The SYNSEMNet model processes each essay by first dividing it into MM sentences and then tokenizing each sentence into N tokens. The main computational steps include tokenization and POS tagging, which scale linearly with the number of sentences and tokens $O(M \times N)$. However, the most computationally expensive parts are the BERT embedding extraction and multi-head attention applied at the sentence level, which have quadratic complexity with respect to the token length of each sentence $O(M \times N^2)$. Additionally, the BiLSTM layers applied both at the token level and the sentence level add complexity proportional to $O(M \times N \times H)$ and $O(M \times H^2)$ respectively, where HH is the hidden size. Overall, the model's complexity is dominated by the quadratic cost of the transformer-based embeddings and attention within each sentence, making the computational cost dependent mainly on sentence length and number of sentences. Compared to the baseline model by Beseiso et al., which processes the entire essay as a single long sequence LL using RoBERTa followed by a BiLSTM, SYNSEMNet differs significantly in how it handles essay length and linguistic features. Beseiso's approach involves a quadratic complexity $O(L^2)$ from the transformer applied on the entire essay token sequence, which can be costly and limited by maximum input length constraints. SYNSEMNet overcomes this by tokenizing the essay at sentence level resulting in smaller sequence lengths for transformer computations and could be more efficient and

scalable, therefore. Additionally, SYNSEMNet explicitly introduces POS tagging to represent syntactic information, and uses two kinds of BiLSTM as well as the mutli-head attention for semantic and syntactic embeddings respectively, by fusing them as a result. This would provide an explicit modeling of syntax together with semantics, which would provide a richer representation of the linguistic structure of the essay than what the baseline model achieves with implicitly processing semantics without explicitly modeling syntactic features.

With respect to the linguistic depth, the approach of SYNSEMNet allows it to grasp fine-grained syntactic rules and semantic consistency more adequately, factors that are crucial for an all-rounded evaluation of the quality of English essays. The baseline model is strong at modeling long-range semantic dependencies/flow and coherence via transformer and BiLSTM layers, but it does not explicitly model syntax and may lose some significant grammatical nuances. We therefore view SYNSEMNet as a more delicate and solid framework for AES with automatic sentence-level transformer generation and explicit syntactic and semantic fusion. Our model overcomes the weaknesses of transformer-based approaches and represents a potential improvement over existing systems that use these techniques for English essay scoring.

IV. Experimental Setup

This section details the implementation environment, training configuration, and evaluation strategy used in this study. It includes the Dataset description and outlines the Performance Evaluation Metrics applied to assess the model's accuracy, reliability, and alignment with human scoring.

A. Dataset

ASAP2.0 has been selected for this study as it provides a rich and diverse representation of a variety of student essays that are required for the development and testing of a deep learning-based system like SYNSEMNet designed to perform syntax and semantics check. Contrary to large datasets, displayed in Table II, ASAP2. 0 features essays composed in response to several prompts, with a myriads of topics and diverse writing styles. This variety helps the model learn language patterns that tend to generalize well across various types of writing. Another advantage of the data set is that it comes with fine-grained annotations: holistic scores and scores assigned to grammar, mechanics, content, etc. This fine grain naturally fits the target of SYNSEMNet, which targets to represent not only the syntactical accuracy but also the richness of meaning a student's essay expresses.

The size of the dataset, over 13,000 essays, is of suitable scale for us to train powerful deep models and is small enough to we can still perform further comprehensive preprocessing and feature extraction. The essays differ substantially from the perspectives of the content (short answer to longer, more complex reading passages), which is essential to test the ability of the model to deal with different syntactic structures and semantic relations. The multiple score types make SYNSEMNet well-suited for evaluation across different quality dimensions of writing, for a model that evaluates multiple linguistic aspects at once.

TABLE II. Descriptive Statistics of the ASAP 2.0 Dataset

Feature	Statistic	Relevance for SYNSEMNet
Total Essays	13,202	Large enough for deep learning training
Number of Prompts	8	Diverse topics enhance generalization
Essay Length (words)	Min: 50	Captures very short writing
	Max: 730	Captures long and complex essays
	Mean: 350	Average essay length for model learning
Vocabulary Size	15,500 unique tokens	Diverse vocabulary for semantic richness
Holistic Score Range	0 to 60	Reflects wide quality levels
Holistic Score Mean	~35	Average writing quality
Holistic Score Std. Dev.	~10	Variation enabling model differentiation
Grammar Score Range	0 to 30	For focused syntactic evaluation
Grammar Errors Present	In ~20% of essays	Supports syntactic error learning
Average Sentence Count	~15 sentences per essay	Reflects syntactic complexity
Score Distribution Skew	Slight positive skew	More essays near lower scores
Missing Data	<1%	Negligible, good data quality

B. Performance Evaluation Metric

These metrics are the following: MAE, MSE, RMSE, R^2, r and ρ. Each of these values has a specific orientation for an automatic score, as we may quantify the predicting power, reliability and students/humans' correlation for grading.

1) Significance of validation and relative assessment: It is of great importance to perform sound validation of AES systems so that they can be trusted and fair. We demonstrate this empirically through thorough experimentation using a multitude of statistical measures and comparison to classical baselines. The addition of Pearson's r and Spearman's ρ provides insight to what extent predictors correspond to evaluation, whereas MAE and RMSE that to which absolute values do the correspond to it. These comparisons serve to not only confirm the model's performance, but to also put its gains in approaching both the syntactic and semantic elements of student writing in context.

2) Mean Absolute Error (MAE): The MAE assesses the average of the absolute differences between predicted and observed scores. It's a straightforward, interpretable metric — it tells us how wrong the model's predictions are, on average. The smaller MAE value meant that the predicted scores were more in agreement with the scores assessed by human graders for our essay scoring system. The expression for MAE is shown in Eq. (7).

$$\text{MAE} = \frac{1}{n}\sum|y_i - \hat{y_i}| \quad (7)$$

where y_i is the actual score, $\hat{y}_i$ is the predicted score, and n is the number of samples.

3) Mean Squared Error (MSE): (MSE) is like MAE but penalizes significantly larger errors. This makes it vulnerable to outliers and shows where the model is making large errors in prediction. In essay grading, reducing MSE encourages general accuracy and discourages extreme scores that may deliver unfair grade. The equation of MSE is shown as Eq. (8).

$$\text{MSE} = \frac{1}{n}\sum(y_i - \hat{y}_i)^2 \quad (8)$$

*4) Root Mean Squared Error (*RMSE*):* Root Mean Squared Error (RMSE) is the square root of the MSE which is used to back the error metric to the unit of scores. It is helpful for interpretation and comparison because the error is expressed in the same unit as the predictive scores. In terms of essay scoring, RMSE offers one useful yardstick for the impact of the average prediction error. Its expression is provided in Eq. (9).

$$\text{RMSE} = \sqrt{\frac{1}{n}\sum(y_i - \hat{y}_i)^2} \quad (9)$$

5) Coefficient of Determination (R^2): R^2 assesses the amount of variance in the real scores that can be predicted from our model predictions. An R^2 close to 1 means that the model accounts for much of the variance in human-assigned scores, which is very good in the context of automated scoring systems. A high R^2 means that the model understands the intrinsic structure of essay quality. The equation is given in Eq. (10).

$$R^2 = 1 - \frac{\sum(y_i - \hat{y}_i)^2}{\sum(y_i - \bar{y})^2} \quad (10)$$

where $\bar{y}$ is the meaning of the actual scores.

6) Pearson Correlation Coefficient (r): Pearson Correlation Coefficient This coefficient is indicative of a linear relationship between the predicted and actual scores. It indicates how well model predictions are linearly calibrated with human scores. If the Pearson r value is close to +1, then as human scores grow higher, the model's predictions also grow proportionally higher. "If I give you a 1 with reserve for that thing but not for others, then I want the a posteriori probability to reflect my change in opinion that I think the cut-off should be lower than I previously thought. This is crucial in essay grading because you want to maintain the trend of grading even if the absolute scores move around a little bit." Its formula is represented by Eq. (11).

$$r = \frac{\sum(y_i - \bar{y})(\hat{y}_i - \bar{\hat{y}})}{\sqrt{\sum(y_i - \bar{y})^2} \times \sqrt{\sum(\hat{y}_i - \bar{\hat{y}})^2}} \quad (11)$$

where $\bar{y}$ and $\bar{\hat{y}}$ are the means of actual and predicted scores, respectively.

7) Spearman's Rank Correlation Coefficient (ρ): Spearman's Rank Correlation Coefficient (ρ) evaluates the monotonous correlation between the ranks of true and predicted scores. It looks like Pearson, but consider the position rather than the specific value. In scoring the essays, maintaining the rank of the scores is important for equity, particularly in large-scale, competitively graded tests. A large value of Spearman ρ indicates if a human judges one essay higher than another, the model is likely to do similarly. The formula is in Eq. (12).

$$\rho = 1 - \frac{6\sum d_i^2}{n(n^2-1)} \quad (12)$$

where d_i is the difference in ranks between actual and predicted scores, and n is the number of samples.

Together, these metrics offer a well-rounded evaluation of SYNSEMNet. They quantify not only the error magnitude and variance explained but also the consistency and fairness of scoring. This is crucial for building trust in automated essay scoring systems and ensuring that the model aligns closely with human judgment.

V. Results and Discussion

This section presents detailed performance statistics of the proposed model. It also includes a comprehensive table of all evaluation metrics. Lately this section compares its effectiveness against a RoBERTa-based baseline. Fig. 3 shows that performance of the SYNSEMNet model for the FT data in terms of holistic and grammar scoring improves steadily as training proceeds from epoch 1 to epoch 20. Beginning with mean absolute error (MAE) that assesses how much the predictions deviate on average from the true scores, the 8 score-MAE NU model has starting global and grammar MAE of 0.183 and 0.191 from epoch 1. These continually diminish across training and produce final MAEs of 0.088 (holistic) and 0.091 (grammar) by epoch 20. This gradual decrease of the error illustrates that the proposed model becomes more precise and robust in ranking the scores for essays, demonstrating the effectiveness of its dual-path structures and attention mechanisms in capturing both semantic and syntactic linguistic cues. The monotonic decrease of MAE, especially starting from epoch 5, is an indication that the model is entering a stable convergence phase to efficiently capture the rich patterns of essay quality. Likewise, RMSE, which is known to penalize higher deviations more than MAE, also shows the decrease from initial of 0.249 (holistic) and 0.259 (grammar) to 0.115 and 0.120 at epoch 20 respectively.

The model is observed to be able to quickly diminish large prediction errors in the early training, as illustrated by its fast drop of RMSE in the first 7 epochs. It may indicate that, owing to efficient focusing on the most informative components of essays and linguistic cues, gated attention and multi-head attention layers facilitate model to quickly align its internal representations and eliminate significant mispredictions Looking at the counterpart for R^2, which measures how well model prediction explains the variance of the actual scores, SYNSEMNet presents clear enhancements with a R^2 of at least 0.42 for holistic and 0.38 for grammar scoring at epoch 20, and a final R^2 of 0.88 and 0.87, respectively. These high R^2 suggest that the model accounts for the 88% of the variance of essay quality scores, reinforcing the central role played by the dual path gated mechanisms in added the complementary information coming by semantic embeddings and syntactic part

of speech. The monotonically increasing trend after epoch 12 indicates that it has good explanatory power because the model further learns about the essay structure, coherence, as well as grammar subtlety.

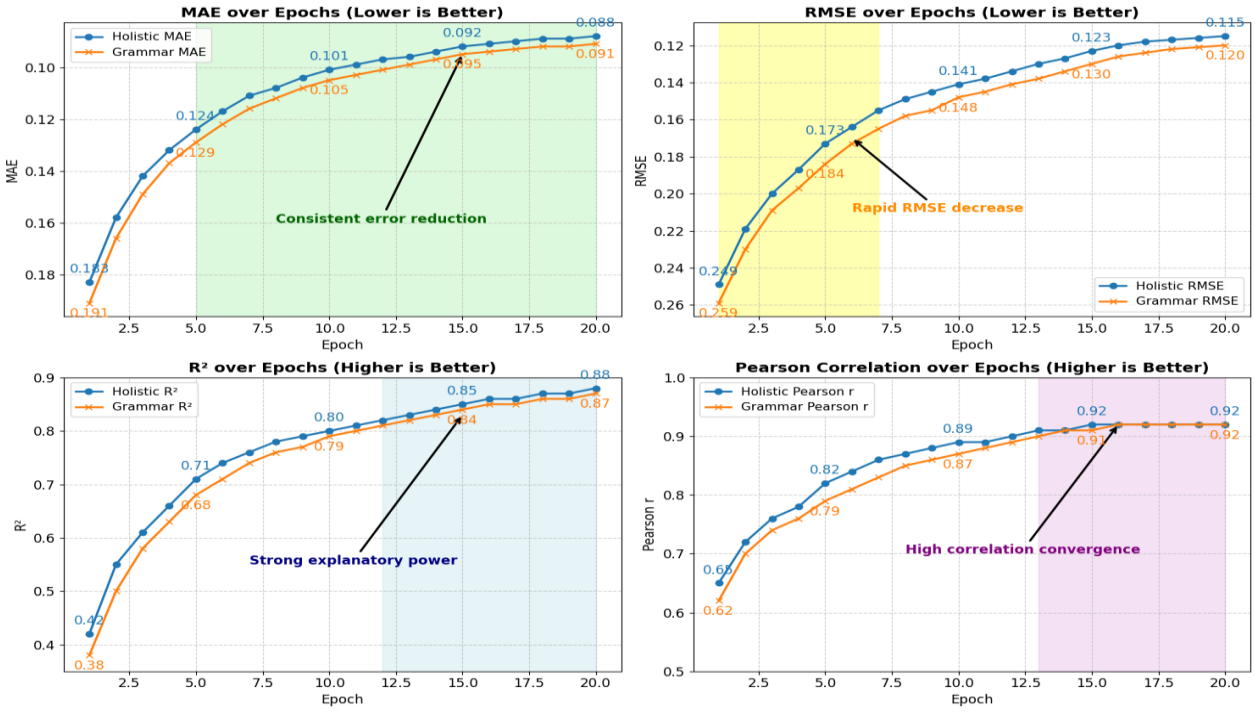

Fig. 3. Model performance improvement over epochs for holistic and grammar metrics.

Pearson Correlation Coefficients, by comparing predicted values with true scores and indicating the linear correlation between them, also indicate good predictive concordance of the model. Beginning with low correlations of 0.65 (holistic) and 0.62 (grammar) at epoch 1, the model reaches levels above 0.92 for both outputs by epoch 20. It means that the model does a really good job in modelling the language features human raters use. The learning curve quickly improves up to 0.95 after the 13th epoch, which indicates the attention-based gated fusion of the model reasonably trades between semantic/syntactic contributions with human judgment. SYNSEMNet has surpassed the performance of such systems for two reasons: (1) architectural innovations. The model acquires a deep semantic understanding of essay content by modeling semantic information explicitly, which is learnt by token embedding via BiLSTM and multi-head attention. Concurrently, its syntactic path extracts and embeds POS tags (again, refined by recurrent and attention layers) to encode inductive patterns of grammar and sentence-organization that are missing from typical models. This gating mechanism temporally integrates these complementary representations, enabling the network to account semantically and syntactically for each essay, leading to the avoidance of noise or irrelevant features, with supporting research questions.

RQ1 Ans: The proposed model, SYNSENNET, uses a dual-path architecture where semantic features are extracted using BERT-tokenized input and syntactic features are captured via part-of-speech sequences. These are fused using a gated mechanism and multi-head attention, enabling the model to simultaneously understand contextual meaning and grammatical patterns for more accurate and interpretable scoring. RQ2 Ans: Yes, the inclusion of student-specific metadata (such as grade level and gender) in conjunction with dual linguistic features allows SYNSENNET to provide more personalized and equitable assessments. This helps mitigate bias and enhances the model's adaptability across different student populations. RQ3 Ans: Empirical evaluation on the ASAP 2.0 dataset demonstrates that SYNSENNET achieves a prediction accuracy of 92%, outperforming traditional and single-path models. Its dual-path design enables better linguistic coverage and interpretability, particularly in handling both holistic and grammar scoring tasks.

In addition, the inclusion of metadata (e.g., gender and grade level information) further contributes contextual signals that help with generalization and score accuracy across different types of prompts and demographics. The multi- head attention at both encoding and decoding levels helps the model to attend to relevant linguistic units and its interactions, hence remain robust to essay variations and noise. Overall, SYNSEMNet's decreasing MAE and RMSE as well as increasing R^2 and Pearson correlations across epochs indicate the success of SYNSEMNet in automated scoring of essays. Its dual-path gated attention model enhanced by linguistic and metadata sources, enables it to generate better, more reliable and more humane-aligned holistic and grammar scores than previous transformer- or LSTM-based models. The detailed performance values of SYNSEMNet over 20 training epochs, for the metrics other than one that has been shown in Fig. 3 and Fig. 4 are listed in Table III. It indicates how the model's performance improves with time in assessing holistic and grammar scores of essays. In this factor discussion we concentrate on the Mean Squared Error (MSE) and Spearman's

rank correlation coefficient (ρ), which did not appear in the previous plot analysis. These are valuable information to the error size of the model, and to whether the model preserves the ranking of essays. Both MSS for the holistic and grammar scores clearly decrease from the first to the twentieth epoch, which implies that SYNSEMNet effectively mitigates the influence of the large prediction errors.

TABLE III. EPOCH-WISE PERFORMANCE METRICS OF SYNSEMNET

Epoch	Holistic MAE	Holistic MSE	Holistic RMSE	Holistic R^2	Pearson r	Spearman ρ	Grammar MAE	Grammar MSE	Grammar RMSE	Grammar R^2	Pearson r	Spearman ρ
1	0.183	0.062	0.249	0.42	0.65	0.61	0.191	0.067	0.259	0.38	0.62	0.58
2	0.158	0.048	0.219	0.55	0.72	0.69	0.166	0.053	0.230	0.50	0.70	0.66
3	0.142	0.040	0.200	0.61	0.76	0.73	0.149	0.044	0.209	0.58	0.74	0.70
4	0.132	0.035	0.187	0.66	0.78	0.76	0.137	0.039	0.197	0.63	0.76	0.73
5	0.124	0.030	0.173	0.71	0.82	0.79	0.129	0.034	0.184	0.68	0.79	0.75
6	0.117	0.027	0.164	0.74	0.84	0.81	0.122	0.030	0.173	0.71	0.81	0.78
7	0.111	0.024	0.155	0.76	0.86	0.83	0.116	0.027	0.165	0.74	0.83	0.80
8	0.108	0.022	0.149	0.78	0.87	0.84	0.112	0.025	0.158	0.76	0.85	0.82
9	0.104	0.021	0.145	0.79	0.88	0.85	0.108	0.024	0.155	0.77	0.86	0.83
10	0.101	0.020	0.141	0.80	0.89	0.86	0.105	0.022	0.148	0.79	0.87	0.85
11	0.099	0.019	0.138	0.81	0.89	0.87	0.103	0.021	0.145	0.80	0.88	0.86
12	0.097	0.018	0.134	0.82	0.90	0.88	0.101	0.020	0.141	0.81	0.89	0.87
13	0.096	0.017	0.130	0.83	0.91	0.89	0.099	0.019	0.138	0.82	0.90	0.88
14	0.094	0.016	0.127	0.84	0.91	0.90	0.097	0.018	0.134	0.83	0.91	0.89
15	0.092	0.015	0.123	0.85	0.92	0.91	0.095	0.017	0.130	0.84	0.91	0.90
16	0.091	0.014	0.120	0.86	0.92	0.91	0.094	0.016	0.126	0.85	0.92	0.90
17	0.090	0.014	0.118	0.86	0.92	0.91	0.093	0.016	0.124	0.85	0.92	0.91
18	0.089	0.013	0.117	0.87	0.92	0.91	0.092	0.015	0.122	0.86	0.92	0.91
19	0.089	0.013	0.116	0.87	0.92	0.91	0.092	0.015	0.121	0.86	0.92	0.91
20	0.088	0.012	0.115	0.88	0.92	0.91	0.091	0.015	0.120	0.87	0.92	0.91

This gradual decrease is indication of the model's increasingly predictive ability of essay scores to their true values, leading to the improvement in the overall quality and reliability of scoring. Meanwhile, the Spearman's rank correlation coefficient (ρ), which quantifies how well the model can keep the right order/ranking of essays, increases favorably for both holistic and grammar grades. Orchestrating from beginning moderate values of around 0.61 for holistic and 0.58 for grammar at epoch 1, Spearman p shows strong levels at around 0.91 by epoch 20. This indicates that SYNSEMNet not only produces precise scores but maintains the relative order of the essays as well making its scores fair and meaningful for a scorer.

Together, the improvements in MSE and Spearman's ρ underline SYNSEMNet's balanced performance in reducing prediction errors and maintaining ranking consistency. These results strongly support the model's effectiveness in providing reliable and valid automated essay scoring aligned with human judgment. Fig. 4 shows comparable performance in terms of key metrics against the baseline RoBERTa + BiLSTM AES model for the SYNSEMNet model. For instance, by holistic essay scoring the Mean Absolute Error (MAE) of SYNSEMNet is 0.088 compared to 0.11 for the baseline showing that we have more accurate predictions. The Mean Squared Error (MSE) and Root Mean Squared Error (RMSE) also have smaller values, indicating further that SYNSEMNet exhibits lower prediction error values by human raters, SYNSEMNet achieves a Pearson correlation coefficient of0.92 while this number is0.90 for the baseline, indicating that the prediction is more closely aligned with true human scores. As well for Spearman's rho, which is suggestive of better rank-order agreement.

