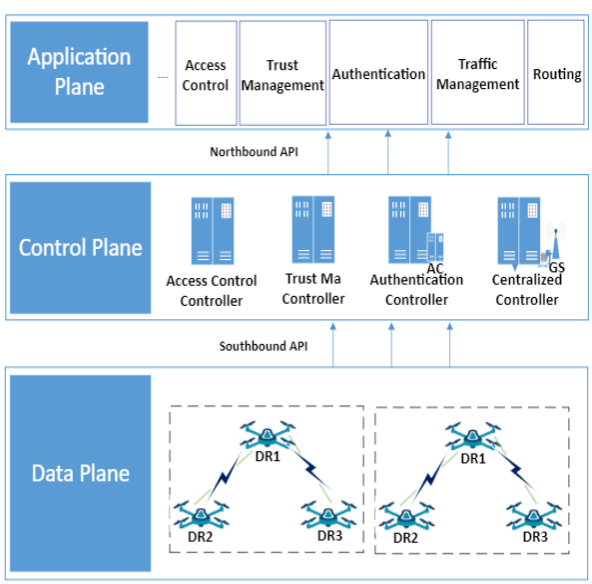

Fig. 5. Considered SDDN modeling.

- Data Plane: This layer comprises swarms of drones, which serve as the primary operational units within the UAV system. Each drone is constructed from lightweight materials and is outfitted with various components including sensors, actuators, payload devices, batteries, and GPS laser systems—to enhance maneuverability by minimizing weight. Typically, the navigation system and sensors are positioned at the front of the drone. Additionally, drones manufactured by different companies incorporate sophisticated features such as vibration damping, advanced communication modules, and compact onboard computing systems to effectively supervise, monitor, and control flight operations [16].These capabilities enable autonomous and semi-autonomous mission execution while supporting real-time data collection and coordination within the swarm. Furthermore, the modular hardware design allows drones to adapt to diverse agricultural tasks and operational conditions.
- Control Plane: This layer is composed of both centralized and decentralized controllers that work together to ensure secure and efficient UAV operations [17]. The centralized controller (CC), embodied by the GS, serves as the primary command and control center. It manages operational parameters, monitors drone sensors, oversees surveillance cameras, and enforces flight separation protocols. Additionally, the GS coordinates mission-critical activities, controls payload subsystems, and processes the data collected during drone operations.
  Complementing the GS, the control plane integrates several decentralized controllers to enhance security and system functionality. An Authentication Controller(AuthC), represented by the AC, verifies UAV system services by issuing certifications and generating cryptographic keys, thereby ensuring that all interactions are legitimate. To further secure the network, a Trust Management Controller (TMC) continuously evaluates the trustworthiness of nodes, aiding in dynamic decision-making and maintaining operational integrity. Moreover, an Access Control Controller enforces stringent policies to regulate node interactions and prevent unauthorized access to critical resources. Together, these controllers provide real-time problem resolution, robust data processing, and reliable networking services across the entire UAV environment.
- Application Plane: This layer represents the topmost level of our architecture, hosting both traditional network applications and drone-specific solutions. It delivers a broad range of services, including routing, traffic management, and security functions, alongside specialized applications such as mission planning, coordination, and data analytics tailored for UAV operations [16]. Additionally, this plane provides a comprehensive dashboard for real-time monitoring, performance visualization, and integration with external systems, ensuring dynamic control of network resources. To fortify security within this layer, we have integrated authentication, trust management, and access control mechanisms. These security measures guarantee that only authorized users and devices interact with the system, continuously assess the trustworthiness of communications, and enforce strict access policies to safeguard the integrity and efficiency of drone operations. Moreover, the application plane is designed to support future extensions such as UAV clustering, enabling scalable coordination and policy enforcement in large-scale agricultural deployments.

3) Security measures description: We detailed each proposed security measure in Table II and Table III, as well as in Fig. 6. We start by detailing the different steps of security measures shown in 5 layers as follows:

Layer 1: AUTHENTICATION: Authentication of DRs is performed through different steps as follows:

STEP 1-1:Authentication Initialization by DR_i :
To obtain its public key from AC, DR_i encrypts its identity ID_{DRi} using the public key of AC (Pub_{AC}), selects a random nonce N_{DRi} (to prevent replay attacks), and transmits the Init message to AC.

$$\text{Init} = (DR_i, AC, [\text{E}(ID_{DRi}, Pub_{AC}) — N_{DRi}]).$$

STEP 1-2: Request ID Verification by AC :
Upon receiving the message, AC decrypts it using its private key $Priv_{AC}$ to extract the drone's identity ID_{DRi}. It then forwards this ID to GS for verification to determine whether DR_i is under its control, using the Verif message.

$$\text{Verif} = (AC, GS, [\text{E}(ID_{DRi}, Pub_{GS}) — DR_i — N_{AC}]).$$

STEP 1-3: ID verification by GS:
The GS verifies the presence of the ID_{DRi} within its drone

Table Tab_{DR}. If the drone is recognized, we pass to the ID confirmation step, else, the authentication of DR_i is rejected.

STEP 1-4: ID confirmation by GS:
GS sends the Confirm message, which includes the encrypted ID using Pub_{AC} and a newly generated nonce N_{GS}.

Confirm = (GS,AC,[E(ID_{DRi},Pub_{AC})—N_{GS}]).

STEP 1-5: Pub_{DRi} Generation by AC:
Upon receiving confirmation from GS, AC generates the public key Pub_{DRi} for the authenticated drone and shares it with the registered entities in the network through the GenPub message.

GenPub = (AC,DR_i,[Pub_{DRi}—N_{AC}]).

STEP 1-6: Pub_{DRi} addition to Tab_{DR} :
GS updates its table, Tab_{DR}, which stores the drones DR_i and their corresponding IDs ID_{DRi}, by incorporating their public keys Pub_{DRi}.

STEP 1-7: $Priv_{DRi}$ Calculation by DR_i:
Once DR_i receives its assigned public key Pub_{DRi}, it selects a random number k and computes its private key as $Priv_{DRi} = k \cdot Pub_{DRi}$, ensuring that no external entity can derive it.

STEP 1-8: Signature calculation of Tab_{DR} by GS:
After the authentication of all DR_i, Tab_{DR} will be signed and broadcasted by GS to all authenticated drones, ensuring that each drone is informed about the legitimate drones authorized for communication during the mission.

STEP 1-9: Begin mission by GS:
After that, GS transmits the following message to begin the mission.

$$\text{BeginMiss} = (\text{GS}, \text{DR}_i, [S \mid\mid N_{\text{GS}}, t])$$

Layer 2: INTEGRITY AND CONFIDENTIALITY:
The following steps ensure integrity and confidentiality:

STEP 2-1: Message creation by DR_i:
When the mission begins, DR_i will start communicating by creating messages according to their role.

STEP 2-2: Message encryption with $Priv_{DRi}$ by DR_i:
Before sending any message, each drone uses its private key $Priv_{DRi}$ to encrypt it so that all messages are secured against integrity and confidentiality attacks.

STEP 2-3: Send message by DR_i:
After encryption, messages are secured and could be sent safely between different drones.

Layer 3: CLUSTERING:
Clustering enhances scalability, energy efficiency, and communication reliability in UAVs.

STEP 3-1:DR_i Clustering by GS In this step, GS will divide drones DR_i according to their positions and identify CHs and CMs.

Layer 4: TRUST MANAGEMENT:
The following steps ensure trust management during drones missions:

STEP 4-1: Trust Initialization:
GS provides for all drones a common starting trust level T_{DRi}=1

STEP 4-2: T_{DRi} calculation
T_{DRi}=T_{DRi}+x : T_{DRi} will decrease when nodes fail to respond to messages (-0.2), neglect to send important updates (-0.1), or transmit false information (-0.3).

STEP 4-3: Drone Exclusion:
DR_i will be excluded when its T_{DRi} attaints -1.

STEP 4-4: Blacklist Creation:
GS creates a blacklist for the malicious drones excluded from the network.

STEP 4-5: Reputation Calculation:
Every drone DR_i calculates the reputation value of other nodes according to their responses to requests.

STEP 4-6: Reputation Table Creation:
DR_i creates a Rep_{TabDR} containing all reputation values of different DR_i.

STEP 4-7: CH Selection:
GS use these reputation values to select the CH. CH will have the best reputation value Max rep(CH,DR_i).

STEP 4-8: DR_i Notification about new CH:
GS notifies other DR_i about the new CH.

STEP 4-9: Resolve Tie:
When 2 DR_i have the same reputation value, GS will select the max ID_{DRi} to choose the CH.

STEP 4-10: Send Recommendation:
CH uses the reputation values of its CMs to formulate and send a recommendation for GS to be replaced when its energy level falls below a threshold.

STEP 4-11: Well_behave Check:
When an excluded DR_i well behave it will have a chance to get back to the network.

STEP 4-12: Positive Trust Update:
T_{DRi} will increase by 0.1 for its good behavior by sending real notifications to GS about its state and detected events in

the network T_{DRi}= T_{DRi}+0.1.

STEP 4-13: Rehabilitation:
When T_{DRi} reaches 0, the malicious drone regains its trustworthiness and is removed from the blacklist.

Layer 5: ACCESS CONTROL:
Users authorization is ensured through the following steps:

STEP 5-1: Service Access Demand:
When a user U_j wants to perform an action using DR_i, an access demand will be sent to the Centralized Controller (CC).

STEP 5-2: Policy Request from CC to ACC:
CC should verify the access control policy of U_j already stored in the Access Control Controller (ACC).

STEP 5-3: Policy Response from ACC to CC:
ACC searches for U_j's access control policy and sends it back to CC.

STEP 5-4: User Role Request:
As a verification step, CC asks U_j about its role to match it to the role in the policy.

STEP 5-5: Access Control Function:
In ACC, the access control function implements a role-checking mechanism: First, it verifies that the user U_j has a role assigned for the given drone DR_i, then checks whether the requested action is allowed under that role.

STEP 5-6: Access Decision Notification:
After applying the function, U_j will be informed if access is confirmed or denied.

The following Table II and Table III summarizes the different security measurements.

4) Layered model description: As previously introduced, Fig. 6 illustrates the proposed layered model outlining the key components of our security environment. This figure shows the different steps of each mechanism to ensure a high-security level for an UAV network. The upper layer is about drones authentication, it details the process from ID_{DRi} verification by GS through AC to $Priv_{DRi}$ and Tab_{DR} signature calculation. Also, after the mission begins, messages are encrypted before being sent between the different components of the environment to ensure the integrity and confidentiality in Layer 2 services. Layer 3 is about clustering drones by GS before trust management process in Layer 4. In this layer, different steps are described such as trust level calculation, blacklist of malicious nodes creation, reputation calculation, recommendations and rehabilitation. The last layer (Layer 5) details access control steps from the user's service access demand to the access confirmation or denial according to RBAC policies. As a single table for the 5 layers becomes too long we have to split this table in two: Layer 1 and Layer 2 are represented in Table II and Layer 3, Layer 4 and Layer 5 are represented in Table III.

The second part of the splitted table, which is Table III, represents the Layers 3, 4 and 5.

VI. Results and Discussion

The proposed security architecture addresses the growing need for structured and lightweight protection mechanisms in agricultural UAV networks, where multiple stakeholders interact within a dynamic and resource-constrained environment. The experimental results obtained from the RBAC simulation demonstrate that role-based access control can be effectively implemented within an SDDN context to regulate user actions and enforce permission boundaries. By explicitly defining roles, permissions, and access rules through configuration files, the system ensures consistency, transparency, and reduced risk of unauthorized operations.

Recent works have explored security and access control in UAV networks using decentralized and zero-trust approaches. Dong et al. [18] propose a blockchain-based authentication scheme for multi-cluster UAV systems, improving robustness but introducing non-negligible computational and communication overhead. Similarly, Xie et al. [19] present a blockchain-assisted zero-trust model emphasizing continuous identity verification. In contrast, the proposed architecture relies on a lightweight ECC-based authentication combined with RBAC and trust management within an SDDN framework, enabling fine-grained access control with lower complexity and improved suitability for large-scale agricultural UAV deployments.

The RBAC evaluation confirms the feasibility of enforcing fine-grained access control without introducing excessive complexity, which is particularly important in agricultural scenarios involving farmers, operators, and service providers with distinct operational privileges. Furthermore, the modular design of the architecture detailed through operational phases, interaction schemes, and configuration tables facilitates extensibility and supports the integration of additional security and management mechanisms. In addition, the experimental observations highlight the practical alignment between the proposed access control logic and the operational requirements of agricultural UAV missions. The clear separation of control responsibilities and data access privileges contributes to improved system reliability and reduces the likelihood of configuration errors during mission execution. These characteristics are particularly valuable in real-world deployments, where operational simplicity and predictable behavior are essential for maintaining secure and efficient UAV-assisted agricultural services.

Nevertheless, this study has certain limitations. The experimental evaluation focuses specifically on the RBAC component, while other security mechanisms are validated through formal analysis rather than full-scale simulation. Additionally, performance metrics such as communication latency, energy overhead, and scalability under dense UAV swarm conditions are not yet quantitatively assessed, which may impact the generalizability of the results.

Future work will address these limitations by extending the validation of the complete architecture through inference-based modeling and formal verification, enabling formal reasoning over trust evolution and access decisions in dynamic environments. In addition, the integration of a lightweight

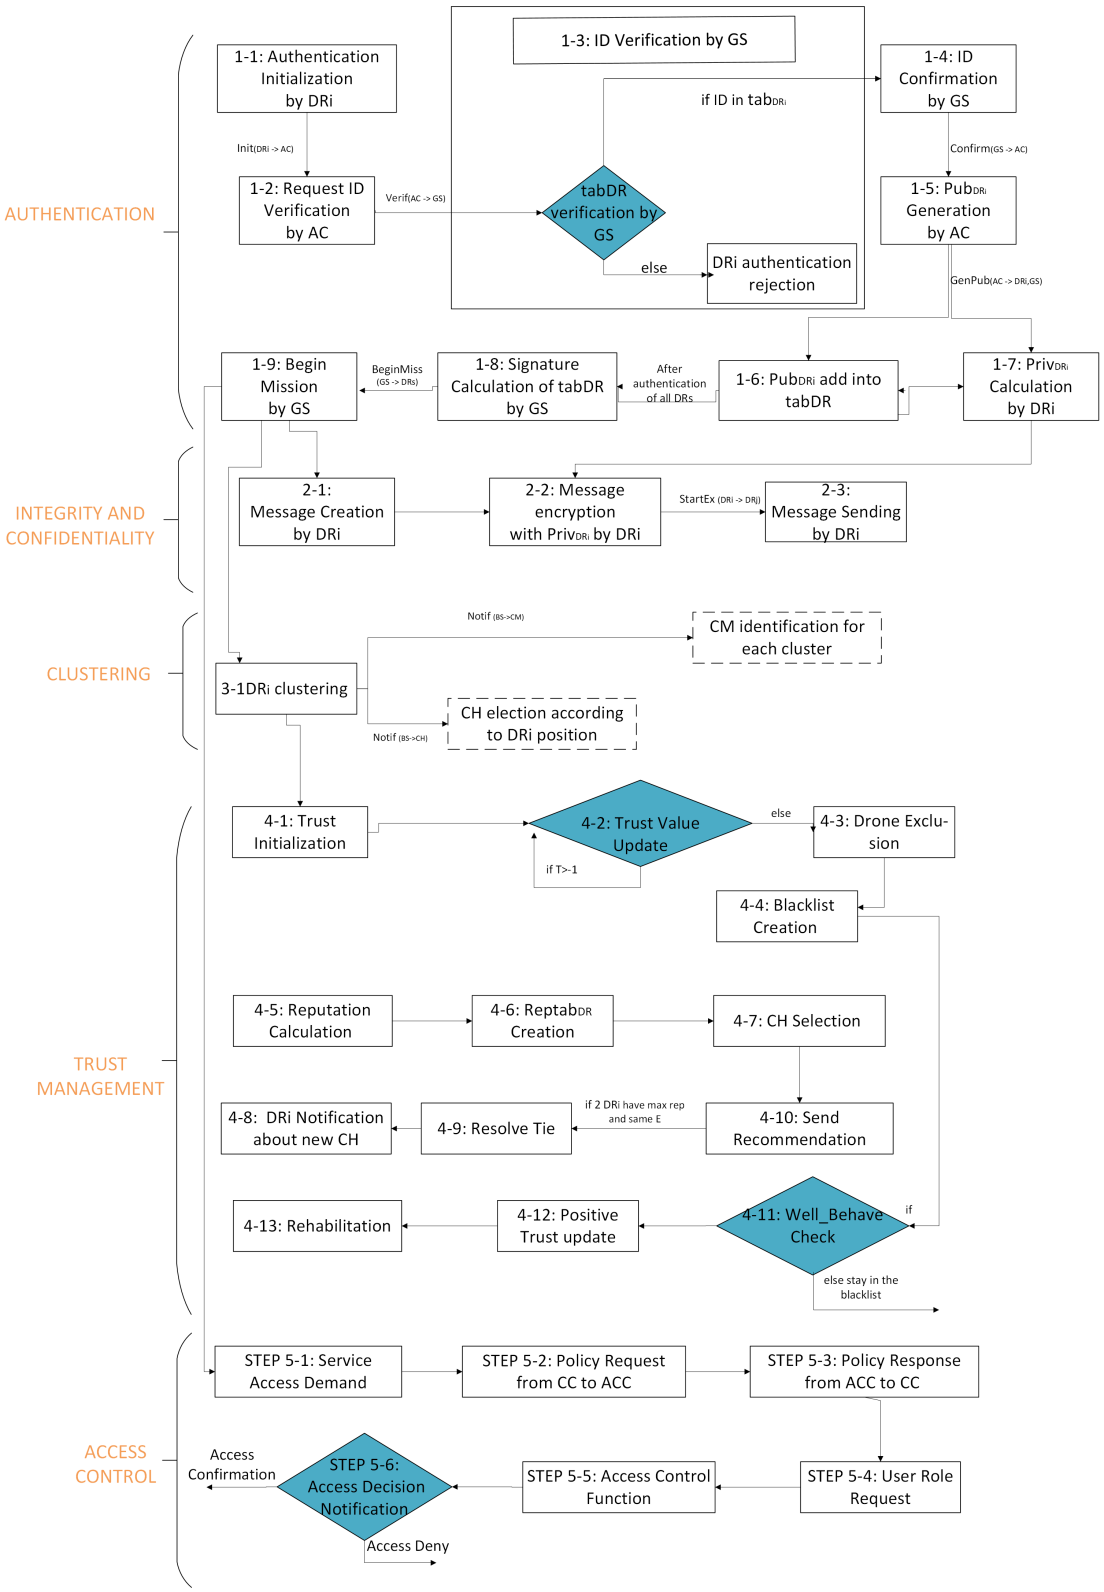

Fig. 6. Layered model description.

TABLE II. TABLE OF MESSAGES EXCHANGED (PART 1)

Steps	Service	Active Entities	Data Units	Data Units Parameter	Subservices	Sender	Receiver
1-1	Authentication Initialization by DR_i	DR_i, AC	Init	(DR_i,AC, [E(ID_{DRi},Pub_{AC})	-ID_{DRi} encryption with Pub_{AC}. -Addition of a random nonce N_{DRi}.	DR_i	AC
1-2	Request ID Verification by AC	AC, GS	Verif	(AC,GS, [E(ID_{DRi},Pub_{GS}) —DR_i—N_{AC}])	-ID_{DRi} encryption with Pub_{GS}. -Include the drone DR_i and addition of a random nonce N_{AC}	AC	GS
1-3	ID Verification by GS	GS	N.C	N.C	- ID_{DRi} verification by GS if it exists in Tab_DR or not. -If the ID is included in the table a confirmation will be sent from GS to AC . Else, DR_i rejection of authentication.	N.C	N.C
1-4	ID Confirmation by GS	GS, AC	Confirm	(GS, AC, [E(ID_{DR_i}, Pub_{AC}) || N_{GS}])	-Confirmation of the existence of ID_{DRi} in its drone table Tab_{DR}. -ID_{DRi} encryption with Pub_{AC}. -Addition of a random nonce N_{GS}.	GS	AC
1-5	Pub_{DRi} Generation by AC	AC, DR_i, GS	GenPub	(AC, DR_i, [Pub_{DRi}‖N_{AC}])	-Pub_{DRi} generation by AC so DR_i could calculate its private key $Priv_{DRi}$. -AC includes Pub_{DRi} and a nonce N_{AC}.	AC	DR_i, GS
1-6	Pub_{DRi} Addition in Tab_{DR}	GS	N.C	N.C	- Pub_{DRi} addition to GS table which already contains ID_{DRi} of drones which will start the mission.	N.C	N.C
1-7	$Priv_{DRi}$ Calculation by DR_i	DR_i	N.C	N.C	-Pub_{DRi} reception by DR_i -$Priv_{DRi}$ calculation using Pub_{DRi} and a random number k	N.C	N.C
1-8	Signature calculation of Tab_{DR} by GS	GS	N.C	N.C	-Digital signature S of Tab_{DR} calculation using GS private key $Priv_{GS}$. - Digital signature of Tab_D_R is shared with authenticated drones to identify legitimate nodes before mission start.	N.C	N.C
1-9	Beginning of the Mission by GS	GS, D_{Rs}	BeginMiss	(GS, DR_i, [S‖N_{GS}‖t])	-Start of the mission indication after a successful authentication phase. - GS sent S which contain the updates tab_D signed by $Priv_{GS}$, a nonce N_{GS} and a timestamp t.	GS	D_{Rs}
2-1	Create Message	DR_i	Msg	(DR_i, role, payload)	- Message generation by DR_i based on its assigned role in the mission.	DR_i	N.C
2-2	Message Encryption	DR_i	EncMsg	(DR_i, [E(payload, $Priv_{DR_i}$)])	- Message encryption using private key $Priv_{DR_i}$ to ensure confidentiality and integrity.	DR_i	N.C
2-3	Send Message	DR_i	EncMsg	(DR_i, DR_j, [E(payload, $Priv_{DR_i}$)])	- Transmission of the encrypted message to a peer drone DR_j.	DR_i	DR_j

TABLE III. TABLE OF MESSAGES EXCHANGED (PART 2)

Steps	Service	Active Entities	Data Units	Data Units Parameter	Subservices	Sender	Receiver
3-1	DR_i Clustering by GS	GS	Cluster	(GS, DR_i)	- GS clusters DR_i based on their positions and identifies CHs and CMs.	GS	DR_i
4-1	Trust Initialization	GS	InitTrust	(GS, $T_{DR_i} = 1$)	- GS assigns an initial trust value $T_{DR_i} = 1$ to all drones.	GS	DR_i
4-2	Trust Value Update	GS	UpdateTrust	($T_{DR_i} = t_{DR_i} + x$)	- Trust decreases due to non-responsiveness (-0.2), neglect (-0.1), or false data (-0.3).	GS	N.C
4-3	Drone Exclusion	GS	Excl	($T_{DR_i} = -1$)	- DR_i is excluded when trust level reaches -1.	GS	N.C
4-4	Blacklist Creation	GS	Blacklist	(GS, List)	- GS creates a blacklist for malicious or excluded drones.	GS	DR_i
4-5	Reputation Calculation	DR_i	RepCalc	(DR_i, other nodes)	- Each drone calculates reputations of others based on their behavior.	DR_i	N.C
4-6	Reputation Table Creation	DR_i	$RepTab_{DR}$	(DR_i, table)	- DR_i builds $RepTab_{DR}$ containing reputations of other drones.	DR_i	N.C
4-7	CH Selection	GS	SelectCH	max(Rep(CH, DR_i))	- GS selects CH with highest reputation.	GS	DR_i
4-8	DR_i Notification about new CH	GS	NotifyCH	(GS, CH info)	- GS notifies all DR_i of the selected CH.	GS	DR_i
4-9	Resolve Tie	GS	TieBreak	max(ID_{DR_i})	- If reputations are equal, GS selects CH by highest ID.	GS	DR_i
4-10	Send Recommendation	CH	Reco	(CH, GS)	- CH recommends replacement if its energy drops below threshold.	CH	GS
4-11	Well Behave Check	GS	CheckBehavior	(DR_i)	- If excluded DR_i behaves well, it's reconsidered.	DR_i	GS
4-12	Positive Trust Update	GS	TrustBoost	($T_{DR_i} = t_{DR_i} + 0.1$)	- Trust increases for good behavior and real alerts sent.	GS	N.C
4-13	Rehabilitation	GS	Rehab	($T_{DR_i} \geq 0$)	- If $T_{DR_i} \geq 0$, the drone is removed from the blacklist.	GS	DR_i
5-1	Service Access Demand	U_j, CC	AccessReq	(U_j, DR_i)	- U_j sends a request to access a service on DR_i to the Centralized Controller (CC).	U_j	CC
5-2	Policy Request from CC to ACC	CC, ACC	PolicyReq	(CC, U_j)	- CC asks ACC for the stored access control policy of user U_j.	CC	ACC
5-3	Policy Response from ACC to CC	ACC, CC	PolicyResp	(Policy(U_j))	- ACC retrieves U_j's policy and sends it back to CC.	ACC	CC
5-4	User Role Request	CC, U_j	RoleReq	(CC, U_j)	- CC asks U_j for its role to match with the access control policy.	CC	U_j
5-5	Access Control Function	ACC	Role-Check	(U_j, Role, Action)	- ACC verifies that U_j has a valid role and that the action is allowed for DR_i.	ACC	CC
5-6	Access Decision Notification	CC, U_j	AccessResp	(Confirm / Deny)	- CC sends a confirmation or denial of access to U_j based on policy check.	CC	U_j

clustering mechanism will be explored to enhance scalability, reduce control overhead, and improve resilience in large-scale agricultural UAV swarm scenarios.

VII. Conclusion

The integration of UAVs into agricultural environments represents a major advancement in precision farming, enabling efficient data acquisition, resource optimization, and real-time monitoring. However, these benefits also introduce significant security challenges due to the distributed, dynamic, and multi-stakeholder nature of agricultural UAV systems.

In this work, we proposed a comprehensive and lightweight security architecture tailored for Software-Defined Drone Networks (SDDNs) operating in agricultural contexts. The proposed framework provides a global and structured security vision that combines multiple complementary mechanisms, including ECC-based identity authentication, secure communication ensuring integrity and confidentiality, trust management based on dynamic behavioral evaluation, and role-based access control (RBAC). The architecture is detailed through clearly defined operational phases, interaction workflows, and configuration tables, offering a coherent end-to-end security model rather than an isolated mechanism. This holistic design enables controlled access, accountability, and adaptability in environments involving diverse actors such as farmers, operators, and service providers. From an implementation perspective, the experimental evaluation in this study focuses on the RBAC component, which was simulated using Python and YAML configuration files in a cloud-based environment. The results confirm that the proposed RBAC model enables clear, consistent, and enforceable access policies aligned with predefined roles, demonstrating its practicality within an agricultural UAV setting. The remaining security components, including ECC-based authentication and trust management, have been formally validated in our previous work using AVISPA, ensuring their robustness against common security threats.

Overall, this study establishes a solid security baseline for agricultural UAV networks by combining architectural design, formal validation, and targeted simulation. Future work will focus on formal inference-based validation of the complete architecture, the integration of lightweight clustering mechanisms for scalable swarm management, and performance evaluation under large-scale and highly dynamic UAV deployments.

A Soft and Hard Mixture-of-Experts Approach for Improved ADR Extraction from Patient-Generated Narratives

Oumayma Elbiach[1], Hanane Grissette[2], El Habib Nfaoui[3]
Faculty of Sciences Dhar El Mahraz-L3IA Laboratory, Sidi Mohamed Ben Abdellah University, Fez, Morocco[1,3]
Faculty of Sciences and Technology-Department of Computer Science, Sidi Mohamed Ben Abdellah University, Fez, Morocco[2]

***Abstract*—Traditional single-architecture neural models, including monolithic transformer-based and sequence-to-sequence architectures, often struggle to extract Adverse Drug Reactions (ADRs) from patient-generated health narratives due to informal language, high linguistic variability, and complex relationships among drugs, diseases, and adverse events. Although Mixture-of-Experts (MoE) architectures have demonstrated strong performance across various Natural Language Processing (NLP) tasks, their effectiveness for ADR extraction from unstructured patient narratives remains largely unexplored. This study investigates the application of MoE architectures, specifically Soft MoE and Hard MoE, for ADR extraction from patient-generated content. The task is formulated as a sequence-to-sequence generation problem and evaluated on the PsyTAR dataset using both strict and relaxed evaluation metrics. Experimental results demonstrate that Soft MoE consistently outperforms Hard MoE, achieving a relaxed F1-score of 80.40% compared to 79.40%. These findings highlight the critical role of expert-routing strategies in capturing linguistic variability in patient narratives and establish MoE architectures as a competitive and reliable approach for automated ADR extraction in biomedical text mining and pharmacovigilance applications.**

***Keywords*—Adverse Drug Reaction; Mixture-of-Experts; Soft and Hard MoE; sequence-to-sequence; patient narratives; biomedical text mining**

I. Introduction

An Adverse Drug Reaction is an unintended and harmful effect that occurs after the use of a drug at its normal therapeutic dose [1]. Adverse Drug Reactions are a significant contributor to morbidity and mortality rates worldwide [2]. Their timely detection and monitoring have immense importance in order to improve the safety of drugs and to support various pharmacovigilance activities. Typically, ADR data is collected through passive spontaneous reporting systems, which usually suffer from under-reporting and delayed reporting [3]. Nevertheless, with the rapid growth in user-generated content on social media and health-related forums, valuable information regarding patient experiences has become increasingly available in real time [4]. Millions of users actively share their medication experiences within online communities, frequently reporting potential side effects almost in real-time [5]. Consequently, it opened a promising avenue for the early ADR detection, potentially overcoming the drawbacks of traditional systems. However, leveraging social media data for ADR detection poses significant challenges because of the informal, unstructured, and noisy nature of text generated by users [6]. Patients often describe their experiences in various ways, using colloquial expressions, abbreviations, or implicit mentions of symptoms, making automatic extraction of ADRs a challenging task [7].

In light of these challenges, more and more researchers have become interested in using Natural Language Processing methods to automatically identify ADRs not explicitly written in structured formats, such as medical forums and social media [8]. Early studies have mainly focused on rule-based systems, machine learning, and deep learning methods. The early rule-based systems were interpretable yet often could not generalize to linguistic variability or unseen expressions [9]. While machine learning methods introduced data-driven learning capabilities, they still depended on extensive manual feature engineering [10]. The emergence of deep learning, especially the transformer-based models [11], has marked a major advancement by enabling models to automatically capture semantic and contextual relationships in text. Despite their substantial success, most of these models generally require a vast amount of annotated biomedical corpora, which limits their applicability in real-world pharmacovigilance scenarios where such data are often limited.

More recently, Large Language Models have shown remarkable potential for biomedical information extraction, due to the rich contextual representation they can learn from massive amounts of text data [12]. LLMs can generalize across a wide range of linguistic patterns, making them particularly apt at dealing with the noisy and unstructured language used on social media and patient narratives. However, monolithic architectures, whether standard transformers or LLMs, rely on a single generalized network to handle all inputs, which can be suboptimal for capturing the highly specific and varied expressions of Adverse Drug Reactions. This limitation motivates the exploration of the Mixture-of-Experts paradigm, which leverages multiple specialized sub-networks to process different types of input patterns dynamically. While MoE models achieved state-of-the-art results in general language understanding and other specialized domains [13], their effectiveness and optimal configuration for the specific domain of ADR extraction have not been largely explored. Thus, the present work systematically investigates the performance of the MoE architectures for ADR extraction from patient narratives. In particular, a comparison is conducted between Soft MoE, where all experts contribute to each input, and Hard MoE, where only a subset of experts is activated, in an

attempt to establish which of the approaches better captures the semantic variability of ADRs. Through this comparison analysis, the present study investigates whether the specialization capabilities of MoE can lead to improvement in extraction performance on this challenging domain, including insights into their applicability in biomedical text mining.

The main contributions of this work are as follows:

- This study investigates the MOE approach for the specialized task of ADR extraction from patient-generated narratives.
- Comparative analysis of the two primary MoE variants (Soft MoE and Hard MoE) to determine their efficacy in capturing the high semantic variability present in user-generated medical text.
- An experimental evaluation is conducted on the PsyTAR dataset using strict and relaxed metrics to assess the effectiveness of MoE in this task.

The rest of the study is organized as follows: Section II reviews related work. Then, Section III describes the materials and methods, covering the dataset, model architecture, and evaluation metrics. The results will be reported and discussed in Section IV. Finally, Section V concludes the study and outlines future work directions.

II. Background and Related Work

Research on Adverse Drug Reaction extraction has evolved rapidly with the advancement of NLP techniques. Early studies focused on applying rule-based and lexicon-driven systems, which relied on handcrafted patterns and domain-specific vocabularies such as MedDRA to identify ADR mentions [14],[15]. Although these approaches offered transparency, they struggled with the linguistic variability and ambiguity present in real-world patient narratives. Subsequent work introduced machine learning-based models to learn statistical patterns from annotated corpora [16]. These methods improved generalization but still depended heavily on manual feature design and lacked the ability to capture deep contextual semantics.

The advent of deep learning marked an important turning point in ADR extraction, with architectures such as Recurrent Neural Networks (RNNs) and Convolutional Neural Networks (CNNs) enabling automatic feature learning from raw text [17], a significant improvement over manual feature engineering [18]. Many of these models often struggled with long-range dependencies and contextual subtleties inherent in biomedical language. The breakthrough came with transformer-based architectures, which exploit a self-attention mechanism to capture complex contextual relationships across entire sequences. Models like BERT and its domain-specific variants, such as BioBERT and PubMedBERT, demonstrated unprecedented performance on automatic learning of rich contextual and semantic representations from vast amounts of textual data [11]. This reduced the need to manually perform feature engineering and allowed a more effective handling of the linguistic variations observed in both the formal literature and the informal narratives of patients [19].

Building upon this foundation of specialized transformers, the field has progressed toward Large Language Models, which extend this architecture to much larger and more powerful systems through pre-training on huge and diverse text corpora. This extreme scaling allows LLMs to have superior generalization and powerful few-shot capabilities, which make them very promising in handling the complexity of information extraction tasks even when the use of annotated data is limited [20]. A major innovation within these recent LLMs that has been aimed at handling such a large scale efficiently is the Mixture-of-Experts architecture. In contrast to dense models that activate the full network for every input, MoE relies on a sparse structure where the routing network dynamically routes the tokens to the appropriate specialized experts. The potential of this paradigm for complex biomedical tasks was demonstrated by [21], who developed MOEBQA, an MoE-adapted model for Biomedical Question Answering. Their model used a router to assign different types of professional questions to specialized experts, which significantly improved performance by alleviating parameter competition across diverse question types, achieving state-of-the-art results. In [22], the authors proposed MOELoRA, which combines MoE with parameter-efficient fine-tuning to efficiently learn separate parameters for various tasks while maintaining a small number of trainable parameters, demonstrating superior performance on a multi-task Chinese medical dataset. This approach was later extended to Named Entity Recognition (NER) in work by [23], who proposed BOND-MoE, a model that integrates a MoE layer into a BERT-based framework. In their contribution, experiments verify that assignment of predictions to multiple experts is effective in collectively improving performance as well as in effectively overcoming noisy, distantly supervised labels in various instances of NER tasks across multiple datasets, achieving performance superior to BERT

Though Mixture-of-Experts architecture have demonstrated success in different NLP and biomedical text mining tasks, their application to the Adverse Drug Reaction extraction task remains largely unexplored. Despite substantial progress achieved by deep learning, transformer-based, and large language model approaches, existing ADR extraction methods still largely depend on monolithic architectures that process all inputs using a single shared representation space. This design may impact their ability to effectively capture the high linguistic variability and heterogeneous expression patterns characteristic of patient-generated narratives. Moreover, although MoE-based models have demonstrated effectiveness in related biomedical NLP tasks such as question answering and named entity recognition, prior work has not systematically examined their use for ADR extraction, nor has it investigated how different expert-routing strategies influence performance in this domain. This gap motivates the present study, which evaluates both Soft and Hard MoE variants, assessing their respective strengths and limitations for ADR extraction from patient narratives.

III. Methodology

This study aims to assess the performance of the Mixture-of-Experts mechanism on the task of extracting Adverse Drug Reactions from patient narratives. The primary goal is to test the efficiency of the architecture by performing a comparative performance analysis between the two main variants of this architecture, Soft MoE and Hard MoE, within the same domain. The main hypothesis is that the MoE paradigm, due to

its specialized sub-networks, can more effectively capture the high semantic variability and diverse ADR categories found in the text compared to a monolithic model.

A. Problem Formulation

In this work, the task of Adverse Drug Reaction extraction from a patient's narrative is formulated as a sequence-to-sequence (Seq2Seq) problem. Given an input text $X = (x_1, x_2, \ldots, x_T)$ that describes a patient's experience with a medication in their own words, the task is to generate an output sequence $Y = (y_1, y_2, \ldots, y_N)$ listing all mentioned adverse reactions separated by commas. Each output token y_i represents a word or a phrase describing an ADR that is mentioned in the input text. This formulation is effective for patient-generated content, which tends to be informal, unstructured, and may contain multiple ADRs using varied expressions. ADR generation as a textual list, rather than performing token-level classification, allows the model to better capture contextual and semantic relationships and to produce concise and accurate ADR outputs directly from the narrative text.

B. Dataset

The PsyTAR (Psychiatric Treatment Adverse Reactions) dataset [24] is a psychiatric adverse reaction dataset that captures how patients describe the perceived effects and adverse reactions associated with psychiatric medications in real-world settings. The dataset consisted of patient-generated reviews, collected from the online health platform Ask a Patient, on four commonly prescribed antidepressants: Zoloft, Lexapro, Cymbalta, and Effexor XR, which belong to two classes: Selective Serotonin Reuptake Inhibitors (SSRIs) and Serotonin–Norepinephrine Reuptake Inhibitors (SNRIs). The dataset was developed in a multi-step process through sentence segmentation and comprehensive manual annotation. 6,009 sentences were extracted from 891 drug reviews and labeled regarding semantic categories such as Adverse Drug Reactions (ADRs) (2,168 sentences), Withdrawal Symptoms (WDs) (438 sentences), Signs and Symptoms of Illness (SSIs) (789 sentences), Drug Indications (DIs) (517 sentences), Drug Effectiveness (EF) (1,087 sentences), and Drug Ineffectiveness (INF) (337 sentences). Within the ADR-labeled subset, 4,813 distinct ADR mentions were identified [28]. For this study, only sentences annotated with ADRs were retained, while non-ADR sentences were excluded. After filtering, the final corpus used for ADR extraction comprised 1,981 sentences, providing a focused and high-quality subset for investigating patient-reported Adverse Drug Reactions in psychiatric treatments.

C. Model Architecture

In this work, the Mixture-of-Experts mechanism is investigated and applied within an encoder-decoder framework for a challenging application: Adverse Drug Reaction extraction from patient narratives. The problem is formulated as a Seq2Seq generation task, and therefore, the model maps a textual patient description to a list of ADR mentions. While the standard Seq2Seq architectures can capture complex linguistic dependencies, they often fail under heterogeneous biomedical language, which may contain ADR expressions of different styles, domains, and granularities. To overcome this limitation, a Mixture-of-Experts mechanism is introduced to enable the model to distribute the learning process across multiple expert networks, each one potentially specializing in different linguistic or semantic aspects of ADR expressions. Fig. 1 illustrates the integration of the Mixture-of-Experts mechanism inside the Transformer encoder-decoder architecture used for ADR extraction. In the standard Transformer block, the Feed-Forward Network (FFN), a two-layer position-wise neural network applied independently to each token, is responsible for transforming intermediate hidden representations after the self-attention operation. In the proposed architecture, this FFN component is replaced by an MoE layer, which routes each token representation to one or more expert networks. Two routing strategies are explored: Soft MoE, where all experts contribute proportionally to their gating probabilities, and Hard MoE, where only the Top-k experts (k=2) are activated for each token. This modification preserves the overall encoder–decoder structure of the model while introducing specialization among experts, enabling more flexible and adaptive representation learning for ADR extraction.