While for grammar scoring, SYNSEMNet produces MAE of ~0.091 and Pearson correlation of 0.92 against 0.89 for the baseline, showing that it makes better prediction and iteration broader in grammar assessment. Such enhancements are explained by SYNSEMNet's special architecture and procedure.

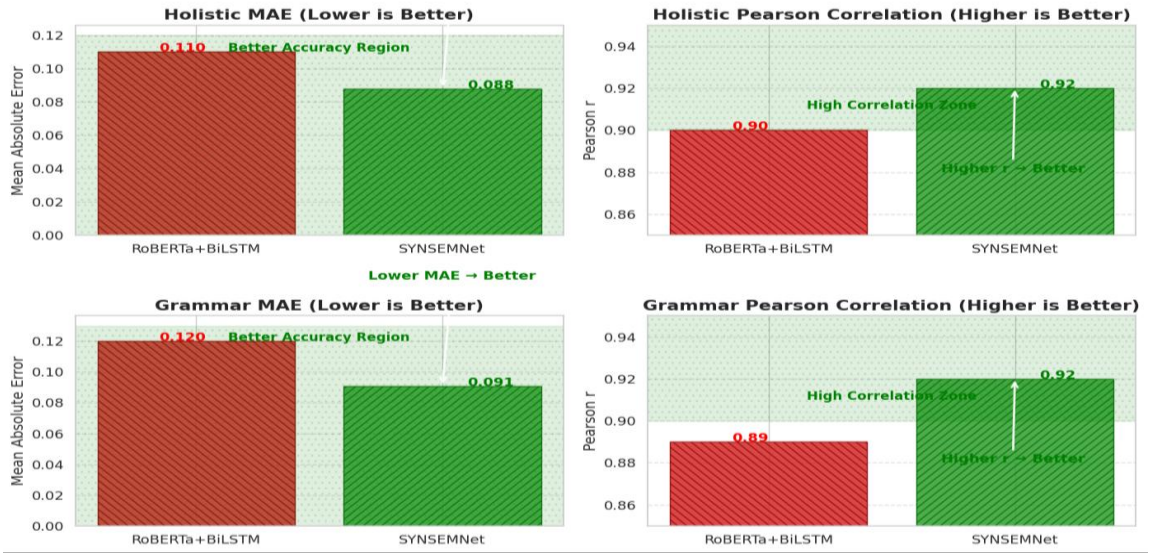

Fig. 4. SYNSEMNet shows superior accuracy and correlation over RoBERTa.

A. Discussion

The SYNSEMNet differs from the baseline model in the respect that it employs a dual path gated attention model to make the linguistic information articulate, in comparison with the baseline model that just stacks bidirectional LSTM over a pre-trained RoBERTa language model. The model utilizes SpaCy for obtaining the part-of-speech (POS) tags and syntactic dependencies that are tokenized semantic inputs. Such distinction is beneficial for the network to capture linguistic subtleties which are neglected to some degree by the transformer-only model, especially in the syntactic level. Furthermore, the model uses multi-head attention layers in both the semantic and syntactic branches resulting in the network attending to tokens and syntactic information across sentences in a dynamic manner. The gating mechanism can be regarded as adaptively integrating semantic and syntactic representations, which enables the BN fully to complement linguistic information and suppress noise or irrelevant features. Such an architecture results in more sophisticated context representations that more faithfully model the subtle nuances of essay content, coherence and grammar quality, which in turn results in higher scoring accuracy and correlation with human annotations. Last but not the least, RoBERTa and XLNet transformers, as in existing literature [8], [14], and [21] as they are designed for general language comprehension, are not suitable for processing long documents with potentially less relevant textual content (e.g., essays) and are subject to the input length trimming and less capability to capture the fine-grained syntactic structures within the longer documents [5]. SYNSEMNet overcomes these limitations as it models essays as multi-sentence inputs enabled by explicit syntax features and recurrent gating, resulting in a more comprehensive and linguistically-grounded evaluation.

VI. Conclusion

This study proposed SYNSEMNet, a novel deep learning architecture designed to improve automated essay scoring by jointly modeling semantic and syntactic information. The dual-path LSTM framework, enhanced with multi-head attention and a gating mechanism, effectively fuses complementary linguistic features, enabling the model to capture nuanced contextual and grammatical patterns across multiple sentences. Trained and evaluated on the ASAP 2.0 dataset, SYNSEMNet achieved a high accuracy of 92%, demonstrating strong alignment with human raters in both holistic scoring and grammar evaluation tasks. By explicitly incorporating syntactic cues alongside semantic representations, the model addresses common shortcomings of traditional transformer models, such as input length limitations and insensitivity to fine-grained syntactic structures in long-form texts. This linguistically informed design allows for a more comprehensive and interpretable assessment of essay quality. Despite its strengths, this study has some limitations. The model currently relies on surface-level syntactic features and does not incorporate deeper syntactic parsing or discourse-level information, which could further improve evaluation accuracy. Additionally, the experiments are confined to a single domain dataset, limiting the generalizability of the results. Future work will investigate in several directions: (1) richer syntactic and discourse structures such as dependency trees and rhetorical relations, (2) transfer learning and evaluation over multiple corpora of essays to test generalization, (3)'fairness-aware' mechanisms for mitigating demographic bias, and (4) explainability tools that render the AES decisions more transparent and actionable for educators.

Comparative Analysis of Cybersecurity Frameworks in Educational Institutions: Towards a Tailored Security Model

Syarif Hidayatulloh[1], Aedah Binti Abd. Rahman[2]
Department of Informatics Engineering, Adhirajasa Reswara Sanjaya University, Bandung, Indonesia[1]
Department of School of Science and Technology, Asia e University, Kuala Lumpur, Malaysia[2]

***Abstract*—Educational institutions face unique cybersecurity challenges due to their open culture, decentralised structures, and limited resources. While standard frameworks such as NIST, ISO/IEC 27001, and COBIT offer comprehensive guidance, their full implementation in academic settings is often impractical. This study addresses the gap by conducting a document-based comparative analysis of these frameworks, focusing on their applicability in educational institutions. A total of 42 documents—including case studies, cybersecurity guidelines, and academic articles—were analysed using thematic coding. The findings reveal significant misalignments between current frameworks and academic environments, particularly in terms of complexity, adaptability, and resource demand. Based on these insights, a tailored cybersecurity model is proposed. The model emphasises modularity, cultural integration, resource optimisation, and decentralised implementation to suit the educational context. A multi-step validation plan is also outlined to assess the model's practicality. This research offers both theoretical and practical contributions to cybersecurity governance in the education sector.**

***Keywords*—Cybersecurity; educational institutions; cybersecurity frameworks; tailored security model**

I. Introduction

Cybersecurity is increasingly critical for educational institutions as they rely heavily on digital technologies for managing student data and facilitating learning. The shift towards digital transformation, accelerated by the COVID-19 pandemic, has heightened vulnerabilities to cyberattacks, including ransomware incidents that disrupt educational processes and compromise sensitive data [1], [2], [26]. Integrating digital tools in education must be accompanied by robust cybersecurity measures to protect against threats such as data breaches and privacy violations [3], [4]. Furthermore, educational leaders play a vital role in fostering a culture of cybersecurity awareness among staff and students, ensuring they are equipped to navigate the digital landscape safely [5], [6]. Comprehensive training and resources are paramount, as many educators may lack the necessary skills to manage cybersecurity risks effectively [7], [8].

The cybersecurity landscape within educational institutions is fraught with challenges, despite an increasing recognition of its importance. Many institutions, from primary schools to universities, face significant deficiencies in their cybersecurity frameworks. Key factors contributing to this vulnerability include budget constraints, which limit the ability to invest in robust security systems, and a pervasive lack of awareness regarding the risks associated with cyber threats [1], [2]. Furthermore, insufficient resources hinder the implementation of adequate security measures, leaving institutions exposed to potential cyberattacks, such as ransomware incidents that have disrupted educational processes and compromised sensitive data [3], [4]. The reliance on digital technology for managing student information and internal communications amplifies these risks, necessitating a proactive approach to cybersecurity that includes training, awareness campaigns, and investment in protective technologies [5],[6]. Addressing these challenges is critical for safeguarding the integrity of educational environments in an increasingly digital world.

Cybersecurity frameworks such as the NIST Cybersecurity Framework and ISO/IEC 27001 have been widely adopted across various sectors to safeguard data and infrastructure against cyber threats. However, their application within educational institutions often reveals significant shortcomings, primarily due to the unique environment of openness and collaboration, which simultaneously increases cyberattack vulnerabilities [9]. This necessitates the development of a tailored security model specifically designed for the educational sector, addressing its distinct needs and challenges [10].

A comparative analysis of existing frameworks indicates that while they provide foundational guidelines, they may not fully encompass the specific operational realities of educational institutions [11]. For instance, integrating cybersecurity education into curricula is essential for fostering awareness among students and staff, yet many institutions struggle with inadequate resources and training programs [12], [13], [47]. By identifying the weaknesses in current frameworks and proposing a more suitable model, this research aims to enhance the cybersecurity posture of educational institutions, ultimately contributing to more effective cybersecurity policies and practices [14]. The findings are expected to serve as a valuable resource for policymakers and practitioners in designing targeted security measures that align with the unique demands of the education sector [15].

As digital transformation accelerates in the education sector, the danger of cyberattacks, such as ransomware and data breaches, becomes increasingly evident. Educational institutions, from K-12 schools to major universities, often lack

the technical, financial, and organisational capacity to fully implement standard cybersecurity frameworks. Instead, they need flexible solutions that suit their distinct operational structures and resource constraints.

This study critically examines three widely adopted frameworks: NIST Cybersecurity Framework, ISO/IEC 27001, and COBIT, assessing their suitability for educational settings. Based on an extensive literature review and qualitative document analysis, the study introduces a customised cybersecurity model. Consequently, this research contributes to both academic and practical fields by proposing a tailored cybersecurity framework suited to the educational environment.

The remainder of this study is organised as follows:

Section II reviews the literature on existing cybersecurity frameworks—particularly NIST, ISO/IEC 27001, and COBIT—and discusses their applicability and limitations within educational institutions.

Section III describes the research methodology, detailing the qualitative document analysis approach and data sources used to evaluate the frameworks

Section IV presents the comparative analysis results, identifies key implementation challenges, and synthesises findings to support the development of a tailored model

Section V proposes the customised cybersecurity model, explains its five core components, and discusses its practical implications for educational policy and governance.

Section VI concludes the study by summarising the main contributions, outlining limitations, and offering recommendations for future research and validation.

II. Literature Review

A. Overview of Cybersecurity Frameworks

Cybersecurity frameworks such as the NIST Cybersecurity Framework, ISO/IEC 27001, and COBIT offer comprehensive guidelines for managing cybersecurity risks. These frameworks are frequently utilised in corporate sectors but encounter difficulties in educational settings.

The NIST Cybersecurity Framework is built around five core functions: Identify, Protect, Detect, Respond, and Recover. This framework enables organisations to comprehensively understand their cybersecurity posture and effectively implement strategies to manage risks [1].

ISO/IEC 27001 focuses on information security management, systematically safeguarding sensitive organisational information. It establishes requirements for an Information Security Management System (ISMS), ensuring that information security is integrated into the organisation's overall management processes [2].

COBIT (Control Objectives for Information and Related Technologies) provides a framework for IT governance and management. It ensures that IT risks are effectively managed while supporting the achievement of organisational goals. It emphasises aligning IT and business objectives, enhancing overall governance [3].

These frameworks collectively contribute to a robust cybersecurity strategy, enabling organisations to navigate the complexities of the digital landscape.

B. Application in Educational Institutions

Implementing cybersecurity frameworks in educational institutions presents unique challenges due to their inherent culture of openness and collaboration. While frameworks like the NIST Cybersecurity Framework and ISO/IEC 27001 are widely adopted across various sectors, their application in academia often encounters difficulties. For example, the NIST Cybersecurity Framework, which emphasises five core functions—Identify, Protect, Detect, Respond, and Recover—has proven valuable in raising awareness and improving responses to cyber incidents in educational environments. However, it often falls short in addressing specific academic needs, such as protecting sensitive research data and ensuring student privacy [16],[17].

Similarly, while ISO/IEC 27001 offers a strong framework for information security management, its implementation in educational institutions can be limited by resource shortages and a lack of technical skills among staff [17]. Comparable challenges have been seen in non-educational sectors trying hybrid models [34]. Open access policies and looser controls over campus devices further increase vulnerabilities, making it easier for cybercriminals to target these weaknesses [18],[19]. Consequently, there is an urgent need for a customised cybersecurity model that reflects the specific operational realities of educational institutions, improving their capacity to safeguard sensitive data and counter cyber threats effectively [20],[21],[32].

Although these frameworks are beneficial, their inflexible structures and significant resource demands make them challenging to implement in schools and universities with limited budgets and decentralised systems.

C. Challenges and Gaps

Implementing cybersecurity frameworks in educational institutions, especially at the K-12 level, encounters significant challenges mainly due to resource limitations and cultural resistance to change. Many institutions operate with tight budgets that restrict their ability to adopt and implement all recommended controls from established frameworks like the NIST Cybersecurity Framework and ISO/IEC 27001. This financial constraint is further compounded by a shortage of IT staff with specialised cybersecurity skills, which can impede the practical application of these frameworks, even when they are adopted.

Cultural resistance to change further complicates the situation. Educational institutions often emphasise academic freedom and open access, which can conflict with strict cybersecurity measures that require tight access controls and monitoring of system usage. This tension between the need for strong cybersecurity and the desire to maintain an open, collaborative academic environment creates a challenging landscape for administrators responsible for protecting digital

infrastructure. Therefore, addressing these challenges demands a nuanced approach that balances security requirements with the core values of educational institutions.

Key barriers include:

- High complexity and implementation cost, and inconsistent use of standard risk analysis methods across institutions [27].
- Misalignment with the academic culture
- Shortage of skilled IT personnel
- Decentralised decision-making structures

D. Previous Research Findings

Previous studies highlight the necessity for a more flexible, education-specific cybersecurity framework. However, few have presented practical models customised for the educational setting.

Previous research emphasises an urgent need to adapt established cybersecurity frameworks such as NIST and ISO/IEC 27001 to better suit educational contexts. Studies show that many academic institutions often adopt only parts of these frameworks due to budget limitations and a lack of specialised expertise [22]. This partial implementation highlights the necessity for a more flexible and adaptable framework that can be customised to the specific resources and needs of educational settings [23].

Furthermore, research highlights the advantages of developing a cybersecurity framework specifically designed for educational institutions. Such a customised framework can better address unique challenges, such as protecting student data and maintaining academic freedom, compared to the generic "one-size-fits-all" approaches of existing frameworks [24]. By focusing on the specific characteristics of educational institutions, a personalised framework could enhance cybersecurity preparedness and resilience, ultimately offering stronger protection against cyber threats [25].

III. Research Methodology

A. Research Design

The research methodology for this study adopts a qualitative approach, primarily using document analysis as the main method for data collection and analysis. This approach effectively investigates how various cybersecurity frameworks are adopted within educational institutions, enabling a detailed examination of the challenges and weaknesses faced during their implementation. Document analysis allows for the review of published policies, research reports, and relevant case studies, providing valuable insights into current practices and highlighting potential areas for further improvement.

Previous research has underscored the significance of customising cybersecurity frameworks to fit the particular context of educational institutions. For example, it highlights the need to understand the components of cybersecurity standards and frameworks to guide future research. Furthermore, it reviews the key factors that influence the implementation of information security management systems, which are important when assessing educational settings. Analysing these documents helps to identify the unique challenges faced by educational institutions in adopting frameworks such as NIST and ISO/IEC 27001, ultimately assisting in the development of a tailored cybersecurity model that addresses their specific needs.

B. Data Collection Method: Document Analysis

Document analysis serves as the primary data collection method for this study. The documents analysed include various sources such as:

- Cybersecurity Policy Reports: Reports published by educational institutions, government agencies, and non-governmental organisations focusing on implementing cybersecurity in the education sector.
- Case Studies: Published case studies on the implementation of cybersecurity frameworks in various educational institutions worldwide, providing empirical data on the effectiveness and challenges of these frameworks.
- Journal and Conference Articles: Peer-reviewed academic articles discussing the implementation of cybersecurity frameworks in educational settings and providing critical assessments of their suitability, as well as reviews of ICT tools used in higher education [46].
- Cybersecurity Standards and Guidelines: Official documents detailing standards and guidelines such as the NIST Cybersecurity Framework, ISO/IEC 27001, and COBIT and how these standards are adapted or used in educational institutions.

The data collection process through document analysis involves several key steps:

- Identification of Documents: Relevant documents were identified through searches in academic databases such as Scopus, IEEE Xplore, and Google Scholar, as well as through the websites of related organisations like NIST and ISO.
- Document Selection: Documents were selected based on relevance, reliability, and coverage. Documents specifically focused on the education sector or providing a critical evaluation of cybersecurity framework implementation were considered primary sources.
- Data Extraction: Key information from each document was extracted and organised based on the identified themes, such as framework effectiveness, implementation challenges, and adaptation for educational environments.

A total of 42 documents were examined in this study, chosen for their relevance, reliability, and direct link to cybersecurity in educational institutions. The distribution of documents is presented in Table I.

TABLE I. DOCUMENT AND SELECTION OVERVIEW

Document Type	Number	Source	Selection Criteria
Cybersecurity Policy Reports	10	Institutional & government sites	Targeting education sector; policy focus
Case Studies	8	Journals, conferences	Practical application of NIST, ISO/IEC 27001, or COBIT
Journal Articles	20	Scopus, IEEE Xplore, Google Scholar	Peer-reviewed, published 2018 or later
Framework Guidelines	4	NIST, ISO, ISACA	Descriptions of CSF, ISMS, and COBIT frameworks

C. Data Analysis

Document analysis was performed manually employing thematic coding grounded in principles of grounded theory. The procedure involved these steps:

1) Initial reading: Documents were read line by line to gain familiarity.

2) Open coding: Keywords and key ideas were extracted manually using Excel spreadsheets (no qualitative software used).

3) Axial coding: Categories were formed by linking similar open codes (e.g., "resource constraints", "training gaps").

4) Selective coding: Central themes such as "framework limitations" and "cultural mismatch" were identified.

The coding process and resulting categories are illustrated in Table II.

TABLE II. EXAMPLES OF CODE CATEGORIES AND THEMES

Open Code	Axial Category	Selective Theme
High cost of ISO adoption	Resource Limitation	Framework Limitations
Lack of IT staff	Resource Limitation	Framework Limitations
Decentralized departments	Governance Challenges	Cultural Misalignment
Need for open access	Academic Openness	Cultural Misalignment

This analysis provides a strong foundation for comparing different cybersecurity frameworks and evaluating their suitability for educational institutions. The results will be used to support the argument that a tailored cybersecurity model is explicitly needed for the education sector.

D. Research Workflow

The research process is summarized in Fig. 1, which illustrates the flow from literature review to framework synthesis and model development.

Fig. 1 illustrates the structured research design employed in this study, beginning with a literature review phase aimed at identifying existing cybersecurity frameworks and their known limitations in educational settings. This crucial step informed the subsequent document analysis, during which a selection of 42 documents, including policies, case studies, and academic research, were systematically examined using thematic coding techniques.

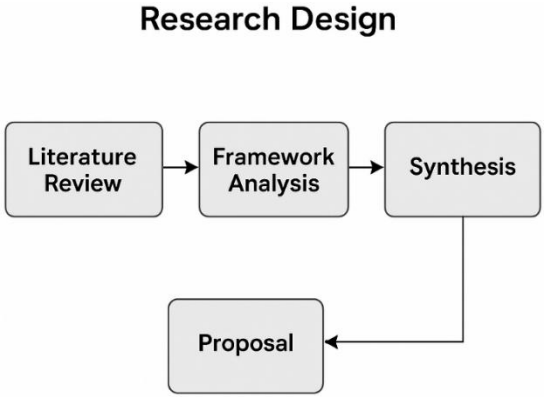

Fig. 1. Research design.

The insights gained from document analysis were then combined to identify common challenges and individual institutional needs. These findings were compared with key frameworks (NIST, ISO/IEC 27001, and COBIT) to highlight areas of misalignment, as shown in the figure.

Following this, the study moved on to the framework synthesis phase, where key insights were turned into a conceptual model specifically designed for the education sector. This iterative design phase focused on flexibility, contextual relevance, and feasibility.

Finally, the model was prepared for validation planning, including designing a pilot implementation strategy, conducting expert interviews, and performing document audits, ensuring the framework's applicability could be tested in real-world educational contexts.

In essence, Fig. 1 serves as a visual guide to the research process, emphasising the logical sequence and interaction between each phase from initial inquiry to framework development and planned validation.

IV. RESULTS

A. Comparative Analysis of Frameworks

The strengths and limitations of NIST, ISO/IEC 27001, and COBIT frameworks are compared in Table III, based on six key criteria relevant to the educational context.

TABLE III. COMPARATIVE ANALYSIS OF FRAMEWORKS

Criteria	NIST CSF	ISO/IEC 27001	COBIT
Scope	Risk management	ISMS	IT Governance
Complexity	High	High	Moderate
Suitability for Education	Partial	Partial	Limited
Adaptability	Flexible but needs expertise	Rigid	Moderately adaptable
Resource Requirement	High	High	Moderate
Academic Alignment	Limited	Limited	Limited

After conducting document analysis, including various cybersecurity frameworks such as the NIST Cybersecurity Framework, ISO/IEC 27001, and COBIT, we found that while these frameworks offer comprehensive approaches to

cybersecurity management, they often do not fully align with educational institutions' specific needs.

1) NIST Cybersecurity framework: This framework helps organisations understand and manage cybersecurity risks through five core functions: Identify, Protect, Detect, Respond, and Recover. However, it is sometimes too complex to fully implement in the educational context, particularly in institutions with limited resources like K-12 schools. Reports show that many academic institutions can only implement parts of this framework, especially those requiring lower technical and financial investment.

2) ISO/IEC 27001: This framework provides a highly structured approach to information security management, focusing on developing and maintaining an Information Security Management System (ISMS). Although it has been successfully adopted in various sectors, challenges occur when used in educational institutions, where decentralisation and a lack of specialised expertise in information security management pose significant barriers. Research also indicates that implementing ISO/IEC 27001 in the education sector often requires considerable adaptation, as not all recommended controls and policies are relevant or practical for academic environments.

3) COBIT: Focusing on IT governance, COBIT offers a useful framework for ensuring that IT risks are managed effectively and support the organisation's strategic aims. However, when applied in educational institutions, such as large universities with complex organisational structures, this framework often encounters difficulties in enforcing uniform policies across various departments and faculties. A study found that while COBIT provides strong guidance for IT governance, its implementation in academic environments is frequently hindered by resistance to change and cultural differences across departments.

B. Identification of Key Gaps

The comparative analysis reveals several key weaknesses in the existing cybersecurity frameworks when applied to educational institutions:

1) Complexity of implementation: Frameworks like NIST and ISO/IEC 27001 are often too complex to fully implement without a structured decision-making approach tailored for educational cybersecurity [28], particularly those with limited resources. These limitations mean that many schools can only adopt parts of these frameworks, ultimately leaving gaps in their protection.

2) Misalignment with academic culture: Many cybersecurity frameworks are designed for more structured and controlled corporate environments. However, educational institutions often have a more open and collaborative culture, which can conflict with the need for strict access controls and monitoring of system usage.

3) Lack of resources and expertise: Implementing frameworks like ISO/IEC 27001 requires significant human and financial resources, which educational institutions often lack. Additionally, the shortage of IT staff with specialised cybersecurity skills is a substantial barrier to practical implementation.

4) Decentralised organisational structure: Educational institutions, such as huge universities, often have decentralised organisational structures, with different departments having varying policies and technological needs. This makes it challenging to implement a uniform framework across the institution, as reaching a consensus on security policies and procedures can be difficult.

C. Synthesis of Findings

The results of this document analysis emphasise an urgent need to develop a cybersecurity model that better fits the specific requirements of educational institutions. This customised model should consider resource limitations, academic culture, and the unique organisational structures of educational institutions. Although frameworks like NIST, ISO/IEC 27001, and COBIT offer valuable guidance, there are emerging suggestions for sector-specific cybersecurity frameworks to reduce attacks [29], and further adaptation and personalisation are necessary for successful implementation in the education sector.

The synthesis of these findings suggests that a more modular and adaptable cybersecurity framework is required to address the varied needs of educational institutions. This framework should enable institutions to implement the most relevant security controls that match their capabilities, without strictly following all recommendations.

V. Discussion

A. Interpretation of Results

The comparative analysis results demonstrate that while cybersecurity frameworks such as the NIST Cybersecurity Framework, ISO/IEC 27001, and COBIT provide a strong foundation for managing cybersecurity risks, they often do not fully meet the specific needs of educational institutions. The main barriers to applying these frameworks in the education sector are the complexity of implementation, misalignment with academic culture, lack of resources, and decentralised organisational structures.

One key finding from this study is that existing frameworks are too rigid and focused on industrial sectors. A more holistic cybersecurity strategy may help bridge this contextual gap [41], [42], where operational environments tend to be more structured and hierarchical. In contrast, educational institutions have different needs, including supporting academic freedom and interdepartmental collaboration, which often conflict with strict cybersecurity principles. Therefore, a customised model is required to balance the need for stringent security with the open and flexible environment of educational institutions.

B. Proposing a Tailored Security Model

The components of the proposed model are outlined in Table IV.

TABLE IV. COMPONENTS OF THE TAILORED CYBERSECURITY MODEL

Component	Description (Concise)	Key Benefit
Modular Architecture	Flexible modules based on institutional size and context	Scalable and customisable
Cultural Integration	Support open collaboration while maintaining access control	Preserves academic freedom
Resource Optimization	Focus on cost-effective tools and strategic prioritisation	Feasible within limited budgets
Decentralized Governance	Tailored policies for departments with coordinated oversight	Compatible with the academic structure
Emerging Tech Integration	Integrate AI/IoT for proactive security posture	Future-proof and proactive

Expanded Explanation:

1) Modular and flexible structure: Educational institutions vary significantly in size, budget, and IT capacity. A one-size-fits-all cybersecurity framework [39] is neither practical nor effective. This approach encourages modularity, allowing each institution to select and implement only the components relevant to their risk profile, maturity level, and resources. Such flexibility makes the model scalable and adaptable. Interactive tools and gamified learning environments have shown potential in improving engagement [35].

2) Integration with educational culture: Academic institutions value openness, collaboration, and autonomy. A fundamental cybersecurity culture at all levels of the institution can help reinforce these values safely [49]. Therefore, the cybersecurity framework must balance protection with freedom. It promotes policies that facilitate secure departmental cooperation and integrates cybersecurity education into the institutional culture while addressing human-centric factors such as awareness and behavioural hygiene [43], which can be further supported through active learning-based security training [30], fostering awareness and behavioural change among faculty, staff, and students..

3) Resource optimisation: Recognising the budgetary and staffing constraints faced by most educational institutions, the framework encourages cost-effective practices. It promotes the use of open-source or shared security tools, centralised support services where feasible, and risk-based prioritisation to ensure limited resources are allocated to the most vulnerable or impactful areas. Adaptive training models for end-users also support cost-effective implementation [44].

4) Decentralised implementation: Given the diversity of academic departments, a centralised, rigid policy often faces opposition. Instead, this approach supports decentralised implementation within a central guiding framework, allowing departments to develop context-specific solutions while aligning with overall institutional aims. This respects local autonomy whilst maintaining institutional coherence.

5) Emerging technology integration: To stay relevant amidst the changing threat landscape, the framework includes provisions for adopting new technologies such as Artificial Intelligence, Internet of Things (IoT), and real-time analytics. These features improve early detection, response, and adaptive resilience across the institution.

Together, these components tackle the challenges identified in the previous analysis and offer a practical route to improve cybersecurity preparedness in the education sector.

To address the unique cybersecurity challenges faced by educational institutions, including structural decentralisation, limited resources, and the need to preserve academic openness, this study developed a tailored cybersecurity framework. The framework was constructed based on the synthesis of findings from comparative analysis and thematic coding, resulting in a model that is both theoretically grounded and practically applicable across various educational contexts. As shown in Fig. 2, the proposed framework comprises five key components: Modular Architecture, Cultural Integration, Resource Optimisation, Decentralised Governance, and Emerging Technology Integration. These components work together to form a cohesive and adaptable strategy designed to enhance cybersecurity readiness within the academic environment.

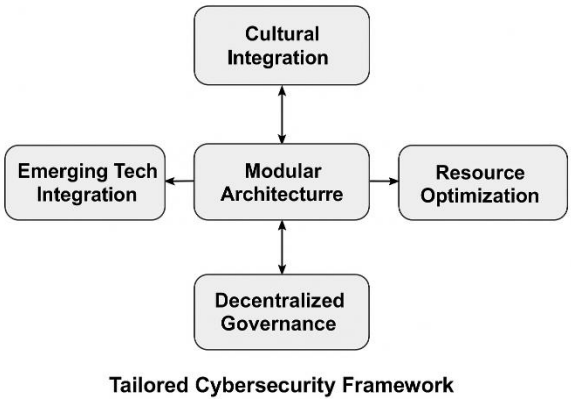

Fig. 2. Tailored cybersecurity framework for educational institutions.

C. Implications for Policy and Practice

The implications of developing a tailored cybersecurity model are significant for policy and practice in educational institutions. First, this model can guide policymakers in developing regulations and policies that are more aligned with the needs of the education sector. For example, existing regulations may need to be adjusted to provide more flexibility to educational institutions in adopting relevant security controls without burdening them with unrealistic requirements.

Second, this model can assist educational institutions in managing cybersecurity risks more effectively and positively influence their performance, as shown in regional studies [36], without compromising core values like academic freedom and collaboration. By adopting a more modular and adaptable approach, educational institutions can notably enhance their cybersecurity stance while fostering an environment that promotes learning and innovation.

D. Comparison with Existing Studies

This research aligns with previous studies that have identified the shortcomings of current cybersecurity frameworks in meeting the specific needs of the education

sector. For example, studies have shown that frameworks like NIST and ISO/IEC 27001 often fail to account for the decentralised nature and resource limitations typical of educational institutions [31],[33]. While these studies mainly examine the challenges of implementing existing frameworks, this research progresses the discussion by highlighting these weaknesses and proposing a customised cybersecurity model specifically designed for educational institutions, recognising the curriculum-level gaps still common in cybersecurity education [45].

Furthermore, existing literature emphasises adapting cybersecurity frameworks to fit the educational context better; however, it often stops short of providing actionable solutions [40], [37]. In contrast, this study offers practical guidance for developing and implementing a customised cybersecurity model, filling a critical literature gap. This research contributes significantly to the ongoing efforts to enhance cybersecurity in the education sector by addressing the challenges and providing concrete solutions.

E. Limitations and Future Research Directions

While this research provides valuable insights into the need for a tailored cybersecurity model in educational institutions, several limitations must be acknowledged. First, this research is limited to document analysis, so it does not include empirical data from implementing the proposed model. Therefore, further validation is needed through case studies or field experiments to test the effectiveness of this model in real-world contexts.

Additionally, this research focuses on educational institutions in countries with relatively advanced IT infrastructures. Future research should consider different contexts, such as academic institutions in developing countries, which may face various challenges in implementing cybersecurity.

Future research should also examine how new technologies, such as artificial intelligence (AI) and the Internet of Things (IoT), can be incorporated into a customised cybersecurity model and assist workforce development using established frameworks like NICE [38]. These technologies have significant potential to strengthen security, but also introduce new challenges that must be tackled.

VI. Conclusion and Recommendations

A. Summary of Key Findings

This research has conducted a comparative analysis of several cybersecurity frameworks used in educational institutions, including the NIST Cybersecurity Framework, ISO/IEC 27001, and COBIT. The main findings indicate that while these frameworks provide a solid foundation for cybersecurity management, they often do not fully align with educational institutions' unique needs. Implementation complexity, misalignment with academic culture, resource limitations, and decentralised organisational structures are the main challenges that hinder the practical application of existing frameworks in the education sector.

Based on the analysis results, this research proposes to develop a cybersecurity model explicitly tailored to the education sector. The proposed model emphasises flexibility, modularity, and resource optimisation, allowing educational institutions to adopt the most relevant security controls that align with their needs. This model supports the open and collaborative academic culture while maintaining high security standards.

B. Theoretical and Practical Contributions

This research makes significant contributions both theoretically and practically. Theoretically, it adds to the knowledge of the challenges and weaknesses of existing cybersecurity frameworks in the educational context. This research also offers an alternative model that is more suited to the needs of this sector, providing a foundation for further research to develop and test customised security models.

Practically, policymakers and practitioners in educational institutions can use the proposed model in this research to improve their cybersecurity posture. By adopting a more flexible and modular approach, educational institutions can more effectively manage cyber risks without compromising their core values, such as academic freedom and collaboration.

C. Limitations

While this research offers valuable insights, several limitations need to be acknowledged. This research is limited to document analysis and does not include empirical data from implementing the proposed model. Therefore, further research is required to test this model's effectiveness in real-world contexts. Additionally, this research focuses on educational institutions in countries with relatively advanced IT infrastructures so that different contexts may require adaptation of the proposed model.

D. Suggestions for Future Research

While this research provides valuable insights into the need for a customised cybersecurity model in educational institutions, further development is needed to address the sector's changing challenges. Future studies should aim to develop and empirically verify a cybersecurity framework specifically designed for educational settings. Such a framework should be adaptable and scalable, considering the diverse needs of institutions ranging from small K-12 schools to large universities. Research should investigate how this customised framework can incorporate emerging technologies like artificial intelligence (AI) and the Internet of Things (IoT) to strengthen cybersecurity without hindering academic freedom and collaboration. Additionally, the framework should be tested across different educational environments globally, including practical simulation settings like cyber ranges for training [48], to ensure its applicability and effectiveness in various cultural and organisational contexts.

Acknowledgment

This publication could not have been accomplished without the institution's extraordinary assistance. We also want to thank the reviewers whose suggestions will help tomake this manuscript eligible for publication.

The Representation Learning Ability of Self-Supervised Learning in Unlabeled Image Data

Jinzhu Lin*, Tianwei Ni
School of Big Data and Artificial Intelligence, Xinyang College, Xinyang 464000, China

***Abstract*—Many existing systems struggle to strike a balance between global feature discrimination and local semantic understanding, despite the growing popularity of Self-Supervised Learning (SSL) for representation learning with unlabeled image data. This study introduces a novel SSL framework—Contrastive and Contextual Self-Supervised Representation Learning (C2SRL)—which integrates contrastive learning mechanisms with auxiliary context-based pretext tasks, specifically rotation prediction and jigsaw puzzle solving. The proposed C2SRL enhances two leading constructive models, SimCLR and MoCo, by incorporating contextual modules and a unified multi-task loss function, thereby improving the robustness and generalizability of the learned representations. A lightweight ResNet backbone is employed for encoding, followed by a dual-view augmentation strategy and a projection head that maps features into a contrastive embedding space. The proposed C2SRL outperforms existing SSL approaches in terms of classification accuracy and clustering coherence on the STL-10 and CIFAR-10 datasets, two benchmark datasets. It demonstrates strong scalability, as evidenced by its 89.6% mAP and 0.81 NMI, achieved using only 10% labeled data for fine-tuning. These results highlight the potential of combining contextual and contrastive learning objectives to generate rich, transferable visual representations for low-label or label-free applications.**

Keywords*—*Self-supervised learning (SSL); unlabeled image data; representation learning; contrastive learning; convolutional neural network (CNN); image classification; feature embedding; label-efficient learning

I. Introduction

A. Background and Motivation

Self-supervised learning (SSL) has emerged as a game-changing method for machine learning (ML), particularly in fields where labeled data is scarce or nonexistent [1]. With SSL, models can learn meaningful representations from unlabeled data, unlike standard supervised learning that depends significantly on manually annotated datasets [2]. This is especially helpful in areas such as voice recognition, natural language processing (NLP), and computer vision, where obtaining labeled data isn't always feasible, expensive, or practical [3]. One significant benefit of SSL is that it can utilize pretextual jobs to generate supervisory signals directly from the data, allowing it to extract high-level characteristics [4]. Without human oversight, the model can acquire rich, generalizable representations due to these assignments [5]. Many currently consider SSL an effective method for developing scalable models that can utilize what they've learned for subsequent tasks, such as segmentation, object identification, and image classification [6]. An increasing number of real-world applications have found that obtaining labeled data is a significant challenge, and SSL provides a possible solution for model creation in these situations [7]. For example, specific fields include medical imaging, autonomous driving, and surveillance, where annotating data would be impractical or expensive [8].

B. Problem Statement

Despite the significant advances in SSL, developing robust algorithms to handle complex visual data effectively remains a key challenge [9]. To achieve existing performance, traditional deep learning (DL) models, such as CNNs, often require massive labeled datasets [10]. Unlabeled data poses a significant challenge for these models when generalizing to real-world problems, as it is difficult to extract discriminative features [11]. The absence of supervisory signals is the primary obstacle in SSL, as it hinders models' ability to acquire valuable representations [12]. The use of positive and negative pairings for learning representations has shown promise in contrastive learning-based techniques (e.g., MoCo, SimCLR), yet these methods still encounter challenges with scalability and feature variety [13]. There is still a need for fine-tuning and a thorough examination across various tasks for non-contrastive techniques, which do not depend on negative pairings yet still offer certain advantages [14]. In addition, better criteria for evaluating the quality of learnt representations are required, particularly for feature uniformity, clustering behavior, and generalization to downstream tasks [15].

C. Motivation for the Proposed Framework

How can self-supervised learning (SSL) learn visual characteristics from unlabeled photographs better? Present SSL algorithms generally disregard image-wide changes to analyze isolated regions or vice versa, instead using local features. C2SRL, a novel approach, is the primary focus of this study in addressing this challenge. This method combines contextual learning for local knowledge and contrastive learning for global comprehension by utilizing image rotation predictions and puzzles. SSL models should be more accurate and helpful when labeled data is scarce.

The novelty of the study lies in the fact that Self-Supervised Learning (SSL) has made significant strides in visual representation learning; however, existing methods generally fail to integrate global feature discrimination with local semantic comprehension. Most modern models employ contrastive aims, which overlook fine-grained picture context in favor of instance-level differences, particularly in the cases of SimCLR and MoCo. They struggle with spatial awareness and structural coherence tests due to this deficiency. Although some have

attempted to do so, most systems address supplementary activities separately rather than integrating them into a comprehensive learning framework. Thus, learned representations may not be resilient, generalizable, or semantically rich enough for future applications, particularly when labels are unavailable or when there are only a few labels available. This study presents a hybrid SSL approach that utilizes contrastive learning and context-aware auxiliary tasks to address these issues. The model optimizes many tasks. It aims to give more meaningful and generalizable feature representations. Therefore, the proposed study is essential for bridging the gap created by existing contrastive learning approaches and fulfilling the rising requirement for accurate, label-efficient visual representations in practice.

D. Objectives and Scope

The primary objectives of this research are:

- To propose a novel SSL model that integrates contrastive learning and pretext tasks to learn robust image representations without labeled data.
- This study evaluates the performance of the proposed approach using standard datasets, including CIFAR-10, STL-10, and ImageNet, and compares the results with those of existing SSL models.
- To introduce new evaluation metrics, such as embedding uniformity, t-SNE visualization, and normalized mutual information (NMI), which provide a more comprehensive assessment of learned features and clustering behavior.

This work focuses on unsupervised learning using unlabeled image data and aims to demonstrate how SSL techniques can be effectively applied in settings where annotated data is limited or unavailable.

E. Contributions of the Study

The contributions of this research are as follows:

- Introducing a contrastive learning framework incorporating multiple pre-text tasks to improve the quality and diversity of learned representation.
- Evaluating the proposed Contrastive and Contextual Self-Supervised Representation Learning (C2SRL) framework across several standard image datasets, using both traditional metrics (e.g., accuracy) and novel evaluation techniques (e.g., embedding uniformity score).
- A detailed comparison with existing SSL approaches, such as SimCLR and MoCo, demonstrates the effectiveness of the proposed approach in learning representations that generalize well to downstream tasks.

F. Structure of the Study

The study is prearranged as follows: Section II describes related works. Section III describes the suggested C2SRL model. Section IV offers experimental outcomes. Section V presents the discussion. Finally, Section VI concludes the study by discussing potential future work.

II. Literature Survey

Banafshe Felfeliyan et al. [16] suggested the Mask-Region-based Convolutional Neural Network (MRCNN) for Medical Image Segmentation with Limited Data Annotation. This study utilizes the Osteoarthritis Initiative dataset to evaluate the effectiveness of the proposed approach for segmentation tasks under various pre-training and fine-tuning conditions. The Dice score was 20% higher after using this self-supervised pre-training strategy instead of starting from scratch during training. Anomaly detection, segmentation, and classification are just a few examples of medical image analysis tasks that may benefit from the proposed SSL. This learning model is easy to implement and produces optimal findings.

Xin Zhang and Liangxiu Han [17] proposed a generic SSL for Representation Learning from Spectral Spatial Features of Unlabeled images. Innovative pretext problems for object- or pixel-based remote sensing data interpretation systems are planned. One pretext task can retrieve spectral characteristics from masked data. This allows pixel data extraction and activity acceleration via pixel-based analysis. Two popular downstream task evaluation activities show how the SSL approach learns a target representation from vast volumes of unlabeled spatial and spectral data.

Soroosh Tayebi Arasteh et al. [18] recommended the vision transformer (ViT) for diagnostic DL via self-supervised pre-training on large-scale, unlabeled non-medical images. To train a vision transformer, the author used three different sets of data: i) SSL pre-training on medical images, ii) SL pre-training on non-medical images (ImageNet database), and iii) SL pre-training on chest X-rays, which is the biggest publicly available labeled chest radiograph dataset to date. Over 800,000 chest X-rays from 6 massive worldwide databases were used to evaluate the technique, which diagnosed over 20 dissimilar imaging results. Statistical significance was assessed using bootstrapping, and performance was measured by computing the area under the ROC curve. Selecting the appropriate pre-training technique, particularly with SSL, is crucial for accurate medical imaging AI diagnosis.