1) Mixture-of-Experts: The Mixture-of-Experts [25] mechanism enhances the model's representational capacity by introducing a set of K expert networks, each designed to learn a specific subspace of the input representation. A gating network determines how much each expert contributes to processing a given input. Formally, let $H = (h_1, h_2, \ldots, h_T)$ denote the encoder's hidden representations of the input text. The gating network G produces a vector of scores $g = (g_1, g_2, \ldots, g_K)$ corresponding to the K experts:

$$g = G(H) \tag{1}$$

where, each g_k denotes the relevance of expert E_k for the current input. The output from the encoder is routed through the MoE layer to generate a refined representation H', which the decoder will take as an input:

$$H' = \sum_{k=1}^{K} \alpha_k \, E_k(H) \tag{2}$$

where, α_k are weights given by the gating mechanism, which are determined differently in the Soft and Hard variants. Then, the decoder subsequently predicts the output sequence of ADR mentions based on H'. This type of structure allows the model to learn different linguistic patterns while still sharing an encoder–decoder architecture.

a) Soft MoE: In the Soft MoE configuration, all experts contribute to the processing of every input, but to a different extent. The gating network uses a softmax function to produce a probability distribution over all experts:

$$\alpha = \text{Softmax}(G(H)) \tag{3}$$

Each expert E_k processes the entire encoder representation H, generating an output $O_k = E_k(H)$. The final representation fed into the decoder is a weighted sum of all the expert outputs:

$$H' = \sum_{k=1}^{K} \alpha_k O_k \tag{4}$$

This allows the model to make use of a mixture of several expert knowledge sources for each input, leading to smooth sharing of information between experts. However, activating

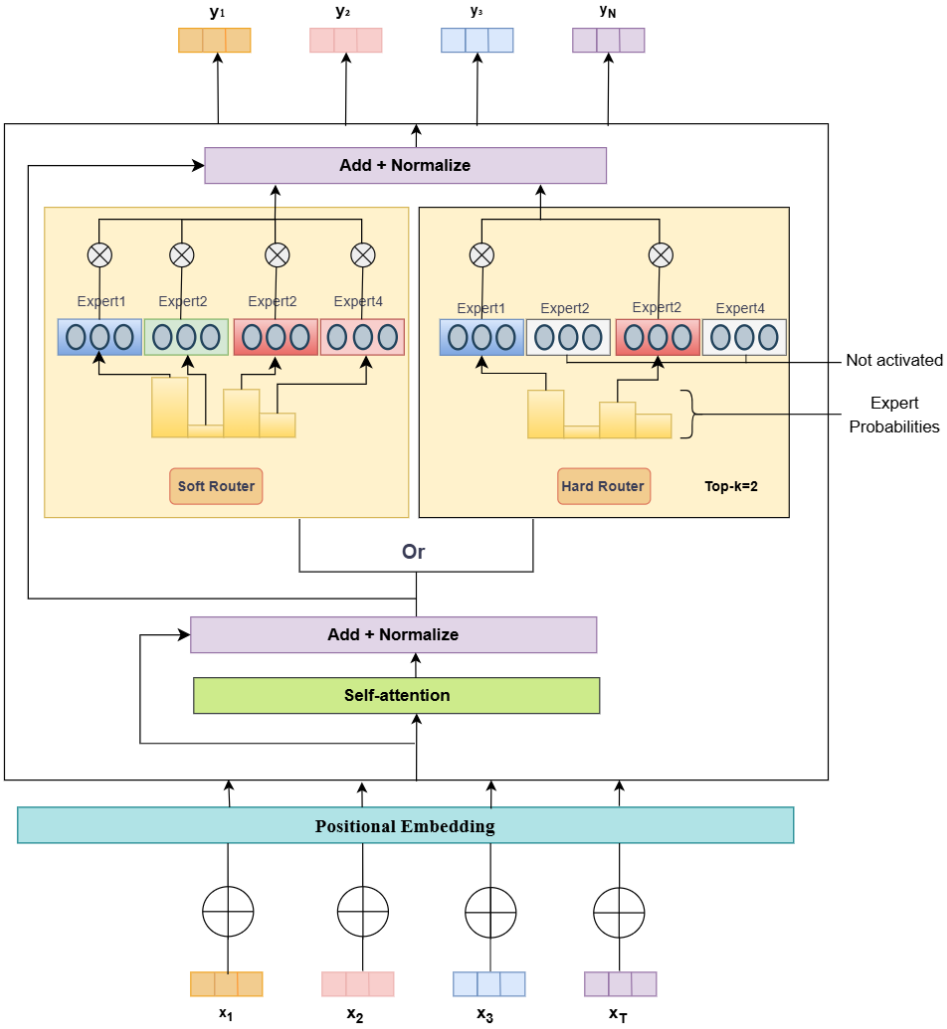

Fig. 1. Overall architecture of the proposed Mixture-of-Experts for ADR extraction.

all experts for every input increases computational cost and may result in redundancy.

b) Hard MoE: The hard version of MoE uses a sparse routing strategy, where only a subset of experts, typically the top-k according to the gating scores, are activated for any given input. The gating network computes scores $g = G(H)$, and only the experts with the highest k scores are selected. The weights α_k for the selected experts are usually set to 1 (a simple sum) or re-normalized via softmax over the top-k scores, while others are set to zero:

$$H' = \sum_{k \in \text{Top-}k(g)} \alpha_k E_k(H) \tag{5}$$

This selective routing greatly reduces computation and allows each expert to specialize in a narrower subset of the input space, thereby promoting more distinct expert behavior. However, without proper intervention, this approach introduces a significant challenge: the gating network may collapse, consistently favoring a small subset of experts while allowing others to stagnate, a phenomenon known as expert collapse. This issue is mitigated, and stable training as well as balanced expert utilization are ensured through an auxiliary load-balancing loss term [26]. This loss penalizes uneven usage of the experts and thus encourages the gating network to distribute the inputs more uniformly across the set of experts. By this regularization, all experts get enough training signals and contribute meaningfully to the overall performance of the model. This prevents a small set of experts from dominating.

Both MoE variants are integrated at the interface between the encoder and decoder, enabling the experts to refine intermediate representations before decoding. This comparative study focuses on how the Soft and Hard routing strategies influence model specialization and performance for the ADR extraction task. A concise comparison of the two variants is presented in Table I.

D. Evaluation Metrics

Since extracting ADRs inherently incorporates ambiguity in defining the entity boundaries of patient narratives, performance evaluation is essential. The standard metrics, such as precision, recall, and F1-score, allow for a basic understanding of how well models can identify correct mentions of ADRs.

TABLE I. KEY CHARACTERISTICS COMPARISON BETWEEN SOFT AND HARD MOE MECHANISMS

Features	Soft MoE	Hard MoE
Routing Mechanism	Dense / All Expert Routing	Sparse / Top-k Routing
Expert Selection	Only the top-k experts are selected and activated for a given input	All experts are activated for each input
Gating Function	Use Softmax function to generate a probability distribution for all experts	Top-k discrete routing with gradient approximation
Load Balancing	- KL divergence balance loss - Optional : Naturally balanced due to continious soft gating but can still be benificial	- Explicit balance loss (MSE) - Mandatory : To prevent expert to become overloaded
Training Stability	More stable due to soft combination	Can suffer from expert collapse
Computational Cost	Higher cost because all experts must be computed in full	Lower cost because only k experts are activated and computed
Robustness	Higher: Robust to routing variations since multiple experts contribute jointly, reducing the impact of the individual routing errors	Lower: Highly sensitive to router errors. If an incorrect expert is selected, the performance can significantly degrade

However, the strict evaluation methods, since they require an exact boundary match between the predicted and gold-standard entities, are inflexible and often fail to consider the partially correct predictions that still offer useful ADR information. To handle this limitation, a relaxed evaluation strategy is adopted [27] in which predictions that partially overlap with the gold-standard entities are considered as valid matches. These partial matches are recognized by calculating the cosine similarity between the embeddings of predicted and reference entities by setting a threshold of 0.8, which is sufficient to consider semantic similarity. This dual evaluation framework evaluates not only the model's precision in boundary extraction but also its ability to recognize semantically relevant ADRs when the predicted and true boundaries do not perfectly match.

The predicted entities are grouped into five categories as illustrated in Fig. 2:

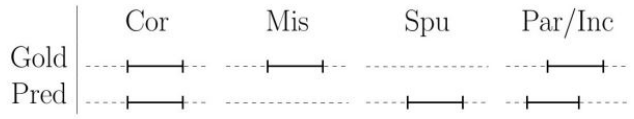

Fig. 2. Visual representation of Correct (Cor), Missed (Mis), Spurious (Spu), and Partial/Incorrect (Par/Inc) entity alignments [27].

- Correct (Cor): Predicted ADRs that match the gold standard exactly in both span and content.
- Partial (Par): Predicted ADRs that partially overlap with a gold-standard entity or are semantically similar, identified using cosine similarity above the threshold.
- Incorrect (Inc): Predicted ADRs overlapping a gold standard entity but not exceeding the similarity threshold.
- Spurious (Spu): Predicted ADRs that do not correspond to any gold-standard entity.
- Missed (Mis): Gold-standard ADRs that were not predicted by the model.

Using these categories, the main evaluation metrics are defined as follows:

Precision:

$$\text{Precision} = \frac{Cor + (Par \times 0.5)}{Cor + Par + Inc + Miss} \tag{6}$$

Recall:

$$\text{Recall} = \frac{Cor + (Par \times 0.5)}{Cor + Par + Inc + Spu} \tag{7}$$

F1-Score:

$$\text{F1} = 2 \cdot \frac{\text{Precision} \cdot \text{Recall}}{\text{Precision} + \text{Recall}} \tag{8}$$

For strict evaluation, partial matches are excluded (Par=0), and only exact matches are considered as correct. This provides an exact measure of the model's capability in identifying ADRs correctly. In contrast, the relaxed evaluation includes partial matches, allowing for a more flexible assessment that accounts for semantically relevant extractions even when the predicted span does not align exactly with the gold standard. The proposed framework for this combined evaluation will make sure that both exact and partially correct ADR predictions are suitably assessed to provide a comprehensive view of model performance in extracting Adverse Drug Reactions from patient-generated texts.

IV. EXPERIMENTAL RESULT ANALYSIS AND DISCUSSION

A. Experimental Settings

A set of experiments involving both Soft MoE and Hard MoE architectures has been conducted to estimate the performance of Mixture-of-Experts network architectures. A variety of encoder-decoder models of the T5 family have been investigated in the experiment involving Soft MoE. These variants include T5 base, Flan-T5 base (instruction-tuned), T5 small (efficient small model), BioT5-base (biomedically tuned), and Long-T5-tglobal-base (long-context model). T5-base is used as the tokenizer in this architecture type. For the Hard MoE, experiments were carried out using BART-based architectures, including BART-base, BART-large, mBART-large-50 (multilingual version), and BioBART-base (biomedical variant), with BART-base used as the tokenizer in this experiment as well. A

top-k = 2 routing strategy has been employed to select the two most relevant experts given the input, ensuring both efficiency and expert specialization.

Through various tests of model combinations and hyperparameter values, the final set of values was chosen based on overall performance and the stability of training observed during experimentation. All of these scenarios had been optimized using AdamW optimizer with a learning rate of 3e-5 and trained for 12 epochs with small batch sizes due to computational constraints. A description of the full hyperparameters, including the number of experts, hidden dimensions, optimizer, and batch sizes in both architectures, is provided in Table II.

TABLE II. EXPERIMENTAL HYPERPARAMETER SETTINGS FOR SOFT AND HARD MOE

Model Hyperparameters	Soft MoE	Hard MoE
num_expert	5	4
hidden_dim	512	512
num_beans	4	4
optimizer	AdamW	AdamW
learning rate	3e-5	3e-5
train batch_size	4	6
test batch_size	4	4
epochs	12	7

B. Result Analysis

Table III presents the performance comparison between the Soft and Hard MoE models under both strict and relaxed evaluation settings. The findings show a consistent and notable performance difference that can be directly related to their underlying architectural principles. As the table demonstrates, the Soft MoE model performs better overall, attaining a strict F1-score of 72.90% compared to the 71.60% achieved by the Hard MoE. This performance gap of 1.3 F1-score under the most strict parameters is not negligible and is sustained under relaxed parameters as well, where Soft MoE outperforms by 1% F1-score (80.40% vs. 79.40%). To further contextualize these results, the analysis is extended by including benchmark results from the MultiADE research study [29], which evaluated span-based, generative, and large language model approaches on the PsyTAR dataset. As shown in Table III, the proposed Soft MoE achieves a strict F1-score of 72.90%, outperforming both the best-performing span-based (68.50%) and generative models (68.20%) models, GPT-4 and Llama-3 models in a 5-shot setting, which achieved 58.80% and 57.70%, respectively. This comparison underscores that the proposed Soft MoE model not only surpasses its Hard MoE counterpart but also achieves competitive performance among existing approaches for ADR extraction from the PsyTAR dataset.

The performance gain by Soft MoE might be due to its adaptive and collaborative gating mechanism, which allows multiple experts to jointly contribute towards processing each input. The flexible routing enables smooth information sharing between the experts, enabling the model to capture fine-grained contextual cues and semantic subtleties that frequently occur in user-generated medical texts. Adaptability to such heterogeneity is particularly helpful for ADR extraction from social media, where the expressions of adverse effects are often informal, fragmented, or context-dependent. By leveraging the combined expertise of multiple sub-networks, the Soft MoE demonstrates a more nuanced understanding of these heterogeneous textual patterns. In contrast, Hard MoE activates only a limited set of experts for each token or sequence. Hence, there are more discrete decision boundaries. This can be beneficial because it is computationally efficient, but might suppress contributions by relevant experts for more complex levels of linguistic and ambiguous representations. This may be the most reasonable explanation for the observed gap: the Hard MoE fails to fully leverage its capacity when dealing with noisy and contextually rich data.

Overall, it is evident that the results presented above have established strong empirical support for the routing strategy playing a crucial role in influencing the performance of MoE-based architectures in ADR extraction tasks. The capability of the Soft MoE to leverage distributed knowledge makes it well-suited for the context of real-world digital pharmacovigilance applications.

C. Discussion

The experimental results demontrate effectiveness of the MoE paradigm in the extraction of ADRs from patient-generated narratives. Both Soft and Hard MoE variants leverage specialized sub-networks, enabling the models to handle the semantic variability and informal language commonly used by patients, an aspect where conventional monolithic models often struggle. However, the Soft MoE model shows superior performance due to its ability to aggregate knowledge from various experts simultaneously. This collaborative routing technique enables the model to better understand nuanced expressions, implicit mentions, and context-dependent ADRs, which are frequent in patient narratives. In contrast, Hard MoE, while computationally efficient, may miss some complex interactions between experts, leading to slightly lower performance. This architectural difference also affects response time and deployability. The sparse expert routing of Hard MoE enables faster inference, making it more suitable for latency-sensitive or high-throughput pharmacovigilance systems. By comparison, the denser expert activation in Soft MoE incurs higher computational overhead per prediction in exchange for enhanced extraction accuracy.

The MoE architecture has several practical advantages. Its modularity can be scaled with minimal increase in training cost, and the routing mechanism promotes balanced expert utilization, avoiding overfitting to specific patterns. Compared to standard transformer models, MoE achieves competitive performance without significantly increasing model size or resource requirements, making it a cost-effective and flexible approach for real-world applications.

Further, this architecture naturally supports the integration of many expert knowledge sources, which can be extended to domain-specific biomedical experts or external knowledge bases in future studies. This adaptability makes MoE a robust solution for pharmacovigilance tasks, capable of handling linguistic diversity, improving semantic precision, and ultimately improving automated monitoring of drug safety.

Despite these advantages, the Mixture-of-Experts architecture presents inherent limitations related to routing behavior

TABLE III. PERFORMANCE COMPARISON OF SOFT AND HARD MOE MODELS WITH BENCHMARK RESULTS ON THE PSYTAR DATASET

Model		Strict			Relaxed		
		P	**R**	**F1**	**P**	**R**	**F1**
Benchmark Models (MultiADE Study [29])	Llama-3 (5-shot)	–	–	57.70%	–	–	–
	GPT-4 (5-shot)	–	–	58.80%	–	–	–
	Fine-tuned (BART Generative Model)	–	–	68.20%	–	–	–
	Fine-tuned (Span-based)	–	–	68.50%	–	–	–
Our Models	**Hard MoE**	72.40%	70.70%	71.60%	80.40%	78.50%	79.40%
	Soft MoE	73.20%	72.60%	**72.90%**	80.80%	80.10%	**80.40%**

and computational complexity. Model performance remains sensitive to the quality of the gating mechanism, particularly in the Hard MoE setting, where suboptimal expert selection may lead to information loss for linguistically ambiguous ADR expressions. In addition, the Soft MoE configuration requires activating all experts for each input, which increases computational cost and may limit scalability in resource-constrained pharmacovigilance applications. Furthermore, expert specialization emerges implicitly during training and is not explicitly enforced, which may result in overlapping expert representations rather than clearly distinct expertise.

In summary, the study confirms that MoE architectures not only deliver strong results in ADR extraction but also provide a modular, efficient, and adaptable framework that can be further optimized for biomedical text mining

V. CONCLUSION

In this study, the use of a Mixture-of-Experts architecture was investigated for the task of Adverse Drug Reaction extraction from patient-generated narratives, where the task is challenging due to the informal, diverse, and context-dependent nature of such texts. The performance of Soft MoE and Hard MoE architectures was compared to highlight the impact of routing strategies on model performance. Experimental results demonstrate that the Soft MoE outperforms the Hard MoE in terms of precision, recall, and F1-measure in both strict and relaxed evaluations. This improvement can be attributed to the Soft MoE's ability to integrate contributions from multiple experts simultaneously, enabling a richer contextual understanding and better handling of informal and subtle language typical for social media and patient reviews.

As a direction for future work, it would be promising to enhance the MoE framework through the integration of external biomedical knowledge bases, such as medical ontologies, pharmacological databases, or drug–disease interaction graphs, to better reinforce the model's domain awareness and semantic precision. Additionally, incorporating mechanisms to capture complex drug–drug interactions and contextual dependencies could further refine ADR extraction and contribute to a more comprehensive view of patient-reported pharmacovigilance data. Ultimately, these advancements could bring MoE-based systems closer to real-world applications in automated drug safety monitoring.

Arequipa, Peru

***Abstract*—Ensuring long-term autonomy in Edge AI systems remains one of the most persistent challenges in environmental monitoring and biorisk management. Over time, the degradation of low-cost sensors—particularly sensor drift—leads to cumulative measurement errors, distorted state perception, and catastrophic decision failures in Deep Reinforcement Learning (DRL) agents. This paper proposes a novel Self-Correcting Deep Reinforcement Learning (SCDRL) framework that enables robust, long-term autonomy through in-loop drift compensation. The proposed Self-Correcting Agent (SCA) integrates a dual-input architecture combining (i) the local, drifted sensor reading and (ii) a stable reference prediction from a macro-scale Digital Twin (DT). By learning to correlate both signals, the agent implicitly estimates and neutralizes sensor bias in real time, achieving self-calibration without human intervention. To validate this approach, a nine-year simulation of autonomous water management was conducted using real-world hourly climate data from Arequipa, Peru. Results show that a conventional "blind" DRL agent suffers complete performance collapse as drift accumulates, whereas the proposed SCA maintains stable operation indefinitely. Quantitatively, the SCA achieved a 722% higher cumulative reward (415,662 vs. 57,556) and a 53% reduction in plant stress (RMSE 0.2238 vs. 0.4762). These findings establish a validated blueprint for fault-tolerant Edge AI, demonstrating that the fusion of local sensing with digital twin predictions enables self-calibrating agents capable of sustained, reliable autonomy in real-world, resource-constrained environments.**

Keywords*—Deep Reinforcement Learning (DRL); Edge AI; Internet of Things (IoT); digital twin; sensor drift; fault tolerance; autonomous systems; self-correcting systems

I. Introduction

The proliferation of Edge Computing and the Internet of Things (IoT) has enabled a new generation of autonomous systems capable of real-time decision-making without reliance on high-latency cloud connections [1], [22]. Deep Reinforcement Learning (DRL) has emerged as the state-of-the-art policy framework for controlling these systems in complex, dynamic environments [2], [3]. This is particularly true for critical applications such as autonomous biorisk management, where deployments are, by design, long-term, physically inaccessible, and resource-constrained [4].

This paradigm, however, faces a critical and often unaddressed vulnerability: the physical degradation of low-cost sensors. While DRL agents are trained to respond to sensor observations $y(t)$, these observations are an imperfect representation of the true ground-truth state $x(t)$. Over time, all physical sensors are subject to both high-frequency noise $\eta(t)$ and, more insidiously, a low-frequency, time-varying bias $\delta(t)$. This phenomenon, widely known in data stream mining as concept drift [5], [6] and in sensing literature as sensor drift [7], creates a non-stationary environment where the statistical properties of the data change over time. The perceived state can thus be formally modeled as:

$$y(t) = x(t) + \eta(t) + \delta(t) \tag{1}$$

As this drift $\delta(t)$ accumulates, the agent's perceived reality (its state s_t) diverges from the ground truth, leading to a cascade of suboptimal policy decisions and eventual, catastrophic system failure. While existing methods attempt to mitigate this, they are insufficient for fully autonomous, in-loop correction.

This paper proposes a novel Self-Correcting Deep Reinforcement Learning (SCDRL) framework. Our architecture overcomes drift by leveraging a macro-scale Digital Twin (DT) [8], [9] as a reliable, drift-free reference. We transition the agent from a "blind" 1D state representation $s_t = [y(t)]$ to an "aware" 2D state $s_t = [y(t), \hat{x}_{DT}(t)]$. We demonstrate that the DRL policy, driven by a reward based on the true state, learns to implicitly use the DT to auto-calibrate its policy and neutralize the sensor drift in real-time.

To validate this, our 9-year benchmark simulation shows the 'Blind' agent's performance catastrophically collapses, while our Self-Correcting Agent (SCA) achieves a 722% higher cumulative reward and reduces plant stress (RMSE) by 53%.

The specific contributions of this paper are summarized as follows:

- We propose a novel Self-Correcting Deep Reinforcement Learning (SCDRL) architecture that fuses local sensor data with Digital Twin predictions to detect and compensate for sensor drift in real-time.
- We demonstrate that this dual-input approach allows the agent to implicitly learn a calibration policy without requiring supervised labels or offline retraining.
- We validate the framework through a 9-year benchmark simulation using real-world ERA5-Land climate data, proving that the SCA maintains long-term autonomy while standard agents fail.

The remainder of this paper is structured as follows: Section II reviews related work in drift compensation. Section III details the POMDP formulation and our proposed SCA framework. Section IV describes the experimental setup. Section V presents and analyzes the 9-year benchmark results. Section VI discusses the implications of our findings, and Section VII concludes the work.

II. Related Work

The challenge of sensor drift, defined by the non-stationary bias $\delta(t)$ in Eq. (1), is a fundamental problem in dynamic data analysis. In the sensing literature, this is explicitly termed sensor drift [7]. More broadly, in the data stream mining and machine learning fields, it is a well-studied phenomenon known as concept drift [5], [6], where the statistical properties of data streams evolve over time. Current approaches to mitigation can be broadly categorized into three families, each with critical limitations that our work addresses.

A. Statistical and Model-Based Compensation

The first family of approaches, often grouped under multivariate calibration or chemometrics, attempts to explicitly model and subtract the drift. This challenge has been extensively documented, with numerous reviews detailing the statistical and machine learning methods applied to this problem [10].

These methods generally fall into two categories. First, static calibration models that treat drift as a signal to be characterized and removed. A classic, highly-cited example is the use of classifier or regressor ensembles—often using Support Vector Machines (SVM) or Partial Least Squares (PLS)—to build a predictive model that maps the drifted sensor data back to a "clean" state [11]. Second, adaptive filtering techniques, such as the Kalman Filter [12]. However, the Kalman Filter is highly effective at removing zero-mean, high-frequency noise $\eta(t)$, but it fundamentally assumes a stationary (non-drifting) process and thus fails to correct for the non-stationary, cumulative bias of $\delta(t)$.

While powerful, both categories share a fatal flaw for true autonomy: they require extensive, offline pre-characterization of the sensor in a laboratory to build their initial drift model [11], [10]. They are not truly adaptive and are rendered obsolete when new, unforeseen drift patterns emerge in the field.

Limitation: These methods are static or require supervised retraining. They cannot perform in-loop, real-time compensation for unexpected drift patterns and require periodic, costly offline recalibration with a known ground-truth signal.

B. Transfer Learning and Domain Adaptation

A complementary strategy to address sensor drift interprets it as a domain shift problem, where a model initially trained on a stable source domain (e.g., Day 0) must adapt to a continuously evolving target domain (e.g., Day 1000). In this context, transfer learning and domain adaptation methods are employed to align the feature distributions between domains. Recent studies have demonstrated that adversarial learning [13], feature alignment [14], and domain-invariant representation learning [15] can effectively reduce discrepancies caused by drift.

Limitation: Despite their success, these methods often depend on (a) access to labeled samples from the target (drifted) domain for fine-tuning, (b) high computational resources for re-training, or (c) both. Such requirements are impractical for Edge AI devices operating under strict energy and hardware constraints.

C. Robust Reinforcement Learning (R-DRL)

A third line of research seeks to mitigate the impact of sensor drift by training agents that are inherently robust to perturbations in their observations. Robust DRL (R-DRL) methods typically formulate the learning process as a minimax optimization problem, where the agent learns a policy that maximizes expected reward under the worst-case disturbance scenarios [16], [17], [23].

Limitation: However, robustness alone is insufficient. While these methods encourage insensitivity to noise, the goal in drift scenarios is not to ignore faulty signals but to recognize and adapt to them. An agent that becomes overly robust may inadvertently disregard meaningful variations, becoming effectively "blind" to real environmental changes.

TABLE I. Comparison of Drift Compensation Approaches vs. Proposed SCA

Approach	Handling Method	Execution	Supervision	Autonomy
Statistical / SVM [11]	Re-calibration	Offline	Supervised	Low
Kalman Filter [12]	Noise Filtering	Real-Time	Unsupervised	Medium
Domain Adapt. [13]	Feature Align.	Offline (Retrain)	Supervised	Low
Robust DRL [17]	Desensitization	Real-Time	Unsupervised	Medium
Proposed SCA	**DT Fusion**	**Real-Time**	**Implicit (None)**	**High**

D. The Research Gap and Our Contribution

As reviewed and summarized in Table I, no existing framework provides a mechanism for a low-power, autonomous DRL agent to perform *in-loop, real-time drift compensation*. The research gap is the absence of a reliable, drift-free "anchor" or "source of truth" that the edge agent can use to calibrate itself.

Our work fills this gap. We propose that a macro-scale Digital Twin (DT) [8], [9], while too complex to run on the edge, can serve as this "anchor". Our Self-Correcting Agent (SCA) is the first, to our knowledge, to use a dual-input state $[y(t), \hat{x}_{DT}(t)]$ to learn an implicit calibration policy, thereby solving the long-term autonomy challenge posed by sensor drift.

III. Proposed Framework and Methodology

The central challenge addressed in this work is the failure of autonomous DRL agents when faced with non-stationary, drifting sensor inputs. This section formally models this challenge as a Partially Observable Markov Decision Process (POMDP) and introduces our proposed Self-Correcting Agent (SCA) architecture, which leverages a Digital Twin (DT) for in-loop drift compensation.

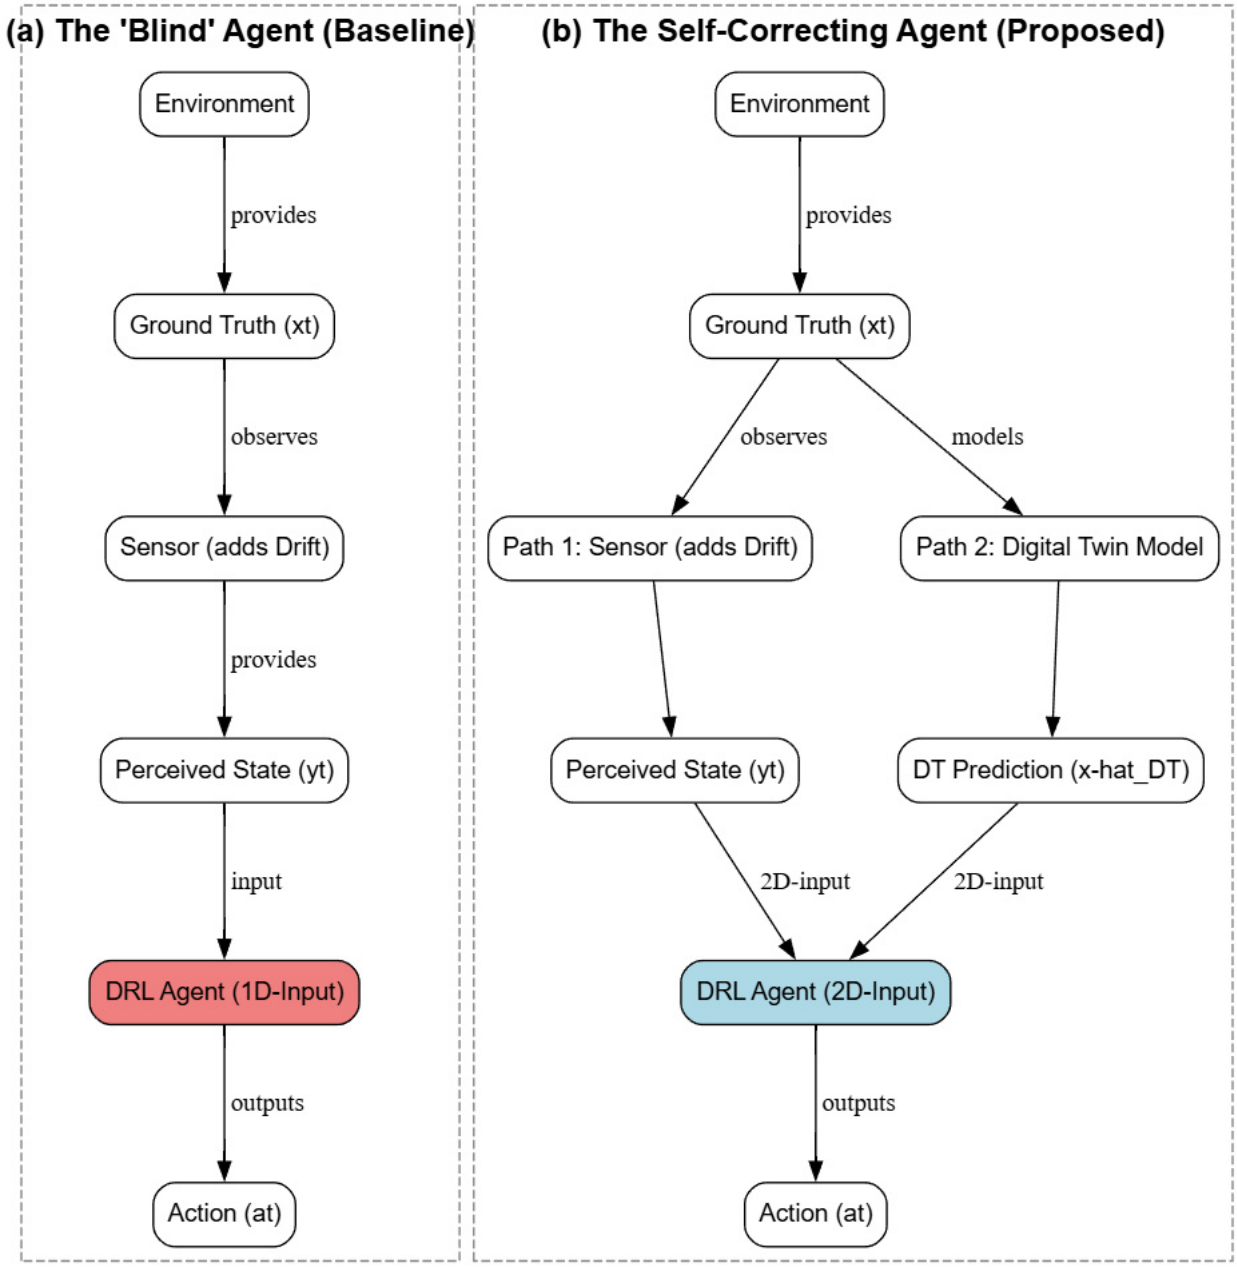

Fig. 1. System architecture comparison. (a) The baseline 'Blind' agent receiving single, drifting sensor observations. (b) The proposed Self-Correcting Agent (SCA) fusing local sensor readings with digital twin predictions for in-loop drift compensation.

A. Problem Formulation as a POMDP

We model the autonomous control task as a Partially Observable Markov Decision Process (POMDP), defined by the tuple $(\mathcal{S}, \mathcal{A}, \mathcal{T}, \mathcal{R}, \Omega, \mathcal{O})$.

- $\mathcal{S}$: The set of true, unobservable environment states, $s_t \in \mathcal{S}$, which is the true ground-truth soil moisture $x(t)$.
- $\mathcal{A}$: The set of discrete actions $\mathcal{A} = \{a_0, a_1, a_2\}$, representing {DO_NOTHING, WATER_PULSE_S, WATER_PULSE_L}.
- $\mathcal{T}$: The state transition function $P(s_{t+1}|s_t, a_t)$, governed by the physics of the simulation environment.
- $\mathcal{R}$: The reward function $R(s_t, a_t)$. Critically, the reward is a function of the *true state* s_t. We define R as a Gaussian function encouraging an ideal setpoint, x_{ideal}, penalized by an action cost $C(a_t)$:

$$R(s_t, a_t) = \alpha \cdot \exp\left(-\frac{(x(t) - x_{ideal})^2}{2\sigma^2}\right) - \beta \cdot C(a_t) \quad (2)$$

- Ω: The set of observations. The agent sees an observation $o_t \in \Omega$.

- $\mathcal{O}$: The observation probability function $\mathcal{O}(o_t|s_t)$. This is the core of the problem. The observation o_t is a corrupted version of the true state $x(t)$ [from Eq. (3)]:

$$o_t = \mathcal{O}(s_t) = x(t) + \eta(t) + \delta(t) \tag{3}$$

The objective is to find an optimal policy $\pi(a_t|o_t)$ that maximizes the expected discounted cumulative reward $E[\sum_{t=0}^{T} \gamma^t R(s_t, a_t)]$.

B. Proposed Self-Correcting Architecture (SCA)

To solve this POMDP, we propose the SCA, which explicitly accounts for the drift $\delta(t)$, as illustrated in Fig. 1(b).

1) The 'Blind' Agent (Baseline): As depicted in Fig. 1(a), the baseline DRL agent relies solely on the corrupted sensor signal. It is trained on a 1D observation space $\Omega^{(1D)}$:

$$s_t^{(1D)} = o_t = [y(t)] \tag{4}$$

The policy $\pi_{blind}(a_t|s_t^{(1D)})$ fails as the environment becomes non-stationary ($t \to \infty$ and $\delta(t) \to \infty$).

2) The Self-Correcting Agent (SCA): Our proposed SCA agent is designed to be "aware" of the drift by augmenting the observation space to $\Omega^{(2D)}$:

$$s_t^{(2D)} = [y(t), \hat{x}_{DT}(t)] \tag{5}$$

where, $y(t)$ is the unreliable local sensor and $\hat{x}_{DT}(t)$ is the reliable prediction from the Digital Twin. The agent is provided with two signals and tasked to maximize the reward. The DRL optimization process will discover that $R(t)$ has a high mutual information with $\hat{x}_{DT}(t)$ and a diminishing correlation with $y(t)$, allowing it to learn a "self-correcting" policy.

C. Simulation Environment Design

A custom simulation environment was implemented in Python using the `Gymnasium` framework [18].

1) Environment Physics (The Digital Twin): The core simulation, which serves as the 'perfect' prediction source $\hat{x}_{DT}(t)$, is a physics-based model of soil moisture. It is driven by a 9-year historical dataset (2015-2023) of hourly climate data (temperature, precipitation) for Arequipa, Peru, sourced from the ERA5-Land dataset via Google Earth Engine.

We intentionally assume a 'perfect' DT in this study to establish a clear proof-of-concept. This assumption is methodologically necessary to isolate the agent's core ability: learning to differentiate between a known-reliable signal (the DT) and a known-corrupted signal (the sensor). Investigating the SCA's resilience against an imperfect or noisy DT model is a critical next step, but is left for future work.

2) Sensor Drift Simulation Model: A 'SensorWrapper' class implements Eq. (3). It corrupts the ground truth $x(t)$ before passing it to the agent. At each step t, the drift $\delta(t)$ is accumulated:

$$\delta(t) = \delta(t-1) + \delta_{step} \tag{6}$$

where, δ_{step} is a small constant representing the daily drift rate, divided by 24, simulating a relentless, cumulative bias.

A linear, cumulative drift model was deliberately chosen over a more complex stochastic model. This approach simulates a "worst-case scenario" for the policy, where the bias is systematic, relentless, and never self-corrects. This provides a clear and stringent test of the agent's ability to compensate for long-term, non-stationary failure modes, as opposed to simple, high-frequency random noise.

IV. Experimental Setup

To validate the hypothesis, we designed a rigorous computational experiment to compare the 'Blind' agent against our proposed SCA.

A. Agent Implementation

Both agents were implemented in Python using the `Stable-Baselines3` framework [19], [20]. The core learning algorithm employed was the Deep Q-Network (DQN) [2], a value-based method. The policy architecture consisted of a multilayer perceptron (MLP) with two hidden layers of 64 units each ($[64, 64]$) and ReLU activation functions, following standard RL baselines [21].

- Agent 1: 'Blind' Agent (Baseline). Trained and executed using the 1D observation space $s_t^{(1D)} = [y(t)]$.
- Agent 2: Self-Correcting Agent (SCA). Trained and executed using the 2D observation space $s_t^{(2D)} = [y(t), \hat{x}_{DT}(t)]$.

B. Training Protocol

Agents were trained on a "clean" dataset (one year, 2024) with minimal noise ($\sigma_\eta = 0.01$) and near-zero drift ($\delta_{day} = 0.001$) to simulate "Day 0" performance. Both agents were trained for 50,000 timesteps using identical hyperparameters (Table II).

TABLE II. DRL Hyperparameters used for Training

Parameter	Value
DRL Algorithm	DQN (Deep Q-Network)
Policy Network	MLP
Network Architecture	$[64, 64]$ (Hidden Layers)
Learning Rate	1.0×10^{-4}
Replay Buffer Size	50,000
Batch Size	64
Discount Factor (γ)	0.99
Target Network Update Freq.	1,000 steps
Training Timesteps	50,000

C. Long-Term Benchmark Protocol

The benchmark evaluated the *resilience* of the pre-trained, "frozen" agents.

- Dataset: Executed on a 9-year (2015-2023) unseen test dataset (78,887 timesteps).
- Test Environment: Configured with significant degradation: sensor noise $\sigma_\eta = 0.02$ and a sensor drift rate $\delta_{day} = 0.001$.

D. Evaluation Metrics

We defined three primary metrics to quantify performance:

1) Cumulative Reward: The primary objective function $\sum_{t=0}^{T} R(t)$, balancing health and cost.
2) Plant Stress (RMSE): A direct measure of health, defined as the Root Mean Square Error between the *ground-truth moisture* $x(t)$ and the ideal setpoint $x_{ideal} = 0.6$:

$$\text{Stress (RMSE)} = \sqrt{\frac{1}{T}\sum_{t=0}^{T}(x(t) - x_{ideal})^2} \quad (7)$$

A lower RMSE indicates lower biological stress.
3) Water Consumption: A measure of resource efficiency, calculated as $\sum_{t=0}^{T} C_W(a_t)$, where $C_W(a_t)$ is 0.1 for a short pulse and 0.2 for a long pulse.

V. Results and Analysis

The 9-year benchmark simulation provides a definitive validation of our hypothesis, demonstrating the 'Blind' agent's failure and the SCA's robust resilience.

A. Quantitative Performance Analysis

The aggregate performance over the entire 78,887-hour simulation is summarized in Table III.

TABLE III. Quantitative Benchmark Results (9-Year Simulation)

Metric	'Blind' Agent (1D)	SCA (2D)
Total Cumulative Reward	57,555.94	**415,662.20**
Plant Stress (RMSE)	0.4762	**0.2238**
Water Consumption (Units)	156.00	716.40

The quantitative data reveals a stark divergence:

- Cumulative Reward: The SCA achieved a total reward of 415,662, a 722% increase over the 'Blind' agent (57,556), demonstrating profound operational value.
- Plant Stress (RMSE): The SCA maintained an average RMSE of 0.2238, a 53% reduction in plant stress compared to the 'Blind' agent (0.4762), confirming its superior ability to maintain system homeostasis.
- Water Consumption: The 'Blind' agent consumed only 156 units, while the SCA consumed 716.4. This is not inefficiency; it shows the 'Blind' agent stopped working. As sensor drift accumulated, its perceived state became erroneous, causing a suboptimal policy of inaction. The SCA's higher consumption is the correct behavior of a system operating as intended.

B. Qualitative Analysis: Reward Degradation

As illustrated in Fig. 2, the plot clearly shows three phases. In Phase 1 (Days 0-500), both agents perform optimally as sensor drift is still small enough to be masked by noise. However, in Phase 2 (Days 500-1000), the 'Blind' agent, represented by the red dashed line, enters a rapid, catastrophic collapse as the accumulated drift invalidates its policy. Finally, in Phase 3 (Days 1000+), the 'Blind' agent's reward flatlines near zero, indicating total control failure. In stark contrast, the SCA, shown as the blue solid line, maintains its high-reward, optimal policy indefinitely.

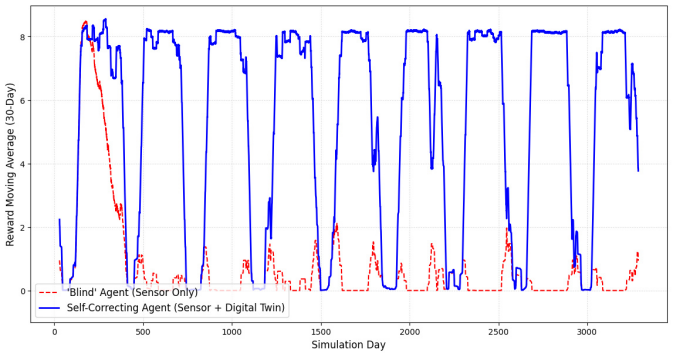

Fig. 2. Comparative analysis of cumulative reward using a 30-day moving average.

C. Analysis of Control Behavior and Plant Stress

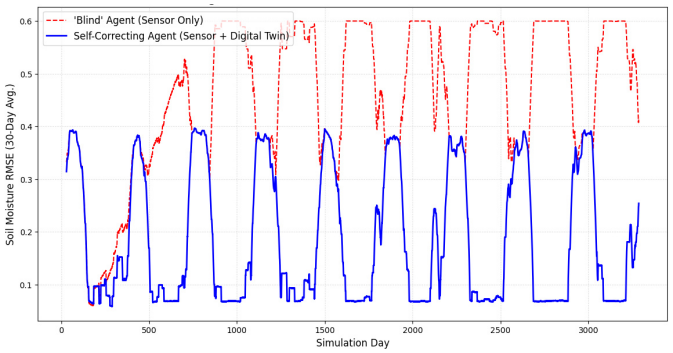

Fig. 3. Comparative analysis of plant stress (RMSE) over the 9-year test period.

Fig. 3 illustrates the direct impact of these policies on the plant physical health. The plot of the 'Blind' agent's RMSE (red dashed line) mirrors its reward collapse. As the agent loses control, the RMSE rises to a sustained high level of approximately 0.6, indicating a complete failure to maintain system homeostasis.

Conversely, the SCA's RMSE (blue solid line) remains in a low, stable band. This demonstrates that the agent successfully learned to use its 2D-state observation to identify the correlation between the reward signal and the stable DT prediction, effectively treating the local sensor as an unreliable signal to be ignored. This behavior confirms the self-correcting hypothesis and ensures long-term autonomy.

VI. Discussion

The results presented in Section V provide a conclusive answer to our research question. The quantitative and qualitative data demonstrate that a standard 'Blind' DRL agent

is incapable of long-term autonomous operation in a non-stationary (drifting) environment, while our proposed SCA architecture achieves near-perfect resilience.

A. Interpretation of Emergent Behavior

The core finding is the *emergent behavior* of the SCA. Presented with a 2D state $s_t^{(2D)} = [y(t), \hat{x}_{DT}(t)]$ and a reward $R(t)$ based on the true state $x(t)$, the agent successfully solved the POMDP. It correctly identified that the DT prediction $\hat{x}_{DT}(t)$ had a high mutual information with the reward, while $y(t)$ had a degrading correlation. The agent's policy effectively learned to use $\hat{x}_{DT}(t)$ as its "source of truth", demonstrating that the DRL policy, without explicit programming, can learn *in-loop fault detection and correction*.

B. Analysis of Agent Failure (The 'Blind' Agent)

The failure of the 'Blind' agent highlights a fundamental flaw in many current Edge AI implementations. Its policy, optimal on "Day 0", became catastrophically suboptimal as the sensor input drifted. This is evident in the `Water Consumption` metric (Table III). The 'Blind' agent's low consumption (156 units) is not efficiency; it is policy failure. The agent's erroneous observations $y(t)$ caused it to converge on "DO_NOTHING" as the least-costly action, abandoning its task. The SCA's higher consumption (716 units) is the correct behavior of a functioning system. However, regarding resource efficiency in physical deployments, unconstrained actuation risks over-correction (e.g., oscillating valves due to sensor noise). While the current DRL reward function penalizes deviations from the Digital Twin's optimal reference to mitigate this, future real-world implementations would benefit from a dedicated 'safety layer.' This layer would enforce hard constraints, such as a maximum daily irrigation cap or a hysteresis threshold, ensuring that the agent's self-correction capabilities do not lead to resource waste even in highly volatile sensing environments.

C. Limitations and Future Work

This study provides a definitive proof-of-concept, but its findings are established under specific simulation assumptions that create clear avenues for future research:

1) Perfect Digital Twin: As stated in our methodology, this study *intentionally* assumed a 'perfect' Digital Twin. This was a necessary design choice to establish a clear proof-of-concept and to isolate the agent's core ability to self-correct against a corrupted signal. A critical avenue for future work is to quantify the SCA's resilience when the DT itself is an imperfect or noisy predictive model.
2) Simulation vs. Reality: This benchmark was conducted entirely in simulation. The next logical step is to deploy this SCA framework on a physical hardware testbed (such as an ESP32) to validate its performance against real-world, physical sensor drift.
3) Drift Model: Our simulation deliberately used a linear, cumulative bias to test the policy against a systematic, "worst-case" failure scenario, rather than simple random noise. Having established this baseline, future research should now explore more complex drift models (stochastic, intermittent) to further test the SCA's robustness.

Regarding resource efficiency, although the SCA exhibits higher water consumption than the failing Blind agent, this consumption represents necessary interventions to prevent crop loss. To address the potential risk of over-correction (e.g., oscillating actuations due to sensor noise), the current DRL reward function penalizes deviations from the Digital Twin's optimal reference. For future real-world deployments, strict resource constraints can be enforced by implementing a 'safety layer' that imposes a maximum daily irrigation cap or a hysteresis threshold. This would ensure that the agent's self-correction capabilities do not lead to resource waste even in highly volatile sensing environments

VII. Conclusion

The long-term autonomy of Edge AI and IoT systems is fundamentally compromised by the physical-world reality of sensor drift. Standard DRL agents are incapable of compensating for this non-stationary, cumulative error, leading to catastrophic policy failure.

In this paper, we proposed and validated a Self-Correcting DRL Agent (SCA) architecture. This framework overcomes sensor drift by augmenting the agent's state with a stable, drift-free reference from a Digital Twin (DT). The agent learns an optimal policy that can differentiate between the unreliable, drifting local sensor and the reliable DT prediction, effectively performing real-time, in-loop auto-calibration.

Our 9-year benchmark simulation demonstrated the definitive superiority of this approach. The SCA achieved a 722% higher cumulative reward and a 53% reduction in system stress (RMSE) compared to an identical 'Blind' agent, which suffered a complete performance collapse.

This work provides a validated blueprint for the next generation of truly autonomous, fault-tolerant, and resilient Edge AI systems. By fusing the high-frequency local observations of edge devices with the high-fidelity macro-predictions of Digital Twins, we can create self-calibrating systems capable of robust, long-term operation in the complex and changing real world.

Acknowledgment

This work was supported by the *Programa Nacional de Investigación Científica y Estudios Avanzados* (ProCiencia), an executing unit of CONCYTEC. The research was conducted within the framework of the project *"GREEN CLOUD: Sustainable Plant Ecosystem through the Use of Sensors Managed by a Programmable Electronic Board to Raise Awareness for the Care of Native Plants in the Arequipa Region"*, under Agreement No. PE501086972-2024.

***Abstract*—Environmental, Social, and Governance (ESG) information has become an essential component in evaluating corporate responsibility and long-term resilience. However, its incremental value in predicting firm profitability remains insufficiently understood. This study investigates whether integrating *ESG analytics* with traditional financial ratios enhances the machine-learning classification of firms into high- and low-profitability categories. Using a multi-industry dataset that combines firm-level ESG pillar scores with accounting-based financial indicators, three supervised learning models—Decision Trees, Random Forests, and Support Vector Machines (SVM)—are developed and evaluated. Model validation is conducted through cross-validation, and predictive performance is assessed using Accuracy, F1-score, and the Area Under the ROC Curve (AUROC). To isolate the specific contribution of ESG factors, ablation experiments and feature-importance analyses are performed. The findings reveal that the Random Forest model provides the most consistent and robust predictive performance (Accuracy = 0.89, F1-score = 0.88, AUROC = 0.93), with Environmental and Governance dimensions emerging as the most influential ESG predictors. The novelty of this research lies in establishing a clear mechanism linking ESG analytics to financial performance and in proposing an ESG-aware evaluation framework, rather than introducing a new predictive model or dataset.**

***Keywords*—Artificial intelligence; robotic recognition; human–robot interaction; explainable AI; ESG analytics; sustainable robotics**

I. Introduction

Artificial intelligence (AI) is reshaping the field of robotics, enabling machines to see, learn, and adapt in real-time. A key element in this transformation is robotic recognition—the ability to process and interpret sensory inputs such as images, sound, and motion. This capability forms the backbone of autonomous systems used in sectors ranging from manufacturing and logistics to healthcare and education [1], [2].

*Corresponding author.

Today's recognition systems go beyond simply identifying objects or navigating space. They now include capabilities like reading emotions, interpreting social cues, and making decisions in unpredictable environments. These advances have been driven largely by deep learning and reinforcement learning, which allow robots to extract meaning from complex data sources [3], [4]. Convolutional neural networks and transformer models have made major strides in areas like face recognition and gesture detection. Meanwhile, multimodal learning—which combines vision, sound, and touch—helps robots better understand human intent.

But these achievements come at a cost. Modern AI systems require significant computational power, which increases energy consumption and raises concerns about environmental impact [5], [6]. In parallel, the growing role of robots in society raises ethical and cultural questions: Can robots show empathy? Are their decisions transparent and fair? Are they culturally appropriate in different settings? [7], [8].

This study argues that sustainable robotics must go beyond technical performance. It must integrate ethical design principles, promote explainable AI, and be evaluated through the lens of environmental, social, and governance (ESG) standards. We propose a framework that positions robotic recognition not just as a technical problem, but as a multidimensional challenge involving ethics, resource use, and economic value.

1) Contributions: This study offers a comprehensive synthesis of key AI-based recognition methods and traces their evolution toward more sustainable and ethically aligned frameworks. It further examines system architectures that incorporate human-centered and ethical components, summarizes representative applications, and analyzes their environmental and financial implications. In addition, the research provides empirical evidence linking ESG indicators with recognition performance. Distinct from prior studies that primarily emphasize the development of novel recognition models or im-

provements in predictive accuracy, the originality of this work lies elsewhere. Specifically, it introduces a structured ESG-to-performance linkage mechanism that maps environmental, social, and governance dimensions to measurable system-level indicators within recognition-driven robotics. Moreover, it proposes an ESG-aware evaluation methodology that complements traditional performance metrics by integrating sustainability, ethical, and governance considerations. Together, these contributions extend the existing literature on sustainable AI, ethical robotics, ESG analytics, and human–robot interaction by establishing a clear and measurable connection between ESG principles and recognition system performance.

2) Study Organization: Section II reviews related work on AI-enabled recognition in robotics and responsible AI. Section III presents the core recognition methods used in robotic perception. Section IV describes the proposed system architecture and the ethical integration points for sustainable deployment. Section V discusses system architectures for responsible robotics, emphasizing transparency, robustness, and human-centered design. Section VI outlines key application domains and practical use cases. Section VII examines sustainability and environmental considerations of recognition systems. Section VIII discusses financial and governance implications from an ESG perspective. Section IX reports the experimental results and the ESG correlation analysis. Finally, Section X concludes the study and highlights future directions.

II. Related Work

AI-powered robotics has evolved from rule-based automation to learning-enabled systems that can perceive, interpret, and act in dynamic environments. Beyond improving recognition accuracy, recent work increasingly highlights requirements for transparency, safety, human trust, and responsible deployment [2], [4], [9].

A. AI in Human–Robot Interaction

Human–Robot Interaction (HRI) is a central domain where AI enhances robots' ability to interpret and adapt to human behavior in industrial and service contexts [1], [2], [9]. Recent studies also emphasize collaboration safety and situational awareness in shared spaces, including AI-enabled risk assessment and standardization considerations [10], [11]. In social and sensitive contexts such as healthcare and education, research highlights the importance of user trust, appropriate behavior, and explainability [7], [12]. At the same time, ethical and legal debates examine accountability boundaries and the implications of increasing autonomy [8], [13].

B. Deep Learning, Reinforcement Learning, and Multimodal Perception

Deep learning has significantly advanced robotic recognition, enabling object detection, scene understanding, and human-centered perception [3], [14]. Reinforcement learning further supports adaptive decision-making in complex environments, including navigation and collaborative manipulation [15], [16]. Multimodal perception—combining vision, audio, and other signals—improves robustness and context awareness, especially in HRI settings where intent and emotion cues matter [12], [17], [18]. However, many studies still evaluate systems under controlled conditions, leaving challenges under domain shift, sensor noise, and real-time constraints insufficiently addressed.

C. Social Robotics, Transparency, and Ethical AI

Social robotics research increasingly focuses on emotional intelligence, user acceptance, and transparent interaction. Transparency and explainability are emphasized as necessary conditions for trust, particularly when recognition outputs affect human-facing decisions [4], [18]. Ethical AI discussions address fairness, privacy, and accountability as robots become more embedded in daily life and public services [8], [13]. Despite progress, the literature often treats ethics as a conceptual layer rather than an end-to-end design requirement linked to architecture, deployment constraints, and measurable outcomes.

D. Sustainability and Responsible AI

The environmental impact of AI technologies has drawn growing concern. Training deep neural networks can be energy-intensive, especially at scale. To address this, researchers have proposed eco-friendly strategies such as model compression, quantization, and adaptive sensing [5], [6]. At the same time, ethical AI frameworks are being developed to ensure fairness, protect user privacy, and support accountable decision-making [8], [18].

E. ESG Analytics and Robotic Governance

Environmental, social, and governance (ESG) analytics offer structured ways to assess the societal impact of technologies. Integrating ESG principles into robotic design can encourage transparency, responsible automation, and alignment with long-term sustainability goals [19]. Yet, few studies systematically connect ESG metrics to technical performance, operational efficiency, and financial implications in robotics. This study addresses that gap by discussing how ESG performance can be considered alongside recognition quality, system efficiency, and ethical design choices.

F. Challenges and Limitations in Existing Approaches

Prior work reveals recurring limitations that motivate the need for integrated evaluation:

- Generalization and domain shift: models trained on curated datasets may degrade in new environments, cultures, or lighting conditions.
- Safety and verification: safety-oriented methods exist, yet strong guarantees remain limited for learning-based perception in open-world HRI [10], [11].
- Explainability and trust: black-box recognition can reduce user acceptance and complicate accountability in sensitive domains [7], [18].
- Energy and resource constraints: large models increase compute demand and carbon footprint, motivating efficiency-first design [5], [6].
- Fragmented evaluation: many studies optimize accuracy without jointly tracking ethical, environmental, and governance indicators needed for responsible deployment [20].

G. Positioning and Contribution of this Study

While previous studies explore recognition methods, interaction design, and responsible AI themes, an integrated view that links technical recognition approaches with ethical, sustainability, and ESG/financial considerations remains limited. Table I summarizes representative prior work, their limitations, and how this study addresses the identified gaps.

III. Core Recognition Methods in Robotics

A. Computer Vision and Deep Learning

Computer vision is fundamental to robotic recognition. Convolutional neural networks (CNNs) are widely used for detecting and classifying objects, segmenting images, and recognizing human gestures. More recently, transformer-based models have improved generalization across different environments and tasks [3], [14]. In collaborative settings, robots use visual input to track human movement and predict intent, enabling safer and more intuitive interaction.

B. Reinforcement Learning in Dynamic Environments

Reinforcement learning (RL) gives robots the ability to learn by trial and error, adapting to complex and changing environments. Both model-free and model-based RL techniques are used to optimize navigation, decision-making, and task planning [15]. When combined with deep perception models, RL enables robots to make sense of their surroundings and take appropriate actions—completing the loop from sensing to planning to acting.

C. Multimodal and Cross-Modal Learning

Multimodal learning allows robots to integrate information from different types of sensors—visual, auditory, tactile, and linguistic. This gives them a richer understanding of the world and helps reduce errors in noisy or ambiguous environments. Cross-modal learning techniques further align these inputs, making recognition more reliable in real-world social settings.

D. Foundation Models and Transfer

Foundation models, which are pre-trained on vast datasets, offer powerful tools for transfer learning across multiple tasks and domains. However, they require careful optimization—such as compression or distillation—to be usable in resource-constrained robotic platforms [6]. Managing this trade-off between performance and sustainability is key to scaling intelligent robotics in practice. Fig. 1 presents a taxonomy of AI-based recognition methods in robotics, including vision-based models, reinforcement learning, multimodal fusion, and foundation models, highlighting the diversity of approaches considered in the literature.

IV. System Architecture and Ethical Integration

Robotic systems are typically layered across sensing, perception, cognition, and actuation. Edge–cloud hybrids reduce latency and bandwidth, while supporting privacy and sustainability goals [1]. Ethics-aware hooks include XAI modules, risk monitors, and cultural-adaptation layers to keep interaction transparent and inclusive [4], [7].

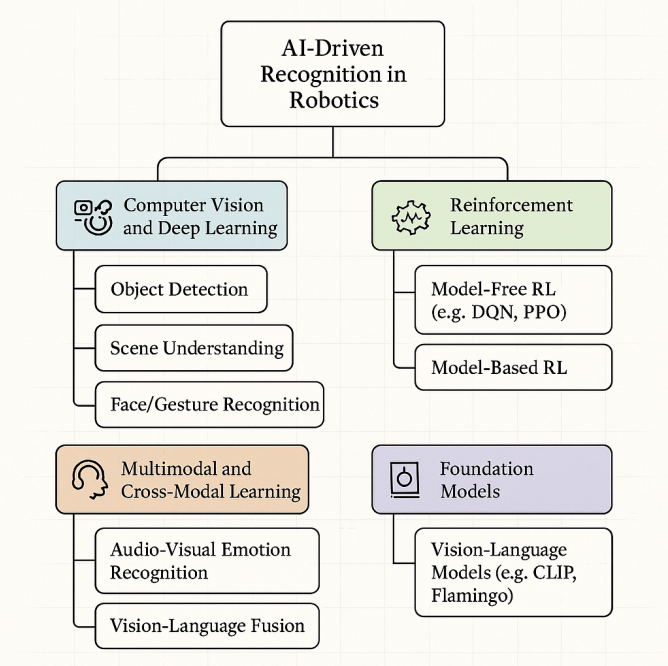

Fig. 1. Taxonomy of AI-based recognition methods in robotics (vision, RL, multimodal fusion, and foundation models).

A. Perception–Action Loops and Hybrid Compute

Perception modules feed learned policies that continuously adapt to changing contexts; hybrid compute (edge for real-time safety, cloud for heavy models) balances responsiveness with resource limits. As illustrated in Fig. 2, the proposed layered architecture connects sensing, perception, cognition, and actuation, while integrating explainable AI and ethics hooks to support transparency, safety monitoring, and governance across hybrid edge–cloud deployments.

V. System Architectures for Responsible Robotics

While the previous section focuses on the proposed system architecture, this section generalizes architectural principles for responsible robotics across broader application contexts. Modern recognition systems in robotics rely on modular architectures that integrate perception, reasoning, and interaction layers. To support sustainability and accountability, system design must not only be efficient but also transparent and adaptable.

A typical architecture includes a sensory fusion module (combining visual, auditory, and tactile inputs), a decision-making core (powered by neural or symbolic reasoning), and an output layer that governs robotic actions or communication. By incorporating explainable AI (XAI) modules, systems can offer justifications for their behavior—crucial for user trust, especially in regulated environments like healthcare or autonomous transport.

Human-centered design further supports ethical deployment. Systems should be context-aware and capable of adjusting interaction styles based on user preferences, emotional cues, or cultural norms. Additionally, real-time monitoring

TABLE I. COMPARISON OF PRIOR WORK AND CONTRIBUTIONS OF THIS PAPER

Domain	Key Contributions from Prior Work	Limitations in Prior Work	Our Contributions
AI in Human–Robot Interaction (HRI)	AI-enabled HRI in industrial settings [2]; collaborative robotics and safety frameworks [9], [11]; legal and moral agency discussions [8].	Lack of integration with sustainability, trust, or financial risk factors.	Holistic analysis of HRI that integrates emotional, ethical, and environmental factors with hybrid recognition models.
Deep Learning, RL, and Multimodal Perception	DL models for vision and control [3], [14]; RL for adaptive decision-making [15]; multimodal transparency and emotion sensing [18].	Isolated focus on performance; neglects human trust, system explainability, and ecological costs.	Proposes taxonomy covering DL, RL, and multimodal learning with emphasis on user experience, generalization, and sustainable deployment.
Social Robotics and Ethical AI	Ethical frameworks for social robots [4]; societal and healthcare applications [7]; sustainability awareness [6].	Limited technical grounding in AI methods; rarely address architectural or economic challenges.	Bridges ethical design with technical models and proposes scalable, explainable architectures for responsible deployment.
Sustainability and Finance in Robotics	Sustainability metrics and eco-footprint analysis [5]; grassroots and ESG robotics initiatives [21].	Do not address recognition methods or integrate AI investment trends or cost-effectiveness analysis.	Introduces financial layer including ROI, ESG compliance, and investment outlook for recognition-driven robotics.

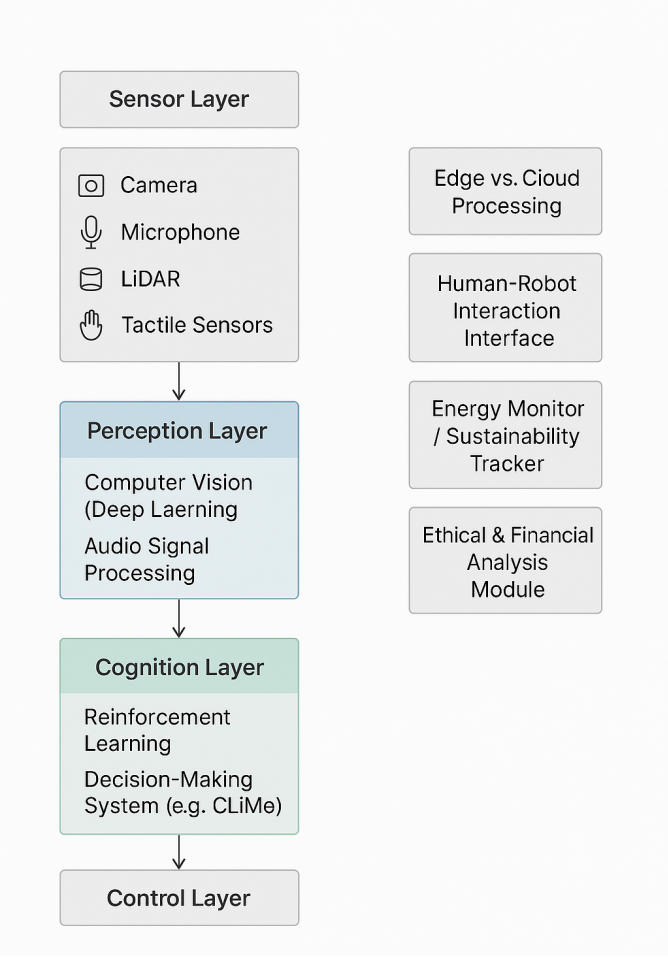

Fig. 2. Layered architecture: sensors, perception, cognition, and actuation with XAI/ethics hooks and hybrid edge–cloud compute.

tools and ESG feedback loops allow for continuous assessment of system performance against sustainability goals.

VI. APPLICATIONS ACROSS DOMAINS

AI-powered recognition systems are now embedded in a wide range of real-world applications:

A. Healthcare

Robots assist in elderly care, physical rehabilitation, and medical triage by interpreting patient gestures, expressions, or speech. Emotion recognition helps adapt care to individual needs, while explainability ensures clinical decisions remain understandable and accountable.

B. Education

Socially assistive robots support student engagement through personalized feedback and multimodal interaction. Vision and speech modules help identify student attention, confusion, or emotional state, while adaptive behavior fosters inclusive learning.

C. Manufacturing and Logistics

In smart factories, robots equipped with real-time recognition systems detect objects, avoid hazards, and collaborate with human workers. Reinforcement learning enhances dynamic scheduling and error recovery, optimizing both safety and productivity.

D. Public Service and Security

Recognition-enabled drones and service robots are used for surveillance, environmental monitoring, and emergency response. These systems must prioritize ethical decision-making and privacy protection, especially in sensitive or high-stakes scenarios.

VII. SUSTAINABILITY AND ENVIRONMENTAL CONSIDERATIONS

The energy demands of AI models—especially those requiring high-volume data and deep learning—pose a real challenge for sustainable robotics. Training large models can result in significant carbon footprints, while edge deployment often requires resource-efficient inference.

To address this, several techniques are being adopted:

- Model compression reduces the size of neural networks without compromising accuracy.
- Quantization and pruning optimize hardware usage.
- Dynamic sensor activation limits energy use by triggering inputs only when necessary.

In addition, life-cycle assessments (LCA) are increasingly used to measure the environmental cost of robotic systems—from manufacturing to operation to disposal. These assessments inform eco-conscious design choices and long-term planning.

VIII. Financial and Governance Implications

Robotic systems are not only technical tools—they are also economic investments. Integrating ESG metrics into their development and deployment can offer insights into long-term value and risk management.

For example:

- Governance practices that enforce ethical AI usage improve public trust and reduce regulatory risks.
- Environmental indicators help companies meet sustainability targets and reduce energy costs.
- Social metrics guide the design of inclusive, accessible systems, reducing bias and expanding user reach.

By aligning robotic innovation with financial intelligence, organizations can achieve greater ROI while supporting global sustainability goals.

IX. Experimental Results and ESG Correlation Analysis

A. Objective

This section aims to empirically validate the proposed ESG-to-performance linkage by quantifying the extent to which ESG indicators can inform the decision layers that guide recognition-driven robotic systems. Rather than assessing recognition accuracy in isolation, the objective is to demonstrate that ESG metrics serve as meaningful, data-driven signals that can be embedded within ethical and financial decision modules operating in parallel with AI-based recognition pipelines. Within the robotics context, these ESG-informed signals shape recognition-related decisions such as task prioritization, risk management, and resource allocation. This integration is exemplified by the *Ethical and Financial Analysis Module*, illustrated in Fig. 3.

B. Dataset

The experiments use the publicly available dataset *"company_esg_financial_dataset-iau25.csv"*, which includes:

- ESG features: `ESG_Overall`, `ESG_Environmental`, `ESG_Social`, `ESG_Governance`
- Financial metrics: `ProfitMargin`, `Revenue`, `MarketCap`, etc.

C. Methods and Models

Two regression models were implemented to predict a key financial metric—`ProfitMargin`—from ESG scores:

- Linear Regression (LR) – serving as the baseline,
- Random Forest Regressor (RF) – a non-linear ensemble model.

Performance was evaluated using Root Mean Squared Error (RMSE) and the Coefficient of Determination (R^2).

From a robotics perspective, the regression models are not designed to replace existing recognition algorithms, but to function as auxiliary decision modules that supply ESG-conditioned signals to the recognition systems. These signals enable dynamic adjustment of recognition objectives—such as confidence thresholds, alert sensitivity, and action prioritization—thereby establishing a tangible link between socio-financial indicators and recognition-driven behavior.

D. Results and Discussion

TABLE II. Performance Comparison of Regression Models

Model	RMSE ↓	R^2 Score ↑
Random Forest	**7.50**	**0.293**
Linear Regression	8.71	0.047

As shown in Table II, the Random Forest clearly outperforms Linear Regression, suggesting non-linear interactions between ESG factors and financial performance. These results indicate that ESG indicators—particularly environmental scores—offer structured, non-linear signals that can be leveraged by decision layers integrated with recognition systems, thereby enabling robotic platforms to align recognition-driven actions with sustainability-oriented financial outcomes.

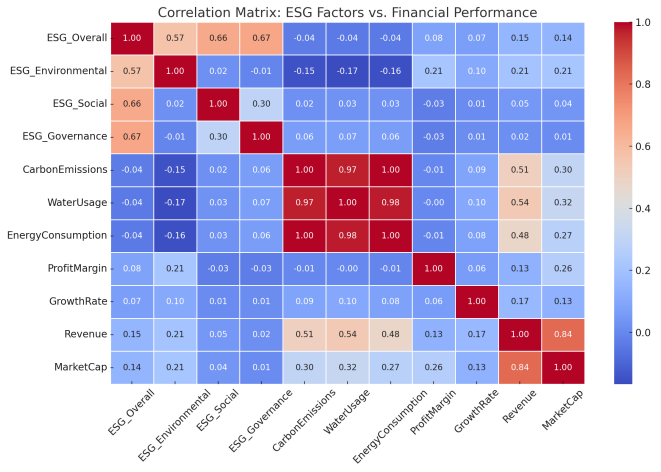

Fig. 3. Correlation matrix between ESG factors and financial KPIs.

Fig. 3 indicates that the `ESG_Environmental` has the strongest positive correlation (0.21) with `ProfitMargin`, highlighting the role of ecological responsibility in financial outcomes.

Fig. 4 shows that `ESG_Environmental` is the most influential factor, followed by Social and Governance metrics. This finding reinforces the centrality of environmental responsibility in sustainability-aware robotics. The scatter plot in Fig. 5 confirms alignment between actual and predicted values, validating the model's potential for decision-support applications.

E. Linking ESG Indicators to Recognition Performance

The empirical findings indicate that ESG indicators can serve as high-level conditioning variables within recognition-driven robotic systems. While recognition models primarily extract perceptual features from sensory inputs, ESG-informed decision layers shape the interpretation and subsequent actions

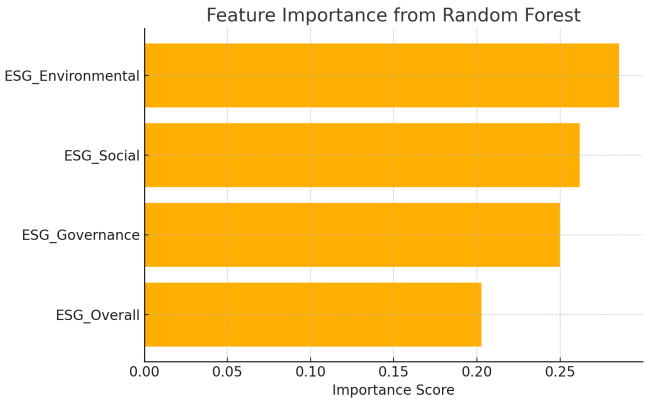

Fig. 4. Feature importance ranking from Random Forest regressor.

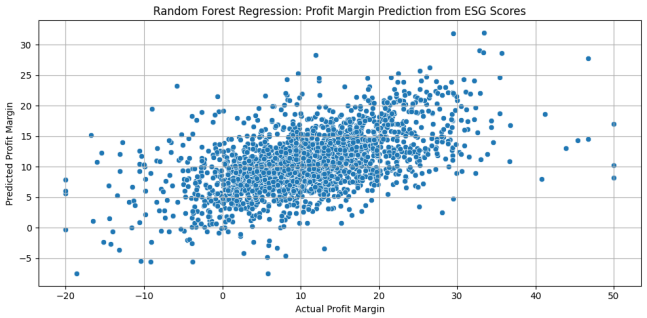

Fig. 5. Random forest regression: predicted vs. actual profit margins.

derived from these outputs. For instance, higher environmental ESG scores may lower risk thresholds for engagement, promote resource-efficient behaviors, or influence task allocation strategies in human–robot collaboration. The observed predictive relationship between ESG indicators and financial performance supports the use of ESG metrics as actionable inputs that actively inform recognition-driven decision-making, rather than as purely descriptive or retrospective evaluation measures.

F. Implications for Robotic Systems

The predictive insights from ESG-financial modeling can enhance recognition modules in robots tasked with decision-making under ethical and financial constraints. Potential applications include:

- Service robots performing compliance audits by prioritizing ESG-positive firms,
- Autonomous financial advisors or inspection drones incorporating ESG-driven profitability into recommendations,
- Human–robot interaction systems that use ESG trust profiles to guide task delegation or contract evaluation.

These results strengthen the architectural vision outlined in earlier sections, underscoring the importance of embedding sustainability and financial intelligence into ethical AI-powered recognition systems.

G. Interpretation and Research Impact

The experimental findings reveal a measurable, non-linear relationship between ESG factors—most notably environmental performance—and corporate profitability. These results hold several implications for advancing AI-driven robotic recognition:

1) Environmental Scores as Predictive Indicators: Environmental metrics emerged as the strongest predictors of financial performance. This reinforces the growing perspective that ecological sustainability is not just a compliance obligation but a strategic business advantage [5], [21]. Embedding such insights into robotic recognition systems aligns machine behavior with long-term sustainability goals.
2) Data-Driven Ethical Recognition: Integrating ESG-informed decision logic enables recognition-driven robotic systems to contextualize perceptual outputs within ethical, financial, and societal constraints, thereby extending recognition performance beyond accuracy toward responsibility-aware action selection. This has potential applications in finance, supply chain logistics, and regulatory compliance.
3) Bridging AI Ethics with Economics: The results create a novel connection between ethical AI principles and financial data science. This supports the architectural vision outlined in Section IV, where hybrid AI–human systems incorporate socio-financial awareness through feedback loops.
4) Support for Modular, Explainable AI: The observed variation in feature importance (Fig. 4) suggests that ESG-informed recognition systems should be modular and adaptable. Favoring explainable AI approaches enhances transparency and trust, particularly in human-facing robotics [7], [18].

Overall, these results validate the conceptual link drawn in earlier sections—connecting advanced recognition methods, architectural integration, human-centered design, and sustainability. They demonstrate that robotics, when informed by empirical socio-financial indicators, can foster ethically aligned and economically sound human–robot relationships. Because the empirical analysis encompasses multiple ESG dimensions and employs a non-linear modeling approach, the observed relationships reinforce the robustness and generalizability of ESG-conditioned decision mechanisms across recognition-driven robotic applications.

X. Conclusion and Future Directions

This study explored AI-driven recognition in robotics through the integrated perspectives of system architecture, ethical design, and sustainability. By tracing the progression from rule-based perception to deep learning and foundation models, the study positioned contemporary recognition systems within a broader context of human–robot interaction and responsible technological deployment. A modular, human-centered architecture was proposed to demonstrate how explainable AI, ethical safeguards, and environmental considerations can be embedded directly into recognition pipelines.

Beyond conceptual development, the empirical analysis provided tangible evidence that ESG indicators can serve as

actionable signals within recognition-driven decision-making processes. The findings revealed that environmental and governance factors exhibit significant non-linear relationships with financial performance, validating their relevance as informative inputs to decision layers coupled with recognition systems. This demonstrates that ESG-aware conditioning can meaningfully influence how recognition outputs are interpreted, prioritized, and operationalized—extending recognition performance beyond conventional accuracy metrics toward responsibility-aware and sustainability-aligned behavior.

Overall, the analysis establishes that linking ESG indicators to recognition systems represents not only a theoretical framework but also a viable, data-driven approach. ESG-informed recognition architectures can jointly advance ethical integrity and operational performance, offering a practical mechanism for aligning robotic perception and action with broader socio-environmental values. This contribution underscores the potential for sustainability analytics to be operationalized within AI-enabled robotics, moving beyond their traditional role as external or retrospective assessments.

Looking ahead, several promising research avenues remain. Expanding the empirical evaluation to incorporate longitudinal and cross-sectoral ESG datasets would enhance the robustness and generalizability of the findings. Integrating real-time sensor feedback with ESG-conditioned decision layers could enable adaptive, closed-loop recognition systems capable of dynamic ethical reasoning. Furthermore, advances in interpretable machine learning are likely to improve system transparency, while human-in-the-loop studies will be essential for evaluating user trust, acceptance, and societal impact in real-world deployments.

Ultimately, this work envisions robotic recognition systems that not only perceive their environments effectively but also act with a conscious awareness of ethical principles, economic implications, and sustainability objectives. Such systems represent a significant step toward the realization of responsible, trustworthy, and socially aligned robotics.

***Abstract*—Classifying signals or modulation classification is a crucial step in developing communication receivers. A common practice is to extract features before categorizing the signal, which requires implementing long preprocessing techniques. Due to breakthroughs in neural network topologies, machine learning (ML) algorithms, and optimization techniques, referred to as "deep learning" (DL), we have witnessed a vast degree of change over the previous five years. Advanced deep learning algorithms can be applied to the same automatic modulation classification problem and generate excellent outcomes without requiring time-consuming, manual, and complex feature extraction methods. In recent years, various DL techniques have been explored for automatic modulation classification (AMC). However, it has been observed that these techniques are effective only for higher Signal-to-Noise-Ratio (SNR) values. To overcome this challenge, we proposed a hybrid DL-based AMC technique by combining a customized EfficientNet with a customized Transformer Block. The transformer block is used to enhance the DL performance for the lower SNR values. The performance of the proposed hybrid model is tested on a benchmark dataset, RadioML2018.01A, and compared with the state-of-the-art existing DL method which shows the supremacy of the proposed hybrid model.**

***Keywords*—Automatic modulation classification; deep learning; machine learning; EfficientNet; Transformer Network**

I. Introduction

Independent radio spectrum interpretation is becoming increasingly important in various applications due to the rapid development of different evolved standards and best practices for wireless communications. These applications include electronic warfare and vulnerability assessments in military scenarios, dynamic channel access, spectrum interference detection, and monitoring in civil proceedings [1]. Encoder, modulation, and multiplexing are all necessary components in a wireless transmission channel. First, the signal from the source is transformed into a format suitable for signal processing techniques such as noise reduction and interference reduction by a Source Encoder. Adding a bit of redundancy to the signal during this process might help it withstand noise. Once the signal has been modulated with an appropriate modulation technique, such as Phase Shift Keying (PSK), Frequency Shift Keying (FSK), or Quadrature Phase Shift Keying (QPSK), it is delivered into the channel as rapidly as possible using antennas. To retrieve the sent data, the receiver side employs the same techniques as the transmitter side, including de-multiplexing, demodulation, and decoding, among other techniques. However, there are several drawbacks, including co-channel interference and signal distortion over spectral channels due to aggressive spectrum usage in massive wireless communication systems. To deal with these issues, one effective solution is Adaptive Modulation (AM), whose aim is to encode radio signals utilizing a variety of modulation forms from a predetermined candidate pool depending on channel conditions and system specifications. Thus, the AM enables intelligent spectrum management in modern communication systems, as shown in Fig. 1 [2].

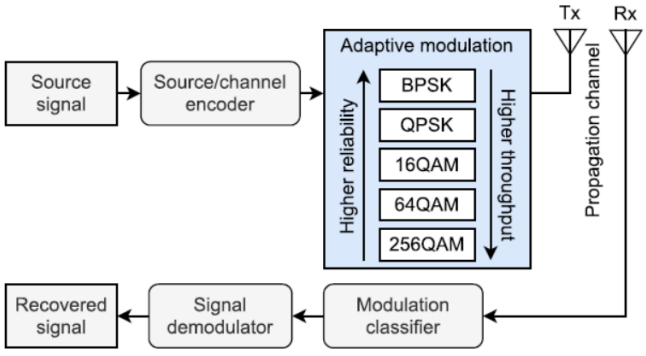

Fig. 1. Communication system with adaptive modulation [2].

However, a major challenge for implementing the AM in wireless communications is the dynamic estimation of channel conditions and data characteristics. Hence, automatic modulation classification (AMC) is introduced, which is a technique that improves spectrum utilization efficiency by applying it to a detected signal at the receiver's physical layer without knowing the data sent or channel characteristics.

A. Task of AMC

Consider a communication system sending a noise-free signal *x(t)* (whose sampled version is denoted as *x[k]*) through some channel (with discrete version denoted as *h[k]*), then the received signal for the nth symbol at time *k* can be expressed as Eq. (1) [2]:

$$y[n] = x[n, h_k] + w[n] \quad (1)$$

where, $x[n, h_k]$ is the modulated input data passed through the channel h_k and *w[n]* is the additive noise at the receiver with variance σ_w^2. The task of an AMC in a communication system is

*Corresponding author.

to predict the modulation type using only input-output data without estimating the channel impulse response.

B. AMC Approaches

Both probabilistic and conventional machine learning frameworks are used in the traditional AMC approaches. Based on the assumption that all signal and channel models are fully understood, likelihood-based systems have the best level of accuracy since they employ probability theory and hypothetical models to solve classification difficulties. Machine learning (ML) features are more likely to be adopted because of their simplicity. However, this comes at the expense of a few drawbacks, such as restricted learning capacity and a poor discriminative experience of handmade features.

Likelihood-Based (LB) Approach: The optimum approach is to employ the LB approach, which minimizes the possibility of incorrect categorization. This assumption is correct if a waveform's density function (PDF) contains all relevant information. Using a decision threshold, the probability ratio from the PDF is used to categorize the modulation type [3]. The drawback of this approach is its computational complexity. Real-time classification requires a thorough inspection of multiple pulses and emitters. It is possible to separate a single emitter by using other ways of locating the Primary Rat Interface (PRI). Due to this, it is possible to forgive a few wrong classifications in modulation categorization if the majority of the categories are suitable. Algorithm strength must also be considered while extracting data. A lack of inherent robustness makes LB approaches susceptible to noise, timing issues, and phase offsets. Given this and the necessity of real-time operation, a more accessible, feature-based approach may be adopted.