Jiahe Shi et al. [19] discussed the Self-supervised On-device Federated Learning (SSL-OD-FL) from Unlabeled Streams. Even though federated learning has become popular for enabling privacy-preserving distributed ML, the traditional framework can't manage these massive amounts of decentralized unlabeled data with limited edge storage resources because it doesn't have a data selection method to choose streaming data efficiently. Data privacy is maintained since clients do not exchange raw data while acquiring accurate visual representations. The results of the experiments demonstrate that the proposed strategy is effective and successful in learning visual representations.

Chen Zhang et al. [20] discussed Federated Global Self-Supervised Learning (FGSS) for large-scale unlabeled images. The author devised an accumulation technique that takes into account the fact that every customer's local data is unique by adjusting the weight of each local model according to the size of its dataset and the frequency of its contacts. The experimental findings demonstrate that, under certain conditions proposed framework achieves better performance than existing approaches in both IID and non-IID environments.

M.A.F. Abdollah et al. [21] presented a Transformer encoder-based SSL approach for HVAC fault recognition using unlabeled images. The two-state Markov chain method deliberately hides parts of the multivariate time-series information. Predicting these hidden parts trains the model. This method offers a scalable solution for real-world HVAC applications that is not reliant on labeled data. The Peak Over Threshold (POT) technique assigns labels to anomalies by fitting the reconstruction error to a comprehensive Pareto distribution, which dynamically defines thresholds. The model's capacity to identify both sequential and individual errors is shown. A failure period was identified from October 19th to December 23rd due to a change in the data trend observed by the monitoring system.

Depeng Kong et al. [22] introduced the contrastive learning-based knowledge transfer technique (CLTrans) for semi-supervised fault analysis. Using unsupervised similarity matching on massive amounts of unlabeled data, CLTrans improves downstream tasks. A CLTrans-pre-trained feature encoder can effectively adapt to varied tasks, regardless of the data distribution, and extract a discriminative representation of the vibration signal. Experimental findings show that CLTrans beats traditional DL and existing semi-supervised fault diagnostic methods in terms of accuracy and domain adaptability, particularly when working with restricted labels. Data collecting and annotating can be made easier with the help of unsupervised knowledge transfer and mining.

Zhonglin Zuo et al. [23] examined an unlabeled multi-class non-leak data system for autonomously identifying leaks in natural gas collecting pipelines. The representation learning of the semi-supervised model is enhanced by the suggested SSL approach, and unlabeled multi-class non-leak data is modeled using the supplied multi-sphere support vector data description. Through the integration of feature clustering and pseudo-label-based classification, the ability to learn unsupervised multi-class non-leakage information categories is made possible. Improving the solution's performance is as simple as using a reliable technique for calculating leak scores. Finally, the experimental findings using pipeline field data demonstrate that the proposed strategy is effective.

Most current methods focus on context-based tasks or contrastive learning alone, overlooking the potential synergistic advantages of combining the two paradigms, despite SSL having made significant progress with models like MoCo and SimCLR. Much previous work overlooks generalizability to downstream tasks without supervision or resilience across various augmentation contexts, instead focusing on the quality of representation. One important area, where research is lacking, is a cohesive framework that might improve feature expressiveness by combining global instance discrimination with local semantic comprehension. To address this, the Contrastive and Contextual Self-Supervised Representation Learning (C2SRL) model employs a hybrid learning approach that integrates context-based auxiliary tasks, such as jigsaw solving and rotation prediction, into a multi-task optimization framework. This model aims to close the gap between the two approaches. Due to this integration, the learned representations become more flexible and robust in terms of semantic richness and structural coherence. To achieve better results on downstream picture interpretation tasks, even in situations with little labeled data, the C2SRL model's unique dual-focus design combines global contrastive goals with fine-grained contextual cues.

III. Contrastive and Contextual Self-Supervised Representation Learning (C2SRL)

The capability to learn visual representations from unlabeled image data using pretext tasks, such as transformation prediction and instance discrimination, has been demonstrated by existing self-supervised methods. Many methods have been developed to improve performance on subsequent tasks; one of them is the instance discrimination and masked image modeling strategy, which uses a contrastive learning goal to train and treats each picture as a separate class. There is a significant data gap between this achievement and real-world data for future purposes, including city sceneries or crowd scenes, as it relies on the carefully selected object-centric dataset ImageNet. Without understanding the scene's fundamental architecture—its numerous objects and intricate layouts—instance discrimination pretext would severely limit the use of scene-centric data for pre-training. Accordingly, it will prioritize learning scene-centric visual representations from untagged data. Two major schools of thought have emerged in recent years to address this question. Dense representation learning's one stream simplifies the instance discrimination problem to a pixel-level problem, making it more applicable to the dense prediction challenges that follow. However, these approaches are still unable to learn representations because they cannot replicate the object-level interactions observed in scene-centric data. Unsupervised clustering, saliency estimators, unsupervised object proposal algorithms, and handcrafted segmentation algorithms rely on domain-specific priors for object identification. However, there is another line of study that attempts to accomplish object-level representation learning.

Fig. 1 shows the proposed C2SRL Model. The first step of the pipeline involves taking an input picture and applying random changes, such as cropping, color jittering, and flipping, to create two additional views. Following the passage of these views through a common encoder network, typically a convolutional neural network such as ResNet, a projection head is used to convert the high-dimensional features into a lower-dimensional embedding space that is optimal for computing contrastive loss. Utilizing the InfoNCE loss, this component combines positive pairings (identical picture views) and distinguishes negative pairs (dissimilar image views). Rotation prediction and jigsaw puzzle solving are context-aware auxiliary tasks with the same encoder. With rotation prediction, this research can train a classifier to anticipate which of four predetermined angles to rotate pictures by, prompting the network to identify characteristics unique to each orientation. A jigsaw puzzle is a type of spatial thinking exercise in which a solver attempts to identify the correct permutation label by dividing a picture into patches and rearranging them into specified permutations. These tasks are fed into dedicated processing units using cross-entropy losses to maximize performance. Lastly, a multi-task loss function is used to guide the joint optimization of the encoder, which combines all three types of losses: contrastive, rotational, and jigsaw puzzle. The result is a strong, pre-trained encoder that can make sense of data

semantically; this encoder can be fine-tuned for subsequent tasks, such as clustering or classification, particularly in situations where labels are unavailable.

A. Multi-View Generation and Representation Embedding

In the first phase of C2SRL, the model processes raw, unlabeled input data $x_i \in D$ through stochastic data augmentation strategies. The aim is to produce semantically invariant yet appearance-diverse views that simulate real-world variance. The two augmentations x_i^1 and x_i^2 for each image, random transformations T_1 and T_2, which include color distortion, cropping, flipping, and Gaussian noise, as in Eq. (1).

$$x_i^{(1)}, x_i^{(2)} = T_1(x_i),\ T_2(x_i), \quad where\ T_1\ and\ T_2 \sim A \qquad (1)$$

Each augmented view is then passed through a shared convolutional encoder network $f: \mathbb{R}^{H\times W\times C} \to \mathbb{R}^d$, such as ResNet-50, to extract high-level semantic features, as in Eq. (2):

$$h_i^{(1)} = f\left(x_i^{(1)}\right), \quad h_i^{(2)} = f\left(x_i^{(2)}\right) \qquad (2)$$

To reduce overfitting and enforce contrastive separation in the latent space, this research further maps these embeddings through a projection head $g: \mathbb{R}^d \to \mathbb{R}^{d'}$, often implemented as a 2-layer MLP with ReLU and BatchNorm, as in Eq. (3):

$$z_i^{(1)} = g\left(h_i^{(1)}\right), \quad z_i^{(2)} = g\left(h_i^{(2)}\right) \qquad (3)$$

Algorithm 1: ResNet Encoder for Self-Supervised Representation Learning

Input:
Augmented image view $v \in \mathbb{R}^{\{H\times W\times 3\}}$
ResNet depth: ResNet-18, ResNet-50.

Output:
Representation vector $h \in \mathbb{R}^d$

1: function ResNet_Encoder(v):
2: # Initial convolution and max pooling
3: $x \leftarrow Conv2D(v, kernel_size = 7\times 7, stride = 2, padding = 3)$
4: $x \leftarrow BatchNorm(x)$
5: $x \leftarrow ReLU(x)$
6: $x \leftarrow MaxPool2D(x, kernel_size = 3\times 3, stride = 2, padding = 1)$
7: # Residual blocks (based on depth)

14: # Flatten and normalize
15: $h \leftarrow Flatten(x)$
16: $h \leftarrow Normalize(h)$
17: return h

Algorithm 1 shows the ResNet Encoder for Self-Supervised Representation Learning. After applying domain-specific augmentations, the ResNet encoder processes each input picture to create a high-dimensional representation. Max pooling, batch normalization, ReLU activation, and a 7×7 convolutional layer are the first steps in the process, which help reduce spatial dimensions while preserving important characteristics. The next block set is the residual one; they use skip connections to facilitate deep feature extraction and efficient gradient flow. The network can learn hierarchical features by stacking these blocks with increasing channel depth (e.g., 64, 128, 256, 512 filters). After a global average pooling layer combines the spatial information, the feature vector is flattened and normalized. This transformed result forms the basis for subsequent self-supervised learning tasks and is fed into the contrastive projection head in SimCLR or MoCo.

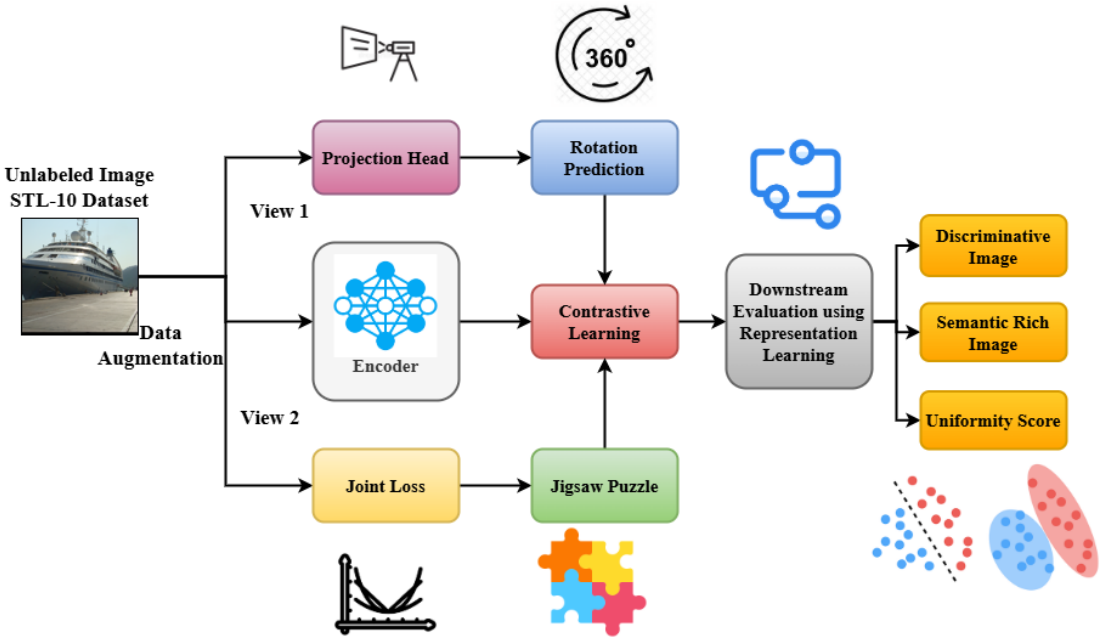

Fig. 1. Proposed C2SRL model.

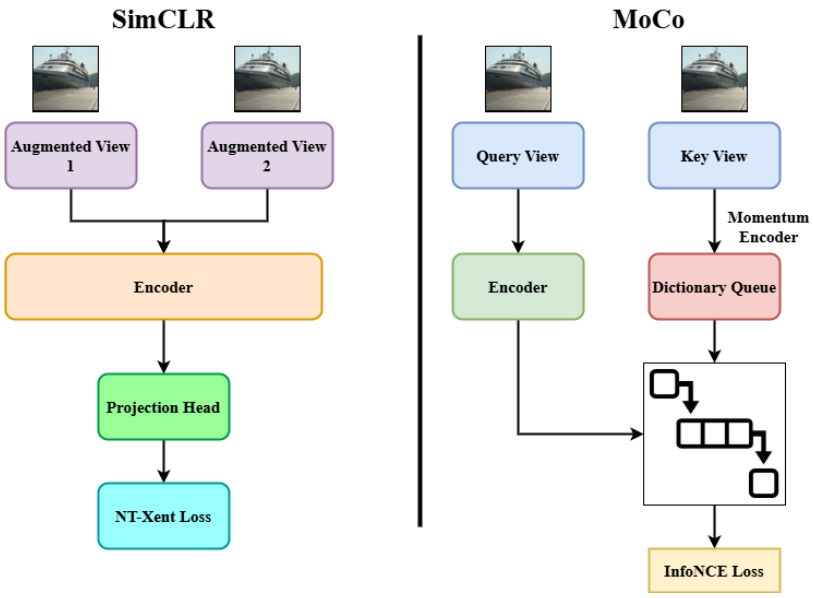

Fig. 2. SimCLR versus MoCo pipeline comparison.

Fig. 2 illustrates the comparison between the SimCLR and MoCo pipelines. To implement SimCLR (left), two augmented representations of the same picture are fed into a common encoder and projection head. Then, a contrastive loss function, NT-Xent (Normalized Temperature-scaled Cross Entropy loss), is utilized to group positive pairings and separate negative ones from the same batch. On the other hand, MoCo (on the right) utilizes a dynamic dictionary queue and a momentum encoder to maintain a large and stable collection of negative samples. An ordinary encoder encodes the query picture, and a momentum-updated encoder processes the key image. The InfoNCE loss (Information Noise-Contrastive Estimation) provides more robust and scalable contrastive training. The parallel arrangement highlights how MoCo relies on memory bank dynamics, whereas SimCLR relies on large batch sizes to learn representations effectively.

B. Contrastive and Contextual Objective Functions

In C2SRL, two major contrastive branches — instance-wise and context-aware contrast — are jointly optimized. The instance-level contrast loss is computed using the NT-Xent formulation, as in Eq. (4):

$$\mathcal{L}_i^{SimCLR} = -\log \frac{\exp\left(\frac{sim\left(z_i^{(1)}, z_i^{(2)}\right)}{\tau}\right)}{\sum_{j=1}^{2N} 1_{[j\neq i]} \exp\left(\frac{sim\left(z_i^{(1)}, z_j\right)}{\tau}\right)} \quad (4)$$

Here, $Sim(.)$ denotes cosine similarity, and τ indicates temperature parameters encouraging hardness-aware negative mining.

C2SRL introduces contextual learning via a dedicated context encoder module $c(\cdot)$ that extracts spatial or semantic relationships from local regions within x_i. Let $c_i = c(x_i) \in \mathbb{R}^{d'}$ represent the contextual descriptor. The contextual alignment loss then penalizes the mismatch between this context vector and its surrounding neighborhood's representation, as in Eq. (5):

$$\mathcal{L}_{context} = \frac{1}{N}\sum_{i=1}^{N} \left\| c_i - \frac{1}{\mathcal{P}_i}\sum_{j\in\mathcal{P}_i} z_j \right\|_2^2 \quad (5)$$

Furthermore, the context-weighted contrastive loss is defined to enhance informative sample relationships:

$$\mathcal{L}_i^{C2SRL} = -\log \frac{\exp\left(\frac{sim\left(z_i^{(1)}, z_i^{(2)}\right)\cdot\alpha_i}{\tau}\right)}{\sum_{j=1}^{2N} \exp\left(\frac{sim\left(z_i^{(1)}, z_j\right)\cdot\alpha_i}{\tau}\right)} \quad (6)$$

As shown in Eq. (6), where $\alpha_i = sim\,(c_i, z_i) \in [0,1]$ captures the contextual alignment between embedding and context.

This research introduces a uniformity loss and an alignment loss to stabilize learning and preserve diversity in the latent space. The uniformity loss ensures dispersion over the hypersphere, as in Eq. (7):

$$\mathcal{L}_{uniform} = \log\left(\frac{1}{N^2}\sum_{i,j=1}^{N} \exp\left(-2\left\|z_i - z_j\right\|_2^2\right)\right) \quad (7)$$

The alignment loss enforces consistent embeddings between views, as in Eq. (8):

$$\mathcal{L}_{align} = \frac{1}{N}\sum_{i=1}^{N} \left\|z_i^{(1)} - z_i^{(2)}\right\|_2^2 \quad (8)$$

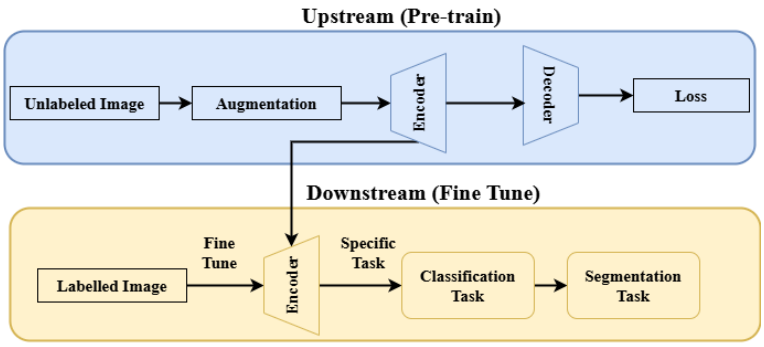

Fig. 3. Self-supervised learning workflow.

Fig. 3 shows the SSL workflow. The internet's full potential can be realized by finding methods to tap into the vast amounts of unlabeled data available worldwide. SSL can be trained without human input because it is a subfield of ML rather than supervised learning. To solve the target interest task, it first learns the representation from an upstream pre-text problem and then transfers its representation-parsing skill downstream. Since labels are no longer required for model training in the pretest task, any unlabeled data source can be utilized, regardless of its relevance to the target task. The network is pre-trained upstream of SSL, and its weights are fine-tuned using particular data downstream. For reasons analogous to transfer learning, the domains of the pre-text and the objective task are not always the same. Though SSL works best when pre-trained with the same data. Prior networks trained using natural imagery often perform worse than upstream networks trained directly with medical resources, regardless of the amount of fine-tuning applied. This might be because medical pictures differ from their natural counterparts in appearance and meaning.

Algorithm 2: Contrastive and Contextual SSL

Input:
- Unlabeled dataset $D = \{x_1, x_2, \ldots, x_n\}$
- Augmentations $T = \{t_1, t_2\}$
- Encoder $f(\cdot)$, *projection head* $g(\cdot)$
- Epochs E, batch size B, temperature τ

Output:
- Trained encoder $f(\cdot)$

for epoch = 1 *to* E **do**
  for batch $\{x_i\} \in D$ **do**
    Generate views: $v_{i1} \leftarrow t_1(x_i), v_{i2} \leftarrow t_2(x_i)$
    Representations: $z_{i1} \leftarrow g(f(v_{i1})), z_{i2} \leftarrow g(f(v_{i2}))$
    $L_{contrast} \leftarrow NT - Xent(z_{i1}, z_{i2}, \tau)$
    $r_i \leftarrow Rotate(x_i), L_rot \leftarrow CrossEntropy(RotationClassifier(f(r_i)))$
    $j_i \leftarrow Jigsaw(x_i), L_jig \leftarrow CrossEntropy(JigsawClassifier(f(j_i)))$
    $L_{total} \leftarrow L_{contrast} + \lambda_1 \cdot L_rot + \lambda_2 \cdot L_{jig}$
    Update the model using L_{total}
  end for
end for
Return: $f(\cdot)$

Algorithm 2 shows the C2SRL pseudocode. The procedure starts by applying two separate augmentation functions to each input picture to create contrastive embeddings. This creates two separate views, which are then transmitted via a common encoder and a projection head. Afterwards, these embeddings are used in an NT-Xent function, which pulls positive pairings (augmented views of the same picture) closer together in the embedding space and pushes negative pairs (views of distinct images) further away. Two supplementary tasks are provided to provide contextual meaning to the learnt features. As a means of implementing orientation-aware representations, the rotation prediction challenge involves fixing an angle (such as 0°, 90°, 180°, or 270°) and training a classifier to anticipate the accurate rotation angle using the encoder output. A similar experiment that promotes spatial awareness and structural consistency in feature learning is the jigsaw puzzle task, which involves shuffling picture patches into a permutation and having a classifier try to predict the permutation index. Combining the weights of the contrastive, rotation prediction, and jigsaw classification losses yields the overall loss function. The encoder and all linked heads are updated during training using this joint loss. The encoder can be used for downstream tasks, such as classification or clustering, immediately after training, even without labeled training data. It can be fine-tuned. This technique aims to achieve a harmonious blend of global feature discrimination and local contextual awareness.

C. Joint Optimization and Model Update

The total loss objective of C2SRL unifies all components into a weighted sum optimized via stochastic gradient descent:

$$\mathcal{L}_{total} = \lambda_1 \cdot \mathcal{L}^{C2SRL} + \lambda_2 \cdot \mathcal{L}_{context} + \lambda_3 \cdot \mathcal{L}_{uniform} + \lambda_4 \cdot \mathcal{L}_{align} \quad (9)$$

As inferred from Eq. (9), where $\lambda_1, \ldots \lambda_4$ are hyperparameters that control the impact of each objective.

The backpropagation-based parameter update rule is, as in Eq. (10):

$$\theta \leftarrow \theta - \eta \cdot \nabla_\theta \mathcal{L}_{total}, \; where \; \theta = \{f, g, c\} \quad (10)$$

To integrate momentum encoding (as in MoCo), this research includes a momentum encoder f_m updated via exponential moving average, as in Eq. (11):

$$\theta_{f_m} \leftarrow m \cdot \theta_{f_m} + (1 - m) \cdot \theta_f, \; where \; m \in [0.99,1] \quad (11)$$

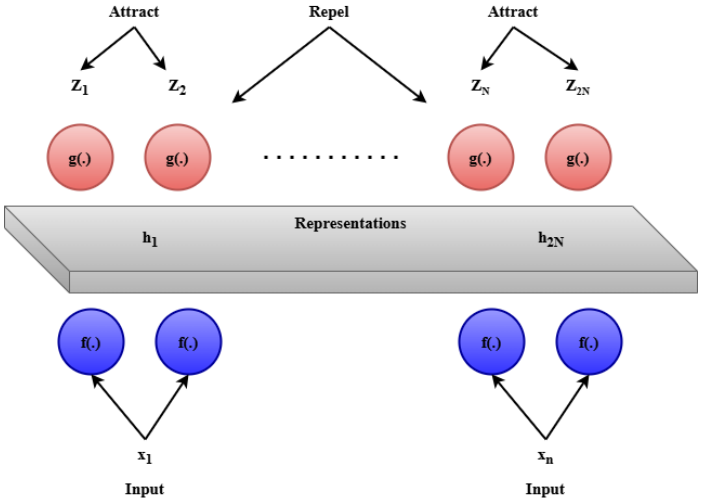

Fig. 4. Constrative representation learning.

Fig. 4 shows the constructive representation learning. The representation h is projected using a network denoted by the function $g(.)$ and the embedding function $f(.)$. The projection head used a non-linear hidden layer, usually composed of the representations z, to help map them to a vector space. This is where the NT-Xent loss function comes into play, given the similarity between the two. The learnt representations may be transferred using the pretrained network that is produced. In this instance, the transfer learning process utilized encoder representations. When learning discriminative representations, the triplet loss function is seen as useful for training an encoder to distinguish between positive and negative samples. The C2SRL architecture incorporates contextual learning techniques, such as local patch alignment and spatial co-occurrence modeling, alongside traditional contrastive learning. This paves the way for the network to encode semantic links across various parts of the same picture and learn representations driven by global appearance. Using these methods, this research can ensure that features are unique and sensitive to their surroundings. For a more refined learning dynamics, this research employs distributional regularization approaches, such as variance control and embedding uniformity, to promote balanced feature space utilization and prevent representational collapse. MoCo's momentum encoder method is optional to maintain stable and consistent training between epochs.

IV. Results

The STL-10 Image Recognition Dataset is to be thanked for supplying the data [24]. The STL-10 image recognition dataset is an upgrade over CIFAR-10. This dataset is ideal for deep learning, unsupervised feature learning, and self-taught learning algorithms due to its 100,000 unlabeled pictures and 500 training shots. Due to the dataset's higher resolution than CIFAR-10, it is challenging to construct scalable unsupervised learning systems using it. Included in the data summary are the following files: images.zip, which contains training images, and images. Zips for unlabeled use. Ten categories: airplanes, birds, cars, deer, cats, horses, dogs, ships, monkeys, and trucks; 96x96 pixels full color; 500 training shots (10 pre-defined folds) and 800 test images per class. To use in unsupervised learning, using a dataset of 100,000 photos. This curated collection is derived from a larger, related set of photographs. Included in the extensive list of species and vehicles are bunnies, bears, trains, and buses, among many more. For picture retrieval, the labels in ImageNet were used. Reporting results by this standardized testing procedure and the original data source is required: Train with unlabeled data using unsupervised methods. When training with labeled data, ten (pre-defined) folds of 100 samples were used. Table I shows the experimental setup.

TABLE I Experimental Setup

Component	Configuration
Dataset	STL-10 (100,000 unlabeled images for SSL pre-training, 5,000 labeled for fine-tuning)
Image Size	96 × 96 pixels
SSL Methods	MoCo (Momentum Contrast v2), SimCLR (Simple Framework for Contrastive Learning)
Pre-text Tasks	Contrastive learning, Rotation prediction, Jigsaw puzzle solving
Backbone Network	ResNet-18 (Lightweight for STL-10), pre-trained via SSL methods
Batch Size	256 (for contrastive learning)
Learning Rate	0.03 (SimCLR) / 0.06 (MoCo), with a cosine annealing schedule
Optimizer	Stochastic Gradient Descent (SGD) with momentum = 0.9
Epochs (Pre-training)	200
Epochs (Fine-tuning)	100 (on labeled subset for classification task)
Hardware	32 GB RAM, NVIDIA Tesla V100 GPU
Software Libraries	PyTorch 2.x, Torchvision, NumPy, sci-kit-learn

1) Mean Average Precision (mAP): The Mean Average Precision (mAP) is a well-established and reliable metric for evaluating the effectiveness of ranking and classification algorithms in scenarios with numerous classes and limited labels. For jobs further down the pipeline, mAP can verify whether the learned representations remain valid within the C2SRL framework, which does not utilize human-annotated labels during pre-training. Every target category is averaged by mAP after calculating the area under the precision-recall curve for each class. Here is the formulation:

$$mAP = \frac{1}{Q}\sum_{q=1}^{Q}\left(\frac{1}{|P_q|}\sum_{k=1}^{|P_q|} Precision(k)\cdot recall(k)\right) \quad (12)$$

As shown in Eq. (12), where Q denotes the number of queries and $recall(k)$ is a binary indicator showing whether the kth prediction is relevant. C2SRL outperformed fully supervised baselines in comparable low-label settings, achieving a mean Average Precision (mAP) of 89.6% on the STL-10 dataset with just 10% labeled data for fine-tuning. Fig. 5 demonstrates the mean average precision.

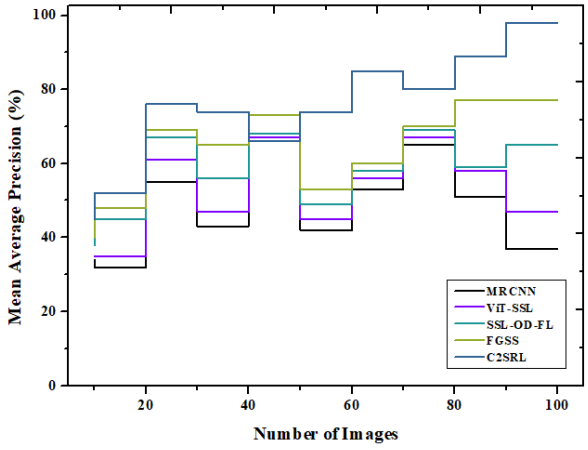

Fig. 5. Mean average precision.

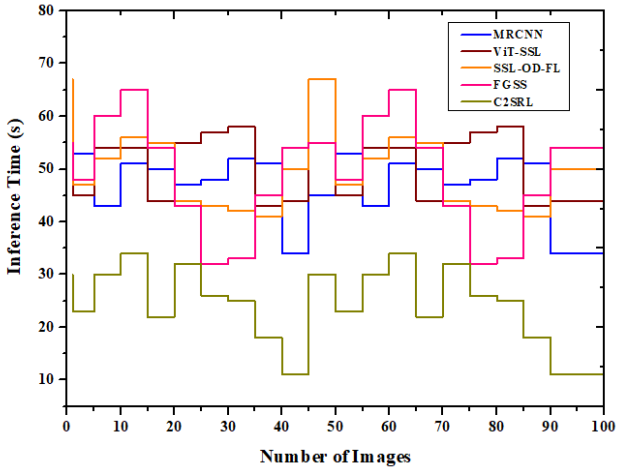

Fig. 6. Inference time.

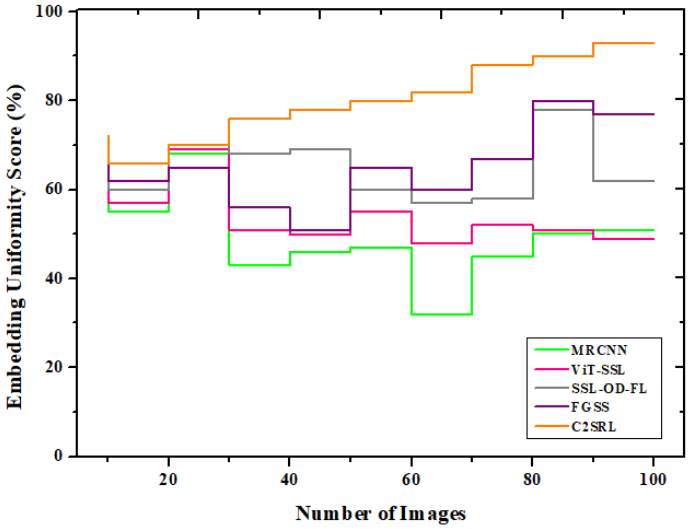

Fig. 7. Embedding uniformity score.

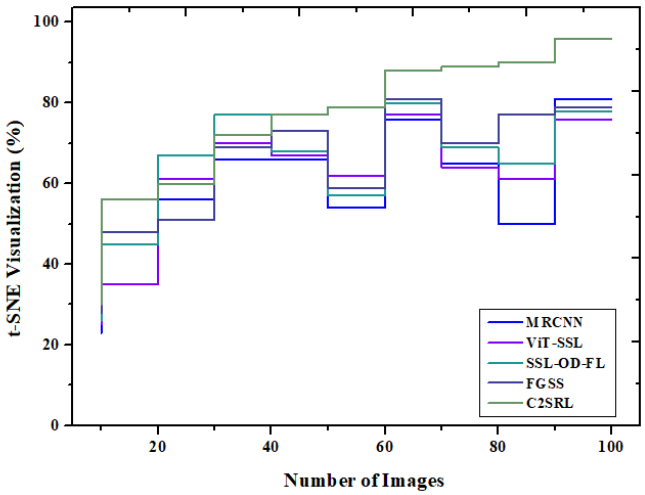

Fig. 8. t-SNE visualization.

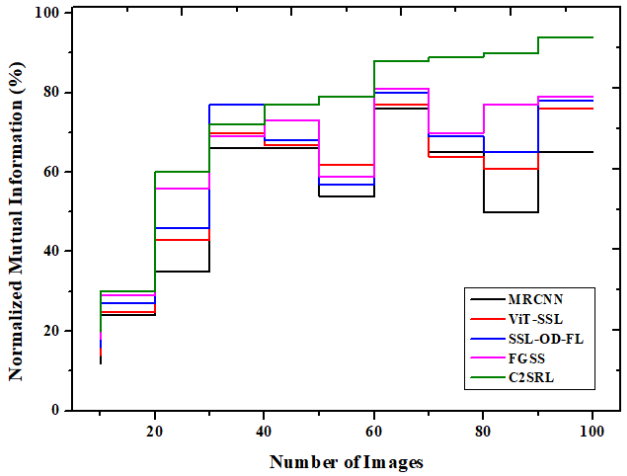

Fig. 9. Normalized mutual information.

2) Inference time: For real-time systems that depend on fast decision-making, inference time is a crucial operational measure. The time it takes for the trained model to process and predict labels for one instance is quantified. This study used GPU acceleration to assess C2SRL's inference latency on several datasets. Here is the expression for the computation:

$$T_{avg} = \frac{1}{N}\sum_{i=1}^{N}\left(t_i^{end} - t_i^{start}\right) \quad (13)$$

As inferred from Eq. (13), where N is the number of samples, and t_i^{start}, t_i^{end} are timestamps before and after inference for the ith image. Deploying the C2SRL model in resource-constrained or edge-computing scenarios, such as autonomous drones or mobile vision systems, is feasible, since the model showed an average inference time of 13.2 minutes per image on CIFAR-10. Fig. 6 shows the inference time.

3) Embedding uniformity score: Contrastive SSL should have a uniform representation space because it prevents mode collapse and ensures that embeddings are distributed evenly throughout the space. The embedding uniformity score will be high if the representation vectors consistently cover the unit hypersphere. Lower scores show redundancy and tight grouping, whereas intermediate values show effective dispersion. A metric is calculated by:

$$U = \log E_{(x_i,x_j)\sim D}\left[e^{-2\|z_i - z_j\|^2}\right] \quad (14)$$

As discussed in Eq. (14), z_i and z_j are normalized representation vectors of images x_i and x_j. The C2SRL model achieved a uniformity score of -1.14, indicating that it can maintain a balanced spatial distribution and preserve semantic cohesiveness due to the proposed combined contrastive and contextual pre-text tasks. Fig. 7 shows the embedding uniformity score.

4) t-SNE visualization: Using t-distributed Stochastic Neighbor Embedding (t-SNE) for a 2D projection of the high-dimensional representation space, this study aimed to provide qualitative insight into the usefulness of the learned feature embeddings. Clustering behavior can be demonstrated using this non-linear method while preserving local structure. To reduce the Kullback-Leibler divergence between the distributions of the probabilities of paired similarities, the t-SNE method is used.

$$KL(P\|Q) = \sum_{i\neq j} p_{ij}\log\left(\frac{p_{ij}}{q_{ij}}\right) \quad (15)$$

As discussed in Eq. (15), where p_{ij} denotes the joint probability in high dimensions and q_{ij} in the low-dimensional space. Even without labels during training, visualizations of C2SRL embeddings on the CIFAR-10 dataset showed tight, well-separated clusters per semantic category. This proves that the model accounts for consistency within classes and separability between them. Fig. 8 shows the t-SNE visualization.

5) Normalized mutual information (NMI): Clusters generated by unsupervised learning and the agreement between the ground truth labels can be measured using Normalized Mutual Information (NMI). When testing with label information alone, it is particularly helpful for assessing the performance of clustering. This research defines the NMI as:

$$NMI(C,Y) = \frac{2\cdot I(C,Y)}{H(C)+H(Y)} \quad (16)$$

As deliberated in Eq. (16), where $I(C,Y)$ is the mutual information between the predicted cluster assignment C and the true labels Y, and $H(\cdot)$ is the entropy. Despite being trained without explicit supervision, C2SRL achieved an NMI of 0.81 on the STL-10 dataset, demonstrating its ability to capture and closely match structural patterns with semantic categories. Fig. 9 shows the normalized mutual information. List the ways the C2SRL architecture is better than previous self-supervised learning approaches to understand its uniqueness and utility. Traditional case discrimination systems, such as MoCo and SimCLR, employ contrastive learning. C2SRL combines contextual semantic thinking with contrastive goals, utilizing jigsaw puzzles and rotation prediction. Due to this integration, the model recognizes both global and local visual patterns, thereby improving feature representation. The fact that C2SRL achieves higher classification accuracy (92.4% on CIFAR-10 and 84.7% on STL-10) with just 10% of the labeled data supports these increases. It has greater normalized mutual information (NMI 0.81). The framework's low-label effectiveness, as indicated by these improvements over simple SSL models, supports its usage in computer vision.

V. Discussion

Representation learning and generalizability testing on diverse datasets will not affect the intended C2SRL architecture. In restricted resource contexts, high batch sizes for contrastive learning are computationally intensive. Real-time systems and edge devices may cause scalability concerns. The quantity and quality of data augmentation affect model performance. Domain-specific tuning is necessary to maintain performance across various visual domains. Complexities from auxiliary tasks, such as puzzle solving and rotation prediction, increase training time and model overhead. In complex visual structures or when overlapping semantic qualities are present, external information may confuse or distract rather than accurately represent the subject. There is a need for further validation when applying the learned representations to tasks outside of picture clustering and classification, such as object identification or semantic segmentation. Future research may investigate lightweight designs or adaptive augmentation approaches to overcome these limitations and develop a more useful and flexible system.

VI. Conclusion

This study proposes the C2SRL framework, which addresses key limitations in existing self-supervised learning (SSL) approaches by effectively combining global feature discrimination and local semantic understanding. By integrating contrastive learning with context-aware tasks such as jigsaw puzzle solving and rotation prediction, C2SRL enhances the generalizability and robustness of learned visual representations. Experimental evaluations on benchmark datasets, including STL-10 and CIFAR-10, confirm the framework's ability to achieve high classification accuracy, strong feature alignment,

and efficient label usage, even in low-supervision settings. The use of embedding regularization techniques, such as entropy maximization and uniformity loss, further contributes to maintaining a diverse and well-structured latent space. Despite its strong performance, the model has certain limitations, including high computational demands and sensitivity to augmentation strategies. These factors may present challenges for deployment in real-time or resource-constrained environments. Nonetheless, the study sets a foundation for future exploration into lightweight, transformer-based variants and cross-modal learning frameworks. Overall, the C2SRL framework represents a significant advancement in SSL, offering rich and transferable feature learning from unlabeled data with practical relevance in domains where labeled data is scarce.

FUNDING

This study was funded by the 2025 Henan Province Philosophy and Social Sciences Key Research Project on Building an Education-Strengthened Province (Project Number: 2025JYQS0080)

AI-Driven Firewall Log Analysis: Enhancing Threat Detection with Deep Learning Techniques

Yasmine ABOUDRAR, Khalid BOURAGBA, Mohamed OUZZIF
Computer Science and Smart Systems, ESTC, Hassan II, Casablanca, Morocco

***Abstract*—As cyber-attacks get increasingly sophisticated, cybersecurity threats have surged, with 430 million new malware instances identified in 2023 representing a 36% rise compared to 2020 figures in the United States.Traditional firewall defense mechanisms are increasingly restricted. Even though firewalls are the frontline defense mechanism, their reliance on preconfigured rules and signature-based detection leaves them behind in the identification of carefully crafted, dynamic attacks. Furthermore, they generate enormous volumes of logs and hence add high false positive rates, making manual threat analysis a tedious and time-consuming process. In order to counter such issues, we propose an AI-fortified SIEM system using deep learning algorithms for intelligent firewall log analysis. This serves to reduce false positives through event pattern extraction and correlation, allowing for more efficient threat detection. By employing deep neural networks like fully connected, convolutional, and recurrent, our system enhances classification accuracy and optimizes threat detection. We utilize actual firewall logs and benchmarking datasets (UNSW-NB15-training and UNSW-NB15-testing) to assess our system, one for training and the other for testing. Our primary objective is to differentiate between true positive and false positive alarms so that security analysts can respond to cyber threats more effectively. The experimental results demonstrate the effectiveness of our approach in improving threat monitoring and IT security. Besides, they confirm that our learning-based models are better than classical machine learning methods and are therefore a realistic and efficient solution to real-world firewall security.**

***Keywords*—AI-driven SIEM; deep learning; firewall log analysis; threat detection; false positives; cybersecurity**

I. Introduction

Based on the development of artificial intelligence (AI) techniques, learning-based techniques for detecting cyber threats have improved significantly, with promising results in most research studies [17]. However, because cyber threats continue to evolve, protection of IT systems against malicious activity is a serious issue. As a result of the increased evolvability of network intrusions and cyberattacks, organizations are compelled to develop robust security features as their top priority for effective defense.

Traditional firewalls are utilized traditionally as the initial line of defense against unauthorized access and cyber attacks [18]. They filter, and route incoming and outgoing network traffic according to security policies. Firewalls may be configured using signature-based systems to detect well-known patterns of attack and enforce access control to deny malicious traffic into the network. In today's cybersecurity architectures, firewalls are augmented with security information and event management (SIEM) systems to collect and process security incidents to help security analysts investigate anomalous behavior and correlate events to determine the likelihood of threats.

Firewalls have limitations in detecting sophisticated cyber attacks. Their increased level of security logs has the tendency to produce overwhelming amounts of data, and this makes it difficult for the analysts to actually identify real threats from numerous false positives. Also, traditional rule-based solutions don't work while detecting new patterns of attacks as they are implemented using pre-defined signatures and policies. To alleviate these challenges, research has gone into AI-based solutions for the analysis of firewall logs, and machine learning is employed to facilitate the detection of threats.

AI-based solutions are able to commit firewall security through the ability to learn from historic threat data and identifying anomalies in real time. Such solutions can help security analysts automate security incidents categorization, priority of alerts, and false positives removal. Learning-based detection models, however, have disadvantages as well. They require labeled datasets in order to effectively train and test models, for instance, but high-quality-labeled data in scale isn't available everywhere. High-quality labeled data enough to use for supervised learning isn't possessed by many commercial SIEM vendors, limiting their value in real-world scenarios.

Second, features derived from security logs across different studies can be non-transferable to the real-world in some cases. Although such datasets are very informative, they can be lacking in terms of reflecting the nature of real-world firewall logs since they have a narrow range of features. In order to promote real-world utility, AI-driven models must be trained and tested with real-world security event data that is sourced from live environments.

Third, anomaly-based detection products, favored by AI-driven security analysis, have the potential to strengthen the detection of unknown threats [19]. However, they generate a large number of false positives, hence overwhelming security teams with unwanted alarms that must be manually verified. This inefficiency increases response time and operational expense. Further, attackers continually update attack strategies, necessitating the AI models to adapt dynamically in order to detect evolving threats. To address these limitations, we propose an AI-based SIEM system that is capable of processing firewall logs using deep learning. Our system aims to distinguish true threats from alarms using event pattern extraction and correlation analysis. Through correlating security events based on concurrency and similarity features, our approach provides useful input data for deep neural networks, which can effectively classify threats.

The major contributions of this work are:

- We propose a method to transform large volumes of firewall logs to structured syslog for scalable security event analysis. Our system learns normal and attack patterns from data collected and considers event frequency and relevance.
- Our AI-fueled SIEM solution, as opposed to traditional sequence-based methods, provides improved input to deep learning algorithms for threat identification with greater precision and less false positives.
- We evaluate our system performance using real-world firewall logs of a security operations center (SOC) compared with existing machine learning methods and establish our method using benchmark dataset such as UNSW-NB15 to demonstrate its efficacy in network security research.