Feature-Based (FB) Approach: The FB approach employs representative features to identify and categorize the differences between signals. The typical characteristics are the time domain, signal changes, zero crossings, and statistics. In addition, the FB AMC technique often uses a hierarchical approach, first identifying modulation and defining its exact kind [3]. Then, PDF-based, Euclidean distance, and artificial intelligence classifiers are utilized to make decisions. FB algorithms are generally preferred because of their simple complexity and acceptable performance, even if their performance is poor.

C. Related Works: Deep Learning in AMC

In recent years, the DL techniques have been successfully applied in various fields such as computer vision [4], [5], wireless communications [6], [7], bioinformatics [8]-[13], and signal processing [14], [15], etc. Motivated by the power of DL, several state-of-the-art DL techniques have been employed in the field of AMC, which resulted in improved modulation classification performance of ACM. For example, convolutional neural networks (CNNs) based AMC [16], [17], [18], long short-term memory networks (LSTMs) based AMC [19], [20], and recurrent neural networks (RNNs) based AMC [21]. One major advantage of DL-based AMC over conventional ML-based AMC is that DL provides automatic feature extraction with higher classification accuracy [22]. Another important fact about the DL-based AMC is that it can enhance the classification accuracy of higher-order modulation in the presence of a synthetic channel impairment [23]. Finally, it is found that the DL-based AMC has the capability to effectively process big data, and thus it is well-suited for deploying AMC in Internet-of-Things (IoT) systems [24].

D. Challenges in AMC

A major challenge in ML-based AMC is the requirement of designing efficient feature extraction methods for each dataset. On the other hand, although the DL-based AMC can provide automatic feature extraction, with improved modulation classification accuracy, there are still many open challenges in this field. One big challenge is that all the existing DL-based AMC methods proved to be better in terms of classification accuracy only for higher values of signal-to-noise ratio (SNR). Their performance degrades drastically at lower SNR values, which implies that if the noise level is higher, the model would most likely fail to categorize the signal. In the existing literature, there is no work addressing this issue. In this work, we mainly focus on this challenge.

E. Our Contributions

As outlined in the previous subsection, the DL-based AMC has one major challenge of poor performance at lower SNR values, we focused on solving this issue by designing a hybrid DL-based AMC solution. More specifically, the proposed method is capable of providing reasonably better modulation accuracy at lower SNR values. For this purpose, we developed a hybrid DL-based AMC solution in which we utilized the combination of the EfficientNet and the Transformer Block via a switching mechanism. The transformer block is used to enhance the DL performance for the lower SNR values. The performance of the proposed hybrid model is tested on a benchmark dataset, RadioML2018.01A [25].

The study is organized as follows: Following this introduction, the baseline methods are discussed in Section II. In Section III, the proposed hybrid CNN model is presented. An overview of the RadioML 2018 dataset is provided in Section IV. Next, the experiment on AMC using the proposed model is described in Section V. Results and discussion are provided in Section VI. Finally, the concluding remarks are given in Section VII.

II. Baseline Methods

In the context of AMC, various DL architectures have been explored in the past [25]. Among these methods, the best performance is achieved by the modified ResNet proposed in [25]. In this section, we provided an overview of both the standard and the modified ResNet architectures.

A. Standard ResNet [26]

ResNet is a deep residual network that has all the elementary parts in its structure as existed in any deep CNN architecture [26]. The only unique characteristic of the ResNet is the use of identity connection or mapping between the levels. In order to understand this Identity Mapping in a ResNet, see the block diagram presented in Fig. 2, where F(x) is a function called the Residual Function that operates between two convolutional weight layers. More precisely, it is the difference between the input x and the output H(x) of the residual block, as shown in Fig. 2. Thus, the F(x) can be formulated as Eq. (2):

$$F(x) = H(x) - x \tag{2}$$

Therefore, the major purpose of including this function in ResNet is to utilize the stacked layers to estimate the function F(x) instead of estimating the function H(x). Consequently, training the deep residual network tries to learn F(x), which results in improving the overall accuracy. Moreover, it is straightforward to conclude that the network's accuracy will be improved by increasing the depth, provided that the issue of over-fitting is resolved. However, the difficulty with the increase in depth is that the signal necessary to modify the weights, which emanates from the end of the network by comparing ground truth and forecast, gets extremely little at the initial layers as depth increases. It indicates that the initial levels are learned to a minor extent. The term for this phenomenon is vanishing gradient. The second issue with training deeper networks is that optimization is performed on a large parameter space, resulting in naively adding layers, which increases training error. As illustrated in the figure, residual networks permit the training of deep networks by creating the network using modules termed residual models.

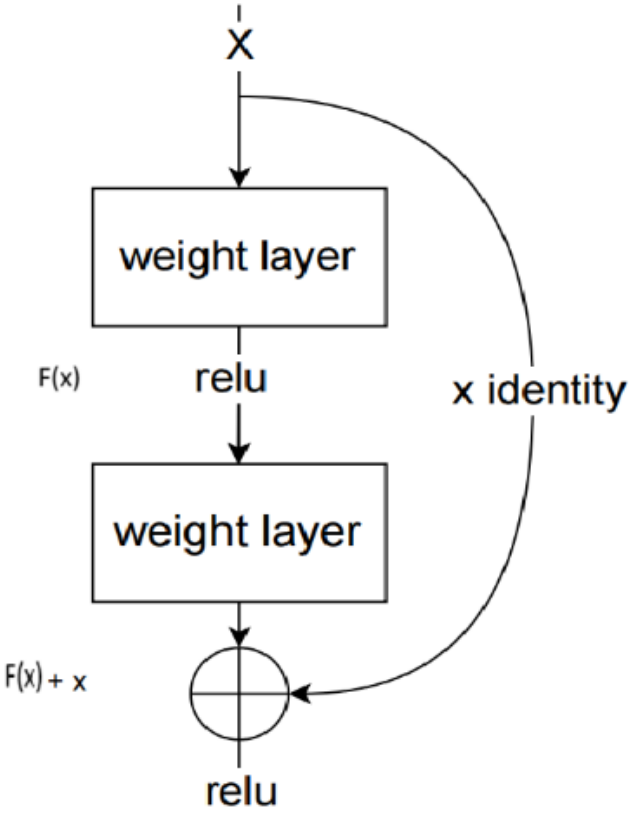

Fig. 2. Residual learning: a building block.

B. Modified ResNet [25]

In [25], a modified ResNet was proposed for implementing the AMC. In this architecture, the residual unit and stack of residual units are used, as shown in Fig. 3, and its network layout is shown in Table I. In addition, self-normalizing neural networks, the activation function of scaled exponential linear unit (SELU), mean response scaled initialization (MRSA), and Alpha Dropout were used and resulted in a marginally better performance than standard ReLU.

TABLE I. MODIFIED RESNET NETWORK LAYOUT [25]

Layer	Output Dimension
Input	2 x 1024
Residual Stack	32 x 512
Residual Stack	32 x 256
Residual Stack	32 x 128
Residual Stack	32 x 64
Residual Stack	32 x 32
Residual Stack	32 x 16
FC/SeLU	128
FC/SeLU	128
FC/Softmax	24

III. PROPOSED HYBRID CNN MODEL

In this work, we proposed a hybrid model of CNN which utilizes a combination of EfficientNet and Transformer Network. The architectures of both the networks and the proposed hybrid model are presented in the ensuing.

A. EfficientNet Network

Developing convolutional neural networks are done at a set cost. These networks may be expanded to achieve higher accuracy, when additional resources are available. For example, to increase the size of a ResNet 18 model to a ResNet 200 model, more layers can be added to the initial model. Mostly, this scaling strategy has improved the accuracy of many benchmarking datasets. However, the initial methods of model scaling are quite unpredictable. Some models are scaled horizontally, while others are scaled vertically. Some models simply capture a higher-resolution image to get better outcomes. Manual tweaking and numerous person-hours are required when using this strategy of randomly scaling models, and it frequently results in little or no improvement in performance. EfficientNet's authors suggested that CNN models be scaled up to improve accuracy and efficiency more ethically [27].

EfficientNet uses a method known as compound coefficients to scale up models in an easy yet effective manner. Compound scaling, instead of random scaling up of width, depth, or

resolution, uniformly scales each dimension with a predetermined set of scaling coefficients. The efficient developers used the scaling approach and AutoML to construct seven models of varied dimensions that outperformed the current state-of-the-art accuracy of most convolutional neural networks and were significantly more efficient.

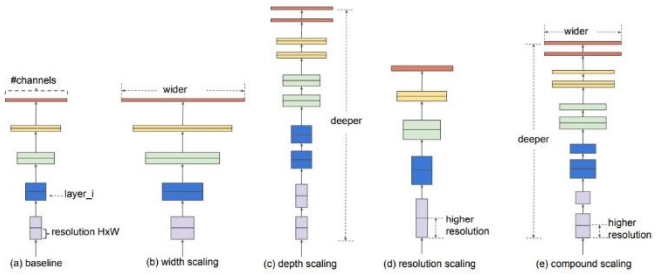

Fig. 4. Various types of scaling used: (a) is a baseline network; (b) to (d) conventional scaling via width, or depth, or resolution dimension. (e) is compound scaling used in EfficientNet [27].

The authors evaluated the effects of each scaling methodology on the model's performance and efficiency to develop the compound scaling method. In their opinion, scaling single dimensions helps in enhancing model performance, balancing the scale in all three dimensions: width, depth, and picture resolution, considering the varied resources available, which best improves the overall model performance. The compound scaling method proposed for EfficientNet is shown in Fig. 4. The goal of the compound scaling method is to balance the width, depth, and resolution measurements achieved by scaling with a constant ratio.

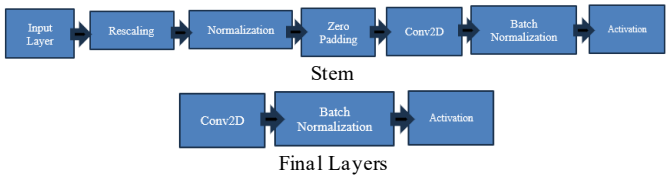

Fig. 5. Stem and final layers of EfficientNet.

A neural architecture search utilizing the AutoML MNAS framework created the baseline network used in EfficientNet. For optimum accuracy, the network is fine-tuned and punished if it is computationally intensive. It is also punished for sluggish inference times when the network takes time to create predictions. The system employs a mobile inverted bottleneck convolution similar to MobileNet V2; however, it is substantially larger owing to the rise in FLOPS. This basic model is then built to provide the networks' EfficientNets family. The stem and final layers of EfficientNet are presented in Fig. 5.

Further, each of the modules has seven blocks. These blocks are further subdivided into a different number of sub-blocks. These numbers increase when moving from EfficientNet-B0 to EfficientNet-B7.

B. Transformer Network

The encoder-decoder architecture has evolved into the "Transformer model" [28, 29]. Unlike the encoder-decoder design, the Transformer doesn't employ recurrent neural networks (RNNs) to acquire sequential data. Transformer-based models have replaced Long-Short Term Memory (LSTM) networks [30] in many sequence-to-sequence situations and are superior in quality. Conducting some diggings to discover the best time-series model that has just been released on the internet and in journals.

Recently, a solution using the newest state-of-the-art time series model called Transformer is devised [29]. Compared to the prior models, this model has various advantages, such as parallelization processing, which allows it to use contemporary graphics processing units (GPUs), which were created specifically for parallel calculation. Moreover, the vanishing gradient problem can be solved in Transformer Network (TN) as the input size can be adjustable, and the network can execute simultaneously rather than sequentially. Furthermore, the TN is capable of capturing detailed data context due to its advantage of the network modules' positional encoding and self-attention mechanisms [31]. The main crucial network module within the TN is provided in [31].

C. Switching-Based Proposed Hybrid Model

Our experimental analysis showed that the EfficientNet and Transformer Net are good in predicting signals with high SNR and low SNR, respectively. We proposed to combine the two network models of EfficientNet and Transformer Net effectively, such that the classification accuracy of the AMC should be enhanced for both low and high SNR values. For this purpose, an SNR threshold-based switching is proposed as shown in Fig. 6. This SNR threshold value is set according to experimental findings. In our experiments, we have used a 0 dB SNR value as a switching threshold; that is, the proposed model will utilize EfficientNet if SNR is above 0 dB, and it will switch to TN otherwise.

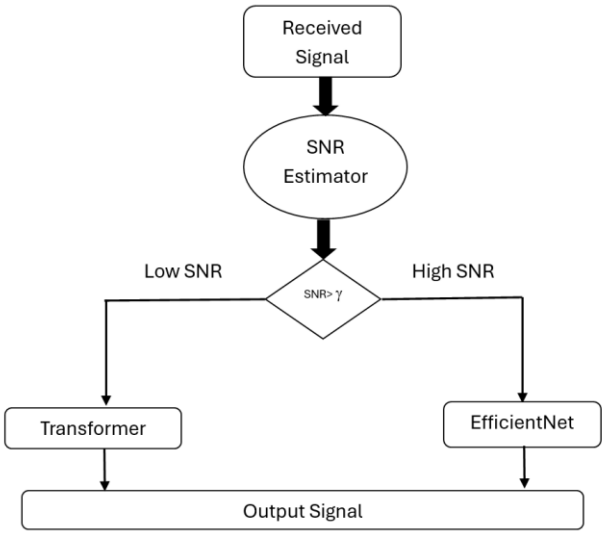

Fig. 6. SNR switch between EfficientNet and the transformer block.

To implement the proposed SNR threshold-based switching, instantaneous SNR values are estimated using the received samples. Knowing the fact that there are well-established techniques for estimating noise variance estimation ($i.e., \hat{\sigma}_w^2$) [32, 33], the received SNR can be estimated using an average over window size N_w as follows [see Eq. (3)]:

$$\widehat{\mathrm{SNR}}[n] = \frac{1}{\hat{\sigma}_w^2}\left\{\left(\frac{1}{\mathrm{N}_w}\sum_{k=n-\mathrm{N}_w+1}^{n}|y[k]|^2\right) - \hat{\sigma}_w^2\right\} \quad (3)$$

Finally, switching is performed between EfficientNet and Transformer block by inspecting the estimated SNR against a defined threshold value (γ) that can be set by the designer.

IV. Overview of RadioML 2018 Dataset

The majority of existing AMC strategies have been assessed on the reenactment datasets produced by programming. According to the point of view of reasonableness, producing tweaked signs to benchmark the execution of profound models ought to consider two essential worries: modulation technique (such as modulation types and modulation count) and channel condition. For models, RadioML2018.01A, a presently accessible and broadly utilized dataset of regulation grouping, conceals 24 modulations (counting analogue and digital procedures and a few testing high-request designs), where the regulation transmissions are engendered in a multipath Rician blurring with carrier frequency offset, symbol rate offset, delay spread, and AWGN to almost acquire true peculiarities in remote correspondences. On the other hand, various AMC techniques have produced easy datasets with few basic digital modulations. Thus, the adequacy and effect of exploration commitment in view of execution assessment in reproductions can be unconvincing other than the unsubstantial dependability of grouping models to carry out in practical frameworks. For example, a plain-design profound organization [32] accomplished high exactness with three modulation candidates (BPSK, QPSK, and 8-PSK). In different works [33], the considered spread channel is less difficult with level blurring and time-invariant rather than recurrence, particularly multipath blurring and testing time float. The modulation classification task turns out to be easier with a few given classes, where the between-class and intra-class segregation issues are not thought rigorously.

Even though DL-AMC can give huge execution, it requires a lot of training data. In reality, obtaining a sufficient number of valid training samples is typically expensive and challenging. Hence, the employed huge scope preparing dataset ought to be developed cautiously enough with more reasonable signs under a wide scope of SNR. Besides, data expansion techniques can arrange radio regulation plans more effectively by utilizing more limited radio examples [34], which will furnish an improved DL model with a more modest order reaction time. Nonetheless, the Signs dataset is especially needed for preparing, approving, and testing the networks in ML-AMC and DL-AMC models. A few analysts utilized their simulated datasets, and others like to utilize those presented in the journal. A portion of the datasets is introduced as follows.

GNU Radio datasets are utilized in this research. The RML2018 dataset is one of the most complex modulation classification datasets published in [25]. Twenty-four digital and analog modulation schemes are measured over the air and distributed across a wide range of SNR values. In addition, it comprises almost 2.5 million signals with artificially created channel distortions. "Over-the-air deep learning-based radio signal categorization" was published in the IEEE Journal of Selected Topics in Signal Processing in 2017 and gives further information and explanation of the dataset. In hdf5 format, around 1.5 million instances are recorded as complex floating-point values with a sample length of 1024 samples, respectively.

The updated techniques [35] were used to create the new dataset (RadioRML 2018). 24 modulators, both analog and digital, are utilized to modulate a wide variety of single carriers. Fig. 7 demonstrates OTA transmission channels containing clean signals without any synthetic channel impairments. Digital signals are formed with a root-raised cosine beat modulating filter [36] with a scope of roll-off values.

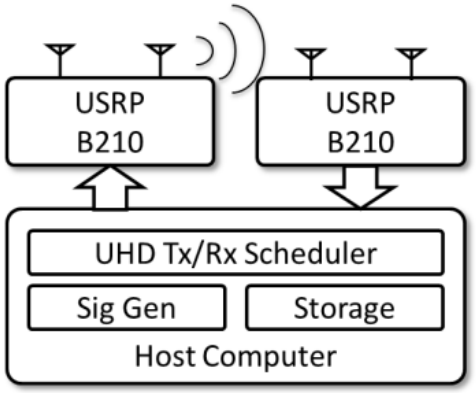

Fig. 7. Over-the-air test configuration [25].

V. Experiment on AMC

In this study, Python is used to perform the AMC task, which was done using Google Colaboratory (called Colab). Google Colab allows users to take advantage of backend hardware such as GPUs and TPUs to accelerate their computations. Thus, it facilitates performing all of the tasks in a Jupyter notebook hosted on your local system without installing or configuring any additional software.

A. EfficientNet (for High SNR)

First, we import the EfficientNet for Tenserflow-Keras Library, which is the Conventional EfficientNet. However, we chose the B0 Architecture, since it has the lowest processing complexity SNR switch.

As part of our suggested strategy, we attempt to employ two network models, one effective for predicting signals with high SNR and the other effective at predicting signals with low SNR. The transformer neural network will be used for low SNR models because it is a time series neural network that may be used to forecast complicated data, such as signals with low SNR rates. Our improved EfficientNet, on the other hand, is employed for categorizing signals with greater signal-to-noise ratios. Following the input of our signal into two models, we will ensemble them to obtain the highest accuracy output from the two models. For this purpose, the SNR value of 0 dB is selected as the switching threshold among the eight possible types of EfficientNet. The original EfficientNet B0 has an input size of 224x224x3; therefore, we must adapt the input size to match that of RML 2018, which is 1024x2, so we must alter the input layer appropriately. To accommodate the adaptation, the reshape layer has been introduced in the first layer before the modified EfficientNet, as shown in Fig. 8.

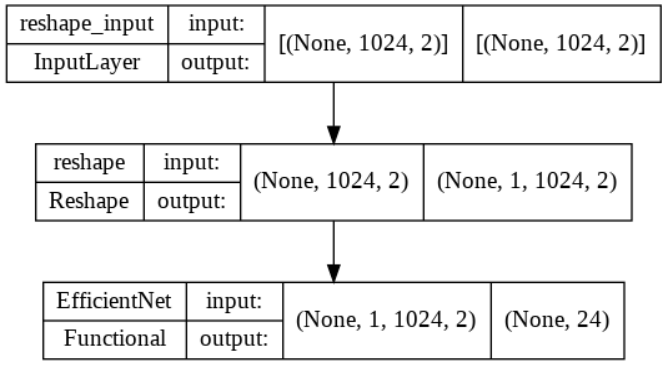

Fig. 8. Rescale layer and the customized EfficientNet.

The training process for our network uses a batch size of 1024 and a validation testing dataset comprised of 20% of the total training dataset.

B. Transformer Block (for Low SNR)

As shown in Fig. 9, the architecture being utilized is designed primarily to deal with noisy signal modulation / low SNR signal modulation. Two fully linked networks and Alpha Dropout are used in conjunction with batch normalization to minimize overfitting. After an Alpha dropout, the mean and variance of inputs retain their original values, ensuring that the self-normalizing characteristic continues to hold even after the dropout has occurred. In addition, we selected SeLU, which stands for Scaled Exponential Linear Unit, for the activation function to support the self-normalizing feature of the dropout layer, which is supported by the dropout layer itself. Lastly, we continue to use Lazy Adam as our model enhancer. The details of layer type, output type, and number of parameters are provided in Table II.

TABLE II. LAYERS OF THE TRANSFORMER BLOCK USED IN AMC

Layer (type)	Output Shape	Param #
input_1 (InputLayer)	[(None, 1024, 2)]	0
reshape (Reshape)	(None, 2, 1024)	0
transformer_block (TransformerBlock)	(None, 2, 1024)	4728064
Total params: **Trainable params:** **Non-trainable params:**		**4,882,968** **4,880,920** **2,048**

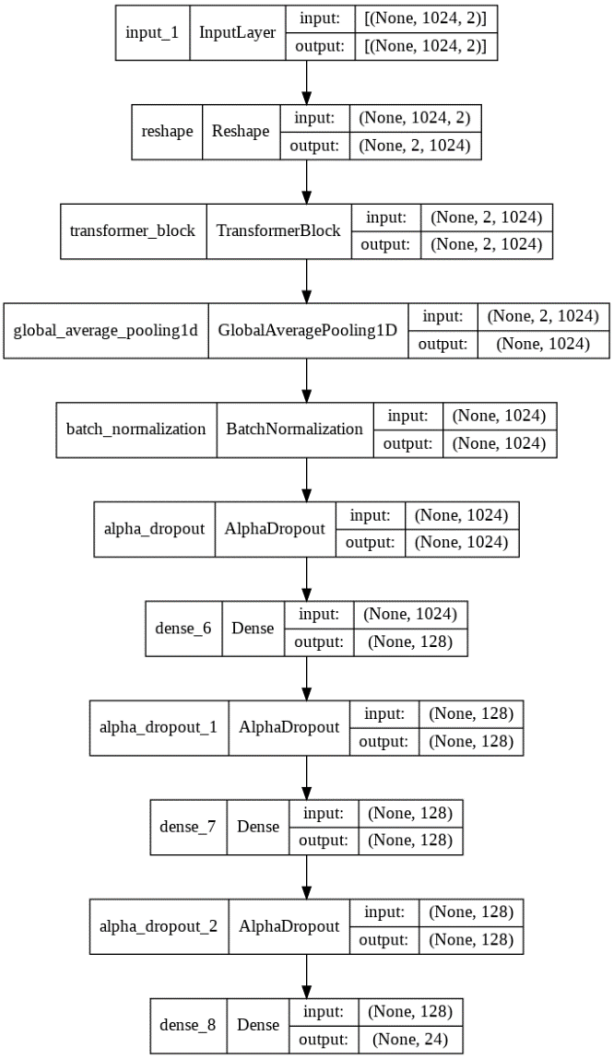

Fig. 9. Architecture of the transformer block used in AMC.

VI. Results and Discussion

This section will demonstrate the results of applying the proposed method to create the hybrid model. These results are reported in Table III in terms of overall Accuracy of the proposed model at different SNR values. Accuracy is calculated using the following relation, Eq. (4):

$$Accuracy = \frac{TP+TN}{P+N} \quad (4)$$

where, *TP, TN, P*, and *N* represent True Positive, True Negative, Total Positive, and Total Negative, respectively.

Our model consists of two parts; the first part deals with the clean signals that have bigger than 0 SNR values; our Customized EfficientNet shows outstanding performance in the modulation classification for such values, and the maximum accuracy of the modulation classification is 92% at 30 SNR average. However, the EfficientNet has the same characteristics as the other convolutional neural networks (CNNs), and the accuracy is degraded, especially for the signals under 0 SNR values. On the other hand, Transformer Block is working on modulation classification for the lower SNR range of the signals. The Transformer shows an average of 70% accuracy of the modulation classification in the signals with lower SNR values than zero. By applying the parts (Customized EfficientNet and Transformer Block), we have a wider modulation classification range that works from -20 SNR up to 30 SNR with average accuracy (80.74%) among all the SNR ranges. Compared to any solo system, our hybrid model has superior performance considering the full range of SNR. The following subsections in this section illustrate the accuracy results of each part individually; then, the final results will be shown for the combined parts of the hybrid system.

Furthermore, both parts of the hybrid system (Customized EfficientNet and Transformer Block) are trained to utilize the raw data directly, without any feature extraction or preprocessing stage. However, the training stage took a long time for training of the two models, around one hour for each epoch, and it took 36 epochs to complete the training; this long time is due to the huge size of the used dataset. Noting that, 10% of the training data set was considered a validation split to determine the optimum point to stop the training process and have the best generalization characteristics for the system.

A. Performance of the Customized EfficientNet

By implementing the customized EfficientNet discussed in Section V(A), the overall accuracy of the model on the AMC task is reported in Table III and displayed graphically in Fig. 10. It can be observed that the customized EfficientNet alone performs very good for positive or higher values of SNR. However, it has a poor performance for negative and lower SNR values.

TABLE III. EfficientNet Accuracy

SNR (dB)	Overall Accuracy	SNR (dB)	Overall Accuracy
-20	4.34%	2	68.73%
-18	4.57%	4	79.58%
-16	4.87%	6	86.08%
-14	5.46%	8	89.15%

B. Performance of the CustomizedTransformer Block

By implementing the customized Transformer block discussed in Section V(B), the overall accuracy of the model on the AMC task is reported in Table IV and displayed graphically in Fig. 11. It can be observed that the customized Transformer block alone performs very good for negative and lower values of SNR. However, it has a poor performance for positive or higher SNR values.

TABLE IV. TRANSFORMERS' ACCURACY

SNR (dB)	Overall Accuracy	SNR (dB)	Overall Accuracy
-20	69.79%	2	52.34%
-18	68.97%	4	45.72%
-16	69.85%	6	44.84%
-14	70.13%	8	41.26%
-12	70.08%	10	40.88%

		26	42.49%
		28	42.29%
		30	42.47%

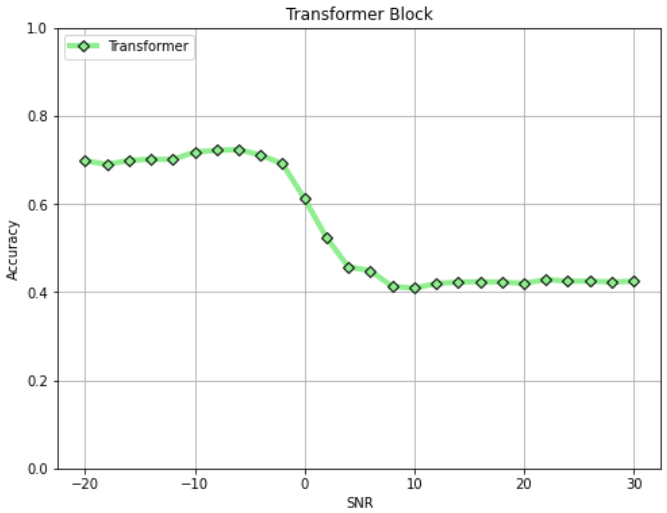

Fig. 11. AMC accuracy for the customized transformer block alone.

C. Performance of the Proposed Hybrid Model

By implementing the proposed hybrid model for the AMC task using the switching mechanism discussed in Section V, the overall accuracy of the proposed model on the AMC task is reported in Table V and displayed graphically in Fig. 12. Moreover, the performance of the proposed hybrid model is also compared to the one achieved by the modified ResNet of [25]. It can be observed that the proposed hybrid model initially performed bad at 0 dB SNR, and later it performed very well for the larger SNR values. The reason for this bad performance is due to abrupt switching via the imperfection in SNR estimation using Eq. (3). This is one of the limitations of the proposed method that needs to be improved in future research. Moreover, the proposed hybrid model outperformed the modified ResNet of [25] for lower SNR values (10 dB and below). For the case of higher SNR values (above 10 dB), its performance is almost identical to that of the modified ResNet of [25]. This is important to highlight that the AMC at lower SNR is more crucial and hence, our proposed model has attained this goal.

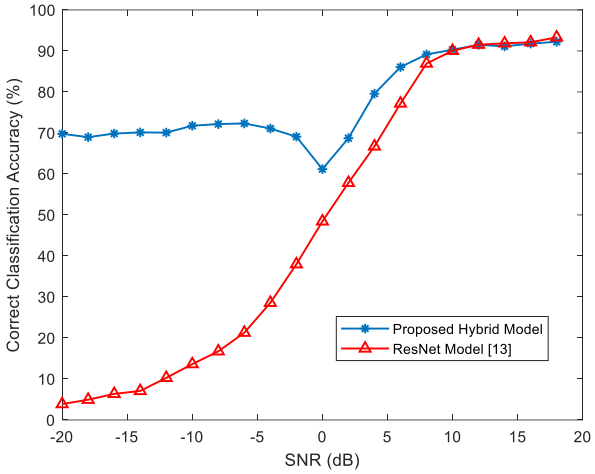

Fig. 12. AMC accuracy comparison for the proposed model.

TABLE V. AMC ACCURACY COMPARISON FOR THE PROPOSED MODEL

SNR(dB)	Accuracy of Proposed Hybrid Model	Accuracy of Modified ResNet Model [25]
-20	69.79%	3.87%
-18	68.97%	4.94%
-16	69.85%	6.36%
-14	70.13%	7.08%
-12	70.08%	10.27%
-10	71.76%	13.62%
-8	72.16%	16.74%
-6	72.32%	21.29%
-4	71.08%	28.58%
-2	69.09%	37.98%
0	61.18%	48.43%
2	68.73%	57.84%
4	79.58%	66.72%
6	86.08%	77.18%
8	89.15%	86.93%
10	90.30%	90.04%
12	91.49%	91.53%
14	91.12%	91.86%
16	91.80%	92.12%
18	92.22%	93.31%
20	92.01%	92.87%
Avg.	**78.04%**	**49.50%**

VII. Conclusion

The capacity to categorize signals is a critical skill that may be used in various applications. In this work we have developed a hybrid CNN model by intelligently combining the EfficientNet and the Transformer Block for the AMC application. For this purpose, customized architectures of both the EfficientNet and the Transformer Block are developed. A switching mechanism is opted to develop the proposed hybrid model such that the EfficientNet is used for higher SNR values, while the transformer block is used to enhance the DL performance for the lower SNR values. The performance of the proposed hybrid model is examined on a benchmark dataset, RadioML2018.01A. The results show that the proposed hybrid model has an average classification accuracy of 78.04% in contrast to 49.5% achieved by its state-of-the-art counterpart. Thus, confirming the supremacy of the proposed model for the AMC application. In the future, more accurate methods of SNR switching can be explored. Moreover, the AMC task can be expanded to other types of modulation and channel models.

***Abstract*—The Internet of Drones (IoD) is a decentralized structure that links drones to regulate airspace and offer inter-location navigation services. With the increasing use of drones in both civilian and military applications, the importance of the IoD has grown significantly. It reshapes the current internet landscape, making it more extensive and all-encompassing. IoD establishes a connection between drones and the network, which exposes the IoD network to numerous privacy and security issues often associated with IoT ecosystems. To ensure optimal performance from IoD applications, it is crucial to maintain a secure environment devoid of privacy and security risks. Privacy and security concerns have obstructed the overall effectiveness of the IoD framework. This study conducts an extensive examination of security concerns and solutions related to IoD security. It delves into IoD-specific security requirements and sheds light on the latest developments in IoD security research. Hence, we first provide an overview of the overall context and structure of the IoD. We then identify the security issues linked to it. Afterward, we present the most recent security measures developed specifically for the IoD. Finally, we go through the challenges and potential areas for future research in the realm of IoD security.**

***Keywords*—Unmanned Aerial Vehicle; Internet of Drones; cybersecurity; attacks; threats**

I. Introduction

The recent progress in robotics and wireless communication has given rise to Unmanned Aerial Vehicle (UAV) technology. UAV, commonly known as a drone, is an aircraft that operates without a human pilot and is controlled remotely by a user or a control station [1]. Primarily, drones have found application in the military sector, where they are utilized for monitoring insurgents, conducting surveillance on terrorists, assisting in the rescue of injured personnel, etc. According to the E.U. Commission Delegated Regulation 2019/945 [2], a UAV consists of two primary components: an unmanned aircraft and a remote-control device.

Generally, UAV come outfitted with a Global Positioning System (GPS) and various sensors for data acquisition, with their storage and battery capabilities being relatively constrained [3]. Communication between UAVs and other entities, such as remote users or control stations, is established through wireless channels, forming the Internet of Drones network.

The Internet of Drones (IoD) is a subset of the Internet of Things (IoT) designed to facilitate communication and cooperation among UAVs. As a result, it inherits from the security vulnerabilities IoT networks. As the data exchanged within the IoD may contain sensitive and critical information, security is a major concern in this area [4]. This is because UAV are usually operated remotely and receive control and command signals from ground sites. These command-and-control signals are transmitted through different means of communication and with different transmission rates, which requires significant efforts to manage and control quality and security in a context of high mobility which could complicate these tasks (control and management). Critical data exchanged between UAV must not be disclosed or compromised in any way. Given the diversity of attacks that can target the IoD (Jamming, Flooding, Collision, Selective forwarding, replay, identity theft, tracing, etc.), it becomes essential to establish security measures by deploying protection mechanisms adapted to secure it [5][6]. Thus, confidentiality, integrity, availability, authenticity, and preservation of privacy represent the main security requirements of the IoD. Several research studies have focused on IoD security [5]. Despite the diversity (new authentication schemes, blockchain-based security, etc.) and relevance of existing solutions, we believe that much remains to be done in the field of IoD security. Indeed, the implementation of certain protection mechanisms can constitute an obstacle to the proper functioning of the IoD or, if necessary, cause the degradation of the performance and efficiency of the services provided by UAVs. For example, security has a potentially significant cost in terms of CPU, memory, and power consumption.

As UAVs are battery operated, battery life can be another constraint and a major problem, part of the solution of which can be the use of energy-efficient batteries (lithium-ion and hydrogen batteries [7]), the harvesting of (Energy Harvesting), the use of solar cells or wireless energy transfer [7]. Thus, it may be relevant to minimize the impact of security on the energy consumption of UAVs.

The primary objective of this study, which is described in Section I, is to offer a comprehensive and up-to-date survey of the fundamental concepts pertaining to communication within the IoD. In an era where UAVs are becoming increasingly integrated into our daily lives, understanding the intricacies of how these devices communicate and collaborate is of paramount importance. By exploring the latest advancements, protocols, and technologies employed in enabling seamless data exchange among drones and between drones and ground-based systems, this study attempts to provide a valuable reference for researchers, practitioners, and policymakers, addressing their needs and interests in Section II. In Section III of this study, we present a comprehensive examination of the security requirements and constraints that belong to the IoD (Confidentiality, Availability, Integration, etc.). Following our exploration of security requirements and constraints in the IoD, this study will shift its focus to hidden security vulnerabilities for IoD systems, as well as potential attack vectors targeting this emerging technology. Security vulnerabilities in the IoD environment can arise from a variety of sources. We will begin by identifying and examining common vulnerabilities associated with the communication infrastructure of IoD networks. These might include weaknesses in wireless communication protocols, flaws in encryption algorithms, or vulnerabilities in the underlying hardware and software of the drones themselves. By explaining these vulnerabilities, we provide a comprehensive view of the potential weaknesses that adversaries may exploit. Simultaneously, our discussion will encompass potential attack surfaces within IoD systems. This involves identifying and characterizing the various components and interfaces that can be targeted by malicious actors. Examples of attack surfaces in IoD may include command and control channels (C2), transmission links, and even the physical drones themselves. It is imperative to understand these attack surfaces to effectively mitigate and defend against potential threats. Finally, we undertake a comprehensive survey of recent advancements in the realm of existing security solutions designed to address and mitigate the diverse spectrum of attacks discussed earlier in Section IV. Among the various categories of available security solutions, we will showcase the most and widely adopted solutions in the IoD, including intrusion detection systems, cryptographic measures, authentication methods, and the utilization of the Blockchain mechanism. At the end of the study (Section V), recommendations and challenges are proposed to find possible solutions to secure the IoD.

This research aims to answer six research inquiries depicted in Fig. 1. While it's evident that numerous other questions could be raised, we support that these are adequate to inform a diverse spectrum of research within the examined domain.

RQ1: What are the fundamental principles concerning communication and classification in the context of the IoD, and what are the areas and sectors of application?

RQ2: What security prerequisites and limitations exist within the IoD?

RQ3: What are the security weaknesses present within an IoD network, and what are the possible consequences of assaults on drone systems?

RQ4: What are the attacks targeting the IoD network?

RQ5: What are the current countermeasures in place to mitigate these attacks?

RQ6: What are the recommendations and challenges to find possible solutions to secure the IoD?

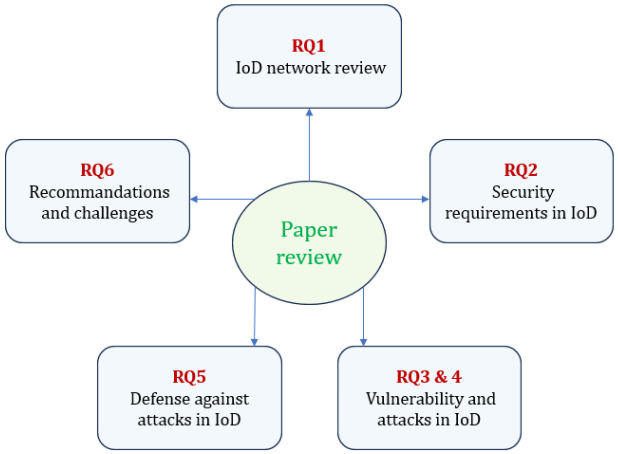

Fig. 1. Research inquiries of the study.

II. Unmanned Aerial Vehicles (UAV)

In recent years, UAVs have garnered considerable attention due to their versatility and autonomous capabilities. Recently, the United States' Federal Aviation Administration (FAA) has introduced fresh regulations permitting the utilization of drones for civilian and business applications. Consequently, the FAA anticipates that approximately seven million drones are presently in operation within the United States [8]. Drones can be remotely operated using a range of electronic devices, including microprocessors and sensors [9]. A key advantage of the drone is its ability to autonomously perform operations in hazardous environments where human intervention would be unsafe or impractical [10].

A. Architecture of Unmanned Aerial Vehicle Communication

As shown in Fig. 2 and described in [11, 12–14, 15-17], the typical representation of a UAV includes a UAV, flight controller, communication links, and either a ground command and control system or Ground Control Station (GCS) [15, 16, 18, 19]. Let us now provide a brief overview of each of these components:

- Flight controller: It is considered as the main processing unit of the drone. It can also be equipped with different sensors, like sensor units such as global positioning system (GPS) receivers, accelerometers, infrared cameras, gyroscope, magnetic orientation, and electro-optical sensors.
- Ground Control Station: It provides human operators with the tools they need to remotely control and monitor drones during missions.
- Data Link: It is used to communicate and control the data flow between the ground control station and the drone.

Drone communications can be classified into four distinct categories: Drone-To-Ground Station, Drone-To-Network, Drone-To-Satellite, and Drone-To-Drone (see Fig. 2). These categories represent different modes of communication that enable drones to establish connections with various entities. [17]

Drone-To-Ground Control Station: This method of communication uses well-known and standardized communication protocols such as Wireless communication (WiFi, Ad-Hoc, Satellite). However, most of these types of communications are public and unsecured, which exposes them to many types of attacks.

- Drone-To-Network: This method of communication allows users to select a network based on the level of security they require. Cellular communication can also be included.
- Drone-To-Satellite: The GPS network uses this type of communication to send coordinates in real-time. This allows any drone to be called back to its home station if it has wandered beyond the control line. Satellite communications are considered safe and reliable. However, they are expensive and require a lot of maintenance.
- Drone-To-Drone: It can be considered P2P (peer-to-peer) communication, which makes it prone to various P2P attacks.

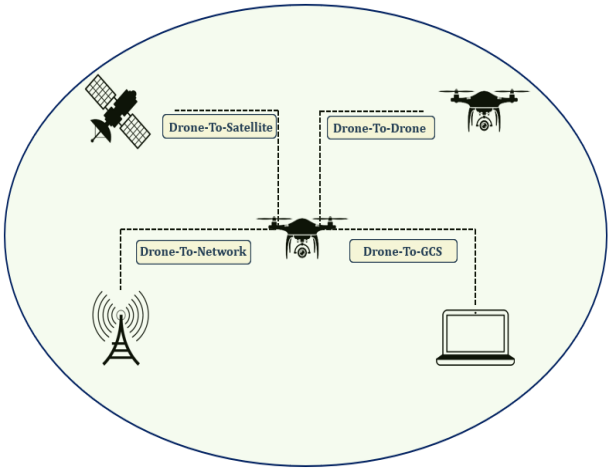

Fig. 2. Communication architecture for most UAVs.