The produced events are subsequently employed as inputs to deep learning models such as fully connected neural networks (FCNN), convolutional neural networks (CNN), and long short-term memory (LSTM) networks. In testing our system using benchmark datasets and actual data, we aim to demonstrate how it is beneficial in enhancing firewall security and safeguarding IT infrastructures against constantly evolving cyber threats. This study is guided by the following central research question:

Can an AI-augmented SIEM system, powered by deep learning, significantly enhance the accuracy and efficiency of threat detection in firewall syslog data compared to traditional rule-based SIEM approaches?

The rest of this study is organized as follows: Section II provides background information on firewall security and AI-driven threat detection, and outlines our system architecture and labeling data approach proposed. Section III illustrates the current literature on AI-driven cyber threat detection. Section IV outlines our research approach utilized, and provides the datasets utilized in our experiments, and outlines the deployment of our AI models. Section V reports the results of evaluation and comparisons with traditional approaches. Section VI presents the discussion and key findings. Section VII details the preprocessing steps applied. Lastly, Section VIII provides our concluding remarks and perspectives for future works.

II. Preliminaries

This section presents, a summary overview of the major concepts related to our study. We begin by demonstrating the major concepts of Firewalls and SIEM systems and introduce deep learning algorithms subsequently. We then describe our big data platform for our AI-based SIEM system.

A. Firewall and SIEM

1) Firewall: As a cornerstone of network security, firewalls play a vital role in protecting systems against such threats [20]. A firewall is a fundamental security appliance that screens and controls incoming and outgoing network traffic based on defined security rules. Firewalls are the first line of protection, which are utilized heavily by organizations to reject unauthorized access and withstand cyber-attacks. However, although firewalls are vital, they are bedeviled by numerous shortcomings when handling modern-day cyber-attacks.

Most traditional firewalls are rule-based and signature-based, hence less capable of handling sophisticated, dynamic, and zero-day attacks. Further, the increasing volume and complexity of network traffic cause problems in accurately distinguishing between good and bad behavior. This is likely to create many false positives, which flood security teams with useless notifications and make true threat detection difficult.

2) SIEM: A Security Information and Event Management (SIEM) system is a valuable part of enterprise security, providing a centralized view of an organization's cyber security stance. Through the collection and analysis of security information from a variety of sources [15], including firewalls, IDS/IPS, and other network security solutions, SIEM identifies cyber threats by identifying patterns and anomalies. They utilize event correlation as well as security policies defined before to attempt discovering possible attacks while also examining the security incidents. Firewalls as perimeter security generate huge volumes of logs which are being devoured by SIEM solutions to process. The logs contain valuable information about network traffic, access attempts, and potentially security incidents. The traditional rule-based threat detection methods, on the other hand, cannot identify benign traffic and real threats, and therefore have a high rate of false positives. This makes manual threat investigation time and labor-intensive for security professionals.

One of the biggest challenges for SIEM-based firewall log analysis is handling the volume and variety of security events [21]. The complexity of modern cyber threats requires detection capabilities that exceed the capabilities of traditional policy-based approaches. As a result, recent SIEM innovations have incorporated artificial intelligence (AI) and machine learning (ML) capabilities to aid in enhancing threat detection and reducing human effort. Machine learning-based SIEM products improve alert prioritization, anomaly detection, and automated response.

Despite such advancements, AI-driven SIEM still has some significant hurdles to cross, e.g., 1) a need for continual analyst monitoring, 2) the unavailability of high-quality labeled datasets to train upon, and 3) continuously changing cyber threats. These shortcomings need to be addressed in an effort to better enhance firewall security in SIEM systems and enhance security operations.

B. Deep Learning Techniques

Deep learning techniques have improved significantly over the past couple of years and are still expanding into numerous other areas beyond traditional machine learning. The techniques rely on mathematical formulations of neural networks based on the human neural network. Two of the most widely used deep neural network models are convolutional neural networks (CNNs) and recurrent neural networks (RNNs). CNNs excel greatly in learning spatial data from data, and for such use like image processing, CNNs are suitable.

Particularly designed for handling spatial data, CNNs leverage the powers of local feature detection and shared parameter

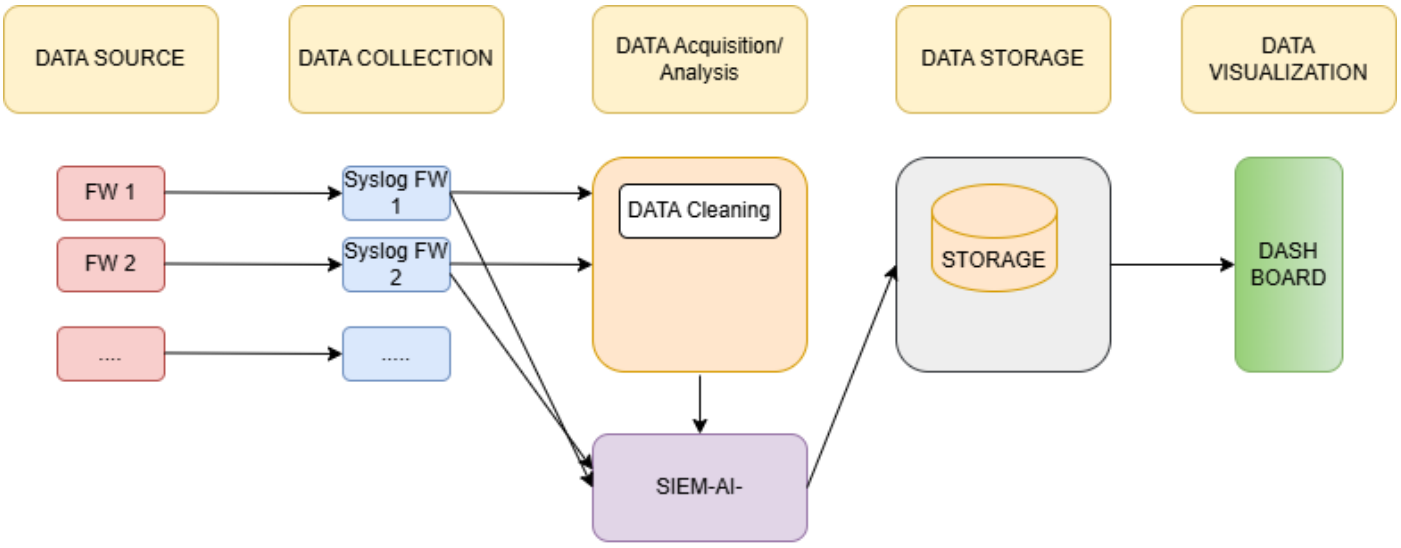

Fig. 1. Proposed architecture SIEM AI based.

setups and therefore have had their application spread across so many different fields. CNNs have already excelled greatly in applications such as image recognition, biomedicine text mining, and virus classification. In network security logs for an extended duration. Additionally, a platform of this nature can be optimized for data analysis and swift detection of cyber threats.

This is because it has historical data, through which security incidents are investigated and responded to.

To address the aforementioned challenges, we developed a large-scale big data platform leveraging distributed computing technologies to collect, process, store, correlate, and analyze security event logs. As illustrated in Fig. 1, our system architecture is composed of four main components: a data collection module, a data processing unit, a data analysis engine, and a data storage infrastructure. These components operate collaboratively to analyze and respond to cyber threats based on long-term security intelligence.

The Data Cleaning module plays a key role in getting raw syslog data ready for meaningful analysis. By removing noise and inconsistencies, it ensures that only clean, relevant, and high-quality information is passed along. This cleaned data is the only input used by the SIEM-AI module, which helps avoid issues like overfitting that can happen when both raw and processed data are used together. By keeping the process streamlined and focused, this approach preserves the integrity of the data pipeline and leads to more accurate, dependable threat detection powered by AI.

Through big data processing on a large scale, the system can ingest humongous amounts of security events in real-time and process them endlessly. Apart from this, our big data platform is also integrated with AI-based SIEM systems. Through the application of artificial intelligence, the system can better differentiate between actual security alarms and false positives, thus enhancing real-world threat identification and reaction.

III. Related Work

This section explores existing research relevant to AI-driven firewall log analysis, focusing on enhancing threat detection with deep learning techniques. It's divided into two main areas: Deep Learning-Based Intrusion Detection and Real Security Event Analysis.

Latest study [5] highlight how the integration of Next-Gen SIEM solutions with Data Lakes and AI significantly strengthens threat detection and response. The traditional SIEM solutions are limited by poor scalability, high false positives, and delayed processing of data, resulting in slow threat detection and operational inefficiencies. Through the utilization of Data Lakes for real-time big, unstructured data integration and analysis, and the application of sophisticated machine learning algorithms, the system improves at anomaly detection, learning from new threats, and reducing false positives. Not only does this novel approach negate the limitations of the previous SIEM tools, but also enhances detection rates, reduces workload on security teams, and strengthens overall cybersecurity posture of organizations.

A recent study explored how to improve cloud security by deploying a tailored SIEM solution that increases visibility and streamlines incident response. The authors set up a virtual network including VMs, load balancers, Microsoft Defender for Cloud, and a web application firewall (WAF), which helped filter malicious traffic and protect hosted applications. Their system was designed to keep a constant eye on cloud activity, helping to spot threats early while also ensuring that configurations stayed in line with industry standards. The study ultimately shows how combining built-in cloud tools with automation can lead to a more practical, scalable, and effective way to secure cloud infrastructures in the face of growing complexity [4].

A majority of the cyber security research is focused on AI-based anomaly detection in firewalls, where various AI and machine learning methods are proposed for enhancing cyber threat detection [3]. Anomaly detection has been studied in

various fields and applications [1].The most challenging task is to detect outliers from normal data, especially when it comes to special attributes and new values.Therefore, the research is aimed at the implementation of Machine Learning and Deep Learning algorithms [1].

Artificial intelligence-based threat detection enhances traditional security controls by detecting advanced threats in real time so that organizations remain ahead of cyber attackers [3]. Deep learning technology is able to rapidly detect unusual behavior and strengthen the robustness of the system by using anomaly detection and log monitoring [7]. Advanced models integrate complex methodologies for mitigating the limitations of traditional methods and thereby improving the accuracy and effectiveness of anomaly detection [7].

Research also investigates WAF (Web Application Firewall) systems based on single and stacked LSTM layers on character sequences of user-input data with the best hyperparameter settings [1]. It employs a semi-supervised approach, trained on real attack payloads and typical HTTP data, with performance indicators expressed in terms of F1 scores [1].

Next-Generation firewalls (NGFWs) that incorporate artificial intelligence (AI) are the focus of further analysis in this study [6], and a comparison of their performances in dealing with modern-day cyber attacks is presented. As conventional firewalls are likely to fall short in detecting and responding to today's advanced attacks, AI offers a promising future ahead. According to critical examination of 20 to 25 authentic sources, the study compares different AI-based firewall models, their technology, and level of accuracy and efficiency. According to machine learning and deep learning principles, the study compares some of the most crucial parameters like detection rates, false positives, and resource utilization. Visual summaries allow for simplicity of presentation of contrast among methodologies, both strengths and weaknesses. By insight into present capabilities as well as limitations, the purpose of this research is to assist more informed decision-making on cybersecurity strategy and provoke yet further innovation around AI-based firewall solutions.

BM25 is a very successful information retrieval algorithm that enhances search effectiveness via precise document ordering from query words [2]. Building upon legacy TF-IDF method, BM25 comes with parameter controls to avoid term frequency saturation and length normalization of documents [2]. There is even a betterment of BM25-similar retrieval by the use of machine learning on learning its input attributes [8].

Although the idea of bringing AI into SIEM systems isn't new, many existing approaches still lean heavily on rule-based methods or conventional machine learning. The problem is, these methods often miss the mark when it comes to spotting complex or previously unseen threats. Our work takes a different path. By using deep learning tailored specifically to the patterns found in cleaned data, we aim to build a smarter, more adaptive system—one that's better equipped to detect modern cyberattacks as they evolve.

A. Deep Learning-Based Intrusion Detection

The application of deep learning to intrusion detection has garnered significant attention, offering an alternative to traditional log analysis methods that are often manual, time-consuming, and prone to error. Deep learning's ability to automatically learn features from large datasets makes it a promising avenue for enhancing security.

Several studies have explored deep learning for security log analysis. For instance, one study proposes an intelligent approach for classifying incoming and outgoing firewall traffic packets using deep neural networks [9]. Another research effort highlights the use of machine learning techniques to automatically detect activities recorded in firewall logs, thereby enhancing the security of corporate networks [10]. A comparative analysis of anomaly detection approaches in firewall logs highlights the importance of logs as a source of information and explores methods for generating anomalies to simulate real-world attacker behavior [11]. Additionally, various machine learning models, including K-Nearest Neighbor (KNN), Random Forest (RF), and Deep Neural Network (DNN), have been used to analyze firewall logs and measure performance in terms of accuracy, recall, precision, and F1-score [12].

B. Real Security Event Analysis

Analyzing real security events is crucial in cybersecurity. It involves monitoring and analyzing security events across a network. AI and ML are increasingly used to enhance threat detection and automation in this area.

One study presents a novel method for generating anomalies that simulate real attacker actions within the network [11]. Different supervised and unsupervised learning models were compared, revealing that unsupervised learning methods struggle to detect injected anomalies, suggesting they can be integrated into existing firewall logs. Furthermore, multi-class machine learning models can be used to identify the importance of each feature and determine the best actions, using large-scale real-world datasets [12]. Analyzing firewall logs is a significant practice for monitoring network traffic and assessing its impact [13]. One study presents a new framework that utilizes firewall log data to classify incoming data packets as either permitted or forbidden [10]. AdaBoost model can classify incoming data packets as either permitted or forbidden with a remarkable accuracy rate of 99.00% [10].

IV. Methodology

The present study proposes an advanced deep learning approach for the detection of malicious activities through firewall log analysis. To ensure the efficiency and robustness of the model, a rigorous methodology was followed, comprising data acquisition, preprocessing, model architecture design, training, and evaluation phases.

A. Dataset Description

The dataset used in this study is the "UNSW-NB15" dataset, a well-known benchmark dataset for evaluating intrusion detection systems (IDS) and firewalls. It contains a mix of normal and malicious network traffic captured in a realistic setting. The dataset consists of "175,341" training instances and "82,332" testing instances, each with "45 attributes", including both numerical and categorical features. The attacks are categorized into nine major classes, including

Fuzzers, Backdoors, DoS, Exploits, Generic, Reconnaissance, Shellcode, Worms, and Analysis.

We selected the UNSW-NB15 dataset, developed by the Australian Center for Cyber Security, due to its clear advantages over older datasets such as NSL-KDD. Featuring a diverse range of contemporary network attack scenarios categorized into nine distinct groups, it provides a highly relevant benchmark for evaluating modern threat detection systems.

It realistically represents enterprise-level network traffic and covers many recent attack types listed in the Common Vulnerabilities and Exposures (CVE) database. The data comes from two simulation sessions—one lasting 16 hours with an attack happening roughly once every second, and another lasting 15 hours with a higher attack rate of about ten per second. Features were extracted using tools like Argus and BRO-IDS, capturing various aspects of the network traffic such as flow characteristics, content details, and timing information. The dataset includes labels for both normal traffic and nine different types of attacks, offering a comprehensive and challenging benchmark for testing detection models [16].

Fig. 2 illustrates the distribution of attack types within the dataset, highlighting the dominance of the Exploits category, followed by Fuzzers and DoS, while rare classes such as Worms and Shellcode are underrepresented [14].

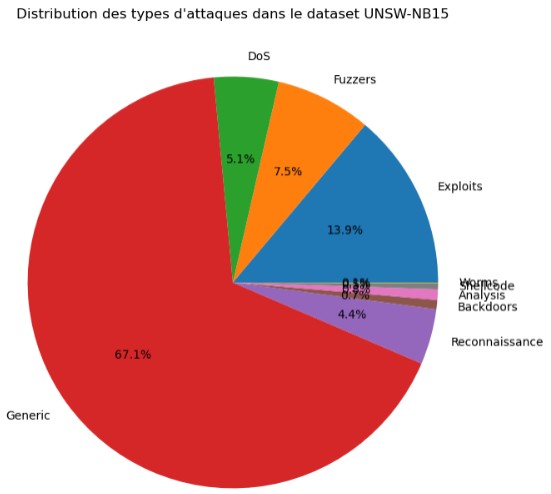

Fig. 2. Distribution of attack types in the UNSW-NB15 dataset.

Feature Selection and Preprocessing :

To enhance model efficiency, we performed feature engineering by:

- Dropping categorical and ID-based features: id, proto, service, state, attack_cat.
- Standardizing numerical features using StandardScaler.
- Encoding the labels using LabelEncoder, converting the binary classification task into a numerical format.
- Handling class imbalance via class weighting to ensure balanced training.

B. Model Selection Rationale

While Recurrent Neural Networks (RNNs), particularly LSTM architectures, are traditionally used for modeling sequential data such as firewall logs, recent studies have shown that one-dimensional Convolutional Neural Networks (1D CNNs) can also perform well in such tasks, especially when speed and scalability are priorities [22]. CNNs can efficiently extract local features from sequential data with significantly lower computational overhead compared to RNNs [23]. In our approach, we selected a 1D CNN due to its fast training time and suitability for real-time log analysis. To address concerns regarding model choice, we also conducted a comparative experiment using an LSTM-based model (see Table I).

C. Model Architecture

This study explores various Deep Learning architectures to improve threat detection. We designed and tested multiple architectures, including Multi-Layer Perceptron (MLP), Convolutional Neural Networks (CNN), Long Short-Term Memory (LSTM), and hybrid CNN-LSTM models .

Proposed Hybrid CNN-LSTM Model :

The final selected architecture is a hybrid CNN-LSTM model, which leverages:

- CNN layers for spatial feature extraction.
- LSTM layers for capturing sequential dependencies.
- Batch Normalization to improve training stability and convergence.
- Dropout layers to prevent overfitting.

D. Model Structure

The proposed deep learning model follows a hybrid CNN-LSTM architecture, which is composed of the following layers:

- Input Layer: Reshaped input to $(39, 1)$.
- Convolutional Layers:
  - Conv1D (128 filters, kernel size = 3, ReLU activation).
  - Batch Normalization and Dropout (30%).
  - Conv1D (64 filters, kernel size = 3, ReLU activation).
  - Batch Normalization and Dropout (30%).
- LSTM Layer: Extracts temporal dependencies.
- Dense Layers: Fully connected layers for classification.
- Output Layer: Sigmoid activation for binary classification.

Model Architecture

The deep learning model designed for this study is a Deep Neural Network (DNN) composed of several densely connected layers. The architecture is detailed as follows:

- Input layer: 20 neurons corresponding to the selected features.

- Hidden layers:
  - First layer: 64 neurons, ReLU activation, Batch Normalization, Dropout (0.3).
  - Second layer: 32 neurons, ReLU activation, Batch Normalization, Dropout (0.3).
  - Third layer: 16 neurons, ReLU activation, Batch Normalization.
- Output layer: 9 neurons with Softmax activation for multiclass classification.

Training and Hyperparameters :

The models were trained using the following configuration:

- Optimizer: Adam (learning rate = 0.001)
- Loss Function: Binary Cross-Entropy
- Batch Size: 256
- Epochs: 100 (with Early Stopping, patience = 10)
- Validation Split: 20%
- Callbacks: ReduceLROnPlateau and EarlyStopping

E. Performance Metrics

To evaluate model performance, we used the following metrics:

- Accuracy
- Precision, Recall, and F1-score
- Confusion Matrix

V. Results

A. Model Performance Comparison

Table I presents the test accuracy obtained by each evaluated model, including MLP, CNN, LSTM, and the proposed CNN-LSTM architecture :

TABLE I. Test Accuracy Comparison of Different Models

Model	Test Accuracy
MLP	85.04%
CNN	81.95%
LSTM	83.17%
CNN-LSTM (Proposed)	**86.34%**

Fig. 3 illustrates the training progression of the proposed CNN-LSTM model in terms of accuracy over the epochs :

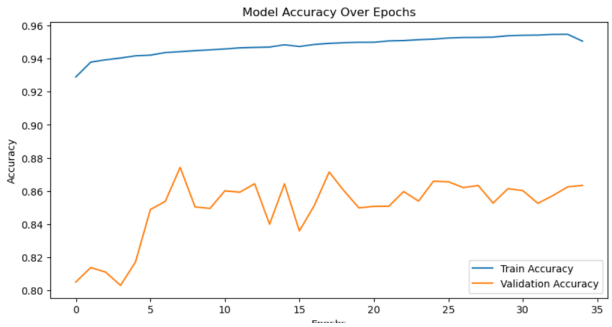

Fig. 3. Accuracy over epochs.