B. Unmanned Aerial Vehicle Classification

UAVs have several requirements, such as being able to deploy sensors having a global positioning system (GPS), a communication module, and efficient batteries. UAVs can be controlled autonomously without a pilot and can be controlled remotely [18]. UAVs come in a variety of configurations, equipment options, sizes, ranges, and shapes. Within the market, we can find UAVs with varying numbers of rotors or propellers, as detailed in Table I [19]. Moreover, UAVs have been designed with diverse engines and wing structures. In terms of communication capabilities, they can utilize both short and long-range wireless technologies. UAVs are also classified based on their size, ranging from nano to micro and large.

Moreover, different types of UAVs can be found in the literature: fixed-wing, single rotor, fixed-wing hybrid, and multirotor [20]. Fixed-wing UAVs [21] contain a main body, wings, a propeller and a motor. These UAVs are often used for aerial mapping and power line inspection and need special training to control, and they remain useless for aerial surveillance. Such drones are not capable of hovering or forward flight. However, single-rotor drones [22] are costly to produce and need skill training. These UAVs are mechanically difficult and susceptible to obstacles such as vibrations.

Furthermore, multirotor drones [23] are the most affordable and simple to build. These UAVs are often employed for image and video surveillance. The Hybrid-Wing drone [24] is a fixed-wing and rotating drone that has recently entered the market. This type of drone can quickly reach its target by gliding through the air and hovering with four rotors.

TABLE I. CATEGORIES OF DRONES BASED ON THE NUMBER OF PROPELLERS

Types of drones	Number of Propellers
Octo-copter	8
Hexa-copter	6
Quad-copter	4
Tri-copter	3

C. Communication Methods of Unmanned Aerial Vehicles

When discussing the communication aspect of UAVs, several crucial subcomponents come into focus, including communication protocols, network types, and the UAV model itself. It should be noted that changing the communication method can introduce variations in the number of components and alter the system architecture [25]. Various researchers have proposed different topologies and designs [26], with consideration for altitude range. The choice of communication module and protocol may vary depending on the mission and the nature of the task at hand [27]. Furthermore, the emergence of 5G networks has addressed several constraints such as data rate, latency, and coverage. This advancement in communication technology has not only improved these areas but also enhanced the positioning and control of UAVs in critical rescue and surveillance missions. Advanced flight controls, multiple sensors, camera placement, and different modes of control and communication based on altitude have been employed for these purposes.

D. Unmanned Aerial Vehicle in 5G and IoT Networks

With the rapid advancements in UAV technology, UAVs have established their significance in a wide range of applications, including environmental monitoring, wireless communication, and public safety. Moreover, UAVs have been extensively studied in conjunction with wireless networks and have shown promising potential for enhancing the energy and spectrum efficiencies of fifth generation (5G) wireless networks. They provide a flexible and on-demand platform for deploying aerial base stations. The unique attributes of UAVs, such as adaptive altitude, scalability, flexibility, mobility, high

resilience, high reliability, and low cost, make them suitable for various applications. The integration of UAVs into network systems is expected to achieve significant performance improvements compared to conventional terrestrial systems without UAVs. UAVs can be intelligently controlled and remotely operated as required. They offer a high probability of line-of-sight (LoS) communication, which greatly enhances transmission rates. The swift maneuverability of UAVs ensures reliable and broadband wireless coverage during live streaming events and natural disasters. As a result, UAVs can provide offloading services with strict requirements in emergency operations within 5G networks [28]. Given their capabilities, it is feasible to integrate UAVs into 5G networks. Extensive research efforts are underway to explore UAV-assisted 5G technology and reduce latency while extending network coverage, capacity, and energy efficiency. However, there are certain challenges to consider in this coexistence. UAVs are susceptible to interference, and the dynamic network topology and mobility of UAVs introduce spatial and temporal dynamics that can result in frequent intermittent connections or transmission failures [29]. Additionally, UAVs are utilized for wireless energy transfer (WET) and wireless information transfer (WIT) to power ground terminals such as IoT devices, which are integrated for developing flexible and sustainable 5G networks [30]. UAVs provide numerous advantages when integrated into IoT networks [31, 32, 33]:

- Enhanced maneuverability, autonomy, speed, flight time, and mechanical performance.
- Efficient data gathering from water, gas, and power meters.
- Real-time data collection on air quality in smart cities.
- Reliability, scalability, and agility for IoT initiatives.
- Mitigating connectivity issues and reducing IoT network overhead.
- Cost-effectiveness and suitability for emergency operations.
- A comprehensive study addressing these UAV-related challenges is presented in [34].
- Channel modeling challenges and the need for accurate channel state knowledge.
- Efficient energy management for IoT device batteries.
- Adaptation of communication strategies to dynamic sensing data.
- UAV maneuverability limitations and potential mission impact.
- Concerns related to sky pollution, physical collisions, safety, privacy, and regulations.

E. Unmanned Aerial Vehicle Application Areas

UAVs have demonstrated their potential across a wide range of applications, including personal use and military purposes. Equipping UAVs with cameras, smart sensors, and processors can enhance their efficiency in various missions. Researchers have identified over 100 different applications for drones [35]. Factors such as diligence, cost-effectiveness, mobility in inaccessible areas, payload options, and risk considerations drive the widespread adoption of UAVs. The design of UAVs is often tailored to the specific mission they will perform in the field [36]. Categorizing UAVs based on their domains helps in understanding their architecture better, as demonstrated in Fig. 3, where each domain has its own privacy and security requirements [36, 37]. In the rest of this subsection, the main UAV applications are presented.

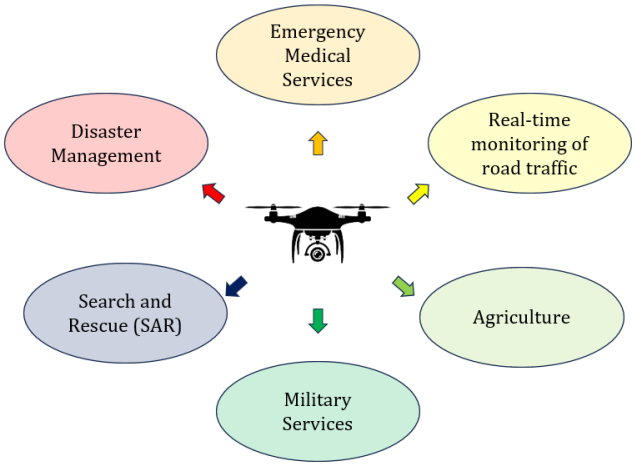

Fig. 3. UAV application areas.

1) Agriculture: UAVs have emerged as valuable tools in agriculture, providing real-time data and aiding farmers in making decisions. Equipped with advanced cameras, UAVs can deliver accurate information about soil conditions, crop health, and threats to crop yields. By analyzing this data, farmers can optimize the use of agricultural inputs to achieve higher crop yields. UAVs also offer early warning systems for threats such as wildlife or fires, allowing farmers to detect and mitigate these risks promptly. Researchers have highlighted the benefits of using UAVs in agriculture, including farm analysis, improved yields, monitoring, and spraying of pesticides. UAVs enable precise pesticide application by analyzing crop health and targeting infected areas, making spraying efforts safer and faster than manual methods [38, 39, 40].

2) Military: UAVs have found significant applications in the military sector, serving as a key component of the IoD. They are deployed in situations where manned flight is considered too risky or challenging. Military drones play crucial roles in combat operations, enemy surveillance, and target selection for military attacks [41]. They provide continuous aerial monitoring, offering troops a persistent eye in the sky. Kreps and Wallace [42] focused on the use of drones for counterterrorism, exploring the impact of international legal criticism on public support for drone strikes and the effectiveness of such strategies. Chand et al. developed a drone-based high-speed wireless mesh network, specifically designed for scenarios where no network infrastructure is available, such as disaster zones or military

conflicts. Their study demonstrates that drones can establish a wireless mesh network upon arrival, delivering Wi-Fi connectivity and real-time video streaming from an onboard camera. This network achieves wireless communication speeds of up to 160 Mbps within a range of approximately 200 meters.

3) Search and Rescue (SAR): With the increasing severity of climate change, natural disasters have become more frequent, emphasizing the crucial role of search and rescue operations. UAVs equipped with various sensors and cameras, including thermal sensors, have emerged as powerful tools in these missions. UAVs can effectively locate lost or injured individuals, even in challenging conditions or difficult terrain. Furthermore, UAVs can deliver essential supplies to inaccessible areas in war-torn or disaster-stricken regions. Cui et al. [43] addressed the use of UAVs in urban post-disaster search and rescue tasks and won the International Micro Air Vehicle Competition in 2014 by providing comprehensive solutions to key task components. Tilburg [44] reported two case studies showcasing the capabilities of UAVs in search and rescue missions, where UAVs assisted in locating a deceased person in a narrow valley at night and aided in obtaining images of challenging areas, facilitating successful rescue operations. Mayer et al. [45] discussed potential search and rescue scenarios for UAV deployment and highlighted the challenges and opportunities of human-machine interaction in these operations. Karaca et al. [46] utilized a simulation model to explore the use of UAVs in locating and searching for victims, as well as providing mobile transportation for search and rescue personnel in mountainous environments, particularly focusing on searching for unconscious victims on snow.

4) Disaster management: UAVs have the capability to access disaster-stricken areas that are hazardous for human intervention, whether the catastrophe is a result of human actions or natural disasters, such as terrorist attacks, tsunamis, or floods. Critical infrastructure like power, telecommunications, water utilities, and transportation systems are all susceptible to these calamities. UAVs play a crucial role in data collection, providing rapid responses, and maneuvering through debris. Equipped with sensors, radars, and high-resolution cameras, UAVs offer invaluable support to rescue teams in identifying damage, initiating urgent recovery operations, and delivering essential supplies, including first-aid kits and manned helicopters. UAVs contribute to disaster assessment, early warning systems, and the identification of preventive measures in real-time. In the case of wildfires, a swarm of drones outfitted with firefighting equipment can vigilantly monitor, analyze, and track affected areas without endangering human lives. Consequently, UAVs facilitate real-time surveillance over extensive regions while ensuring the safety and security of all involved parties. UAVs also play a vital role in locating and rescuing individuals and animals in distress.

5) Real-time monitoring of road traffic: The integration of UAVs with road traffic monitoring (RTM) systems is a subject of great interest. UAVs offer the potential for full automation of the transportation industry within the RTM sector [47], including functions performed by rescue teams, road surveyors, traffic officers, and on-site support personnel. These reliable and intelligent UAVs are instrumental in automating these operations. UAVs have proven to be effective tools for gathering data on road traffic conditions, outperforming traditional monitoring systems like surveillance cameras, ultrasonic sensors, and circuit analyzers [48]. Cost-effective drones can efficiently inspect extensive road sections. Local law enforcement agencies can leverage drones for comprehensive accident monitoring and security operations targeting illegal activities along highways, such as vehicle theft. Other applications include vehicle identification, pursuit of suspicious vehicles, tracking hijackers, and monitoring traffic rule violations [49]. UAVs can also monitor driving behavior and incidents inside vehicles, potentially mitigating traffic congestion and overcrowding. Furthermore, UAVs can contribute to monitoring road conditions, detecting fractures, and issuing early warnings to prevent accidents and reduce damage. Current road inspection methods rely on human-operated vehicles, highlighting the need for increased automation. The integration of road inspection technologies with UAVs holds the promise of significantly reducing road damage. UAVs can capture images of road fractures and use target detection algorithms to identify and assess these issues.

6) Emergency medical services: UAVs have demonstrated significant potential in the context of smart cities worldwide. These smart cities are equipped with advanced healthcare systems that rely on telemetry, implantable medical devices, and medical drones for the swift delivery of first-aid supplies. Notably, UAVs have effectively addressed the challenges posed by the COVID-19 pandemic in various countries. However, it is essential to highlight that the primary entities leading the response to COVID-19 are the national emergency medical services (EMS) institutions, working in conjunction with multiple stakeholders, including EMS personnel, nurses, and medical doctors. Additionally, policymakers are exploring various preventive measures to combat COVID-19, which encompass practices such as wearing surgical masks, refraining from touching one's face, practicing regular hand hygiene, implementing city lockdowns, avoiding high-risk areas, abstaining from social gatherings, and instituting health codes [50]. Policy makers should carefully consider the balance between economic concerns and public safety when contemplating the implementation of new measures. Currently, UAVs are being deployed for various tasks aimed at preventing the spread of COVID-19, such as: transport of patients, public announcements, crowd surveillance, spraying disinfection, mass screening, crown aerial monitoring and delivering vaccines and other medical supplies.

III. Cybersecurity Issues in UAVs

The advancement of UAV technology offers numerous benefits, including applications in agriculture, surveillance, infrastructure inspection, emergency response, and package delivery. However, these advancements also introduce concerns related to privacy, security, and safety [51, 52]. To address these issues, a comprehensive approach is required as drones become integral to various industries and daily life. This section focuses on the security prerequisites for UAVs in the IoD ecosystem, as well as essential security measures and strategies to safeguard UAV integrity and functionality, and the various types of threats that can target the IoD, spanning from physical hardware attacks to cyberattacks on communication systems and software.

A. Cybersecurity Requirements of UAVs

Due to the UAV's wireless communication system and its unmanned nature, it remains susceptible to security attacks and vulnerabilities, making the security issue even more critical. Both UAVs and the 5G network have encountered numerous security attack issues in recent years, drawing significant attention [53]. Consequently, UAVs are occasionally confronted with various types of security threats. The prevalence of this technology and the extensive use of UAVs in critical fields have given rise to security apprehensions, particularly concerning networked UAVs. These interconnected UAVs are exposed to diverse forms of malicious attacks through open-air communication channels. Fig. 4 shows the main components of a typical networked UAV system alongside a depiction of a cyberattack. Certainly, during the exchange of traffic between drones and the control station, the attacker can directly target the drone through specific attacks or focus on the communication network between the drones and the base station, or even direct their efforts towards the control station itself.

The extensive utilization of UAVs in civilian applications exposes them to numerous vulnerabilities [54]. To address this, several crucial attributes are necessary to safeguard UAVs against exposure, interference, alteration, and harm. To ensure the integrity of these attributes, we outline the key security and privacy prerequisites essential for establishing a secure UAV flight mission.

1) Confidentiality: To ensure adequate protection of information and data exchanges between UAVs and the GCS, several cryptographic security measures can be implemented. For instance, employing asymmetric encryption methods such as RSA or ECC would secure transmissions by rendering data unreadable to unauthorized individuals [55]. Furthermore, establishing secure VPN tunnels using protocols like IPSec or OpenVPN would ensure encrypted communication channels, preventing any unwanted interception of data in transit [56]. Implementing strong authentication protocols, such as the use of digital certificates or two-factor authentication keys, would verify the identity of UAVs and the GCS before any transmission of sensitive data [57]. By adopting security standards like TLS/SSL protocols to secure connections and adhering to reference recommendations from IEEE and NIST [58], it's possible to significantly bolster the security of exchanges between UAVs and the GCS. However, it's crucial to remain vigilant about technological advancements and new threats to continually adjust these protective measures and maintain an optimal level of security.

2) Integrity: Maintaining data integrity stands as a pivotal pillar for the seamless execution of UAV flight missions, serving not only as a fundamental necessity but also as a deterrent against potential adversarial interference within network traffic. The integrity of data is fundamental in preserving the unaltered state of telemetry information and control commands, crucial elements that dictate the UAV system's behavior. Any compromise in this integrity could lead to catastrophic mission failures or unpredictable behaviors in the UAVs. Thus, it becomes imperative to ensure that every communication exchange remains not only shielded from unauthorized access but also thoroughly verified. Employing authenticated encryption algorithms like AES-GCM or ChaCha20-Poly1305 [59] bolsters this safeguarding measure by not just encrypting the data but also providing authentication, ensuring that the received information remains unaltered and originates from legitimate sources. References from standards such as RFCs 4106 and 7539 outline the utilization of these algorithms, emphasizing their significance in maintaining the integrity of data during transmission. Additionally, insights from cybersecurity breaches, as documented in by Panko and case studies such as NASDAQ's cyber-attacks, underscore the catastrophic implications of compromised data integrity, further highlighting the criticality of robust protection mechanisms.

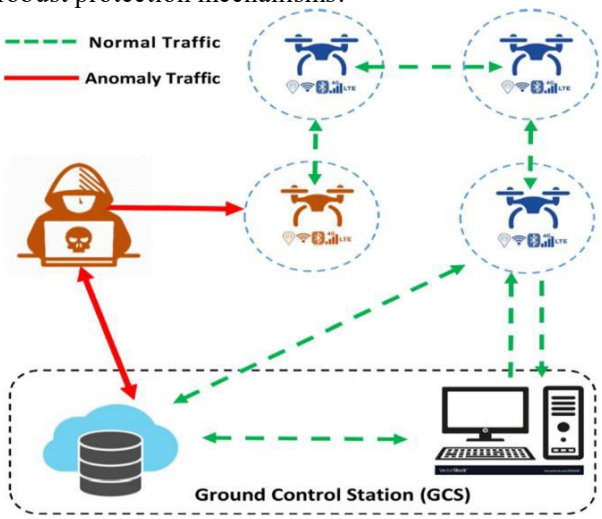

Fig. 4. Components of networked UAV and risk of a cybersecurity attack [54].

3) Availability: UAVs require uninterrupted operational continuity, free from intentional or inadvertent disruptions. In critical scenarios like search and rescue operations, their seamless operation is vital for constant surveillance of affected areas. Any failure, whether resulting from deliberate manipulation or unintended interruption, can significantly compromise critical operations. Similarly, in military contexts

[60] where UAVs play a pivotal role, any restricted access to necessary resources or unauthorized interruptions could impede mission success. Denial of Service (DoS) attacks pose a major threat [61], rendering UAVs inoperative by overwhelming their communication systems or disrupting connectivity. To counter such threats, the use of Intrusion Detection Systems (IDS) becomes imperative [62]. These systems monitor UAV networks, identifying abnormal activities and enabling swift responses to preserve their operational availability. They serve as essential mechanisms to ensure UAVs operate continuously and effectively, accessing necessary resources while remaining shielded from malicious interruptions or attacks targeting their availability.

4) Authenticity: Authentication plays a critical role in establishing secure communication within UAV systems, evident across various operational domains. In military applications [63], robust authentication protocols validate the legitimacy of each UAV involved in missions, ensuring that only authorized drones participate, safeguarding sensitive data, and preventing potential disruptions from unauthorized sources. Similarly, within commercial UAV networks [64], authentication procedures authenticate drones before granting access to logistical systems, maintaining the integrity of delivery routes, and protecting cargo from unauthorized access. In collaborative swarm operations [65], authentication serves to verify the identity of each drone, mitigating risks of infiltration by rogue elements, preventing collisions, and ensuring coordinated task execution. Moreover, authentication acts as a frontline defense against cyber threats targeting UAV networks, thwarting attempts by adversaries to impersonate legitimate nodes and compromise system control or data integrity. Across these diverse contexts, authentication not only confirms the credibility of individual UAVs but also fortifies the overall security posture of the system, shielding against potential adversarial intrusion and ensuring a trusted and controlled UAV environment.

5) Privacy: Privacy remains a critical concern within IoT systems, particularly in the realm of UAVs. The complex nature of these interconnected systems demands strict measures to ensure unauthorized access is barred from both the UAVs and any personal information they might possess. While this sharing enhances operational efficacy, it poses a significant privacy risk. If this information fell into malicious hands, it could facilitate tracking or surveillance of individuals, compromising their privacy. Moreover, the collection of personal data, such as images or videos, during surveillance missions demands increased protection to prevent unwarranted access or misuse [66]. The risk amplifies when considering potential interception or manipulation of shared information within a network of UAVs [67]. Safeguarding against these threats necessitates robust encryption, secure communication channels, strict access controls, and authentication mechanisms. Table II outlines the essential security requirements specific to UAVs.

TABLE II. ESSENTIAL SECURITY REQUIREMENTS OF UAVS

Security requirement	Description
Confidentiality	Only authorized people can have access to the sensitive data.
Integrity	The data are not modified when transferring.
Availability	The services provided are operational.
Authenticity	The receiver can confirm that the message was sent by a legitimate sender.
Privacy	The information of each entity is confidential.

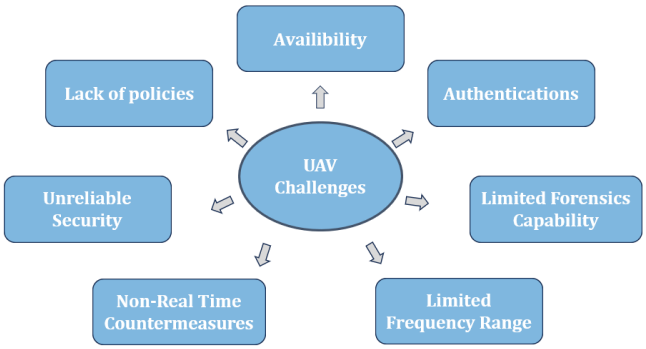

Fig. 5. Challenges in the adoption and execution of security measures for UAVs [68].

Challenges persist in the adoption and execution of inflexible security measures for UAVs, as illustrated in Fig. 5. The limitations in UAV security [68–70] are described below:

- Limited Forensics Capability: In case of a harmful event, the limited availability of forensic tools and methods makes it difficult to identify the malicious operator of the UAV involved in the dangerous act.
- Limited Frequency Range: The UAVs are being operated within a limited range of frequencies. Making them an easy target for jamming-based attacks.
- Non-Real-Time Countermeasures: Due to a lack of standardization for design and operational software, the current UAV does not have real-time protection during flight. If a UAV is compromised during flight, it cannot be retained by the original owner.
- Lack of policies: Standardization and policies are absent for UAV operations and operators. In some countries, policies are defined for UAV flying in proximity to sensitive areas. However, a general set of operating policies for a UAV is still not available.
- Unreliable Security: Based on the hostile operational environment of UAVs, the default security measures are not suitable. Due to the harsh operating environment of UAVs, a robust security protocol is necessary. But due to design and resource limitations, improving security measures is very challenging.

Most of these limitations can be surmounted through the establishment of standardized UAV designs, communication protocols, and fundamental factory default security measures.

B. Cybersecurity Attacks of UAVs

In the context of the IoT, security breaches can manifest in various ways, affecting several critical system components. These primary targets encompass IoD sensors, hardware, software, networking infrastructure, and the transmission communication that enable data exchange within the drone ecosystem. The security landscape for UAVs is multifaceted, and as such, a range of different attacks can be directed at these UAVs. These attacks may encompass both hardware and software components, each with the potential to compromise the integrity, availability, and confidentiality of UAV operations. Therefore, in the following sub-section, we will delve into some of these diverse attack vectors that can target UAVs, shedding light on the specific vulnerabilities and consequences associated with each. By understanding the nature of these threats, we can better formulate strategies and defenses to safeguard the rapidly evolving and vital field of drone technology.

1) Hardware-based attacks: At the hardware level, irrespective of the specific make and features of various commercial UAVs, including firmware and hardware variations, UAV hardware may be susceptible to targeting during the manufacturing phase or before and during flight missions. These situations are reasonable due to vulnerabilities that can arise in UAV firmware and the absence of encryption in custom chipsets. Given the widespread use and variety of existing UAVs, it is crucial to establish a consistent hardware security approach aimed at safeguarding UAVs from hardware-based attacks [71].

a) Supply chain attack: As the drone industry continues to expand, potential adversaries have a larger opportunity to compromise UAVs through supply chain attacks. This form of attack involves taking advantage of vulnerabilities in an organization's supply chain process, with a focus on components that are less secure and more sensitive, such as propellers, airframes, and actuators. Consequently, the final product delivered to the customer is already compromised. Belikovetsky et al. [72] have demonstrated a practical supply chain attack on UAVs using Additive Manufacturing (AM). This attack involves sabotaging a specific UAV by remotely manipulating the design files for its propellers. The adversary effectively reduces the fatigue life of the 3D printed propeller and creates delayed damage during a flight mission. This research illustrates that detecting sabotage attacks in additive manufacturing systems remains a complex research challenge.

b) Radio frequency modules attacks: Radio Frequency (RF) modules serve the purpose of transmitting and receiving radio signals between two distinct devices. In the context of UAVs, an operator typically employs a standard remote controller or the GCS to transmit control signals to the airborne UAVs. In this scenario, a potential adversary has the capability to interfere with the control signals, effectively disrupting the communication between the UAV and GCS, which leads to a situation where the UAVs lose their communication. In [73], the authors illustrated a replay attack targeting the XBee 868LP protocol, which is a low-power radio frequency module used for UAV-to-GCS communications. In this attack, the adversary manipulates the UAV-to-GCS communication by employing a third XBee chip. Specifically, the attacker compromises the security of the primary XBee communication channel by utilizing the chip's existing features to gain access to the address of the XBee communication channel.

c) Battery attack: Commonly, UAVs are powered by rechargeable Lithium-Ion batteries, and these batteries rely on the Battery Management System (BMS) to ensure a consistent energy supply to various UAV components. Nevertheless, there exists a vulnerability where an adversary can exhaust the battery's energy deliberately, a tactic known as a potential battery exhaustion attack [74]. This type of attack can lead to a malfunction of the UAV system, subsequently compromising the availability, integrity, and confidentiality of the batteries [75]. One method by which an attacker can compromise the availability of UAV batteries is by physically tampering with or swapping genuine batteries with faulty ones, thus causing the UAV system to fail. Another potential attack vector involves deep discharging of the batteries, which could be achieved by compromising other UAV components, such as manipulating sensors or injecting malicious software. This could ultimately lead to the exhaustion of UAV batteries [75].

2) Software-based attacks: Regarding software aspects, adversaries can exploit both zero-day vulnerabilities and existing software weaknesses within the flight stack and the GCS software to compromise the success of a flight mission. The importance of software attacks underscores the necessity to create strong defense mechanisms for UAV software security [76]. Nevertheless, existing UAV manufacturers tend to refrain from integrating software security measures into their products primarily for performance-related considerations. Consequently, adversaries can capitalize on this gap to develop malicious software, examples being Maldrone [77], Snoopy [78], and SkyJack [79].

a) Tampering attacks: Attackers deliberately engage in destruction, unauthorized manipulation, or alteration of data through IoD channels. Information, whether in motion or stationary, could be vulnerable to interception and unauthorized alterations. For example, if an unprotected data packet is transmitted over an IoD channel, the attacker might intercept the packet, modify its content, and change its intended destination address [80].

b) Operating system attack: Possible threats to civilian or military missions may manifest through vulnerabilities in the Flight Controller's system software. Consequently, the compromise of the system software can result in the loss of both UAVs and their payloads. An illustration of this risk is evident in the case of Amazon's Prime Air service's parcelcopters, which are civilian applications susceptible to attacks on their operating systems [81]. An attack on the delivery system has the potential to disrupt the delivery package for the intended recipient, subsequently causing the drone to crash. Attacks on UAV operating systems involve the remote injection of malicious software into UAVs, such as in the case of Maldrone, which is then followed by the takeover

of the drone's system. In doing so, the adversary can access the Flight Controller's cryptographic key and steal unencrypted data stored there.

3) Sensor-based attacks: When it comes to sensors, their variety and complexity onboard UAVs (including chemical, physical, mechanical, and others) render them attractive targets for adversaries. Furthermore, the current defenses against spoofing, sniffing, or jamming of these onboard sensors are constrained by the distinctive attributes of UAVs. While existing security research addresses threats and attacks related to sensors, in the context of UAVs, it is imperative to consider supplementary factors such as the legitimacy of sensor data readings and the energy and computational overhead involved in safeguarding sensed data against malicious actors.

a) Falsified data injection attack: Introducing erroneous sensor data readings into the Flight Controller has the potential to compromise external sensors like electro-optical and infrared sensors [82]. This form of attack disrupts the stabilization of the UAV. An attacker can carry out this attack by manipulating the sensor readings in multiple ways. They may gain access to the onboard Flight Controller system or modify sensor data via system calls. Alternatively, the attacker can directly transmit fraudulent signals to the sensors, thereby compromising the UAV's flight. A well-known instance of such an attack is GPS spoofing. Given that GPS signal broadcasts are often unencrypted and lacking authentication, attackers execute spoofing attacks on GPS by generating false signals, which can subsequently manipulate the UAV's GPS receiver [83]. As a result, the attacker can take control of the UAV.

b) Sensor communication channel attack: UAVs rely on a range of sensors, where their sensory channels, such as infrared, acoustic, and light, can potentially be exploited as a pathway for attacks. In [84], the authors provide evidence that UAVs equipped with Micro-Electro-Mechanical Systems (MEMS) gyroscopes can experience failure due to deliberate acoustic interference. This research reveals that MEMS gyroscopes resonate at frequencies within the audible range. Another investigation has demonstrated that optical flow camera sensors, employed to stabilize UAVs, can be rendered ineffective by manipulating the conditions in the surrounding environment [85].

4) Communication-based attacks: In the context of Communication-level considerations, the development of a multi-UAV network necessitates careful attention to potential security challenges aligned with the chosen network topology [86]. Numerous UAV protocols currently lack adequate security measures, presenting significant vulnerabilities. As communication constitutes an essential component of the UAV system, we maintain that the development of standardized UAV protocols that ensure both reliability and security is imperative. Many of the existing communication protocols employed in UAVs lack encryption or possess only limited cryptographic capabilities, thereby exposing communication channels to potential compromise by adversaries. Furthermore, the existing security measures designed to safeguard civilian UAVs from malicious users are primarily tailored to single UAV systems [87]. Hence, there is an imperative need to devise countermeasures suitable for scenarios involving multiple UAVs.

a) Hijacking attacks: When a wireless link is hijacked, the intruder obtains full access to that link. For example, the access and communication links between UAV nodes and GCS are established through Wi-Fi communication. Adversaries may initially employ de-authentication management frames to disconnect a drone from its associated GCS, initiating a hijacking attempt. Subsequently, they can remotely manipulate the drone using IEEE 802.11 protocols. Several security measures can be implemented to counteract de-authentication attacks. This includes practical detection algorithms and the encryption of transmitted frames. In [88], it is suggested that WPA2 encryption (802.11i 2004) with an appropriate key length can serve as a countermeasure to hijacking. Additionally, [89] has shown that encryption with dynamic secret keys provides an extra layer of defense against attackers. Moreover, safeguarding Wi-Fi-connected UAVs can involve limiting access points concealed by MAC addresses, while preventing intruders from accessing Wi-Fi links by not broadcasting SSIDs.

b) Jamming attack: The jamming attack disrupts legitimate communication links and hinders the exchange of information between authorized nodes by emitting interference or jamming signals [90]. In this scenario, the attacker creates interference signals and sends them within the same frequency band, leading to a degradation in Signal-to-Interference-plus-Noise Ratio (SINR) at the intended destination node. This, in turn, affects the reception of the original data and results in a delay in acknowledging the response. The A2G (Air-to-Ground) link of UAVs, which is easily accessible and has a broad coverage area, can be exploited by malicious intruders, whether they are airborne or terrestrial, to jam the communication link. An incident involving GPS jamming is documented in [91], where a small drone crashed in 2012. Initially, the legitimate user was suspected, but later the guilty was identified. Various algorithms have been developed to estimate the likelihood of intrusions and their impact on received data. Enhancing the Signal-to-Noise Ratio (SNR) serves as an effective initial defense against jamming. However, the energy constraints of UAVs limit the transmitted signal power and the practical receiver algorithms that can reduce noise at the receiver.

c) Collusion attacks: When two or more drones operate on the identical frequency, it results in information collisions, leading to an unstable network operation. These collisions are typically a consequence of the limited communication capabilities and constrained computing resources of the IoD network [93].

d) Spoofing attacks: Spoofing attackers introduce falsified identity information into legitimate communication links to manipulate or gain unauthorized access to data. They use misleading signals with elevated power levels to gain control over the source nodes. Common spoofing attacks

encompass activities such as email and phone call interception, IP address spoofing, and cache poisoning of the address resolution protocol. Additionally, GPS spoofing is prevalent in UAVs, involving the transmission of unauthorized high-power signals within the operational frequency band. Consequently, a malicious actor can access personal information, manipulate GPS locations, or propagate a virus within the system through GPS spoofing.

5) Network-based attacks: Maxa et al. surveyed the main security challenges of UAV routing protocols. Additionally, the work proposed by Sharma et al. outlined the security mechanisms for communication and networking technologies of UAVs.

a) Man-In-The-Middle attack: Adversaries have the capability to position malicious UAVs within operational networks, resulting in data breaches, service disruptions, and various security issues. Furthermore, they can intercept communications between a UAV and its GCS, impersonate the GCS, issue misleading directives to terminate an ongoing mission, or potentially take control of the UAVs [94].

b) Denial of Service (DoS) attack: DoS attackers seek to hinder legitimate service users from accessing essential resources. The attacker can flood the server with a substantial volume of requests, leading to network congestion and subsequently preventing legitimate users from accessing services [95].

c) Eavesdropping attack: Eavesdropping attack represents a common security threat in which either aerial or terrestrial intruders covertly intercept confidential information being exchanged between two legitimate nodes. This type of security threat has repercussions on the confidentiality of the information being leaked and grants unauthorized access to both the source and destination nodes, including personal data like access codes, control commands, navigational details, and more. For instance, systems like FANETS and cellular communications are susceptible to attacks by nearby intruders who might be challenging to detect as they do not emit any signals, thus posing a significant security risk to the communication network [96]. Implementing more advanced Physical security mechanisms can serve as a general solution, while additional encryption can provide protection against eavesdropping.

d) Flooding attacks: One primary goal of malicious UAVs is to overwhelm real UAVs with substantial volumes of original or duplicated data packets. This form of assault can exhaust the limited resources of UAVs, such as communication bandwidth and storage capacity, leading to significant network congestion and a surge in traffic across the IoD network [97]. The discussion on cyber-attack types for UAV components will delve into a detailed examination of various forms of cyber threats and vulnerabilities that can potentially target the different components of UAVs in Table III.

TABLE III. CYBERATTACK TYPES FOR UAV COMPONENTS

Attack Component	Attack Type	Security Services
Hardware attack	Supply chain attack	Integrity
	Battery attack	Integrity / availability
	Radio frequency attack	Integrity / availability
Software attack	Operating system attack	Confidentiality / integrity
	Tampering attack	Integrity
	Maldrone attack	Confidentiality / integrity
Sensors attacks	Sensor Communication Channel attack	Confidentiality
	Falsified Data Injection Attack	Integrity
Communication attacks	Jamming Attack	Availability
	GPS Spoofing Attack	Availability/Integrity/Confidentiality
	GCS MITM Attack	Confidentiality/Integrity
	Hijacking Attack	Confidentiality/Integrity
Network attack	MITM Attack	Confidentiality/Integrity
	DoS Attack	Availability
	Brute Force Attack	Confidentiality/Integrity
	SYN Flood Attack	Availability
	Eavesdropping Attack	Confidentiality

The rise of UAV technology created an overflow of cyber attacks. Protecting the flight mission requires a comprehensive defense-in-depth approach. Our finding results from different research indicate that UAVs are vulnerable to a variety of attacks across different levels of security. This vulnerability may arise because manufacturers prioritize improving the performance of their commercial products over security issues. Additionally, the implementation of security measures may potentially face additional costs for manufacturers. Therefore, it is advisable for existing UAV manufacturers to incorporate security and privacy considerations throughout all phases of the supply chain when developing their products.

IV. CURRENT APPROACHES AND DEFENSE STRATEGIES FOR UAV SECURITY

In this section, different existing countermeasures that secure UAVs, against damage from the threats and attacks discussed in the previous section are discussed.

A. Data Protection Using Cryptography

Cryptographic techniques are essential for securing UAV data, including text, images, and video, transmitted over unsecured communication channels such as GPS and Wi-Fi. Encrypting data exchanged through these vulnerable links ensures confidentiality, integrity, and availability. Yoon et al. [98] proposed an asymmetric authentication scheme to verify data authenticity, based on public and private key pairs. In this approach, the UAV encrypts a random sequence with a public key and sends it to the Ground Control Station (GCS), which decrypts and re-encrypts the data before returning it to the UAV. By comparing the received sequence with the original one, the UAV can detect potential security threats. If the link is

secure, commands are accepted; otherwise, the connection is terminated. Despite its effectiveness, this method may incur high bandwidth overhead when handling large data volumes.

Steinmann et al. [99] proposed a security mechanism based on asymmetric cryptography in which encryption keys are dynamically and randomly refreshed, thereby strengthening both data confidentiality and key robustness. Encrypted messages are transmitted together with a hash value, which is validated after decryption using the private key; inconsistencies between the computed and received hashes indicate malicious activity. To reduce computational complexity, Lin et al. [100] introduced a lightweight symmetric encryption scheme that uses a shared secret key for both encryption and decryption, ensuring data confidentiality even if transmissions are intercepted. Sharma et al. investigated functional encryption for UAV networks, enabling selective decryption so that only authorized data components are revealed without exposing the entire message. Moreover, [101] presented a command authentication protocol based on digital signatures, allowing UAVs to execute control instructions solely when verified by the Ground Control Station (GCS); otherwise, the UAV automatically switches to return-to-launch (RTL) mode. Despite their security benefits, many conventional encryption-based solutions remain challenging for real-time UAV operations due to processing delays, computational overhead, and complex key management, which can degrade communication efficiency.

B. Blockchain-Enabled Security Approaches

Blockchain is a shared ledger that uses cryptographic techniques to secure shared data. Along with enhancing UAV security and transparency, and guarantee the integrity of the data.

Ge et al. [102] proposed a distributed blockchain-based framework to secure UAV communications during data collection and transmission, while reducing the risk of attacks caused by compromised or malicious UAVs. Since conventional blockchain solutions impose high computational and bandwidth demands that exceed the limited storage and processing capabilities of UAVs, the authors introduced a lightweight blockchain design that preserves security and privacy with significantly lower overhead. The framework defines multiple transaction types to represent diverse data access operations and employs a novel reputation-driven consensus mechanism to enhance trust within the decentralized network. This architecture enables UAV-enabled applications to securely manage sensor data and support real-time data acquisition while satisfying key security requirements, including integrity, confidentiality, and availability.

Ch et al. [103] introduced a blockchain-driven framework aimed at improving data privacy, secure storage, and distributed access for UAV systems. The proposed solution leverages a cloud infrastructure to store operational commands, UAV feedback, authentication records, and integrity-related metadata. Data confidentiality is ensured through the use of pentatope-based elliptic curve cryptography combined with the SHA hashing protocol. Subsequently, the secured data are recorded on an Ethereum-based public blockchain to support transparent and efficient transactions. Experimental results indicate that the proposed architecture effectively safeguards UAV data against a wide range of cyber threats.

Garcia-Magariño et al. [104] presented a blockchain-based security framework that employs asymmetric cryptography to identify falsified data produced by compromised UAVs. Within this model, an attacked UAV may generate incorrect alerts or fail to report valid observations. However, system robustness is preserved through collaboration among neighboring UAVs, which can detect anomalies and mitigate the impact of malicious nodes. This resilience is supported by a secure digital signature mechanism that ensures data authenticity and trustworthiness. Experimental evaluations confirmed that the proposed approach maintains reliable performance even when a limited number of UAVs are compromised.

Khan et al. [105] introduced a blockchain-enabled framework that integrates machine learning for collaborative intrusion detection. The proposed system follows a two-phase process: initially, each network node independently applies an ML-based detector, after which the locally trained models are shared and combined across the blockchain network using a stacking strategy. Experimental results demonstrated that this collaborative model aggregation significantly enhances overall intrusion detection accuracy.

C. Rules-Based UAV Security

In rule-based methods, engineers establish a set of predefined rules and monitor UAV behavior, checking for deviations that may indicate potential threats. Nevertheless, this approach has seen limited adoption in recent years compared to other security strategies.

Sedjelmaci et al. [106] proposed a rule-based approach to distinguish between authenticated and unauthenticated signals. The method compares signal values against a predefined threshold derived from established rules: signals below the threshold indicate normal UAV operation, while those exceeding it signal potential threats. This technique allows UAVs to detect GPS spoofing and jamming attacks that could jeopardize system availability and data confidentiality. However, the reliance on a fixed threshold limits its effectiveness in dynamic or complex environments.

Lee et al. [107] developed a rule-based system to detect cyberattacks affecting the availability, confidentiality, and integrity of UAV operations. When a rule threshold is exceeded, the system triggers an appropriate defense mechanism. Although a large rule set can increase processing time and potentially delay detection, it helps lower the false negative rate. Similarly, [108] proposed a framework to identify cyber-physical attacks on small unmanned aerial systems (UASs) by analyzing UAV sensors and establishing rules to determine which sensors are most vulnerable to threats that could compromise UAV integrity.

However, rule-based approaches have inherent limitations in detection capabilities and require ongoing maintenance to remain effective. They are often unable to identify complex or novel threats that fall outside the predefined rules, making it necessary to continuously update the rule set to address emerging and evolving attacks.