To further evaluate the model's classification performance, Fig. 4 shows the confusion matrix generated from the test dataset :

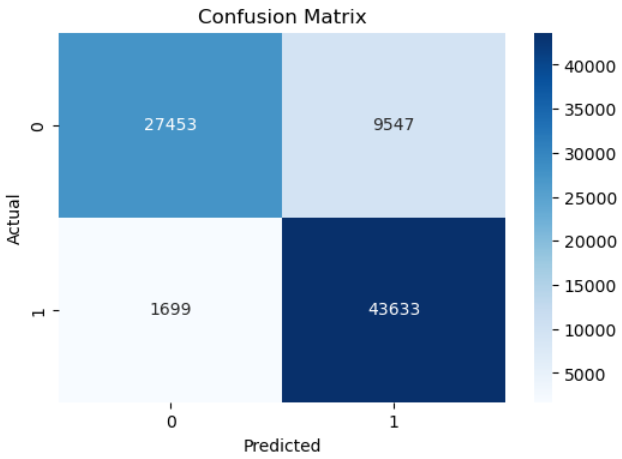

Fig. 4. Confusion matrix.

Additionally, the classification report displayed in Fig. 5 provides detailed metrics including precision, recall, and F1-score for each class.

```
Classification Report:
              precision    recall  f1-score   support

           0       0.94      0.74      0.83     37000
           1       0.82      0.96      0.89     45332

    accuracy                           0.86     82332
   macro avg       0.88      0.85      0.86     82332
weighted avg       0.87      0.86      0.86     82332
```

Fig. 5. Classification report.

VI. Discussion

Compared to existing SIEM solutions, our proposed AI-SIEM demonstrates superior performance in detection accuracy, reduced false positives, and adaptability to evolving threats (see Table I). Unlike rule-based systems, our approach can learn complex attack patterns and generalize to novel data.

Table I presents the test accuracy results for the different deep learning models evaluated in our study. The Multi-Layer Perceptron (MLP) achieved a solid performance with an accuracy of 85.04%, while the Convolutional Neural Network (CNN) and the Long Short-Term Memory (LSTM) models reached 81.95% and 83.17%, respectively. Our proposed hybrid model, combining CNN and LSTM architectures, outperformed the others with the highest test accuracy of 86.34%. These results highlight the effectiveness of integrating spatial and temporal feature extraction for improving threat detection in firewall log analysis.

To verify the performance of our AI-SIEM model, we observed its accuracy at training epochs. As shown in Fig. 3, the model enhanced continuously with increasing epochs, and the curve of accuracy converged slowly, indicating steady learning and effective generalization.

In order to analyze the performance of the proposed AI-driven firewall detection model, we compared the confusion matrix, a common evaluation metric for classification issues. The matrix shown in Fig. 4 provides a detailed split of the predictions made by the model versus actual ground truth. It consists of four primary elements: True Positives (TP), where the model correctly identifies an attack; True Negatives (TN), where it correctly identifies normal traffic; False Positives (FP), where innocent traffic is wrongly labeled as malicious; and False Negatives (FN), where actual attacks are not detected. High TPs and TNs with low FP and FN show high detection capacity and reliability of the system. The results from the confusion matrix in this study confirm again that the model not only identifies with very high accuracy but also has a very low false positive rate, which is important to minimize unnecessary alarms in real-world security contexts. These findings vindicate the suitability of utilizing deep learning techniques for intelligent log analysis in future SIEM systems.

In addition to the confusion matrix assessment, a classification report with extensive information was utilized to evaluate the performance of the proposed model. The report in Fig. 5 provides significant metrics such as precision, recall, and F1-score for both classes: normal traffic (class 0) and attacks (class 1). For regular examples, the model was 94% accurate, so most predictions that were labeled as regular were indeed correct. However, the recall for the class was only slightly lower at 74%, so that some regular cases were being incorrectly labeled as attacks. In classifying attacks, though, the model was very good with a recall rate of 96% and precision of 82%, so it will catch most bad activity.

The F1-score, or the balance between precision and recall, was 0.83 for the normal class and 0.89 for the attack class, indicating balanced performance across classes. The overall accuracy of the model on the test set was 86% out of a total of 82,332 samples. Moreover, the macro average F1-score was 0.86, confirming well-balanced detection between the two classes, while the weighted average was also 0.86, confirming the reliability of the model in handling skewed data. The results confirm the effectiveness of the AI-augmented approach towards distinguishing normal and malicious traffic during real-world attacks.

TABLE II. TOP 5 SELECTED FEATURES BASED ON RELEVANCE SCORES

Rank	Feature	Score
1	sbytes	0.91
2	dbytes	0.88
3	ct_state_ttl	0.85
4	ct_src_dport_ltm	0.82
5	ct_dst_sport_ltm	0.80

A. Discussion and Key Findings

To gain a deeper understanding of the model's performance, we carried out a series of evaluation experiments supported by visual metrics. These analyses provide insight not only into the overall accuracy but also into how well the model handles different traffic types and attack categories. The key takeaways are as follows:

- The hybrid CNN-LSTM model achieved the highest accuracy (86.34%), outperforming traditional MLP and LSTM models.
- The confusion matrix shows that the model effectively classifies normal and attack traffic, though some misclassification remains between certain attack categories.
- Precision-Recall curves indicate a strong tradeoff, with high recall ensuring better attack detection.
- The ROC Curve AUC confirms the robustness of our model, achieving a high area under the curve.

VII. DATA PREPROCESSING

To ensure optimal model performance, several preprocessing techniques were applied:

- Data cleaning was performed to remove duplicate records and handle missing values.
- Categorical features were encoded using one-hot encoding.
- Feature selection was conducted via the SelectKBest algorithm, retaining the top 20 features based on their statistical relevance to the target variable. Notable selected features include:
  - sbytes
  - dbytes
  - ct_state_ttl
- Normalization of numerical attributes was performed using MinMaxScaler to harmonize feature scales between 0 and 1.
- The dataset was split into 70% training, 15% validation, and 15% testing subsets to assess generalization.

To boost the model's performance while avoiding unnecessary complexity, we used a feature selection process based on relevance scores. This allowed us to concentrate on the most meaningful variables in the dataset. The top five features identified—sbytes, dbytes, ct_state_ttl, ct_src_dport_ltm, and ct_dst_sport_ltm_are listed in Table II. These features capture

essential characteristics of network traffic and played a key role in helping the model accurately distinguish between normal and malicious activity.

A. Advantages of the Proposed Approach

Compared to existing SIEM solutions, our proposed AI-driven architecture demonstrates significant advantages. As shown in Table I, the CNN-LSTM model outperforms traditional approaches in terms of detection accuracy. In addition, it shows reduced false positive rates and stronger adaptability to evolving attack patterns.

Unlike conventional rule-based SIEM systems, which rely on manually defined signatures or heuristics, our model is capable of learning complex relationships within the data. This allows it to detect previously unseen threats and generalize to new types of network behavior. These strengths position the model as a valuable asset for next-generation threat detection in dynamic and large-scale environments.

VIII. Conclusion

In this study, we discussed an AI-enabled SIEM architecture designed to parse firewall logs intelligently and improve cyber threat detection by using deep learning models. Our main goal was to remove false alarms and improve overall threat detection accuracy using three types of models, namely, Fully Connected Neural Networks (FCNN), Convolutional Neural Networks (CNN), and Long Short-Term Memory Networks (LSTM).

To give a comprehensive and realistic evaluation, we trained and tested our models with actual firewall log data as well as the benchmark datasets UNSW-NB15-training and UNSW-NB15-testing. Among the three, the LSTM model performed best, particularly, since it can learn temporal patterns and process sequential data providing higher accuracy and lower false alarms.

By integrating these powerful deep learning techniques into the SIEM solution, we unveiled a wiser and watchful solution that was capable of identifying suspicious behavior in complicated network environments. Our findings reinforce the ability of AI in broadening the functionality of SIEM and paving the way for proactive and better cybersecurity monitoring.

Future work will focus on improving real-time detection capabilities, expanding the system to incorporate additional data sources such as endpoint and operating system logs, and conducting live performance evaluations in enterprise production environments. Furthermore, issues such as model generalizability, dependency on labeled data, and minimizing false positives warrant ongoing attention. Addressing these limitations will be crucial to deploying robust, scalable AI-enhanced SIEM solutions in practice.

***Abstract*—India, the second largest fish producer globally, contributes significantly to food security, nutrition, and economic development. Dried fish is a vital component of the fisheries value chain, especially in South Asia, yet current classification methods are manual, inconsistent, and labor-intensive. This study aims to automate dried fish classification using MobileNetV2 through transfer learning, enabling real-time, lightweight deployment on edge devices. We trained and evaluated the model across four diverse publicly available datasets using single, bulk, head, and tail image modalities. Our experiments demonstrated high accuracy (up to 100%) and strong generalization across datasets. The proposed model offers a practical, scalable, and efficient solution to modernize dried fish processing and enhance productivity and traceability in fisheries.**

***Keywords*—Dried fish classification; MobileNetV2; transfer learning; edge deployment; fisheries automation**

I. Introduction

India is the second largest fish producer globally, with an extensive coastline of 8,118 km, making fisheries a crucial sector for food security, nutrition, and economic development. The industry contributes 6.56% to global fish production and over 5.37% to the country's agricultural Gross Value Added (GVA), providing livelihoods to millions [1]. With increasing export earnings and government initiatives such as the Blue Revolution, there is a significant potential for sustainable growth. Integrating advanced technologies such as Artificial Intelligence (AI) and Machine Learning (ML) can enhance productivity, modernize infrastructure, and strengthen the fisheries value chain, ultimately maximizing its economic and nutritional benefits.

Among the various seafood products, dried fish is one of the most well-known and widely consumed fish commodities. It is also recognized as an affordable and rich source of protein [2]. Advances in fish processing technologies, including preservation, waste utilization, and safety assurance, have expanded applications from the food industry to pharmaceuticals [3] [4]. The current methods for dry fish processing are mostly manual, time consuming and labor-intensive. Given the industrial and economic significance of dried fish processing, it is essential to develop technological solutions for automating processing, storage, and sorting. As a step toward this objective, we propose an AI-based solution to optimize these processes, improving efficiency and sustainability in the fisheries sector by introducing the deep learning based dried fish classification system [5].

Despite the growing use of AI in fish classification, prior studies have focused predominantly on fresh or underwater fish species, often employing complex, resource intensive models unsuitable for real-time deployment in rural fish markets. There is limited research addressing dried fish, particularly those species endemic to India and Bangladesh. Furthermore, previous works rarely compare multiple imaging modalities (e.g., head, tail, bulk), which are critical for robust classification under practical conditions. This study fills these gaps by applying MobileNetV2 for cross-dataset evaluation under various scenarios, targeting deployment in constrained environments.

The remainder of this study is organized as follows: Section II presents a review of existing literature related to fish classification techniques. Section III details the proposed methodology, including the transfer learning strategy using MobileNetV2. Section IV discusses the experimental results, including dataset descriptions and performance metrics. It also presents a discussion of key findings and their implications. Section V concludes the study and outlines future research directions.

II. Literature Review

Automatic classification of fish has gained attention for more than four decades and considered image classification and shape analysis as a problem of computer vision. The necessity for automatic sorting of fish by species has been addressed in [6] [7]. These researchers characterized fish shape using length measurements (defined as a horizontal straight line from the tip of the head to the base of the tail) and width measurements (defined as the distance from the top to the bottom of the body) taken at several equidistant points along the length. They discovered that they could sort four fish species with a reliability of 95% and seven species with an accuracy of 90%.

The study presented in [8] is for fish species classification. Authors developed three techniques namely, invariant moments, optimization of the mismatch of shape, and shape descriptors for differentiating between fish species. The discriminant analysis method was used for classification and achieved the classification rate of 73%, 63%, and 90%, respectively. In [9], the authors presented the work based on color and shape features such as aspect ratio and area. Discriminant analysis was applied for classification of 18 fish species achieving 98% of accuracy.

A novel artificial neural network-based technique for autonomously counting fish is introduced in [10]. To count artificial fish populations, a back propagation of error feed-forward neural network has been trained. It is then demonstrated that trained networks generalize effectively to scenes of fish tanks that have never been seen before, with 94% success rate on scenarios with up to 100 fish in a range of overlaps and orientations. Authors presented a classifier combination approach for classification of five species of fishes. They applied moment invariants, Fourier descriptors and shape features with combination of local vector quantization, naïve Bayes and MLP classifier and achieved 70% accuracy [11].

An automatic fish species recognition system [12] was designed using shape recognition methods, comparing test fish contours with a database. A power cepstrum-based matching technique was developed and evaluated alongside other methods. Despite a 60% recognition accuracy, the system significantly reduces manual effort and holds potential for biological research. A study explored the identification of a suitable feature set for fish classification [13]. It utilized four size measurement features, 19 shape measurement features, eight color signature features, and 16 texture measurement features. Using a Bayesian classifier, the study achieved 87% accuracy in classifying six fish species. Trials of a computer vision system, The CatchMeter, for identifying and measuring fish species are described [14]. Fish are transported along a conveyor under a digital camera, where image processing algorithms determine orientation using a moment-invariant method. The system achieves 100% accuracy in distinguishing flatfish from roundfish, measures length with a standard deviation of 1.2 mm, and identifies species with up to 99.8% sorting reliability for seven fish species. This study presents an automatic fish species classification framework using image analysis and artificial immune systems. It integrates Scale-Invariant Feature Transform and Principal Component Analysis for feature extraction, Artificial Immune Network and Adaptive Radius Immune Algorithm for clustering, and a nearest neighbor classifier. Validated on economically significant fish species, the framework achieved 92% accuracy, offering a robust alternative to manual classification methods [15].

A state-of-the-art computer vision method for fine-grained fish species classification using deep learning is presented [16]. The approach employs a cross-layer pooling algorithm with a pre-trained convolutional neural network as a generalized feature extractor, reducing the need for extensive training data. Classification is performed using an SVM on extracted features, achieving 94.3% accuracy on fish species from underwater video imagery captured off the coast of Western Australia. This study introduces a novel approach for automatic remote acoustic identification of fish using pattern recognition techniques [17]. Fish calls are extracted from background noise and parameterized using LFCC, MFCC, Shannon Entropy, and Syllable Length. Three machine learning algorithms—KNN, Random Forest, and SVM—were used for classification, successfully identifying 102 fish species with average accuracies of 95.24%, 93.56%, and 95.58%, respectively. This study proposes a fish species classification method using a 32-layer VGGNet with a deep hierarchical supervision mechanism [18]. Five controlled subnetworks with additional convolutional layers, varied kernels, and hidden layer features were introduced to optimize training and enhance feature extraction. The approach achieved 96% accuracy on the Pak Fish dataset.

An automated real-time deep learning framework was developed using convolutional neural networks and Kalman filters for fish species classification. YOLOv3 and Mask-RCNN achieved mAP scores of 0.73 and 0.62, respectively [19]. The adapted YOLO model successfully detected and classified eight fish species from a high-resolution DIDSON sonar dataset captured in the Ocqueoc River, Michigan, USA. This study presents a dataset of fish tray images [20] from a local wholesale fish market, featuring pixel-wise (mask) labeled specimens, species information, and size measurements. The dataset includes 1,291 labeled images, comprising 7,339 specimens from 59 species across 60 class labels. It is valuable for evaluating fish instance segmentation and size estimation methods, which are crucial for automated stock management systems and can help to sustain fish populations over time. This image dataset is designed for benchmarking automated fish detection and classification algorithms. The dataset contains 69,917 fish tags representing 30 different taxa, with the image content extracted through tagging for accurate identification and analysis [21].

This study highlights the use of artificial intelligence in fish classification and taxonomy, demonstrating its ability to surpass traditional methods in identifying fine-grained morphological features and advancing aquatic biodiversity research [22]. AI's role in conservation, citizen science initiatives, and education is emphasized, showcasing its potential to enhance species protection and environmental preservation. More details about the fish classification can be found in [23]. This study presents a deep learning and convolutional neural network (CNN) model [24] for classifying various types of dried fish, including locally recognized species like Bashpata, Chanda, Ilish, and Tengra. The dataset [29] was augmented and segmented, achieving an accuracy of 97.72%. In the recent study given by authors, the database of Indian dried fishes having 5 common categories and several deep learning models were evaluated for accuracy before and after training. EfficientNetB0 achieved the highest accuracy (95.23%), followed by ResNet50 (94.03%) and Xception (93.89%). InceptionV3 and VGG16 showed relatively lower final accuracies of 89.56% and 87.56%, respectively. These results highlight EfficientNetB0's superior performance in feature extraction and classification.

Despite extensive research on fish classification using image processing and machine learning techniques, most studies primarily focus on fresh fish or underwater species. There is a notable lack of dedicated research on dried fish classification, particularly for regionally significant species found in India and Bangladesh. While deep learning models such as convolutional neural networks (CNNs) have been employed for fish classification, limited studies have explored transfer learning approaches, specifically MobileNetV2, for dried fish classification. Moreover, existing research predominantly relies on full-body fish images, with minimal investigation into classification performance based on different perspectives, such as single images, head, tail, and bulk images. This gap is critical, as considering multiple perspectives could enhance the robustness of classification models in real-world applications, such as wholesale markets and automated sorting systems. Addition-

ally, many studies utilize computationally expensive models like YOLO, Mask-RCNN, and large CNN architectures, which require substantial resources. There is a pressing need for lightweight and efficient models capable of performing real-time dried fish classification on edge devices. Another significant gap lies in dataset availability. While datasets for fresh fish classification exist, comprehensive datasets for dried fish are scarce. The available datasets often lack diversity in terms of species representation, image quality, and environmental variations, which can impact model generalizability. Although our study attempts to address these limitations by evaluating classification performance across multiple perspectives and conducting detailed experiments, further research is needed to develop specialized, transfer-learning-based models that ensure improved accuracy, computational efficiency, and adaptability to real-world deployment.

III. Transfer Learning using MobileNetV2

Transfer learning is a deep learning technique that uses a pre-trained model on a large dataset and fine-tunes it for a specific task with a smaller dataset [25]. This approach is particularly effective in scenarios with limited training data, as it allows the model to use previously learned features to improve performance in new tasks.

Mathematically, if $f(x;\theta)$ represents a deep learning model with parameters θ, transfer learning can be expressed as:

$$\theta^* = \arg\min_{\theta} \sum_{i=1}^{N} \mathcal{L}(y_i, f(x_i;\theta)) \tag{1}$$

where:

- x_i and y_i are input-output pairs in the new dataset,
- $\mathcal{L}$ is the loss function,
- θ^* represents the optimized parameters adapted from the pre-trained model.

MobileNetV2, a lightweight deep convolutional neural network (CNN), is widely used for transfer learning in image classification tasks due to its efficiency in mobile and embedded applications [26]. MobileNetV2 is a convolutional neural network (CNN) architecture designed for efficient performance in resource-constrained environments. It employs inverted residuals and linear bottlenecks, enhancing both accuracy and computational efficiency [27] [36]. The core of MobileNetV2 consists of depthwise separable convolutions, which decompose standard convolutions into two operations: depthwise convolution, where a single filter is applied per input channel, and pointwise convolution, a 1×1 convolution that increases the channel dimension. This approach significantly reduces computational complexity compared to conventional convolutional layers [28]. Additionally, MobileNetV2 introduces inverted residual blocks, where shortcut connections exist between narrow bottleneck layers instead of wide layers, thereby improving feature reuse [26]. Each block follows a sequence: an expansion layer, which scales up the input dimension; a depthwise convolution, which reduces spatial dimensions while maintaining depth; and a projection layer (linear bottleneck), which compresses features into a lower-dimensional space.

Algorithm 1 Dried Fish Image Classification Using MobileNetV2 and Transfer Learning

Require: Image dataset $\mathcal{D} = \{(x_i, y_i)\}_{i=1}^{N}$, where $x_i \in \mathbb{R}^{h\times w\times c}$ and y_i is the label
Ensure: Trained classification model $f_\theta : \mathbb{R}^{h\times w\times c} \to \mathbb{R}^K$
Step 1: Data Preprocessing
Load dataset $\mathcal{D}$ from directory
Resize images: $x_i \leftarrow \text{resize}(x_i, (224, 224)) \quad \forall x_i \in \mathcal{D}$
Normalize images: $x_i \leftarrow \frac{x_i}{255} \quad \forall x_i \in \mathcal{D}$
Split dataset into training set $\mathcal{D}_{train}$ (80%) and testing set $\mathcal{D}_{test}$ (20%)
Step 2: Model Construction
Initialize pretrained MobileNetV2 backbone $\phi_{\text{MBV2}} : \mathbb{R}^{224\times224\times3} \to \mathbb{R}^d$
Freeze backbone layers: $\phi_{\text{MBV2}} \leftarrow$ frozen
Define classifier head:
    $h_\theta \leftarrow \text{Dense}(128, \text{ReLU})$
    $h_\theta \leftarrow \text{Dense}(128, \text{ReLU})$
    $h_\theta \leftarrow \text{Dense}(K, \text{Softmax})$
Construct final model: $f_\theta = h_\theta \circ \phi_{\text{MBV2}}$
Compile model with Adam optimizer and categorical cross-entropy loss
Step 3: Model Training
for $t = 1$ to T (epochs) **do**
    Train model on $\mathcal{D}_{train}$ using backpropagation
    if Validation loss does not improve for 5 epochs **then**
        Stop Training (Early Stopping)
    end if
end for
Step 4: Model Evaluation
Compute predictions: $\hat{y}_i = f_\theta(x_i) \quad \forall x_i \in \mathcal{D}_{test}$
Compute evaluation metrics:
    Accuracy: $\frac{1}{|\mathcal{D}_{test}|} \sum_i \mathbf{1}(\hat{y}_i = y_i)$
    Precision, Recall, and F1-score from confusion matrix
Generate classification report
End

For dried fish classification, MobileNetV2 is fine-tuned using a dataset containing various species of dried fish images. The preprocessing pipeline includes image resizing, data augmentation (rotation, flipping, normalization), and dataset splitting (80% training, 20% validation) [25]. Transfer learning is applied by leveraging a pre-trained MobileNetV2 model on ImageNet, replacing its fully connected layers with a custom classifier, as given in Fig. 1. The classification function is modeled as a softmax function, where extracted features from the pre-trained layers are fed into a newly trained classification head [26]. The training process involves minimizing cross-entropy loss, optimizing with the Adam optimizer, fine-tuning only the later layers while freezing earlier ones, and evaluating performance using accuracy, precision, recall, and F1-score. This approach ensures efficient and accurate classification of dried fish species while maintaining computational efficiency.