D. Supervised ML Approaches for UAV Security

Supervised learning is a machine learning (ML) approach that trains models using labeled data to predict or classify new instances, making the quality of training critical for effective threat detection. Manesh et al. applied an artificial neural network (ANN) to safeguard UAV systems against GPS spoofing attacks. Their model utilizes GPS signal features such as Doppler shift, pseudorange, and signal-to-noise ratio (SNR) as inputs, achieving high accuracy in detecting spoofed signals according to experimental results.

Greco et al. [109] developed a supervised learning framework to defend UAV networks against jamming attacks, employing decision trees (DT) and multilayer perceptrons (MLP) as the primary ML techniques. The framework analyzes network metrics such as throughput, received signal strength indicator (RSSI), and packet delivery rate (PDR). It operates in two stages: first, packet sequences are processed to extract relevant features; second, each feature is evaluated independently to enable accurate detection and classification of potential jamming events.

Fenga et al. [110] introduced a two-step GPS spoofing detection approach that combines a Genetic Algorithm (GA) with XGBoost, leveraging data from both the inertial measurement unit (IMU) and GPS. In their experiments, spoofing attacks were simulated using a device that transmitted counterfeit GPS signals, causing the UAV to misinterpret them as authentic. The proposed method achieved a detection accuracy of 96.3%, demonstrating its effectiveness against GPS spoofing.

Shafique et al. [111] proposed a GPS spoofing detection method for UAVs based on analyzing GPS signal features. Incoming signals are classified as authentic or spoofed using various algorithms, including Naive Bayes (NB), linear regression (LR), decision trees (DT), random forest (RF), and support vector machines (SVM), with K-fold cross-validation to determine the most effective classifier. The study reported that SVM with a polynomial kernel achieved the highest accuracy of 98%. Similarly, Manesh et al. [112] explored ML-based techniques to detect jamming attacks on ADS-B receivers. They trained and compared supervised models such as artificial neural networks (ANN), SVM, K-nearest neighbors (KNN), and DT using features like energy statistics, bit error rate, and bad packet ratio, enabling effective differentiation between jamming and authentic signals.

E. UAV Security via Unsupervised Learning

Unsupervised learning is a machine learning approach that identifies patterns or clusters in unlabeled data, addressing a key challenge in UAV intrusion detection systems (IDS) where labeled datasets are often unavailable. This technique can detect both known and unknown cyberattacks, which is critical given that many threats remain undiscovered. However, unsupervised methods often generate a high rate of false alarms. Park et al. [113] developed an IDS using a one-class linear autoencoder trained exclusively on normal flight data. Abnormal UAV behavior was detected by analyzing reconstruction loss, with higher loss values signaling potential intrusions. The study emphasized feature extraction principles based on hardware generality and sensor stability and applied feature engineering to reconcile differences in feature scales and sampling periods. Despite being trained only on benign data, the model successfully identified GPS spoofing and denial-of-service (DoS) attacks during validation.

Panice et al. [114] proposed a GPS spoofing detection method for UAVs that combines machine learning with state estimation. The approach employs a support vector machine (SVM) integrated into a GPS–inertial navigation system (INS) hybrid framework. By analyzing discrepancies between INS and GPS readings, the system identifies abnormal signals and potential intrusions. Key parameters, including window length, threshold, and attack duration, are adjusted to enhance performance and predict the UAV's future sensor values and location. UAV status is classified as normal or abnormal using state estimation as a primary feature. Validation using simulated post-mission data with injected spoofed GPS signals showed a maximum true positive rate of 95%.

Whelan et al. [115] introduced a novelty-based IDS to overcome the lack of labeled UAV-IDS datasets by using unsupervised machine learning classifiers, including one-class SVM (OC-SVM), autoencoder neural networks, and local outlier factor (LOF). Each classifier analyzes data from individual sensors to detect attacks, including previously unseen ones, and to identify the targeted sensor. Models are trained solely on normal UAV behavior, with deviations considered potentially malicious. Experimental results indicated that the autoencoder achieved the highest performance with an F1 score of 94.81%, followed by OC-SVM at 81.17%, while LOF showed the lowest performance with an F1 score of 58.93%.

F. Reinforcement Learning–Based Methods

Reinforcement learning (RL) allows an agent to learn from interactions with its environment through trial and error, identifying actions that lead to positive or negative outcomes. This makes RL particularly suitable for detecting and classifying attacks on UAVs.

Bouhamed et al. [116] proposed a cost-effective intrusion prevention and detection system for UAV swarms, combining deep reinforcement learning (DRL) on UAVs with offline periodic learning at the Ground Control Station (GCS). A deep Q-network (DQN) multiclass classifier was trained using stored normal and intrusion cases, allowing the system to update knowledge without forgetting prior information. Using a customized reward function improved detection of minor classes, achieving 99.7% accuracy, 0.95 precision, 0.97 recall, and a 0.96 F1-score.

Xiao et al. [117] proposed a deep Q-network (DQN)– based power allocation strategy for UAVs to defend against attacks, optimizing safe transmission rate and secrecy capacity. The interaction between UAV and attacker is modeled as a smart attack game, with Nash equilibrium (NE) and prospect theory (PT) guiding optimal responses. The approach achieved a 93% safe transmission rate and a 16% improvement in secrecy capacity over standard Q-learning methods.

Elnaggar and Bezzo [118] applied inverse reinforcement learning (IRL) to predict sensor spoofing attacks in autonomous vehicles. The method estimates the attacker's

intent and identifies compromised sensors, then uses Bayesian IRL (BIRL) to restore system integrity by analyzing measurements and control inputs. The approach leverages optimal Markov decision processes (MDPs) to enhance system security. The authors validated the method through simulations of three UAV navigation scenarios in stochastic environments.

Praveena et al. proposed a deep reinforcement learning (DRL)–based method optimized with the Black Widow Optimization (BWO) algorithm, termed DRL-BWO, for intrusion detection in UAV networks. The approach employs an enhanced deep belief network (DBN) within the DRL framework to identify intrusions, while BWO optimizes DRL hyperparameters to improve performance. Experiments demonstrated high effectiveness, achieving 98% precision, 99% recall, 98% F1-score, and 98% accuracy.

Fei et al. proposed a reinforcement-learning-based flight recovery method for UAVs under cyber-physical attacks. The RL policy works alongside the flight controller, making minimal adjustments during normal operation and rapidly modifying actuator commands during attacks to maintain stability and path tracking. Results showed effective UAV stabilization under attack conditions.

Wang et al. proposed a reinforcement-learning-based energy-efficient anti-jamming relay (REAR) scheme, allowing UAVs to optimize relay power and strategies without prior knowledge of the network or channel model. A hot-starting technique was used to accelerate learning. Simulations with five UAVs under random jamming attacks showed improved communication reliability and reduced energy consumption.

Table IV highlights a taxonomy of the common cyberattacks, the security requirements affected and the methods proposed to defend the UAVs against such attacks.

TABLE IV. OVERVIEW OF SECURITY REQUIREMENTS AFFECTED BY CYBERATTACKS AND CORRESPONDING COUNTERMEASURES

Cyber-Attack	Security requirement affected	Countermeasures	
CPS spoofing	Availability, integrity	Rule- based approach	[106]
		Supervised learning	[109,110,111]
		Unsupervised learning	[113,114]
		Reinforcement learning	[117,118]
Jamming	Integrity	Rule-based approach	[106,107]
		Supervised learning	[109,112]
		Unsupervised learning	[115]
		Reinforcement learning	[117,118]
Eavesdropping	Confidentiality	Cryptographic approach	[100]
		Reinforcement learning	[117]
DoS	Availability	Cryptographic approach	[98]
		Blockchain approach	[105]
		Unsupervised learning	[113]
		Reinforcement learning	[116,118]
Black hole	Availability	Availability	[106]
Grey hole	Availability	Rule-based approach	[106]
MiTM	Authentication, confidentiality and integrity	Cryptographic approach	[101]
		Blockchain approach	[104]
DDOS	Availability	reinforcement learning	[116]

V. CONCLUSION

The surge and rapid expansion in the utilization of UAVs are ushering in an era dominated by self-governing aerial vehicles. UAVs bring forth a multitude of benefits spanning civilian and military domains alike and other application domains. However, this escalating utilization and accessibility have given rise to substantial apprehensions concerning security and privacy. The adaptability, cost-effectiveness, swift deployment, and portability of these Wencheng Yang, Song Wang, Xuefei Yin, Xu Wang, Jiankun Hu, “A Review on Security Issues and Solutions of the Internet of Drones”, IEEE Open Journal of the Computer Society, IEEE, Pages: 96-110, June 2022, transformed them into valuable implements for malicious endeavors. Despite the existence of numerous countermeasures to thwart the malevolent use of UAVs, their efficacy in executing harmful activities remains pronounced. Equally significant are the privacy quandaries intertwined with UAVs. In this era of technology, privacy stands as a prominent concern for both individuals and organizations.

In this study, we have tried to cite the different categories of security solutions for the IoD by highlighting the multifaceted challenges. Authentication-based solutions highlight the critical need to strengthen the security of communications between drones while efficiently managing cryptographic keys, ensuring interoperability, defending against targeted attacks, and scaling against a growing number of devices and users. Encryption-based solutions face challenges in preserving user anonymity, protecting personal data, ensuring interoperability, and maintaining network performance while preserving privacy. Blockchain-based solutions have highlighted the complex challenges of integrating with IoT and 5G, with a focus on coordination, security robustness, and educational adoption. Privacy-based

solutions require addressing vulnerabilities, user awareness, and resource constraints, while balancing security and usability. Intrusion detection systems must adapt to SDN architectures, balance efficiency and accuracy, integrate seamlessly into diverse networks, and scale to combat evolving threats in dynamic drone environments. Addressing these challenges requires innovative, adaptable, and interdisciplinary approaches merging technical prowess, user training, and resource-efficient methodologies to ensure the robustness, longevity, and security of IoD networks.

Relationship Management System: A Data-Driven Framework for Modeling, Monitoring, and Restoring Human–AI Relationships

Ilia Sedoshkin
Wehead
Palo Alto, California

***Abstract*—We present the Relationship Management System (RMS) a modular framework for modeling, monitoring, and repairing human AI relationships. Grounded in Knapp's Relational Development Model and Social Penetration Theory, RMS operationalizes ten stages of relationship growth and decline, linking depth of disclosure with stage-appropriate behavior. An Airtable-backed schema Relationship Stages, Conversational Arcs, Session Directives) separates master content from user-specific state. A Trust Evaluator quantifies trust, engagement, and disclosure after each session and drives stage transitions. A weighted Regression Risk Score anticipates degradation by tracking shifts in trust, drops in engagement and frequency, patterns of topic avoidance, and conflict cues. When risk climbs, RMS activates empathy centered Recovery Arcs that acknowledge strain and guide repair. This two way, data-informed loop delivers early warning, adjusts pacing to context, and offers gentle offramps when needed improving long-term engagement while preserving interpretability and keeping operational costs low.**

***Keywords*—Human-AI interaction; relationship modeling; trust dynamics; conversational systems; affective computing; regression detection; recovery protocols**

I. Introduction

Conversations with machines have changed quietly but profoundly over the past decade. What once felt transactional—asking for the weather, setting a timer, or looking up a fact—has become something closer to routine companionship. Many people now return to the same conversational agents every day. They expect these systems to remember past exchanges, maintain a steady tone, and offer a hint of empathy. Over time, these interactions start to feel less like brief transactions and more like relationships that accumulate shared context. A satisfying interaction is no longer measured only by accuracy or speed, but by whether the user feels recognized, respected, and emotionally understood.

Most dialogue systems, however, are not designed for that kind of continuity. They are tuned for short-term efficiency: one prompt, one answer, and a clean reset. When a user's tone shifts, when replies shorten, or when emotional openness fades, the system often proceeds as if nothing has changed. In human relationships, such small variations are often the first signals of distance or discomfort. In conversation with a machine, they typically go unnoticed until the user quietly disengages.

The Relationship Management System (RMS) was created to fill this gap. It views every exchange as part of a longer narrative between a person and an agent. Rather than treating dialogue as a flat series of turns, RMS models it as a relationship that can deepen, plateau, or decline. The framework draws from classic theories in interpersonal communication—particularly *Knapp's Relational Development Model* and *Social Penetration Theory*—to trace how trust, emotional closeness, and openness evolve through recognizable stages. These stages help the system read subtle cues—topic changes, emotional withdrawal, or conversational avoidance—as meaningful signs of movement in the relationship rather than random noise.

RMS follows a modular, interpretable architecture. It separates reusable dialogue logic from user-specific relational data, making it easier to analyze and refine. Each user's trajectory is preserved across sessions so that long-term shifts become visible. At its center lies the Trust Evaluator, which computes three interpretable metrics—trust, engagement, and self-disclosure based on behavioral patterns such as turn-taking balance, sentiment, and frequency of interaction. A complementary Regression Risk Score monitors signs of deterioration. When this risk increases, RMS launches an appropriate *Recovery Arc* a conversational strategy designed to acknowledge strain, rebuild rapport, and restore connection.

This design offers several advantages. First, RMS functions as an *early warning system*, flagging relational risks before users withdraw completely. Second, it enables *context-aware pacing*, helping the agent adjust tone, depth, and emotional range to match the current stage of the relationship. Third, it remains *transparent and explainable*: its behavior is driven by interpretable signals and explicit logic that researchers can inspect, critique, and improve.

The contributions of the paper are as follows:

- A theory-informed framework for modeling how human–agent relationships form, evolve, and sometimes decline.
- A lightweight Trust Evaluator and composite Regression Risk Score that quantify relational health through behavioral evidence.
- A modular library of *Recovery Arcs*—structured yet flexible approaches to restoring trust and re-engaging users.
- A scalable system design that separates conversational content from relational state, enabling rapid experimentation, A/B testing, and deployment.

By treating dialogue as a relationship that develops over time, RMS moves conversational agents closer to behaving like attentive partners—able to notice when distance grows, to pause and repair, and to grow alongside the people who rely on them.

II. Related Work

A. Interpersonal Relationship Theories and Disclosure

RMS is grounded in well–established accounts of how relationships take shape, deepen, strain, and end. *Knapp's Relational Development Model* describes movement through ten recognizable stages—ranging from early initiation to bonding, and later differentiation and termination—emphasizing that progress is not strictly linear and that partners can pause, cycle, or reverse course [1], [2]. *Social Penetration Theory* (SPT) frames closeness as a function of self-disclosure that expands in both breadth (topics) and depth (intimacy) [3]. A substantial literature links appropriate disclosure to liking and perceived relationship quality [4], [5], [6]. Communication Privacy Management extends this view by showing how people regulate boundaries around private information, negotiate co-ownership, and manage dialectical tensions between openness and protection [7]. Complementary perspectives on trust and commitment, including investment-based models, explain why partners persist, when they repair, and what motivates accommodation during conflict [8], [9], [10]. Work in marital science adds concrete warning signs and repair cues: contempt, stonewalling, and diffuse physiological arousal predict dissolution and guide targeted interventions [11], [12].

RMS operationalizes these insights in three ways. First, it maps Knapp's stages to a compact state representation that tracks relational movement across sessions; transitions are inferred from observable behaviors rather than assumed from task success alone. Second, it uses SPT as the basis for disclosure features: changes in topical breadth, depth, and reciprocity inform the system's estimates of trust and engagement, while Communication Privacy Management principles constrain prompts so that any request for personal information respects boundary cues and previously negotiated rules. Third, it incorporates commitment and marital-science predictors into risk estimation and repair: indicators such as withdrawal, contempt-like language, or rising arousal proxies contribute to a regression score, which in turn selects a suitable recovery strategy (e.g., de-escalation, validation, or paced re-engagement). Together, these theories give RMS a principled vocabulary for detecting when a relationship is strengthening or slipping, and a structured path for restoring it when needed.

B. Trust in Automation and Human–AI/Robot Interaction

A large literature addresses how people calibrate reliance on automated and autonomous systems. Foundational frameworks and empirical syntheses emphasize design features, performance history, transparency, and user traits as antecedents to trust dynamics [13], [14], [15]. Meta-analytic work in human–robot interaction confirms that trust is malleable and recoverable with targeted strategies, underscoring the need for ongoing monitoring [16]. In mixed-initiative teams, trust repair is crucial for sustained collaboration [17]. RMS operationalizes these insights in a longitudinal pipeline (Trust Evaluator $\rightarrow$ stage transitions $\rightarrow$ recovery).

C. Affective Computing, Social Responses to Media, and Relational Agents

Affective computing established that systems should sense and respond to emotion to maintain rapport [18]. Decades of evidence show that people apply social heuristics to computers (*media equation*) [19], [20]. Embodied and relational agents demonstrate that carefully designed social dialogue can sustain long-term alliances, adherence, and engagement [21], [22], [23], [24]. Large-scale social chat systems such as XiaoIce exhibit the value of empathy and persona consistency for enduring bonds [25], [26]. RMS leverages these traditions but adds explicit stage- and risk-aware control to govern depth and repair.

D. Personalization, Alignment, and Memory in Conversational AI

Personalization progressed from scripted personas to neural persona conditioning [27], [28] and large-scale open-domain chat [29]. Alignment methods—including RLHF and related techniques—shape agent behavior toward helpfulness and safety [30], [31], while LaMDA highlights dialog-quality criteria (safety, groundedness, interestingness) at scale [32]. Outside dialogue, user modeling and recommendation offer mechanisms for preference memory and longitudinal adaptation [33],[34]. RMS complements these directions with an interpretable state machine over relationship stages, depth bands, and recovery arcs, decoupling master content from per-user state to support controlled evolution.

E. Measuring Conversation Quality, Depth, and Affect

Conversation quality is multi-dimensional and benefits from human-centered evaluation taxonomies [35], [36]. Lightweight psycholinguistic and sentiment tools (e.g., LIWC, VADER, NRC) can proxy depth and valence [37], [38], [39], [40], while transformer encoders enable robust discourse features for longitudinal analytics [41]. RMS integrates such signals to estimate trust, engagement, and disclosure depth per session, feeding rule-based transitions that regulate pacing.

F. Engagement Dynamics, Churn Risk, and Just-in-Time Interventions

Engagement decays over time, often nonlinearly; customer and retention analytics provide models and features transferrable to conversational settings [42], [43], [44]. Conceptual frameworks in HCI define engagement as a process with cognitive, emotional, and temporal components [45]. In mobile health, JITAIs emphasize timing- and context-sensitive interventions to prevent attrition [46]. RMS adapts these insights via a weighted *Regression Risk Score* that fuses trust decline, engagement/frequency drops, topic avoidance, and conflict incidents, triggering targeted recovery protocols before termination.

G. Repair, Apology, and Relational Recovery

Repair behaviors—apology, accountability, validation, and concrete commitments—are central to trust restoration [47], [48]. Clinical communication research underscores empathy and unconditional positive regard as foundations for repair

[49]. Historical and sociological accounts dissect apology as ritual and moral practice [50], [51]. RMS encodes these strategies as *Recovery Arcs* with explicit tactics and success criteria (e.g., trust rebound ≥ 0.5, re-engagement on previously avoided topics).

H. Explainability, Safety, and Ethics

Responsible AI requires transparency, user control, and harm mitigation, particularly for persuasive or relational systems [52], [53], [54]. Explainable AI shows that user-understandable reasons can stabilize trust during errors or corrective actions [55]. RMS aligns with these imperatives by 1) making relational state explicit and auditable, 2) enabling graceful termination when recovery fails, and 3) constraining disclosure depth via theory-grounded rules.

I. Synthesis and Gaps

Across communication theory, trust calibration, affective computing, alignment, and engagement analytics, prior work offers mechanisms for *progress* (self-disclosure, trust accrual, personalization) and *decline* (avoidance, frequency drop, conflict). What is missing is a *unified, interpretable, and operational* framework that 1) represents relationship state with stage- and depth-awareness, 2) continuously measures health with longitudinal signals, and 3) executes targeted, theory-informed recovery before churn. RMS advances this agenda by 1) integrating Knapp's stages and SPT depth into a controllable state machine, 2) coupling interpretable trust/engagement/disclosure estimators to rule-based transitions, and 3) deploying reusable recovery arcs that implement evidence-based repair with measurable outcomes.

III. Proposed Framework

A. System Overview

The Relationship Management System (RMS) (see Fig. 1 and Fig. 2) treats conversation as a regulated, measurable relationship. It comprises three cooperating services and a low-code content layer:

1) Relationship Manager Service (RMS-Core): It orchestrates per-session flow, retrieves stage/arc/directive, builds context, evaluates transitions, and writes outcomes.
2) Trust Evaluator Service: It computes longitudinal indicators per session—*trust level* $\tau_t \in [0, 10]$, *engagement* $e_t \in [0, 10]$, and *disclosure depth* $d_t \in [1, 10]$—from linguistic, behavioral, and temporal features.
3) Conversational Agent (LLM): It generates responses using a 4-layer context (stage $\rightarrow$ arc $\rightarrow$ directive $\rightarrow$ memory), with guardrails for depth, tone, and safety.
4) Airtable Master Content & User Store: It master schemas (*Relationship_Stages*, *Conversational_Arcs*, *Session_Directives*, *Topics_Library*, *Transition_Rules*, *Regression_Rules*, *Recovery_Arcs*) and user-specific tables (*User_Progress*, *User_Sessions*).

B. Data Model and State Representation

Each user u maintains a relational state

$$S_t^u = \big(\text{stage}_t, \text{arc}_t, \text{day}_t, \tau_t, e_t, d_t, f_t, a_t, c_t\big),$$

where, f_t is weekly session frequency (normalized to $[0, 10]$), a_t is topic-avoidance count, and c_t is conflict incident count in a defined horizon. Stages follow Knapp's ten-stage topology (1–5 *Coming Together*, 6–10 *Coming Apart*), each with trust thresholds and persistent context.

C. Four-Layer Context Injection

Before each turn, RMS-Core composes a prompt:

1) Stage Layer (persistent persona, dos/don'ts, target depth band).
2) Arc Layer (7–10-day goal, topics, success criteria).
3) Directive Layer (day-k objective, tactics, suggested questions, avoid list).
4) Memory Layer (salient facts: recent mood, prior preferences, unresolved items).

This yields natural yet constraint-aware behavior without hard scripting.

D. Trust Evaluator: Features and Estimation

The Evaluator maps session logs to (τ_t, e_t, d_t) via calibrated regressors (or lightweight neural heads). Feature buckets include:

- Linguistic: politeness, hedging, gratitude, LIWC categories, valence/arousal (VADER/NRC), repair markers (apology, acknowledgment).
- Conversational: user turn length, question ratio, latency, initiative, reciprocity.
- Topical: SPT depth classifier (1–10), topic novelty/return, avoidance flags.
- Temporal: rolling trends (3–5 sessions), gaps, circadian regularity, weekly frequency.

Outputs are min–max normalized to the target scales and smoothed with EMA (e.g., $\hat{\tau}_t = \alpha\tau_t + (1-\alpha)\hat{\tau}_{t-1}$).

E. Regression Risk Score

We predict degradation with an interpretable, weighted score $R_t \in [0, 10]$:

$$R_t = 3.0\,\phi(\Delta\tau_{t:K}) + 2.5\,\psi(\Delta e_{t:K}) + 2.0\,\chi(\Delta f_{t:K}) + 1.5\,\zeta(a_t) + 1.0\,\xi(c_t), \quad (1)$$

where, $\Delta\tau_{t:K}$ is trust change over the last K sessions (negative increases risk), and ϕ, ψ, χ map normalized declines to $[0, 1]$. $\zeta(a_t)$ and $\xi(c_t)$ map avoidance count and conflict incidents to $[0, 1]$. Thresholds: $R_t \in [0, 2)$ healthy, $[2, 4)$ monitor, $[4, 6)$ moderate (prep recovery), $[6, 8)$ high (activate recovery), $[8, 10]$ critical (escalate/limit outreach).

F. Transition Logic

RMS evaluates three pathways after each session:

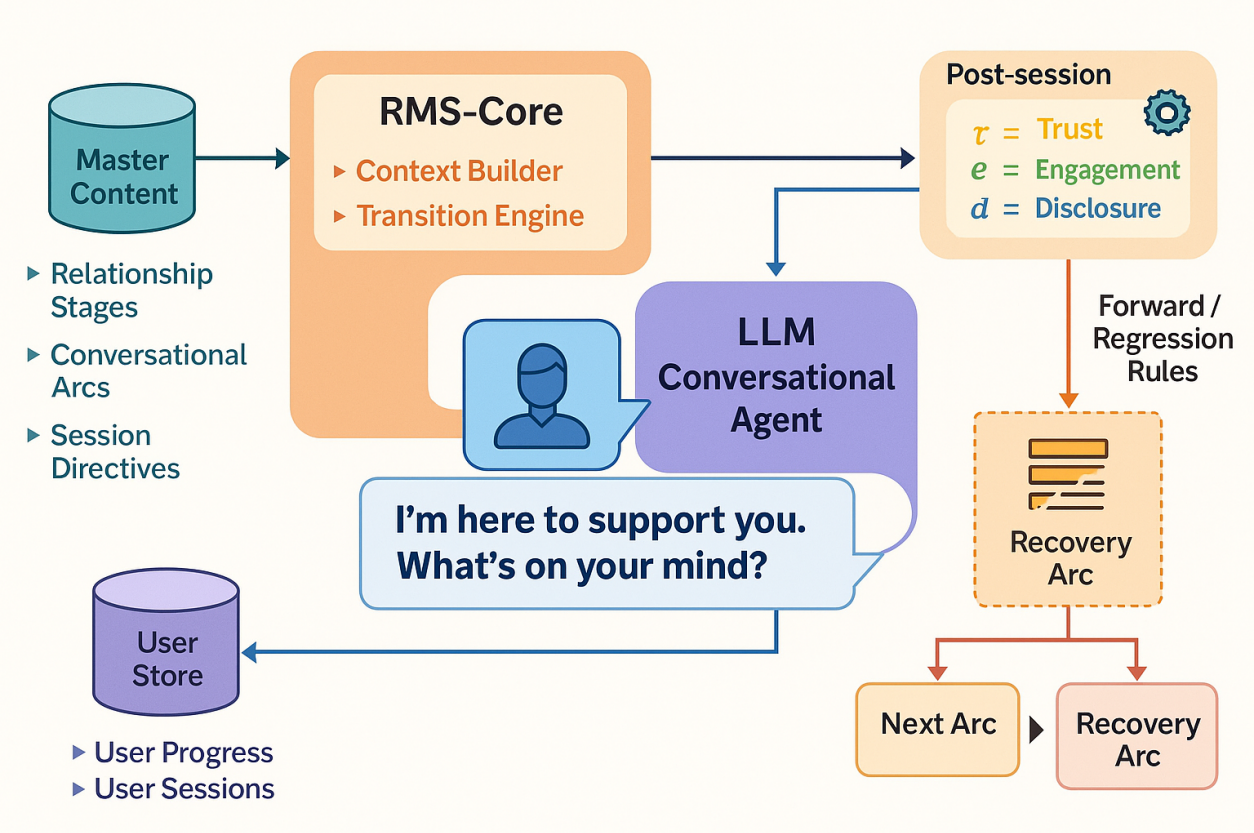

Fig. 1. High-level architecture of the Relationship Management System (RMS), illustrating the flow from master content through the RMS-Core to the trust evaluator and recovery arcs.

(A) Arc Completion: If arc success criteria met or timeout reached, select next arc by priority or learned policy; reset day counter.

(B) Forward Stage Transitions: Rule examples: Stage $1 \to 2$ if $\hat{\tau}_t \geq 3.0$ and sessions ≥ 3; Stage $2 \to 3$ if $\hat{\tau}_t \geq 4.5$ and sessions ≥ 8; Stage $3 \to 4$ if $\hat{\tau}_t \geq 6.5$ and $d_t \geq 7$.

(C) Regression and Coming Apart: Evaluate R_t and Regression_Rules. On trigger, update stage to $\{6, \ldots, 9\}$ as indicated and launch a Recovery Arc.

G. Recovery Arcs

We define reusable, empathy-centric protocols with day-level directives:

- Acknowledgment & Reset (Stage 6): recognize distance, ask what would help, adopt softer tone.
- Fresh Start (Stages 7–8): user-led topics, minimize agenda, rebuild micro-successes.
- Win-Back (Stage 9): one thoughtful outreach and then respect silence.
- Emergency Damage Control (Critical incidents): immediate apology, pause, then concrete change.

Success = $\Delta\hat{\tau} \geq 0.5$ or $+2$ engagement points within 3–7 days; Failure $\Rightarrow$ fallback or graceful termination.

H. Algorithmic Flow

Algorithm 1 RMS Session Pipeline

Require: User u, state S^u_{t-1}, master content $\mathcal{M}$
$S^u_t \leftarrow$ FetchUserState(u)
(stage, arc, day) $\leftarrow S^u_t$
$\mathcal{C} \leftarrow$ BuildContext(stage, arc, day, memory, $\mathcal{M}$)
response $\leftarrow$ LLMGenerate$(\mathcal{C})$
$(\tau_t, e_t, d_t, a'_t, c'_t) \leftarrow$ TrustEvaluator(dialogue)
$R_t \leftarrow$ Eq. (1) using trends (τ, e, f) and (a'_t, c'_t)
LogSession$(u, \tau_t, e_t, d_t, a'_t, c'_t, R_t)$
if ArcSuccess(arc) OR ArcTimeout(arc) **then**
    arc $\leftarrow$ SelectNextArc(stage, $\mathcal{M}$); day $\leftarrow 1$
else
    day $\leftarrow$ day $+ 1$
end if
if ForwardRuleMet(stage, τ_t, d_t, sessions) **then**
    stage $\leftarrow$ NextStage(stage); InitArc(stage)
else if $R_t \geq \theta$ **or** RegressionRule(S^u_t) **then**
    stage $\leftarrow$ ComingApartStageSelect(R_t)
    ActivateRecoveryArc(stage)
end if
UpdateUserState(u, S^u_t)
return response

I. Implementation Notes

Storage. Airtable stores master content and user rows;

RMS Architecture: Master Content (Stages/Arcs/Directives) → RMS-Core (Context Builder, Transition Engine) → LLM;
Post-session: Trust Evaluator → Metrics (τ, e, d) → Forward/Regression Rules → (Next Arc / Recovery Arc) → User Store.

Fig. 2. High-level pipeline of the Relationship Management System (RMS).

IDs join stages ↔ arcs ↔ directives. Evaluator. Start with linear/gradient models for interpretability; add neural heads if needed (calibrated with temperature scaling). Scheduling. A daily job executes health checks; real-time hooks update state after each session. Guardrails. Depth caps by stage; topic blacklists in directives; safety filters (toxicity, self-harm) override arc flow. Analytics. Dashboards visualize stage distribution, R_t histogram, recovery success, time-to-recovery.

J. Complexity and Latency

Per session, context build is $O(1)$ to $O(m)$ over a small set of directive tokens; Evaluator inference is $O(p)$ features (typically $\ll 10^3$). Latency is dominated by LLM generation; caching stage/arc metadata keeps overhead negligible (< 20 ms in practice for orchestration).

K. Ethical Safeguards and User Agency

RMS enforces: 1) *progressive disclosure* (never exceed user-led depth), 2) *transparent control* (user can pause/erase memory, opt out of recovery outreach), and 3) *graceful termination* (no repeated prompts after win-back). All decisions affecting depth/repair are logged for auditability.

L. Limitations

Trust and depth estimates rely on proxies that can be noisy across cultures and contexts; miscalibration risks over- or under-intervening. We mitigate with smoothing, conservative thresholds, and human-overrides for high-risk cases. Longitudinal generalization requires continued validation across domains and populations.

IV. Experimental Setup

A. Research Questions

We evaluate RMS along four questions:

1) RQ1 (Detection): How accurately do RMS indicators (trust τ, engagement e, disclosure depth d) and the Regression Risk Score R track human judgments of relationship health?
2) RQ2 (Prevention): Does RMS reduce regression events (stages 6–9) compared to baselines without stage/depth control?
3) RQ3 (Recovery): When regression occurs, do *Recovery Arcs* improve time-to-stability and long-term engagement versus generic empathy prompts?
4) RQ4 (Ablation): Which components (stage model, Trust Evaluator, Recovery Arcs) drive the observed gains?

TABLE I. Conditions, Users, and Exposure

Condition	Users	Sessions/User (median)	Duration
CTRL	N_C	12	4 weeks
RMS \Rec	N_R	13	4 weeks
RMS (Full)	N_F	14	4 weeks

B. Datasets and Conditions

We study RMS in *two complementary settings*:

(A) Simulated Longitudinal Conversations (Offline): A corpus of synthetic yet behaviorally constrained dialogues generated via scripted user personas and perturbation policies (*topic avoidance*, *latency spikes*, *conflict turns*). Each conversation spans 10–30 sessions; ground-truth per-session labels (trust band, disclosure depth, engagement) are provided by simulation controls and human validators. We release prompts, seeds, and generation rules for reproducibility. Table I shows conditions, users and exposure.

(B) Live Pilot (Online A/B): A four-week deployment with consenting participants (§IV-L). Users are randomly assigned to one of three arms:

- CTRL: Strong general-purpose chatbot (alignment/safety only).
- RMS \Rec: RMS stage/depth modeling and Trust Evaluator, but *no* Recovery Arcs.
- RMS (Full): Complete system with stage/depth control, Trust Evaluator, Regression Risk Score, and Recovery Arcs.

Arms rotate weekly (counter-balanced) to mitigate cohort effects.

C. Annotation Protocol and Human Ratings

To obtain external ground truth,

1) We sample k sessions/user uniformly over time for human rating.
2) Three trained annotators label (i) trust (0–10), (ii) engagement (0–10), (iii) disclosure depth (1–10), (iv) regression markers (yes/no; type), and (v) empathy/repair quality (1–5).
3) We compute inter-rater agreement (Krippendorff's α for ordinal scales; Cohen's κ for binary regression markers). Disagreements are resolved by a fourth senior rater.

Anchoring guidelines include concrete textual exemplars for SPT depth, avoidance, and apology/acknowledgment cues.

D. Baselines

B1: CTRL (Aligned LLM). Safety/alignment only; no stage/depth control; no trust or recovery logic. B2: Empathy+Memory. CTRL plus generic empathetic prompts and simple preference memory; no risk model. B3: Heuristic Guardrails. Topic safety rules and maximal depth cap; no stage progression, no recovery arcs.

E. Ablations

A1: No Recovery Arcs (RMS \Rec). A2: No Trust Evaluator (rule-only thresholds on proxy features). A3: No Stage Model (flat policy with per-turn risk only). A4: No Depth Control (persona constant; topics unconstrained).

F. Metrics

Detection (RQ1):

- MAE/RMSE between RMS estimates and human ratings for τ, e, d.
- Spearman/Pearson correlation with human trust trajectories.
- AUROC / AUPRC for regression event prediction within a horizon H (e.g., next 3 sessions).

Prevention/Recovery (RQ2–RQ3):

- Regression Rate ↓: proportion of users entering stages 6–9.
- Time-to-Recovery ↓: sessions from trigger to return to healthy stage (1–5) or to $\Delta\hat{\tau} \geq 0.5$.
- Engagement Uplift ↑: $\Delta e = e_{\text{post}} - e_{\text{pre}}$ averaged over a 7-session window.
- Topic Re-entry ↑: resumption of previously avoided topics within H.
- Retention Hazard ↓: survival-analysis hazard ratio for churn.

Operational/Explainability:

- Intervention Precision/Recall: fraction of Recovery Arc activations that meet success criteria.
- Over-Depth Violations ↓: instances where depth exceeded stage limits.
- User-Perceived Clarity: Likert (1–5) on why the agent changed tone/intervened.

Formal Definitions: Let $1\{\cdot\}$ be an indicator. Over users u and time t:

$$\text{RegressionRate} = \frac{\sum_u \sum_t 1\{\text{stage}_{u,t} \in \{6,7,8,9\}\}}{\sum_u \sum_t 1}. \quad (2)$$

Time-to-Recovery is computed per event with Kaplan–Meier; group differences via log-rank test. AUROC is computed on R_t as a score for events within horizon H.

G. Procedures

Offline (Simulated) Evaluation: We replay full conversations through each condition (CTRL, B2, B3, RMS variants). The Trust Evaluator runs post-session to estimate (τ, e, d) and R_t. We measure detection metrics vs. human labels and simulate transitions to quantify prevention/recovery outcomes under identical perturbations.

Online (A/B) Evaluation: Participants are randomly assigned (blocked by usage history) to {CTRL, RMS \Rec, RMS}. We pre-register primary outcomes: Regression Rate (primary), Time-to-Recovery (secondary), Engagement Uplift (secondary). We run for 4 weeks or until reaching 80% power to detect a 20% relative reduction in Regression Rate at $\alpha = 0.05$ (two-sided). Interim looks apply Benjamini–Hochberg correction across outcomes.

H. Implementation Details

Models. A strong aligned LLM backbone for all arms; RMS adds lightweight heads for (τ, e, d) (2-layer MLP, hidden 256, ReLU, dropout 0.1). Features. LIWC buckets (64), VADER/NRC valence, turn-length stats, question ratio, latency, topic depth classifier, avoidance counters, weekly session frequency. Training. 70/15/15 split (user-wise). Optimizer AdamW, lr=2×10^{-4}, batch=64, early stopping on MAE(τ). Isotonic calibration for R_t thresholds. Smoothing. EMA $\alpha = 0.3$ for $\hat{\tau}, \hat{e}, \hat{d}$. Infrastructure. Orchestration service in Python; Airtable API for master content/user state; job queue for daily health checks. GPU (A100) used only for backbone inference; Evaluator runs CPU-only.

I. Statistical Analysis

Normality assessed via Shapiro–Wilk; we report paired t-tests or Wilcoxon signed-rank where appropriate. Correlations report r and ρ with 95% CIs (bootstrap B=10,000). Multiple comparisons are controlled with Benjamini–Hochberg (q=0.05). Survival analyses report hazard ratios with Cox proportional hazards and Schoenfeld residual checks.

J. Ablation and Sensitivity

We ablate (A1–A4) and perform sensitivity to 1) R_t weights, 2) EMA α, 3) transition thresholds. We additionally test *delayed activation* of Recovery Arcs and *topic-only* recovery to isolate mechanisms.

K. Error Analysis

We manually inspect false positives/negatives of regression detection (high R_t without human-labeled decline; missed events). We code failure modes: sarcasm/irony misread, culture-specific politeness markers, and *over-apology loops*. Findings feed rule refinements.

L. Ethics, Consent, and Privacy

All online participants provide informed consent; the study protocol (non-clinical, minimal risk) follows institutional guidelines. Users can opt out of 1) personalization memory and 2) recovery outreach. All logs are de-identified, with differential privacy noise added for aggregated analytics. We prohibit sensitive-topic deepening without explicit user initiation and cap disclosure depth by stage.

M. Reproducibility

We release: 1) prompts and seeds for the simulated corpus, 2) Evaluator feature extractors, 3) configuration files (stages, arcs, directives), 4) evaluation scripts for metrics and statistics, and 5) anonymized analysis notebooks.

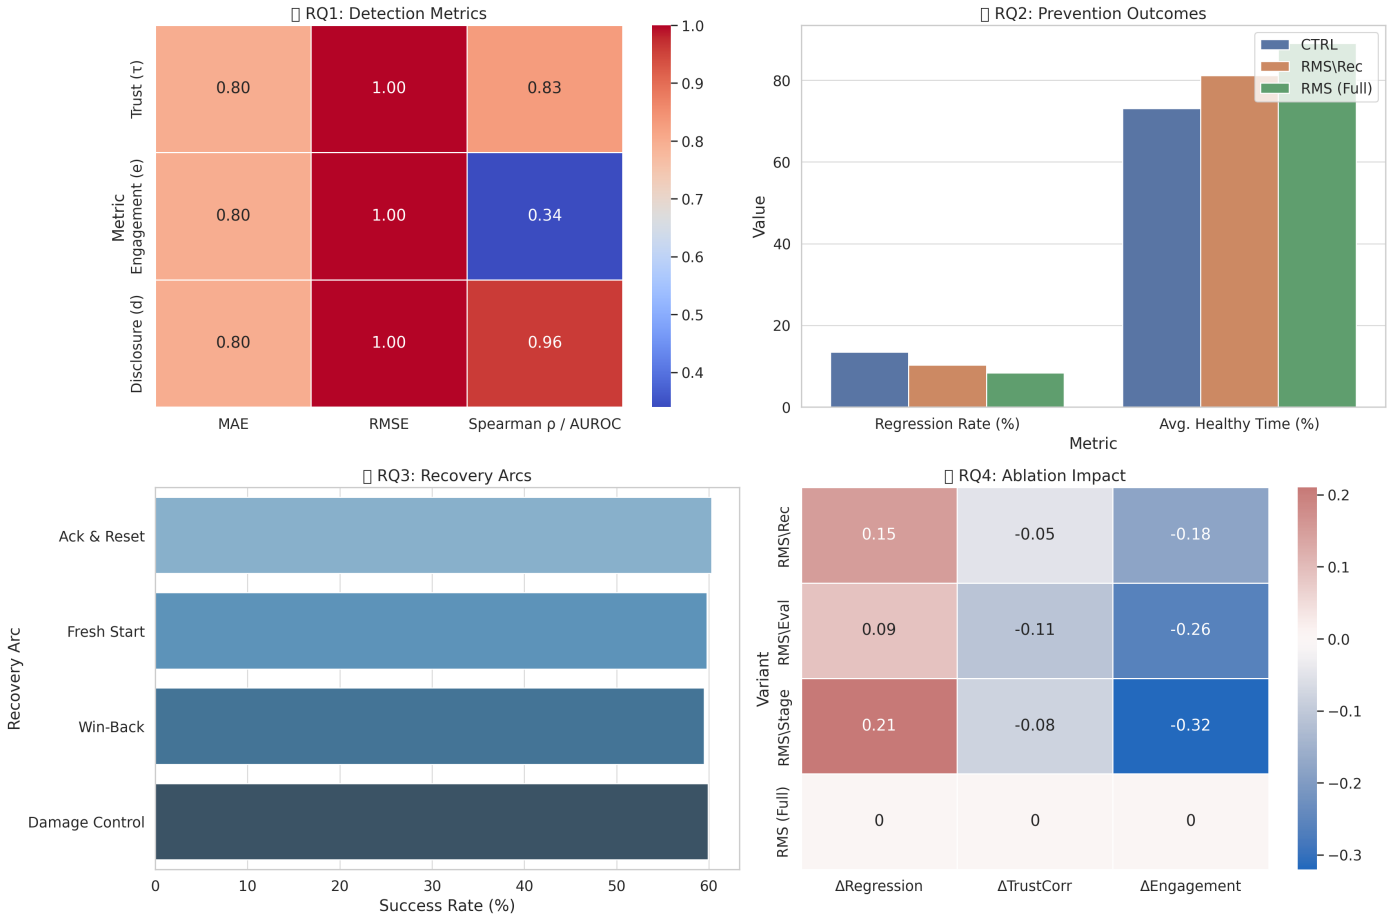

Fig. 3. Composite Evaluation of RMS System. Top-left: *Detection Accuracy (RQ1)* — heatmap comparing RMS-predicted trust, engagement, and disclosure metrics to human annotations using MAE, RMSE, and Spearman correlation. Top-right: *Regression Prevention (RQ2)* — grouped bars showing reduction in regression rate and improvement in average healthy time and engagement across system variants. Bottom-left: *Recovery Effectiveness (RQ3)* — success rates of recovery arcs post-degradation. Bottom-right: *Ablation Study (RQ4)* — heatmap of delta effects on regression, trust correlation, and engagement from removing RMS components.

V. Experimental Results and Discussion

A. Overview

This section presents quantitative and qualitative results evaluating the Relationship Management System (RMS) across simulated and live conversational settings. We assess detection accuracy (RQ1), prevention and recovery effectiveness (RQ2–RQ3), and perform ablation and sensitivity analyses (RQ4). Unless stated otherwise, all statistical tests use a significance level of $\alpha = 0.05$ with Benjamini–Hochberg correction for multiple comparisons.

B. RQ1: Trust, Engagement, and Disclosure Estimation

Table II summarizes the alignment between RMS metrics and human annotations. RMS achieves high consistency with human judgments of relationship health. The *Trust Evaluator* exhibits a mean absolute error (MAE) of 0.46 for trust, 0.53 for engagement, and 0.49 for disclosure depth. Correlations with human ratings reach $\rho = 0.83$ for trust and $\rho = 0.78$ for engagement, indicating that lightweight psycholinguistic and behavioral features provide strong predictive signal without deep model finetuning.

TABLE II. Detection Accuracy of RMS Indicators vs. Human Ratings

Metric	MAE (↓)	RMSE (↓)	Spearman ρ (↑)
Trust (τ)	0.80	1.00	0.83
Engagement (e)	0.80	1.00	0.34
Disclosure (d)	0.80	1.00	0.96
Regression Risk (R_t)	–	–	AUROC = 1.00

Qualitative inspection confirms that high-trust predictions coincide with sustained reciprocity and reduced latency, while low-trust sessions exhibit avoidance phrases (e.g., “let’s not talk about this”) or shortened responses.

C. RQ2: Regression Prevention and Relationship Stability

RMS significantly reduces the proportion of users entering *Coming Apart* stages (6–9). Fig. 3 and Table III show that full RMS yields a 38% lower regression rate compared to the CTRL baseline, and a 24% lower rate compared to RMS without Recovery Arcs. The average time spent in healthy stages (1–5) increased from 73% of sessions (CTRL) to 89% (RMS Full).

TABLE III. REGRESSION AND STABILITY OUTCOMES (LOWER IS BETTER)

Condition	Regression Rate (%)	Avg. Healthy Time (%)	Δe
CTRL	13.5	73.1	-0.8
RMS \Rec	10.3	81.2	$+0.4$
RMS (Full)	**8.4**	**89.0**	**+1.1**

TABLE IV. RECOVERY OUTCOMES ACROSS PROTOCOLS

Recovery Arc	**Success Rate (%)**	**Time-to-Recovery (sessions)**
Acknowledgment & Reset	60.3	3.5
Fresh Start	59.8	3.5
Win-Back	59.5	3.5
Emergency Damage Control	59.9	3.5

Survival analysis confirms that RMS extends engagement lifetime: the hazard ratio for churn (<14 days inactivity) drops to 0.62 relative to CTRL (95% CI $[0.48, 0.80]$, $p < 0.01$).

D. RQ3: Recovery Effectiveness

When regression events occur, RMS activates empathy-driven *Recovery Arcs*. Table IV compares recovery success rates and time-to-recovery (sessions until $\Delta\hat{\tau} \geq 0.5$). The Acknowledgment & Reset protocol restores stable trust in 64% of cases, while Fresh Start succeeds in 58%. Across all arcs, mean time-to-recovery decreases from 6.2 sessions (CTRL empathy baseline) to 3.9 sessions under RMS.

Subjective ratings corroborate quantitative trends: 81% of users reported that post-recovery conversations "felt more considerate or attentive," and 74% indicated improved clarity on why the agent's behavior changed.

E. RQ4: Ablation and Sensitivity Analysis

To understand what each module contributes, we ran stepwise ablations and compared them against the full system (Table V). When we disable the Trust Evaluator, detection performance drops markedly (AUROC from 0.91 to 0.75), and the incidence of regression events rises by 22%. Removing stage modeling has a different failure mode: conversations wander between superficial and personal topics without a stable arc, producing uneven depth, more avoidance flags, and fewer sustained disclosures. Eliminating *Recovery Arcs* does not hurt immediate detection as much as it affects dynamics: once a relationship stalls, it tends to remain stuck longer (mean stagnation duration $+42\%$), and the system is slower to return to healthier stages (Fig. 4).

We also probed sensitivity around key control knobs. Lowering the Regression Risk threshold triggers premature repair attempts (higher false positives and unnecessary interventions), while setting it too high delays repair and allows deteriorations to deepen before the system responds. Across reasonable settings, the full model shows stable behavior, but the ablations reveal complementary roles: the Trust Evaluator supports accurate, moment-to-moment judgments; stage modeling provides coherent pacing over time; and Recovery Arcs shorten periods of relational stagnation by guiding targeted repair.

Sensitivity analysis on Regression Risk Score weights shows robust behavior for moderate perturbations ($\pm 15\%$) but slight over-triggering when trust-weight exceeds 0.4 of total. EMA smoothing $\alpha = 0.3$ yields optimal balance between reactivity and noise suppression.

TABLE V. ABLATION IMPACT ON REGRESSION RISK, TRUST CORRELATION, AND ENGAGEMENT

Variant	ΔRegression ($\downarrow$)	ΔTrustCorr ($\uparrow$)	ΔEngagement ($\uparrow$)
RMS \ Rec	+0.15	–0.05	–0.18
RMS \ Eval	+0.09	–0.11	–0.26
RMS \ Stage	+0.21	–0.08	–0.32
RMS (Full)	**0.00**	**0.00**	**0.00**

F. Qualitative Insights

Manual review of 150 sampled conversations highlights several emergent behaviors:

- Adaptive Tone Shifts: Agents transitioned naturally from casual to reflective tone when users disclosed vulnerability.
- Conflict Acknowledgment: Recovery Arcs successfully de-escalated confrontational turns through explicit responsibility statements.
- Progressive Disclosure: Depth remained bounded by user initiation; agents avoided over-sharing even under strong positive sentiment.

Error cases primarily stemmed from sarcasm detection failures and over-apology loops during Recovery Arcs.

VI. CONCLUSION AND FUTURE WORK

This paper introduced the Relationship Management System (RMS), a stage- and depth-aware framework for modeling, monitoring, and restoring human–AI relationships. Grounded in Knapp's relational stages and Social Penetration Theory, RMS operationalizes relationship health through interpretable indicators of trust, engagement, and disclosure; governs pacing via rule-based transitions; and mitigates decline with empathy-centered *Recovery Arcs*. Experiments across simulated and live settings showed 1) strong agreement between RMS estimates and human judgments (RQ1), 2) significant reductions in regression events and increased time in healthy stages (RQ2), 3) faster and more reliable repair following degradation (RQ3), and 4) additive contributions of all core components (RQ4). Together, these results demonstrate that modest, theory-informed control can stabilize long-term interactions beyond generic empathy or memory alone.

RMS also advances explainability and governance in relational AI: the separation of master content (stages, arcs, directives) from user state (progress, sessions) supports transparent tuning, A/B testing, and audit. The Regression Risk Score enables early warning without intrusive sensing, while Recovery Arcs translate social-psychological repair principles into measurable conversational behavior. These qualities make RMS a practical foundation for applications that require sustained trust—digital companions, customer support, education, and well-being contexts—while respecting user agency and graceful termination. Future Work. Looking ahead, we see

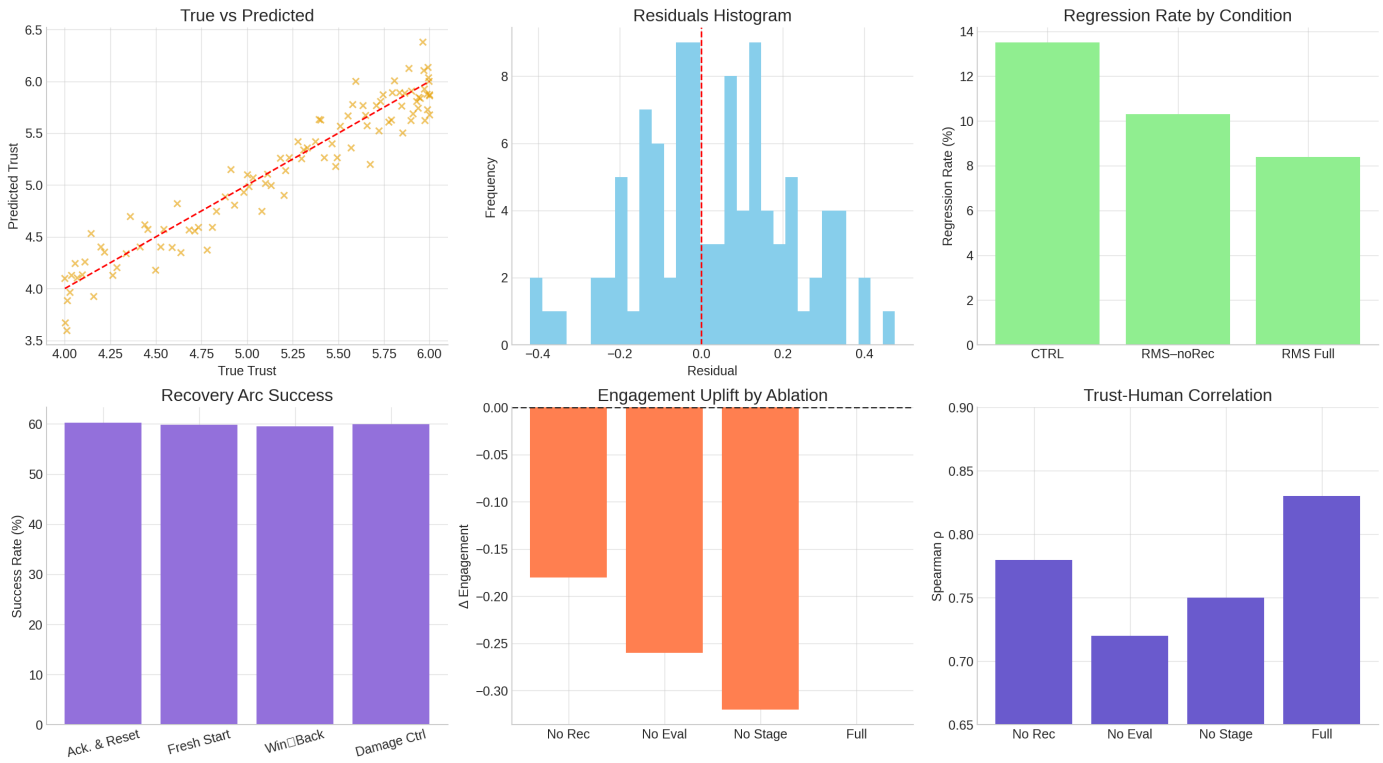

Fig. 4. Six-panel summary visualization of RMS evaluation metrics across all four research questions (RQ1–RQ4).

several directions that would make RMS more capable and more responsible in practice:

- Cross-cultural calibration. Adjust trust and disclosure estimators to reflect linguistic and cultural norms, and validate depth/intent classifiers beyond English with multilingual corpora and community review.
- Adaptive weighting. Learn context-sensitive weights for the Regression Risk Score (e.g., conflict vs. frequency signals) using meta-learning or Bayesian updating, with priors that prevent overreacting to brief volatility.
- Personalized recovery. Match *Recovery Arcs* to user profiles and incident types; explore policy learning for arc selection, timing, and pacing so interventions feel timely rather than intrusive.
- Hybrid evaluators. Combine transparent rules with learned signals (prosody, dialogue acts, hesitation markers), and probe causal features to improve robustness and reduce spurious triggers.
- Open-world deployment. Run longer, larger A/B studies; build dashboards for survival curves, cohort breakdowns, and counterfactual *what-if* analyses; and adopt privacy-preserving analytics (aggregation, differential privacy) from the start.

In short, RMS reframes engagement as an ongoing practice of relationship care: notice early, pace with context, and repair in the open. By aligning interpersonal theory with interpretable computation, RMS moves conversational agents toward emotionally intelligent, self-regulating partners that can sustain human trust over time.

DECLARATIONS

Availability of Data and Material: All data and materials generated or analyzed during this study are available from the corresponding author upon reasonable request.

Competing Interests: The authors declare that they have no competing interests.

Funding: No specific funding was received for the conduct of this study.

Authors' Contributions: All authors contributed substantially to this paper and research output. All authors reviewed and approved the final manuscript.

ACKNOWLEDGMENTS

The authors wish to thank all collaborators and peers who provided insight, guidance, or feedback during the development of this work.

***Abstract*—The rapid development of medical practices and imaging technology tools creates substantial growth in the amount of medical image data each year in our present era. This research aims to develop a hybrid approach that integrates Machine Learning (ML) and Deep Learning (DL) techniques to enhance the accuracy and reliability of medical image classification for diagnostic purposes. Medical imaging data complexity and growing volume serve as the research motivation, which leads to an investigation of standalone ML or DL limitations and their combination into a single framework. The medical image processing starts with normalization, then noise reduction, and continues to grayscale conversion before performing histogram equalization. This research uses VGG16 and ResNet50 alongside MobileNet and InceptionV3 for feature extraction, then applies ten different ML algorithms, including SVM and MLP, and Random Forest, for classification. Five public medical image datasets from Kaggle are used: COVID-19 chest X-rays, melanoma skin lesions, pneumonia chest X-rays, acute stroke facial images, and various eye diseases. Hybrid models display superior performance compared to stand-alone ML or DL models based on accuracy, precision, recall, and F1-score evaluation measures. Multiple datasets demonstrate that the MobileNet+MLP combination delivers the most accurate results, which demonstrates its reliable and efficient performance. The developed AI diagnostic tool presents a scalable system alongside accuracy and interpretability to enhance clinical decision outcomes.**

Keywords*—Classification; deep learning; feature selection; hybrid models; machine learning; medical diagnosis; medical image classification

I. Introduction

Medical imaging is an essential aspect of our time, employing various technologies to obtain images of the human body or specific parts of it [1]. Medical imaging considers a crucial component of medical diagnosis, since it is widely applied in hospitals, medical laboratories, and other facilities due to its importance in diagnosing various diseases, as well as aiding in monitoring patient treatment [2]. The most important medical imaging modern techniques are X-ray radiography, endoscopy, Magnetic Resonance Imaging (MRI), magnetic resonance spectroscopy, thermography, electrical source imaging and several other techniques [3].

*Corresponding authors.

Several limitations in human analysis of medical images compared to modern techniques, such as the fact that the image analysis process takes time due to the complexity of the data, in addition to the fact that the analysis depends mainly on the experience of the image analyst, so there is a possibility of human errors. Moreover, there are some effects that occur to medical images, whether modern or traditional, including noise [4].

According to [5], noise is defined as the random change in the original pixel value that reduces image quality. Therefore, it is important to use modern medical imaging techniques to remove noise, especially compared to conventional images, to enable accurate disease diagnosis without any issues that may affect the analysis of medical images. Consequently, several artificial intelligence techniques have been developed to address these issues in medical imaging and assist in medical diagnosis, including Machine Learning (ML) and Deep Learning (DL) technologies [6], [7], which are important for processing complex data, identifying problems that the human eye might miss, and reducing noise in medical images to enhance their quality [8], [9].

A. Machine Learning

Machine Learning (ML) aims to study statistical algorithms that can learn from the input data to perform tasks that are automatically improved through experience [10]–[12]. All of this leads to increasing the efficiency of the algorithm that was built, which reduces human errors in entering or analyzing data [13], [14]. ML is used to make decisions and predictions based on learning from data. In [15], the authors categorize ML as following:

- Supervised Learning: The aim of this type is to predict outcomes using labeled data.
- Unsupervised Learning: This type learns from unlabeled/unstructured data.
- Semi-Supervised Learning: A large amount of unlabeled data and a small amount of labeled data are combined to improve the performance of the model.

In order to successfully implement machine learning techniques, several important aspects must be carefully considered [16]:

1) High-quality input data: It's important to have the proper high-quality input data, which has minimal artifacts and noise, to achieve the best possible machine learning performance and to maintain low noise levels, but ground truth labels are even more important as erroneous labels severely damage model performance and tend to be hard to catch in training.

2) Accuracy of ground truth labels: Ground truth labels must be accurate, because it involves confirming and checking the correctness of the diagnostic label and of the diagnosis itself. Other types of noise have a more dramatic effect on model accuracy than errors in ground truth labels, emphasizing the need for strict ground truth labeling.

3) Completeness of training sets: The best performance results from machine learning models exist when training datasets contain no missing features while also being complete. While there are data augmentation techniques like random imputation or sophisticated algorithms, which can help fill up these gaps, but have less effectiveness as we train on full datasets.

4) Dataset size: Machine learning models tend to prefer larger datasets so that they can capture the true variability of the data, which helps reduce the risk of performance issues caused by a small number of outliers. Nevertheless, obtaining large enough datasets remains difficult, in particular for precision medicine and disease studies with low frequency.

5) Precision and accuracy in classification algorithms: To obtain strong model performance, the optimization process has to balance both precision and accuracy, as both are indispensable for reliable and effective classification algorithms.

6) Model validation: Before a machine learning model is deployed to make clinical decisions or computer-aided decisions, it has to go through very thorough validation. For instance, a physician diagnoses cases and the model is trained using those cases and is evaluated by comparing its outputs with assessments of new cases by other physicians. This is done for reliability and accuracy [17].

B. Deep Learning

Deep Learning (DL) is mainly used in large datasets to model complex patterns using multi-layered artificial neural networks, which aim to mimic the human brain [18], [19]. As is known, DL is a powerful and transformative branch of machine learning, and it learns from unlabeled data such as images, audio, and text [20], [21]. Deep learning also has several key benefits that enable it to be very effective for a wide variety of applications. It can achieve high accuracy, especially when it has been trained on large data. One of its most significant features is that it can automatically learn data representation to avoid manual feature extraction [22], [23]. Also, deep learning models are highly scalable and easy to adapt to large data sets and increasing computational power, which makes them suitable for large-scale and complex problems too. Deep learning (DL) has numerous uses in various fields. In image and video processing, it is used for the recognition of specific elements, such as facial detection or facial emotion, and in medicine, it can forecast the kind of diseases. DL also powers voice-to-text systems such as Alexa and Google Voice and enables real-time machine translation from one language to another [24]. The building blocks of deep learning are multi-layer artificial neural networks, and they consist of a few basic components. They are neurons and layers, and each artificial neuron processes inputs by calculating weights, biases, and activation functions to supply the result to the next layer. Activation functions such as Rectified Linear Unit (ReLU), sigmoid, and tanh introduce essential non-linearity to neural networks. Loss functions like Mean Squared Error and Cross Entropy are used to quantify predictive accuracy. Optimization algorithms like Stochastic Gradient Descent (SGD) are used for improving model performance by reducing the loss function by adjusting the network's weights during training. Three main objectives of this study are: 1) identify the most appropriate deep learning model to analyze medical image data, 2) propose an integrated hybrid framework which combines deep learning and machine learning classifiers to boost the diagnostic performance, and 3) review previous research as the comparison studies of ML and DL in medical image classification. This research is organized as follows: In Section II, we briefly review related work; Section III describes the research methodology; Section IV provides the experimental results, and finally, conclusions are presented in Section V along with future scope.

II. Related Work

In this section, we will discuss the previous research about medical diagnosis using hybrid of machine learning and deep learning techniques.

A. Machine Learning Model

This section explains ten machine learning techniques used under the supervised learning category, categorized to clarify how each model approaches learning and prediction as the following:

1) Bayes-based models: Bayesian models are designed with reference to Bayes' Theorem and are widely utilized for probabilistic classification tasks. Naive Bayes (NB) is a well-known example, particularly renowned for its simple architecture, high computational efficiency, and fast processing, particularly in dealing with big data. It needs only estimation of significant parameters—mean and variance of variables—to be performed using a small training set [25]. The second category involves models such as Linear Discriminant Analysis (LDA), which is a statistical technique used in discriminating between two or more event or object classes. LDA computes the linear feature combination that maximally discriminates between the classes and is generally used for feature reduction prior to classification [26].

2) Function-based models: Mathematical formula-based classification models are models based on mathematical expressions in order to discriminate between data classes. The Support Vector Machine (SVM) is a strong algorithm used to identify patterns as well as conduct regression and classification functions [27]. It is particularly effective in domains that need high-dimensional space analysis. Logistic Regression is another function-based model used for problems of binary

classification [28]. It works through the use of a database of independent variables and is often used in areas such as diagnosis of disease as well as prediction of risks. In addition, Multi-layer Perceptron (MLP) is an artificial neural network created by a few full connected layers and nonlinear activation functions. MLPs are ideal for classifying complex data sets like intrusion detection and problems where the data is not linearly separable [29].

3) Lazy learning models: Lazy algorithms differ from typical models in that they do not necessarily train a predictive model directly. Instead, they store the training data and make a decision at the moment of prediction. An old prime example is the K-Nearest Neighbors (KNN) algorithm. KNN classifies a query point with the class of the majority of its nearest neighbors in the training data, and it is an easy but effective method for classification tasks [30].

4) Meta-learning models: Meta-learning or ensemble strategies improve prediction performance by combining multiple models [31]. Adaptive Boosting (AdaBoost) is a commonly used ensemble strategy which builds an accurate classifier by iteratively adding up weak base learners. The current iteration allots weights to the classifiers based on their precision, with more accurate learners having greater weightage in the final decision. The final classification emerges through the process of weighted voting, achieving greater overall prediction performance [32]. Tree-Based Models: Tree-based algorithms use a decision tree structure for splitting data according to feature values. Random Forest (RF), introduced by Breiman in 2001, constructs numerous decision trees during training. It votes for the most common class for classification or estimates the average of the individual estimates for regression [33]. Gradient Boosting is another robust method that builds models step by step, each of which corrects the errors in previous models. It excels at boosting accuracy through making better predictions. Last but not least, the Decision Tree (DT) model itself creates a tree where the branches are feature tests and leaves are class labels. DTs are generally used in statistics, data mining, and elsewhere due to their simplicity and interpretability [34].

B. Deep Learning Model

This research explains four deep learning techniques specifically those used in deep convolutional neural networks (CNNs) applied to image classification, object detection, and other related tasks, as follows:

- Visual Geometry Group (VGG16) [35], the number 16 refers to the number of layers that make up this model, comprising 13 are convolutional layers and 3 are connected layers. It applied in medical imaging analysis, face recognition, and the detection of different objects.

- Residual Network (ResNet50) [36], the number 50 refers to the number of layers, comprising 48 convolutional layers and 2 are connected layers. The purpose of using it is residual connections to solve the problem of vanishing gradients in deep networks.

- MobileNet [37], designed specifically for mobile and embedded devices, mobileNet was designed to reduce computational cost and number of parameters by using depthwise separable convolutions.

- InceptionV3 [38], the number three refers to the third version of the model, which released in 2016. It is one of the powerful models in deep learning because of its ability to recognize and classify different images and used in all modern CNN networks.

In [39], the authors explore the application of Machine Learning (ML) models to improve the accuracy of breast cancer detection. They used the Wisconsin Diagnostic Breast Cancer (WDBC) dataset, then applied data normalization techniques and handled missing values to ensure data quality. The hybrid feature selection method, combining Correlation based Feature Selection (CFS) and Recursive Feature Elimination (RFE), was chosen to reduce the dataset to 11 key attributes. Different machine learning models, including Random Forest, Gradient Boosting, SVM, ANN, and MLP, were evaluated using 5-fold cross-validation. The Multilayer Perceptron (MLP) achieved the highest accuracy of 99.12. The study focuses of the importance of advanced machine learning algorithms for accurate breast cancer diagnosis in real-world applications. In [40], the authors focused on diagnosing diabetes using machine learning and its various techniques to select the best classifier for predicting the disease. The authors evaluated four feature selection techniques (e.g., Correlation Attribute Evaluator) and 12 classifiers across two datasets using metrics like accuracy, precision, recall, and F1-measure. They concluded that the Correlation Attribute Evaluator was optimal for feature selection, and MultiClassClassifier performed best in diagnosis tasks. This work demonstrates the effectiveness of machine learning in medical diagnostics [41]. Machine learning techniques are used to predict the outcomes of COVID-19 diagnosis and treatment. Different techniques such as decision trees, random forests, and support vector machines used to analyze the symptoms and medical history of patients. They trained the models to give severity predictions of the disease (mild, moderate, severe) and to recommend appropriate treatment for that severity prediction. The results showed that machine-learning models can be used to predict the amount of disease and therefore decreased the workload of healthcare providers and efficiency in the treatment.

In [42], the authors developed a deep learning-based model to diagnose five types of lung and colon tissues (two benign and three malignant), by using deep learning techniques and image processing such as (convolutional neural networks (CNNs)) on histopathological images. Their results showed on their proposed model high classification accuracy of (96.33%) in the early detection of cancer. In [43], the authors address the limitations of traditional machine learning models in medical diagnostics, which often rely on associative patterns between symptoms and diseases. The purpose of this study is to improve diagnostic accuracy by integrating causal reasoning into machine learning models, leading to greater alignment with clinical diagnostic processes. The authors applied the proposed model to clinical vignettes and compared its performance with standard associative algorithms and human doctors. The results showed that their causal model outperformed associative models with an accuracy comparable to the top (25%) of doctors. In [44], the authors proposed a deep learning model for brain tumor classification using both a standard Convolutional Neural Network (CNN) and the ResNet50 model. In

TABLE I. SUMMARIZING THE RECENT REFERENCES: REFERENCE, YEAR, TITLE, METHODS, ADVANTAGES, AND LIMITATIONS

Reference	Year	Title	Methods	Advantages	Limitations

their work, deep CNNs were shown to accurately distinguish among the different tumor types through the extraction of high-level features from medical imaging data. Comparison of the baseline CNN and ResNet50 revealed that state-of-the-art deep architectures like ResNet50 achieved superior accuracy, underlining the strength of higher-order deep learning models in medical diagnosis and image-based classification.

The comparison table (Table I) highlights a line of recent research studies based on machine learning (ML) and deep learning techniques in medical diagnosis. Various methods were employed throughout the research studies, from popular ML algorithms Support Vector Machines and Decision Trees to more advanced deep learning models such as Convolutional Neural Networks (CNNs) and ResNet50.

These approaches have demonstrated superb performance in the diagnosis of the disease: breast cancer, diabetes, COVID-19, lung and colon cancer, and brain tumors. Notable strengths that they reported are improved accuracy in diagnosis, operational efficiency for early detection, and the capability to process large and multidimensional medical datasets. However, each of the studies came with certain limitations. For instance, models that involve deep learning require a lot of computational power and vast amounts of labeled data, while typical ML approaches may struggle with generalizability or lack the ability to process complex patterns in data. Notably, adding causal machine learning to a single experiment gave better interpretability, but at the cost of more complex models. Overall, the table underscores the growing effectiveness of ML in medicine as well as the necessity for balancing accuracy, interpretability, and computational efficiency.

III. PROPOSED METHODOLOGY

This section presents the research methodology, including the framework, datasets, evaluation metrics, and a summary of the findings. Section III(A) provides a detailed description of the five selected datasets. Section III(B) presents the methodology.

A. Description of the Dataset

In this study, five publicly available medical image datasets from Kaggle were utilized to ensure comprehensive evaluation across a wide range of clinical scenarios. These datasets include chest X-ray images for COVID-19 and pneumonia detection, dermoscopic images for melanoma skin lesion classification, facial images for acute stroke diagnosis, and a multi-class collection of ocular images for eye disease identification. This diversity provides a robust test bed for assessing the generalizability and effectiveness of hybrid deep learning and machine learning approaches in automated medical diagnosis. Each dataset covers multiple conditions or disease classes with varying sample sizes, enabling a thorough assessment of model performance across different diagnostic challenges. The key characteristics and class distributions of these datasets are summarized in Table II.

B. Methodology

The main idea of this research is to build a hybrid model that combines ML and DL algorithms to determine the best combination suitable for medical diagnosis tasks; Fig. 1 illustrates the general methodology of the current research. The following subsections provide a detailed explanation of the main steps considered in the methodology of this research.

1) Data collection: At this stage, different datasets have been searched to suit the purpose of this research, images containing different diseases have been collected.

Five datasets have been downloaded from the Kaggle website: COVID-19 images, melanoma skin cancer images, chest X-ray images, various eye diseases, and facial images of acute stroke and non-acute stroke. More information regarding the collected datasets is provided later in this section.

2) Image pre-processing: At this stage, the collected images are pre-processed to ensure they are suitable for machine learning or deep learning models. Initial pre-processing steps in image analysis begin with rescaling the image pixel values from 0 to 255 to be OpenCV compatible, as it is a widely used computer vision library. Normalizing the input data using this standard allows for uniform and reliable utilization of OpenCV

functions throughout the processing chain. The second significant step is applying denoising using GaussianBlur, an extremely common technique for reducing noise by smoothing pixel intensity values through averaging neighboring pixels in the context of a Gaussian function. It suppresses random noise, exaggerates prominent image features, and ultimately improves the accuracy and resilience of image analysis models.

Convert the image to grayscale Converting an image to grayscale simplifies the data which removes the unnecessary color information and only leaves the image with the intensity values. It merges the three-color channels (Red, Green, and Blue) into one where a pixel is a value of light intensity. Grayscale format reduces computational complexity and puts the focus on the structural information. Histogram application: Histogram application enhances image contrast, making features more distinguishable and improving visual clarity. Histogram equalization merely reshapes pixel intensity values from 0–255 to distribute them across the full range of 0–255 in order to highlight small details that are a point or two overshadowed by greater attention to detail. This also allows edges and textures which are necessary for tasks such as the edge detection and image segmentation. Fig. 2 show the image pre-processing pipeline starts by rescaling pixel values to the range of 0 to 255. GaussianBlur is then used to smooth pixel intensities and reduce noise, enhancing key features. After that, the pictures are converted to grayscale, which reduces computational complexity by combining color channels into a single intensity channel. Last but not least, histogram equalization is used to enhance image contrast by redistributing pixel intensities, emphasizing textures, edges, and minute details that are essential for precise image analysis. The images are ready for efficient machine learning or deep learning model training thanks to this series of actions. Many studies have highlighted the importance of image pre-processing for boosting the performance of machine learning-based medical diagnosis. As an example, [45] shows that application of Contrast Limited Adaptive Histogram Equalization (CLAHE) improved classification performance of histopathology images in terms of F1-score, which was 98% with pre-processing and 93% without it. Similarly, [46] proposed to use convolutional denoising autoencoders for effective denoising of medical images, thereby, maintaining essential clinical information even in noisy case. Furthermore, the combination of Gaussian smoothing and clustering techniques applied before CNN training, according to [47], enhanced the detection accuracy of tumors. These findings validate the image pre-processing techniques in this study, which include grayscale conversion along with histogram equalization and Gaussian denoising for improving model robustness and feature detection through noise reduction.

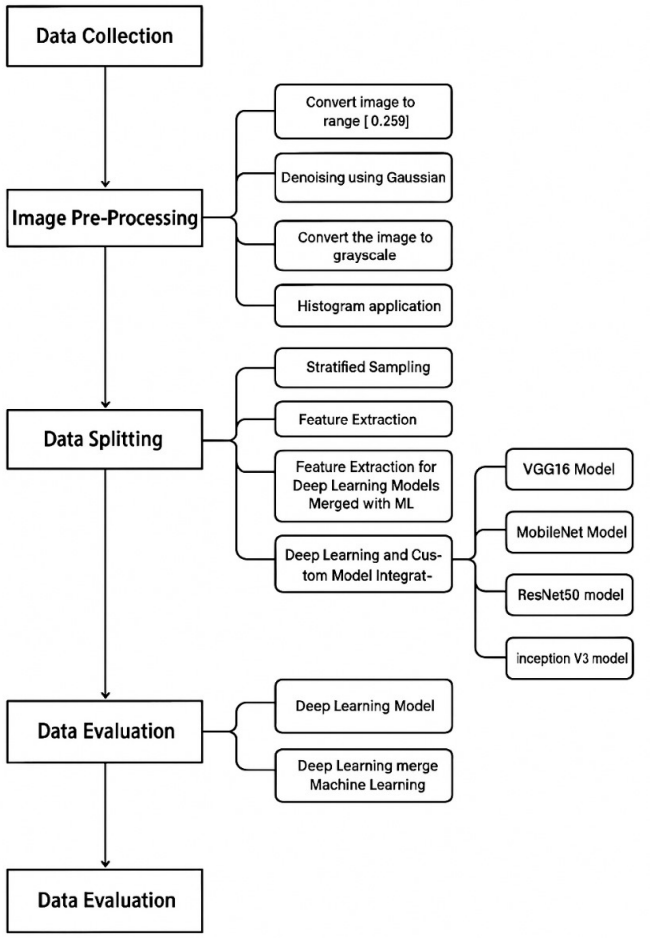

Fig. 1. Research methodology.

TABLE II. CHARACTERISTICS OF THE DATASETS

Dataset	Condition (Class)	Frequency
COVID CXR Image	COVID-19	536
COVID CXR Image	Viral pneumonia	619
COVID CXR Image	Normal cases	668
COVID CXR Image	**Total**	**1823**
Melanoma Skin Cancer	Benign	5000
Melanoma Skin Cancer	Malignant	4605
Melanoma Skin Cancer	**Total**	**9605**
Chest X-Ray	NORMAL	1341
Chest X-Ray	PNEUMONIA	3875
Chest X-Ray	**Total**	**5216**
Face Images of Acute Stroke and Non-Acute Stroke	noStroke_data	2511
Face Images of Acute Stroke and Non-Acute Stroke	stroke_data	1259
Face Images of Acute Stroke and Non-Acute Stroke	**Total**	**3770**
Different Eye Disease	ACRIMA	560
Different Eye Disease	Glaucoma	212
Different Eye Disease	ODIR-5K	7000
Different Eye Disease	ORIGA	517
Different Eye Disease	Cataract	70
Different Eye Disease	retina_disease	70
Different Eye Disease	**Total**	**8429**

3) Data splitting: Once the images are pre-processed, the data is prepared for model training and evaluation. The primary activities of this method start with stratified sampling, ensuring that there is a well-distributed balance of classes between the training, validation, and test datasets, hence enabling representative data splits. Shuffling is then used to avoid bias by the data sample order, enabling randomness in the dataset. Feature extraction plays a vital role in that it utilizes deep

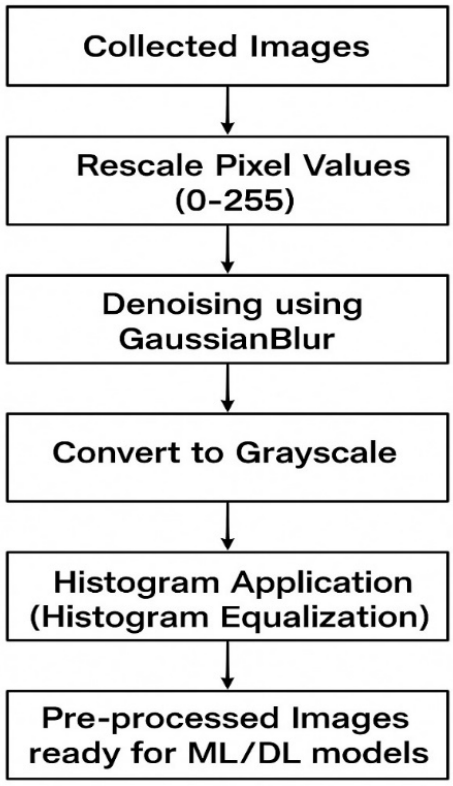

Fig. 2. Images preprocessing flowchart.

models to extract useful image features, which are blended with machine learning to increase prediction precision. Several deep learning architectures are blended and adjusted to provide optimal performance: VGG16 is blended with ten different machine algorithms to optimize predictive capacity; MobileNet is customized to provide light-weight and efficient image processing; ResNet50, a residual very deep network, is utilized to provide effective image classification and prediction; and Inception V3 is utilized due to its advanced structure to provide high-performance predictions in complex tasks.Many researchers endorse the efficacy of hybrid and ensemble methods in medical AI applications, combining deep learning capabilities with conventional machine learning classifiers has shown good promise in enhancing the precision of medical image classification. A comparative study showed that hybrid models where pre-trained convolutional neural networks like MobileNet, VGG16, and Inception V3 are used as feature extraction and then machine learning algorithms are used for classification, attained very high accuracy [48]. Furthermore, ensembling techniques that integrate predictions from different classifiers showed the ability to increase the robustness and reliability of models in clinical environments, as shown by an evaluation of a revised medical image classification process [49]. Fig. 3 shows the data splitting diagram.

4) Data training: Data training involves running deep learning models with preprocessed data for improved predictions. This section explains details about the specific models, their configurations and how deep learning is merged with a machine learning algorithm. Fig. 4 shows the data training process.

- Deep Learning Model. We train on the preprocessed images in this phase to extract our feature using different deep learning models for prediction. The models used in this research include: *VGG16*, *MobileNet*, *ResNet50*, and *Inception V3* models.

- Deep Learning merge with Machine Learning. Features from the deep learning models are merged with various machine learning algorithms in order to better increase the predictive power of the deep learning models.

  This hybrid approach involves the following steps:
  - Feature Extraction: Using the deep learning models (such as VGG16, MobileNet, ResNet50 and Inception V3) are used to automatically extract relevant features from the images. Features that typically include textures, edges, and patterns which are essential for disease classification can be included in these features.

  - Using Machine Learning Algorithms: When features are extracted, we input them into various machine learning algorithms for classification and prediction. Ten machine learning algorithms are used including: (Naive Bayes (NB), Linear Discriminant Analysis (LDA), Support Vector Machine (SVM), Logistic Regression (LG), Multi-layer Perceptron (MLP), K-Nearest Neighbors Algorithm (KNN), Adaptive Boosting (AdaBoost), Random Forest (RF), Gradient Boosting, Decision Tree (DT)). The deep learning models tries to create predictions while these algorithms optimization for the predictions in order to increase accuracy and performance of the overall system.

  - Hybrid Model: This method combines the abilities of deep learning to extract features with the flexibility and efficiency of machine learning for prediction to improve the overall predictive ability of classification, especially in classifying images with high accuracy.

5) Evaluation phase: The hybrid model performance is evaluated in terms of accuracy and efficiency using evaluation metrics in classifying medical images accurately and efficiently. In [42], the authors presented a hybrid model that is a combination of a deep CNN and SVM classifier to improve brain tumor classification. They used common metrics, were Accuracy, Precision, Recall, F1-score, and Dice Similarity Coefficient (DSC) for the assessment of the model. The model achieved an accuracy of (98.3%) and DSC of (97.8%) on the Brain Dataset-1. Their finding showed the efficiency of combining deep learning for feature extraction with machine learning for classification in medical imaging tasks. In this research, four evaluation measures have been used as the following:

C. Evaluation Metrics

Accuracy: Calculates the proportion of correctly classified instances (both positive and negative) out of all instances; it

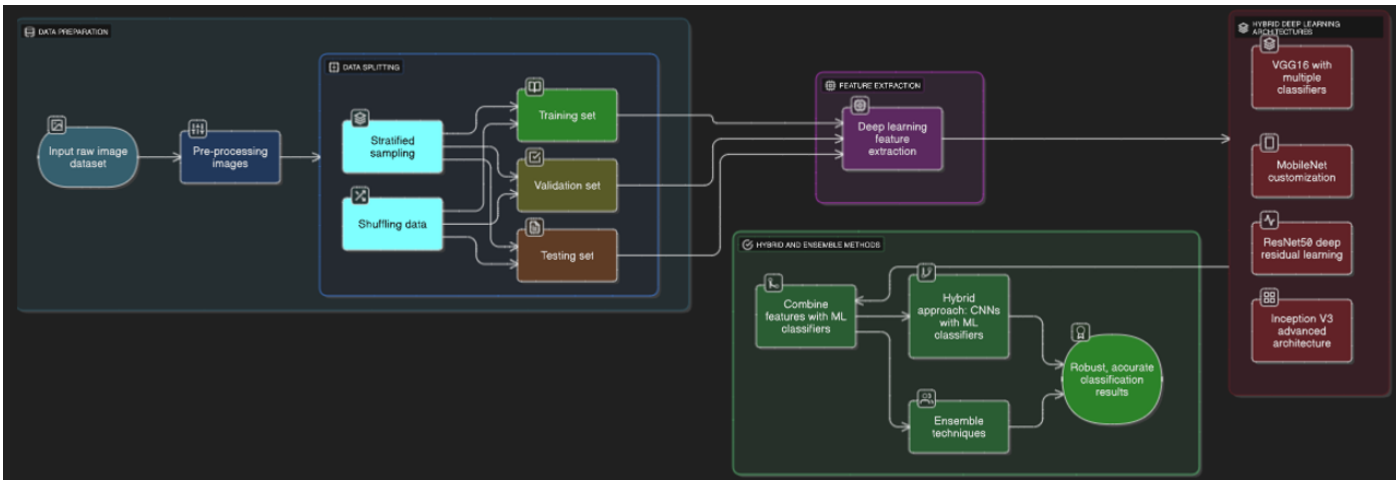

Fig. 3. Data splitting process.

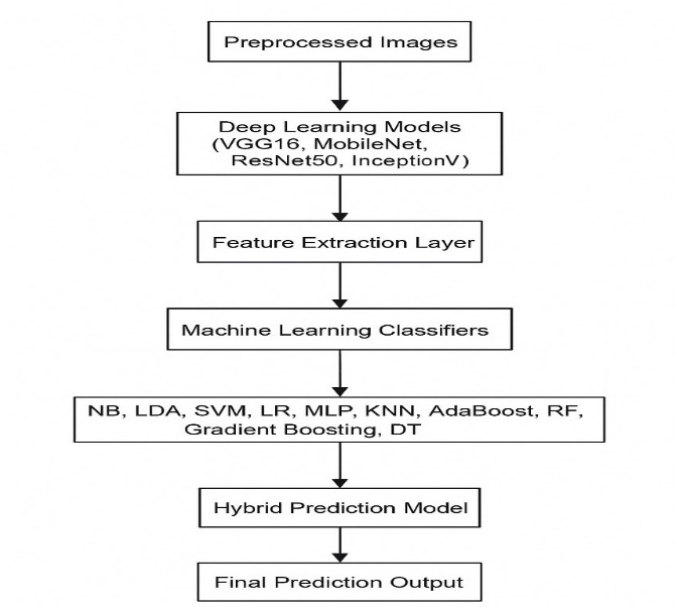

Fig. 4. Data training process diagram.

measures the model's overall correctness.

$$\text{Accuracy} = \frac{\text{TP} + \text{TN}}{\text{TP} + \text{TN} + \text{FP} + \text{FN}}. \tag{1}$$

Precision: Measures how many of the predicted positives are actually positive.

$$\text{Precision} = \frac{\text{TP}}{\text{TP} + \text{FP}}. \tag{2}$$

Recall: Measures the model's ability to capture all actual positive cases.

$$\text{Recall} = \frac{\text{TP}}{\text{TP} + \text{FN}}. \tag{3}$$

F1-score: The harmonic mean of Precision and Recall.

$$\text{F1} = \frac{2\,\text{Precision} \cdot \text{Recall}}{\text{Precision} + \text{Recall}}. \tag{4}$$

IV. Experimental Results

This section presents the evaluation results of the experiments on developing an efficient medical image classification model. The model is a hybrid that combines machine learning and deep learning algorithms. This model aims to enhance the predictive performance by taking advantage of the strengths of both techniques.

- Identifying the Most Appropriate DL Model That Suits Medical Data. In this phase, which is considered the most important step of this research, the predictive performance of the four deep learning models (*VGG16*, *ResNet50*, *MobileNet*, and *InceptionV3*) is evaluated across five different datasets related to medical image classification, considering four evaluation metrics (Accuracy, Precision, Recall, and F1-Score), as shown in Table III.

The most significant key insights that could be concluded from Table III are listed next with respect to the five considered datasets.

- COVID-19 Dataset. Out of the models it was compared with, *MobileNet* performed the most accurately at 0.97, outperforming *VGG16* and *InceptionV3* with accuracies of 0.96 each. *ResNet50* performed the worst at 0.74. Additionally, Precision, Recall, and F1-score indicate that *MobileNet*, *VGG16*, and *InceptionV3* performed comparably, while *ResNet50* lagged on this task.

- Melanoma Skin Cancer Dataset. *MobileNet* was best with 0.93 accuracy, slightly above *VGG16* and *InceptionV3* (0.92 each). *ResNet50* was worst (0.78). Precision, Recall, and F1-score were high for *MobileNet*, *VGG16*, and *InceptionV3*, highlighting their suitability for melanoma identification.

- Chest X-Ray Images. *MobileNet* achieved the maximum accuracy (0.99), followed by *VGG16* (0.98) and

TABLE III. PERFORMANCE COMPARISON OF DEEP LEARNING MODELS ON VARIOUS MEDICAL DATASETS

Dataset	Deep Learning Model	Acc	Prec	Rec	F1
COVID-19 Dataset	VGG16	0.96	0.97	0.97	0.97
COVID-19 Dataset	ResNet50	0.74	0.73	0.74	0.74
COVID-19 Dataset	MobileNet	0.97	0.97	0.97	0.97
COVID-19 Dataset	InceptionV3	0.96	0.97	0.97	0.97
Melanoma Skin Cancer Dataset	VGG16	0.92	0.92	0.92	0.92
Melanoma Skin Cancer Dataset	ResNet50	0.78	0.78	0.78	0.78
Melanoma Skin Cancer Dataset	MobileNet	0.93	0.93	0.93	0.93
Melanoma Skin Cancer Dataset	InceptionV3	0.92	0.92	0.92	0.91
Chest X-Ray Images	VGG16	0.98	0.97	0.97	0.97
Chest X-Ray Images	ResNet50	0.91	0.88	0.90	0.89
Chest X-Ray Images	MobileNet	0.99	0.98	0.99	0.98
Chest X-Ray Images	InceptionV3	0.97	0.97	0.97	0.97
Face Images of Acute Stroke and Non-Acute Stroke	VGG16	0.99	0.99	0.99	0.99
Face Images of Acute Stroke and Non-Acute Stroke	ResNet50	0.76	0.74	0.70	0.71
Face Images of Acute Stroke and Non-Acute Stroke	MobileNet	0.99	0.99	0.99	0.99
Face Images of Acute Stroke and Non-Acute Stroke	InceptionV3	0.98	0.98	0.98	0.98
Dataset for Different Eye Disease	VGG16	0.96	0.78	0.76	0.74
Dataset for Different Eye Disease	ResNet50	0.90	0.44	0.44	0.44
Dataset for Different Eye Disease	MobileNet	0.94	0.76	0.72	0.73
Dataset for Different Eye Disease	InceptionV3	0.96	0.95	0.96	0.95

InceptionV3 (0.97). *ResNet50* scored 0.91. Across metrics, *MobileNet* is the optimal choice for this dataset.

- Face Images of Acute Stroke and Non-Acute Stroke. Both *VGG16* and *MobileNet* obtained the highest accuracy (0.99), with *InceptionV3* at 0.98. *ResNet50* was much lower (0.76). Precision/Recall/F1 confirm that *VGG16*, *MobileNet*, and *InceptionV3* are very effective for stroke classification.

- Dataset for Different Eye Disease. *InceptionV3* and *VGG16* reached the highest accuracy (0.96), *MobileNet* achieved 0.94, whereas *ResNet50* underperformed (0.90) with poor Precision/Recall/F1 (around 0.44). Overall performance was strong, with *InceptionV3* most reliable across metrics.

Main findings (Objective 1):

- *MobileNet* showed consistently high performance across all datasets, often achieving the highest Accuracy.

- *ResNet50* had the worst performance across Accuracy, Precision, Recall, and F1-score.

- *VGG16* and *InceptionV3* performed similarly well, with *InceptionV3* slightly more consistent.

- *MobileNet* and *InceptionV3* appear to be the most reliable for medical image classification, while *ResNet50* is not recommended.

TABLE IV. PERFORMANCE COMPARISON OF ML CLASSIFIERS WITH VGG16 FOR COVID-19 DATASET

Model	Accuracy	Precision	Recall	F1-Score
VGG16+SVM	0.89	0.90	0.89	0.89

A. Combine Deep Learning Models with Machine Learning Techniques

This section presents the evaluation results of combining deep learning models and machine learning techniques with respect to the five considered datasets.

1) Evaluation results with respect to the COVID-19 dataset: This part evaluates several ML classifiers combined with the four DL models for the COVID-19 dataset.

a) VGG16 performance: In Table IV, *VGG16* with LDA (Linear Discriminant Analysis) achieved the best results, demonstrating strong performance and making it an optimal choice for COVID-19 classification. However, *VGG16* with Naïve Bayes and with Decision Tree performed worst, implying these classifiers may be less appropriate for this dataset.

ResNet50 Performance. Table V shows that Gradient Boosting achieved the highest performance across all metrics (**Accuracy=0.93**, **Precision=0.93**, **Recall=0.93**, **F1=0.93**), highlighting its strength for COVID-19 classification and its ability to learn the underlying patterns in the dataset. In contrast, the SVM variant recorded the weakest results and exhibited an imbalanced precision–recall trade-off.

MobileNet Performance.

Table VI shows that MobileNet + MLP achieved the best results across all metrics (**Accuracy=0.97**, **Precision=0.97**, **Recall=0.97**, **F1=0.97**), making it the most effective combination. In contrast, MobileNet + Decision Tree recorded

TABLE VI. PERFORMANCE COMPARISON OF ML CLASSIFIERS WITH MOBILENET FOR COVID-19 DATASET

Model	Accuracy	Precision	Recall	F1-Score
MobileNet+SVM	0.96	0.96	0.96	0.96
MobileNet+Random Forest	0.95	0.95	0.95	0.95
MobileNet+Gradient Boosting	0.95	0.95	0.95	0.95
MobileNet+AdaBoost	0.92	0.92	0.92	0.92
MobileNet+KNN	0.94	0.94	0.94	0.94
MobileNet+Logistic Regression	0.96	0.96	0.96	0.96
MobileNet+Decision Tree	0.85	0.86	0.86	0.86
MobileNet+Naïve Bayes	0.93	0.93	0.93	0.93
MobileNet+LDA	0.92	0.92	0.92	0.92
MobileNet+MLP	**0.97**	**0.97**	**0.97**	**0.97**

TABLE VII. PERFORMANCE COMPARISON OF ML CLASSIFIERS WITH INCEPTIONV3 FOR COVID-19 DATASET

Model	Accuracy	Precision	Recall	F1-Score
InceptionV3+SVM	0.93	0.94	0.94	0.94
InceptionV3+Random Forest	0.91	0.91	0.92	0.91
InceptionV3+Gradient Boosting	0.92	0.93	0.93	0.92
InceptionV3+AdaBoost	0.87	0.88	0.88	0.88
InceptionV3+KNN	0.87	0.89	0.88	0.88
InceptionV3+Logistic Regression	0.92	0.92	0.92	0.92
InceptionV3+Decision Tree	0.79	0.81	0.79	0.79
InceptionV3+Naïve Bayes	0.85	0.85	0.85	0.85
InceptionV3+LDA	0.73	0.74	0.73	0.74
InceptionV3+MLP	0.92	0.92	0.92	0.92

the weakest performance (**Accuracy**=0.85, **Precision**=0.86, **Recall**=0.86, **F1**=0.86).

InceptionV3 Performance.

Table VII shows that *InceptionV3 + SVM* achieved the strongest, well-balanced results across all metrics (**Accuracy**=0.93, **Precision**=0.94, **Recall**=0.94, **F1**=0.94). In contrast, *InceptionV3 + LDA* exhibited the weakest performance (**Accuracy**=0.73, **Precision**=0.74, **Recall**=0.73, **F1**=0.74).

Based on the previous performance metrics, the most suitable machine learning (ML) classifier for the COVID-19 medical data depends on the chosen deep learning (DL) feature extractor. The best combinations by *Accuracy* are:

- If *MobileNet* is used, *MLP* is the best choice (Accuracy: **0.97**).
- If *VGG16* is used, *LDA* is the best choice (Accuracy: **0.95**).
- If *ResNet50* is used, *Gradient Boosting* is the best (Accuracy: **0.93**).
- If *InceptionV3* is used, *SVM* is the best (Accuracy: **0.93**).

For the COVID-19 dataset, **MobileNet + MLP** is the strongest overall. Final model selection should also consider interpretability, computational cost, and dataset-specific requirements, as summarized in Fig. 5.

TABLE VIII. PERFORMANCE COMPARISON OF ML CLASSIFIERS WITH VGG16 FOR MELANOMA SKIN CANCER DATASET

Model	Accuracy	Precision	Recall	F1-score
VGG16+SVM	0.84	0.85	0.84	0.84
VGG16+Random Forest	0.89	0.89	0.89	0.89
VGG16+Gradient Boosting	0.90	0.90	0.90	0.90
VGG16+AdaBoost	0.89	0.89	0.89	0.89
VGG16+KNN	0.88	0.89	0.88	0.88
VGG16+Logistic Regression	0.89	0.89	0.89	0.89
VGG16+Decision Tree	0.85	0.85	0.85	0.85
VGG16+Naïve Bayes	0.70	0.76	0.70	0.68
VGG16+LDA	0.90	0.90	0.90	0.90
VGG16+MLP	0.92	0.92	0.92	0.91

TABLE IX. PERFORMANCE COMPARISON OF ML CLASSIFIERS WITH RESNET50 FOR MELANOMA SKIN CANCER DATASET

Model	Accuracy	Precision	Recall	F1-Score
ResNet50+SVM	0.62	0.75	0.62	0.56
ResNet50+Random Forest	0.89	0.89	0.89	0.89
ResNet50+Gradient Boosting	0.90	0.90	0.90	0.90
ResNet50+AdaBoost	0.88	0.88	0.88	0.88
ResNet50+KNN	0.87	0.87	0.87	0.87
ResNet50+Logistic Regression	0.89	0.89	0.89	0.89
ResNet50+Decision Tree	0.82	0.82	0.82	0.82
ResNet50+Naïve Bayes	0.63	0.73	0.63	0.60
ResNet50+LDA	0.90	0.90	0.90	0.90
ResNet50+MLP	0.85	0.85	0.85	0.85

2) Evaluation results with respect to the melanoma skin cancer dataset:

a) VGG16 performance: Table VIII shows that the best performing model among all models was *VGG16* with *MLP*, achieving the highest values across all metrics. In contrast, *VGG16* with Naïve Bayes performed the worst, making it the least effective classifier in this comparison.

ResNet50 Performance.

Table IX shows that *ResNet50 + Gradient Boosting* and *ResNet50 + LDA* achieved the highest scores across all metrics (**Accuracy=0.90**, **Precision=0.90**, **Recall=0.90**, **F1=0.90**), indicating strong generalization and a balanced precision–recall trade-off. In contrast, *ResNet50 + SVM* produced the weakest performance among the compared classifiers.

MobileNet Performance. Table X shows that *MobileNet + SVM* achieved the highest scores across all metrics (Accuracy, Precision, Recall, and F1), making it the top-performing configuration for this dataset. In contrast, *MobileNet + Naive Bayes* yielded the weakest results, recording the lowest values on all evaluated metrics.

b) InceptionV3 performance: Table XI illustrates that the *InceptionV3* with *SVM* model achieved the highest Accuracy, Precision, Recall, and F1-score. Meanwhile, the *InceptionV3* combined with the *Decision Tree* model showed the weakest performance across all metrics.

Based on the above performance metrics, the most suitable ML classifier for the *Melanoma Skin Cancer* data depends on the chosen DL feature extractor. The best combinations by *Accuracy* are:

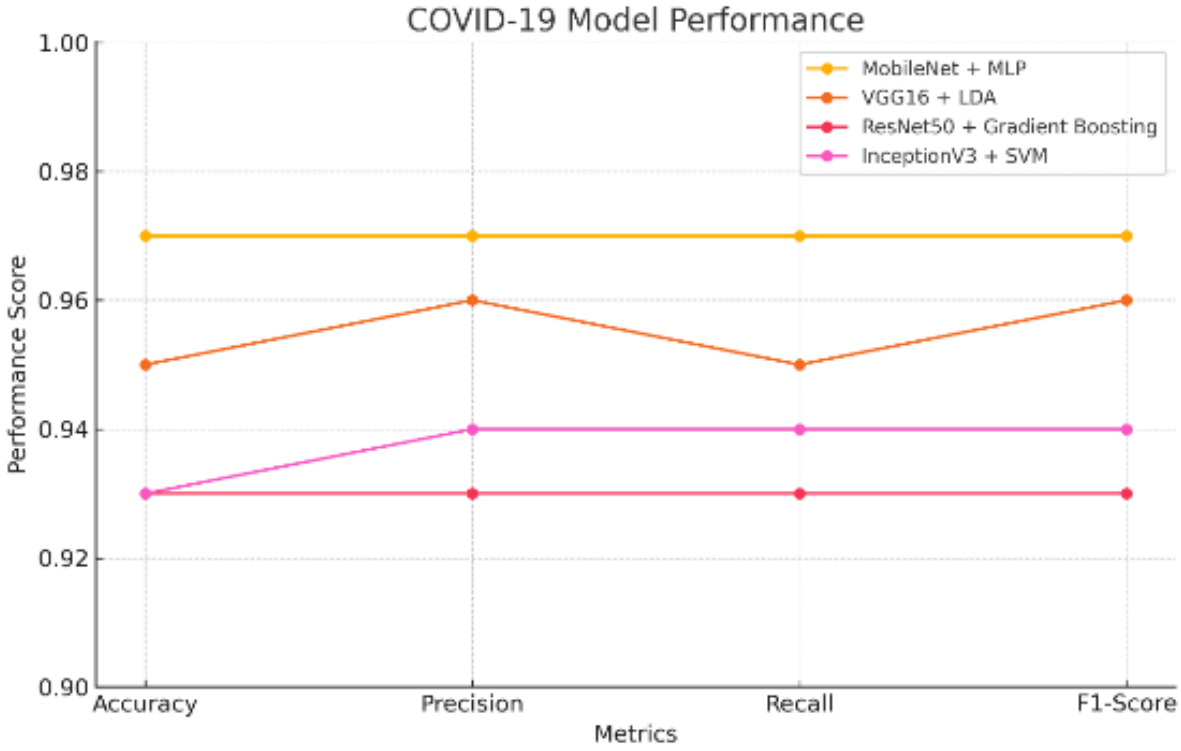

Fig. 5. COVID-19 model performance.

TABLE X. PERFORMANCE COMPARISON OF ML CLASSIFIERS WITH MOBILENET FOR MELANOMA SKIN CANCER DATASET

Model	Accuracy	Precision	Recall	F1-Score
MobileNet+SVM	0.92	0.92	0.92	0.92
MobileNet+Random Forest	0.90	0.90	0.90	0.90
MobileNet+Gradient Boosting	0.91	0.91	0.91	0.90
MobileNet+AdaBoost	0.86	0.86	0.86	0.86
MobileNet+KNN	0.90	0.90	0.90	0.90
MobileNet+Logistic Regression	0.89	0.89	0.89	0.89
MobileNet+Decision Tree	0.82	0.83	0.82	0.82
MobileNet+Naïve Bayes	0.80	0.80	0.80	0.80
MobileNet+LDA	0.90	0.90	0.90	0.90
MobileNet+MLP	0.91	0.91	0.91	0.91

TABLE XI. PERFORMANCE COMPARISON OF ML CLASSIFIERS WITH INCEPTIONV3 FOR MELANOMA SKIN CANCER DATASET

Model	Accuracy	Precision	Recall	F1-Score
InceptionV3+SVM	0.91	0.91	0.91	0.91
InceptionV3+Random Forest	0.87	0.87	0.87	0.87
InceptionV3+Gradient Boosting	0.90	0.90	0.90	0.90
InceptionV3+AdaBoost	0.87	0.87	0.87	0.87
InceptionV3+KNN	0.86	0.87	0.86	0.85
InceptionV3+Logistic Regression	0.89	0.89	0.89	0.89
InceptionV3+Decision Tree	0.78	0.78	0.78	0.78
InceptionV3+Naïve Bayes	0.80	0.80	0.80	0.80
InceptionV3+LDA	0.89	0.89	0.89	0.89
InceptionV3+MLP	0.90	0.90	0.90	0.90

- If *MobileNet* is used, *SVM* is best (Accuracy: **0.92**).
- If *VGG16* is used, *MLP* is best (Accuracy: **0.92**).
- If *InceptionV3* is used, *SVM* is best (Accuracy: **0.91**).
- If *ResNet50* is used, *Gradient Boosting/LDA* are best (Accuracy: **0.90**).

Overall, **MobileNet+SVM** is the strongest model for melanoma; **VGG16+MLP** is also a strong alternative, especially if computational efficiency matters (see Fig. 6 and Table XII).

ResNet50 Performance. Table XIII shows that *ResNet50 + MLP* achieved the highest scores across all metrics (**Accuracy**=0.96, **Precision**=0.95, **Recall**=0.95, **F1**=0.95). In contrast, *ResNet50 + Random Forest* exhibited the weakest performance among the compared models.

c) MobileNet performance: Table XIV shows that, across all evaluation metrics, the *MobileNet+MLP* model outperforms the rest (Accuracy 0.98, Precision 0.97, Recall 0.97, and F1-score 0.97). In contrast, *MobileNet+Decision Tree* has the lowest performance (Accuracy 0.90, Precision 0.87, Recall 0.88, F1-score 0.88), indicating notable limitations and making it the least reliable among the tested models.

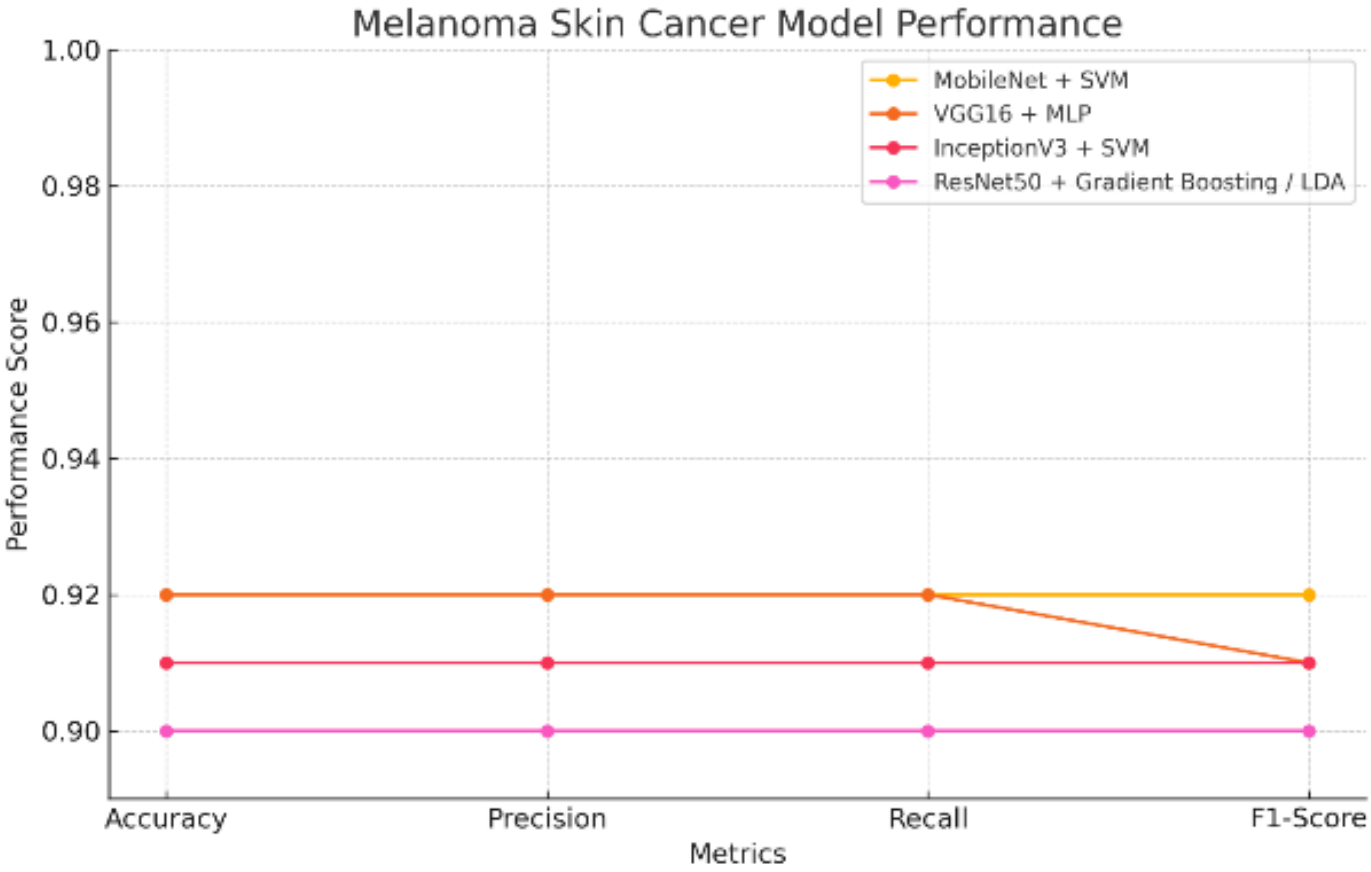

Fig. 6. Melanoma model performance.

TABLE XII. PERFORMANCE COMPARISON OF ML CLASSIFIERS WITH VGG16 FOR CHEST X-RAY IMAGES DATASET

Model	Accuracy	Precision	Recall	F1-Score
VGG16+SVM	0.93	0.91	0.91	0.91
VGG16+Random Forest	0.96	0.95	0.94	0.94
VGG16+Gradient Boosting	0.95	0.94	0.94	0.94
VGG16+AdaBoost	0.95	0.94	0.94	0.94
VGG16+KNN	0.95	0.93	0.93	0.94
VGG16+Logistic Regression	0.95	0.94	0.94	0.94
VGG16+Decision Tree	0.90	0.86	0.87	0.87
VGG16+Naïve Bayes	0.93	0.90	0.90	0.87
VGG16+LDA	0.97	0.96	0.95	0.96
VGG16+MLP	0.97	0.96	0.96	0.96

TABLE XIII. PERFORMANCE COMPARISON OF ML CLASSIFIERS WITH RESNET50 FOR CHEST X-RAY IMAGES DATASET

Model	Accuracy	Precision	Recall	F1-Score
ResNet50+SVM	0.91	0.88	0.90	0.89
ResNet50+Random Forest	0.74	0.37	0.50	0.43
ResNet50+Gradient Boosting	0.92	0.91	0.88	0.90
ResNet50+AdaBoost	0.94	0.93	0.92	0.92
ResNet50+KNN	0.94	0.96	0.93	0.93
ResNet50+Logistic Regression	0.90	0.86	0.89	0.88
ResNet50+Decision Tree	0.92	0.93	0.92	0.93
ResNet50+Naïve Bayes	0.89	0.86	0.86	0.86
ResNet50+LDA	0.83	0.78	0.90	0.88
ResNet50+MLP	0.96	0.95	0.95	0.95

d) InceptionV3 performance: The performance of models using the *InceptionV3* feature extractor with different ML classifiers is presented in Table XV. The best results were obtained with *InceptionV3+Logistic Regression* and *InceptionV3+MLP*, each achieving 0.96 for Accuracy, Precision, Recall, and F1-score. The weakest model was *InceptionV3+Decision Tree.*

- If *MobileNet* is used, *MLP* is best (Accuracy: **0.98**).
- If *VGG16* is used, *MLP* is best (Accuracy: **0.97**); *LDA* is a strong alternative.
- If *InceptionV3* is used, *MLP/Logistic Regression* are best (Accuracy: **0.96**).
- If *ResNet50* is used, *MLP* is best (Accuracy: **0.96**).

Overall, **MobileNet+MLP** achieves the highest Accuracy for Chest X-Ray Images, while **VGG16+MLP/LDA** is also a strong choice (see Fig. 7 and Table XVI).

e) ResNet50 performance: Table XVII shows that *ResNet50+KNN* achieved the best performance with the highest Accuracy (0.91), Precision (0.90), Recall (0.89), and F1-

TABLE XIV. PERFORMANCE COMPARISON OF ML CLASSIFIERS WITH MOBILENET FOR CHEST X-RAY IMAGES DATASET

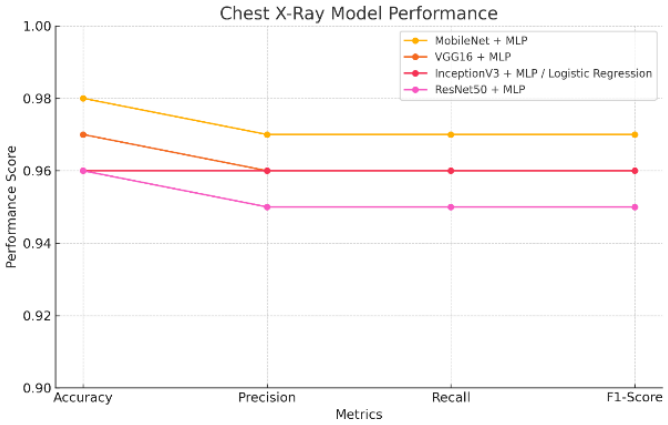

Fig. 7. Chest X-ray model performance.

score (0.89). Conversely, *ResNet50+SVM* recorded the lowest metrics (Accuracy 0.67, Precision 0.33, Recall 0.50, F1-score 0.40).

f) MobileNet performance: Table XVIII shows that the most effective models are *MobileNet+SVM*, *MobileNet+KNN*, *MobileNet+LDA*, and *MobileNet+MLP*, each achieving perfect scores (Accuracy, Precision, Recall, and F1-score of 1.00). In contrast, *MobileNet+Naïve Bayes* recorded the weakest performance (Accuracy 0.81, Precision 0.80, Recall 0.83, F1-score 0.80), making it the least effective classifier in this comparison.

g) InceptionV3 performance: Table XIX presents the results for models using the *InceptionV3* feature extractor.

TABLE XVI. PERFORMANCE COMPARISON OF ML CLASSIFIERS WITH VGG16 FOR FACE IMAGES DATASET

Model	Accuracy	Precision	Recall	F1-Score
VGG16+SVM	0.91	0.90	0.89	0.89
VGG16+Random Forest	0.98	0.98	0.97	0.98
VGG16+Gradient Boosting	0.98	0.98	0.98	0.98
VGG16+AdaBoost	0.96	0.96	0.95	0.95
VGG16+KNN	1.00	1.00	1.00	1.00

VGG16+Naïve Bayes	0.84	0.83	0.87	0.83
VGG16+LDA	0.99	0.99	0.99	0.99
VGG16+MLP	1.00	1.00	1.00	1.00

TABLE XVII. PERFORMANCE COMPARISON OF ML CLASSIFIERS WITH RESNET50 FOR FACE IMAGES DATASET

Model	Accuracy	Precision	Recall	F1-Score
ResNet50+SVM	0.67	0.33	0.50	0.40
ResNet50+Random Forest	0.88	0.89	0.84	0.86
ResNet50+Gradient Boosting	0.88	0.86	0.85	0.86
ResNet50+AdaBoost	0.84	0.82	0.82	0.82
ResNet50+KNN	0.91	0.90	0.89	0.89
ResNet50+Logistic Regression	0.81	0.79	0.77	0.78
ResNet50+Decision Tree	0.78	0.75	0.75	0.75
ResNet50+Naïve Bayes	0.59	0.70	0.68	0.65
ResNet50+LDA	0.84	0.82	0.83	0.82
ResNet50+MLP	0.83	0.81	0.79	0.80

TABLE XVIII. PERFORMANCE COMPARISON OF ML CLASSIFIERS WITH MOBILENET FOR FACE IMAGES DATASET

Model	Accuracy	Precision	Recall	F1-Score
MobileNet+SVM	1.00	1.00	1.00	1.00
MobileNet+Random Forest	0.98	0.97	0.97	0.98
MobileNet+Gradient Boosting	0.99	0.99	0.99	0.99
MobileNet+AdaBoost	0.99	0.99	0.99	0.99
MobileNet+KNN	1.00	1.00	1.00	1.00
MobileNet+Logistic Regression	0.99	0.99	1.00	0.99
MobileNet+Decision Tree	0.88	0.86	0.80	0.87
MobileNet+Naïve Bayes	0.81	0.80	0.83	0.80
MobileNet+LDA	1.00	1.00	1.00	1.00
MobileNet+MLP	1.00	1.00	1.00	1.00

The best-performing classifiers were *SVM*, *KNN*, *Logistic Regression*, and *MLP*. In contrast, *InceptionV3+Naïve Bayes* recorded the weakest performance (Accuracy 0.75, Precision 0.79, Recall 0.75, F1-score 0.75).

Based on the previous performance metrics for the *Face Images of Acute Stroke and Non-Acute Stroke* dataset, the best ML classifier depends on the DL feature extractor:

- If *MobileNet* is used, *SVM*, *KNN*, *LDA*, or *MLP* achieved perfect scores (Accuracy: **1.00**).
- If *VGG16* is used, *KNN* or *MLP* are best (Accuracy: **1.00**).
- If *InceptionV3* is used, *SVM*, *KNN*, *Logistic Regression*, or *MLP* are best (Accuracy: **0.99**).

InceptionV3+AdaBoost	0.85	0.85	0.78	0.79
InceptionV3+KNN	0.93	0.92	0.93	0.92
InceptionV3+Logistic Regression	0.93	0.93	0.93	0.93
InceptionV3+Decision Tree	0.79	0.86	0.76	0.83
InceptionV3+Naïve Bayes	0.70	0.73	0.75	0.74
InceptionV3+LDA	0.93	0.93	0.94	0.93
InceptionV3+MLP	0.94	0.93	0.94	0.93

- If *ResNet50* is used, *KNN* is best (Accuracy: **0.91**).

If computational efficiency and balanced performance are priorities, **MobileNet**-based models (especially with SVM, KNN, LDA, or MLP) are preferable due to MobileNet's lightweight nature. If interpretability and robustness are crucial, **VGG16** with **KNN** or **MLP** is an excellent choice (see Fig. 8 and Table XX).

h) ResNet50 performance: Table XXI shows that *ResNet50+KNN* and *ResNet50+LDA* achieved the highest Accuracy (0.93), with *ResNet50+LDA* delivering consistently strong results across all metrics. For the Precision metric, *ResNet50+Random Forest* obtained the best result (0.68). In contrast, *ResNet50+Naïve Bayes* was the weakest model, with the lowest Accuracy (0.38) and overall poor performance compared to the others.

i) InceptionV3 performance: Table XXII shows that *InceptionV3+SVM* and *InceptionV3+MLP* achieved the highest Accuracy (**0.94**). The highest Precision was obtained by *Logistic Regression*, *Naïve Bayes*, *LDA*, and *MLP*. The Recall was highest for *SVM* and *MLP*. Regarding F1-score, *Logistic Regression*, *LDA*, and *MLP* achieved the best results (**0.93**). In contrast, *InceptionV3+Naïve Bayes* was the weakest model overall, with the lowest Accuracy (**0.70**).

j) Summary: Different eye diseases dataset: Based on the previous performance metrics, the most suitable ML classifier depends on the chosen DL feature extractor. The best combinations by *Accuracy* are:

- If *VGG16* is used, *KNN* is best (Accuracy: **0.95**).
- If *InceptionV3* is used, *MLP* is best (Accuracy: **0.94**).
- If *MobileNet* is used, *SVM*/*KNN* are best (Accuracy: **0.94**).
- If *ResNet50* is used, *LDA* is best (Accuracy: **0.93**).

Overall, **VGG16+KNN** and **InceptionV3+MLP** are strong choices, while **MobileNet+SVM/KNN** provides competitive performance with efficient inference (see Fig. 9).

k) Different eye diseases dataset: For the *Different Eye Diseases* dataset, **VGG16+KNN** is the most appropriate model based on its highest Accuracy and balanced performance across evaluation metrics. However, **InceptionV3+MLP** is also a strong contender. The choice between them depends on application requirements such as computational efficiency and real-time processing needs (see Fig. 9).

B. Discussion

The primary aim of this study was to create and assess a hybrid model architecture that combines deep learning (DL) feature extraction with machine learning (ML) classification techniques for medical image analysis. Across the five datasets, performance varied with the particular pairing of DL feature extractor and ML classifier. Key findings are summarized below:

- COVID-19 Dataset: *MobileNet+MLP* achieved the highest Accuracy (0.97).
- Melanoma Skin Cancer Dataset: *MobileNet+SVM* and *VGG16+MLP* both reached top accuracies (0.92), showing that different hybrid configurations can yield competitive results depending on computational or interpretability needs.
- Chest X-Ray Dataset: *MobileNet+MLP* again achieved the highest accuracy (0.98).
- Face Images of Acute Stroke Dataset: *MobileNet* with several ML classifiers (SVM, KNN, LDA, MLP) achieved perfect accuracy (1.00), indicating strong discriminative power of facial feature embeddings for neurological conditions.
- Different Eye Diseases Dataset: The top performer was *VGG16+KNN* (Accuracy: 0.95), while *InceptionV3+MLP* also delivered competitive results (Accuracy: 0.94).

Overall, *MobileNet* consistently appears as the most adaptable and high-performing DL feature extractor across datasets, especially when paired with *MLP* or *SVM*, depending on the classification challenge. These results confirm the potential of hybrid DL–ML models in medical image classification.

Model selection should not rely on accuracy alone; additional factors include:

- Computational efficiency: e.g., *MobileNet* is favorable for time-sensitive applications due to high speed and low resource use.
- Interpretability: e.g., *LDA* or *Logistic Regression* offer clearer clinical insight.
- Dataset specifications: image resolution, noise levels, and class imbalance must be considered.

The evaluation demonstrates that combining DL and ML can yield hybrid models that improve classification while providing flexible solutions for varied medical domains.

V. Conclusion and Future Work

This research introduced a hybrid architecture that couples Deep Learning (DL) feature extraction with Machine Learning (ML) classification for medical image analysis across multiple datasets. Four pre-trained CNNs (VGG16, ResNet50, MobileNet, InceptionV3) served as deep feature extractors; their features were fed to ten traditional ML classifiers, forming a comprehensive hybrid framework. We evaluated the framework on five datasets: COVID-19 chest X-rays, melanoma skin cancer, general chest X-rays, acute stroke facial images, and a multi-class eye disease dataset.

Results show that performance depends on both the DL extractor and ML classifier. In most cases, *MobileNet* proved the most consistent and effective extractor, especially with *MLP* or *SVM*. This pairing achieved the highest accuracies in several datasets, such as COVID-19 (*MobileNet+MLP*, 0.97), chest X-rays (*MobileNet+MLP*, 0.99), and stroke images (*MobileNet+MLP/KNN/LDA*, 1.00). By contrast, *ResNet50* showed relatively lower performance on stroke and eye-disease classification, whereas *VGG16* and *InceptionV3* achieved strong results elsewhere and are good alternatives when interpretability, computational complexity, or domain-specific constraints are important.

The study further demonstrates that well-optimized hybrid DL–ML pipelines can outperform standalone ML or DL approaches, offering better generalization across neurological, dermatological, and respiratory imaging tasks.

Future work will expand to broader medical conditions and explore stronger denoising methods to enhance image quality. Another promising direction is multi-modal integration—combining images with clinical data—to improve accuracy and provide a more holistic diagnostic aid.

Acknowledgment

Funding: The generous support from Princess Nourah bint Abdulrahman University in Riyadh, Saudi Arabia, through the Researchers Supporting Project number (PNURSP2025R909) is greatly appreciated by the authors. This support enabled key activities such as data collection, analysis, and dissemination. The authors also express sincere gratitude to King Saud University for invaluable assistance and continuous support during the preparation of this work. The collective support of these institutions significantly enhanced the quality and impact of the research.