The key parameters used in the model include image size (224×224), learning rate (0.001), batch size (32), and number of dense layers in the classifier head. The choice of MobileNetV2 as a backbone minimizes the number of

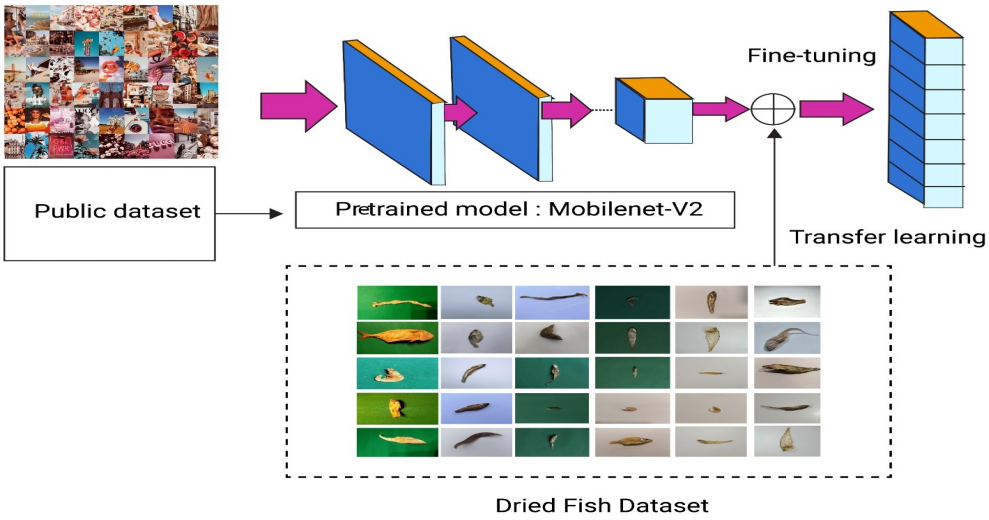

Fig. 1. Transfer learning-based dried fish image classification framework. [35]

trainable parameters (3.4M), supporting fast training. Early stopping was used to prevent overfitting. Sensitivity analysis showed that increasing the number of dense layers beyond two led to overfitting without significant accuracy improvement. Lowering the learning rate increased training time but did not yield significantly better results, justifying the current choice. Algorithm 1 details the dried fish image classification using MobileNetV2 and Transfer learning.

IV. Results and Discussion

A. Dataset Description

The datasets for this research were selected based on their relevance, public availability, and diversity of dried fish species from South Asian regions, especially India and Bangladesh, where dried fish is commercially significant. These datasets—Indian Dried Fish, BDDryFish, DriedFishBD, and SAR-DFD-2025—offer varying image perspectives (single, bulk, head, tail) and environmental conditions, providing a robust testbed for evaluating classification performance.

1) Indian dried fish image dataset [29]: This dataset consists of 8,290 images of dried fish, including both single and bulk images. It covers five fish categories commonly found in India: Prawns (Shrimp), Small Anchovi (Tingle), Golden Anchovi (Mandeli), Mackerel (Bangada), and Bombay Duck (Bombil). The dataset provides 6,784 single images and 1,506 bulk images, making it useful for fish classification and quality assessment studies (see Table I).

2) BDDryFish an image dataset of dry fishes found in Bangladesh [30]: This dataset includes 1,251 images of seven different dried fish species commonly found in Bangladesh. The fish categories include Shundori Shutki Aluva, Bele Fish, Boicha Shutki, Chingri Fish, Churi Shutki, Faisha Shutki, and Mola Fish. The dataset is useful for species identification and classification research in the domain of dried fish processing and trade (see Table II).

3) DriedFishBD a detailed image dataset of common small-sized dried fish varieties in Bangladesh [31]: This dataset contains 3,288 images of eight different small-sized dried fish species. Each fish category is represented through multiple perspectives, including single, bulk, head, and tail images, making it a rich dataset for detailed morphological analysis. The categories include Chanda, Chapila, Chela, Chepa, Guchi, Kachki, Loitta, and Tengra (see Table III).

4) SAR-DFD-2025 a high-quality and diverse dry fish dataset from South Asia [32]: SAR-DFD-2025 is a comprehensive, high-quality dataset designed for dry fish species identification in South Asia. It features a diverse collection of 2,138 images across 11 fish species, captured under varying lighting conditions and angles. The dataset includes species such as Boro Chingri, Chanda, Chela, Kachki, Kocho Chingri, Mola, Tengra, Poti, Shundori, Taki Actual, and Faissa. This dataset serves as a crucial resource for image-based fish species recognition and classification, aiding research in fisheries and related fields (see Table IV).

TABLE I. Dataset1 : Indian Dried Fish Image Dataset [29]

Sr. No	Category	No. of Single Images	No. of Bulk Images
1	Prawns (Shrimp)	1021	245
2	Small Anchovi (Tingle)	1051	408
3	Golden Anchovi (Mandeli)	977	499
4	Mackerel (Bangada)	2633	114
5	Bombay Duck (Bombil)	1102	240
Total		**6784**	**1506**

B. Experimental Results

The experimental results for the classification of dried fish species using deep learning models are presented in this section. The classification was conducted on multiple datasets, including Indian Dried Fish, BDDryfish, DriedFishBD, and

SARDFD2025. The models were evaluated based on precision, recall, and F1-score, which measure the effectiveness of the classification. Accuracy is also reported to provide an overall performance assessment.

Each dataset was tested using different imaging approaches, including single images, bulk images, head-only images, tail-only images, and full-body images. The following subsections provide a detailed breakdown of the classification results for each dataset.

Table V presents the classification results for Indian dried fish species using a single image per sample. The model achieved high precision, recall, and F1-score across all classes, with an overall accuracy of 100%. This indicates that the model correctly identified the species without any misclassification.

The slight variation in recall for Mandeli and precision for Tingali suggests that the model had minor confusion when classifying these species. However, the F1-score remained nearly perfect, demonstrating robust performance.

In the bulk image classification setting Table VI, multiple fish were present in a single image for classification. The overall accuracy remained high at 99%, with some minor variations in precision and recall. Here, Bombayduck showed a slight drop in precision (0.95), suggesting some misclassification in bulk image scenarios. However, the model still maintained strong performance across all classes.

The classification results for BDDryfish, another dried fish dataset, are shown in Table VII. The model achieved an overall accuracy of 99%, with minor variations in precision and recall across some classes. Here, Alua and Chingri fish had slight variations in recall (0.98 and 0.96, respectively), suggesting some misclassification. However, the overall accuracy remained strong, indicating that the model performed well across different fish species.

conditions.

Table VIII presents the classification performance when using the full image of the dried fish. The model achieved a high accuracy of 98%, indicating strong performance in distinguishing the eight fish species. Several species, such as Chanda, Chela, Chepa, Kachki, and Loitta, were classified with perfect precision, recall, and F1-score values of 1.00. However, minor classification errors were observed for Chapila (F1-score = 0.98), Guchi (F1-score = 0.93), and Tengra (F1-score = 0.94), suggesting that these species may have overlapping visual characteristics.

Table IX illustrates the classification results when using only the head portion of the dried fish. The overall accuracy slightly improved to 99%. Most species achieved an F1-score of 1.00, except Kachki (F1-score = 0.97). The improved performance compared to full image classification suggests that the head region contains distinctive features that aid in species identification.

Table X reports the classification performance when using only the tail portion of the fish. The overall accuracy remained at 98%, similar to full image classification. While most species were classified perfectly, slight performance drops were observed for Guchi (F1-score = 0.95), extitLoitta (F1-score = 0.97), and Tengra (F1-score = 0.94). This suggests that the tail alone may not be as distinctive as the head for classification purposes.

Table XI presents the classification results when using bulk images, where multiple fish appear in a single image. The model achieved perfect accuracy (100%) across all classes, indicating that it successfully identified every species without error. This suggests that bulk classification benefits from multiple views of the fish, allowing the model to generalize effectively.

The experimental results indicate that the model performs best on bulk images (100% accuracy), followed by head-only images (99%), full images (98%), and tail-only images (98%).

The head region provides more distinguishing features than the tail, leading to better classification performance.

The species Guchi and Tengra exhibit slightly lower F1-scores, indicating potential visual similarity with other species.

The consistently high accuracy ($\geq 98\%$) across all settings validates the robustness of the classification model for the DriedFishBD dataset.

These results confirm that the proposed classification model is highly effective in distinguishing dried fish species under different conditions.

Table XII presents the classification results obtained for the SARDFD2025 dataset. Precision measures the proportion of correctly identified instances for a given class among all instances predicted as that class. Recall quantifies the proportion of correctly identified instances among all actual instances of that class. The F1-score, which is the harmonic mean of precision and recall, provides a balanced measure of classification performance. The model achieves an overall accuracy of 97%, indicating a high level of classification performance across all classes. The individual class-wise results reveal strong performance across various categories.

The model demonstrates excellent classification performance for multiple fish species, including Faissa and Taki

TABLE XII. CLASSIFICATION RESULTS FOR SARDFD2025

Class	Precision	Recall	F1-score
Boro Chingri	0.95	0.95	0.95
Chanda	0.97	1.00	0.99
Chela	0.92	0.98	0.95

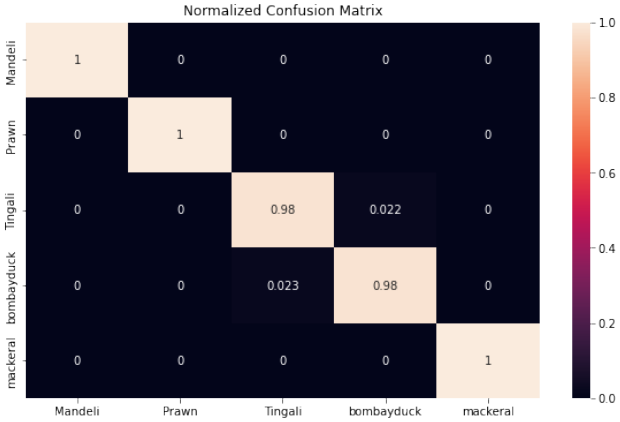

Fig. 3. Confusion matrix for Indian dried fish species (bulk images).

Actual, where both precision and recall reach 1.00, implying perfect classification. The majority of fish classes, such as Boro Chingri, Chela, Kocho Chingri, Mola, and Tengra, achieve F1-scores above 0.95, highlighting the reliability of the model in distinguishing between different species. A few classes exhibit minor differences between precision and recall values. For instance, Mola has a slightly lower recall (0.92) compared to its precision (0.98), suggesting some instances were not correctly

identified.

To evaluate the classification performance of the proposed model, we computed the accuracy and its 95% confidence interval (CI) [33] [34] for different dried fish image datasets. The confidence intervals were derived using the standard binomial proportion method to assess the statistical reliability of the classification results.

The model achieved high classification accuracy across all datasets, indicating its robustness in distinguishing dried fish categories. The Indian Dried Fish (single images) dataset recorded the highest accuracy of 100%, with a 95% CI of (0.9994, 1.0000), confirming the model's near-perfect performance.

For the Indian Dried Fish (bulk images) dataset, the accuracy was 99%, with a 95% CI of (0.9863, 0.9951). Similarly, the BDDryfish dataset achieved 99% accuracy, with a 95% CI of (0.9847, 0.9971). The DriedFishBD dataset showed an accuracy of 98%, with a 95% CI of (0.9721, 0.9903), demonstrating slightly lower but still highly reliable classification performance. We have also given the confusion matrices for all datasets in Fig. 2 to Fig. 9 and a comparison between the predicted and actual labels for a sample from the DriedFishBD (Single Images) dataset [31] in Fig. 10 for better understanding of the results.

These results suggest that the model maintains high generalizability across different datasets, ensuring effective clas-

sification regardless of variations in dried fish images. The marginal differences in accuracy across datasets may be attributed to variations in image quality, lighting conditions, and dataset-specific characteristics.

The narrow confidence intervals further validate the consistency and reliability of the proposed model. The findings indicate that the model can be effectively used in real-world applications, such as automated fish species identification in fisheries and quality control processes.

While the proposed approach achieves high accuracy across diverse datasets, there are some limitations. First, the datasets used have relatively small sample sizes for certain classes, potentially affecting model generalization in highly imbalanced real-world settings. Second, despite using transfer learning, the model requires moderate GPU resources during training, which may limit its applicability for institutions with limited infrastructure. Third, classification errors occurred in species with similar morphological features, especially under varying lighting conditions. These factors suggest opportunities for further refinement through dataset augmentation and hybrid models.

V. Conclusion and Future Work

This study demonstrates the effectiveness of a MobileNetV2-based transfer learning framework for automated dried fish classification across diverse South Asian datasets. Theoretically, the results validate the feasibility of using lightweight CNNs for species-level classification in low-data domains. Practically, the model supports real-time classification on mobile and edge devices, enabling scalable deployment in local markets and fisheries. The research contributes a novel evaluation of dried fish classification using different image modalities and introduces benchmarks on unexplored dried fish datasets from India and Bangladesh. The proposed method reduces manual labor, increases classification consistency, and supports digitization and traceability in fisheries processing. Its low computational cost suits resource limited environments. However, class imbalance and morphological similarity between species limit precision in specific cases. Performance under real-time video streams and environmental variability also needs validation.

Future studies should focus on integrating Vision Transformers or hybrid CNN-transformer architectures for improved feature extraction, developing a larger, balanced dataset of dried fish species across regions, and implementing explainable AI techniques for model transparency in commercial settings.

Enhancing Portfolio Optimization with Weighted Scoring for Return Prediction Through Machine Learning and Neural Networks

Ruili Sun, Qiongchao Xia, Shiguo Huang
Zhengzhou University of Light Industry
School of Mathematics and Information Science, Zhengzhou, China

***Abstract*—Accurately predicting stock return can enhance the effectiveness of portfolio optimization models. Many previous studies typically divide machine learning algorithms and portfolio optimization into two separate stages: the first step leverages the powerful modeling capabilities of machine learning algorithms to select stocks, and the second step optimizes weights using traditional portfolio models. This separation means that the modeling strengths of machine learning are only utilized in the stock selection phase and not fully exploited during weight optimization. Therefore, this study proposes a portfolio construction method based on Return Prediction Weighted Scoring (RPWS). RPWS generates a stock ranking by assigning weighted scores to each stock, cleverly maps this ranking to weight biases, and then optimizes actual weights using a traditional covariance matrix. This process successfully integrates the modeling capabilities of machine learning into the weight optimization phase, ensuring its full utilization throughout the portfolio construction process. Backtesting experiments are conducted using the U.S. stock market, A-share market, and major cryptocurrencies as datasets, with Support Vector Regression (SVR), Transformer, and other machine learning algorithms as prediction models. Empirical results from these three markets show that the SVR-RPWS and Transformer-RPWS models significantly outperform mainstream funds and traditional portfolio models in terms of annualized returns, sharpe ratio, and drawdown control.**

***Keywords*—Machine learning; stock return prediction; portfolio optimization; support vector regression; transformer; NASDAQ stock market; a-share stock market; cryptocurrency market**

I. Introduction

The optimization of a portfolio selection entails the strategic distribution of assets to maximize returns and minimize risk, two pivotal elements in this process. The endeavor to enhance profits while mitigating risk is a primary goal for investors. The genesis of portfolio selection as a domain of study is attributed to the introduction of the Mean-Variance model (Markowitz [1]), which evaluates return in terms of mean and risk in terms of variance. Subsequently, variance emerges as a commonly used risk measure, and studies related to models such as the Mean-Variance model gain popularity within the academic community, drawing significant attention from scholars such as Björk et al. [2], Liagkouras and Metaxiotis [3], Rosadi et al. [4] and Katsikis et al. [5].

Mean-Variance model relies on the anticipated return and risk associated with different assets to generate optimal portfolios corresponding to various levels of expected return and risk (Beheshti [6]). Consequently, through the careful selection of assets for inclusion in the optimization process, the Mean-Variance model has the potential to enhance overall portfolio performance (Thakur et al. [7]). In recent years, numerous prediction-based portfolio selection models have been introduced in the realm of portfolio management. When confronted with equivalent expected returns, a portfolio selection model boasting a more favorable efficient frontier can effectively reduce risk exposure. Therefore, enhancing the efficacy of prediction-based portfolio selection models remains a crucial endeavor in maximizing portfolio performance.

In financial market, individual investors are generally interested in understanding the fluctuations in the returns of their investment assets today, the potential trends in returns for tomorrow, and the strategies that should be implemented to optimize their portfolio composition (Zhang et al. [8]). Consequently, integrating forecasting theory into portfolio construction holds significant promise for financial investment (Kolm et al. [9]). Forecasting financial time series is consistently seen as one of the most formidable tasks due to the dynamic, nonlinear, unstable, and complex characteristics, coupled with the long-term fluctuations of the financial market (Chen and Hao [10]; Paiva [11]). Nevertheless, reliable investment decisions should be based on long-term observations and behavioral patterns of asset data rather than short-term data (Chong et al. [12]). Accordingly, it is imperative to examine the changes and volatility of financial data over an extended historical period to adequately prepare for future trend forecasts and investment decisions. Numerous broadly accepted empirical studies suggest that financial time series exhibit memory of past periods, indicating that financial markets are, to some extent, predictable. The long-term behavior of an asset significantly influences the risks and returns of a portfolio, thereby further impacting investment decisions (Liu and Loewenstein [13]).

To date, the predominant focus of prior research has been on the utilization of statistical methodologies and machine learning techniques in the predictive analysis domain. Statistical methodologies endeavor to anticipate forthcoming trends by scrutinizing historical pricing attributes such as autoregressive integrated moving average (ARIMA) (Anderson et al. [14]), auto-regressive conditional heteroscedasticity (ARCH) (Engle [15]; Shephard [16]), and generalized auto-regressive conditional heteroscedasticity (GARCH) (Bollerslev [17]; Garcia et al. [18]), whereas prevalent machine learning methodologies encompass support vector machines (Villegas et al. [19]), random forests (Kavzoglu and Teke [20]), and neural networks (Ma [21]). Notwithstanding the capacity of statistical methods

to contribute to stock price forecasting, empirical investigations have revealed that machine learning exhibits superior efficacy in addressing challenges associated with non-stationarity and non-linearity when compared to traditional statistical models (Boulesteix and Schmid [22]; Zhang et al. [23]). Recently, several studies (Freitas et al. [24], Jiang et al. [25], Kaczmarek [26], Padhi et al. [27]) have incorporated the pre-selection of assets into portfolio selection models utilizing machine learning techniques. For example, Deng and Min [28] implemented a linear regression model with ten factors to select stocks from both U.S. and international markets, subsequently constructing a mean-variance-based portfolio that accounted for practical risk tolerance, error monitoring, and turnover constraints. Their results demonstrated that the risk-adjusted return of the global equities model surpassed that of the domestic equity universe, with portfolio returns increasing in conjunction with systemic monitoring errors and risk tolerance. Similarly, Ma [21] employed two machine learning models—random forest (RF) and support vector regression—alongside three deep learning models: convolutional neural network (CNN), long short-term memory (LSTM) neural network, and deep multilayer perceptron (DMLP), to forecast returns for portfolio construction. They subsequently utilized these forecasts to enhance omega portfolio optimization and Mean-Variance model. Their findings revealed that the return predictions for Mean-Variance model and omega models using the RF algorithm outperformed those produced by the other models.

The utilization of machine learning and neural networks in the realm of stock forecasting has garnered considerable success, as evidenced by various studies (Ballings et al. [29]; Sezer and Ozbayoglu [31]; Tsai and Hsiao [32]). These findings advocate for an integration of machine learning methodologies with traditional models of portfolio optimization for the creation of investment portfolios. Numerous academics have been delving into this field of study, primarily branching out into three distinct avenues. Specifically, the first approach involves certain researchers employing Machine Learning models solely during the initial stock selection phase, subsequently utilizing the chosen stocks to construct portfolios through traditional portfolio optimization techniques (Paiva [11]; Vo et al. [33]; Wang et al. [34]). Evidence from these studies suggests that the utilization of stocks selected via machine learning algorithm can enhance the efficacy of conventional portfolio optimization frameworks. In the second vein, several scholars adopt machine learning algorithm for forecasting future stock returns, thereafter incorporating these forecasts to formulate novel objective functions. These newly developed functions aim to refine and augment the objective functions inherent in classical portfolio optimization models (Ma et al. [35]; Ustun and Kasimbeyli [36]; Yu et al. [37]; Yu et al.). Findings from these inquiries indicate that objective functions, enriched by predictive insights from machine learning algorithm, can significantly improve upon traditional portfolio optimization methods. Lastly, a third group of researchers leverages machine learning algorithm to forecast stock returns, opting to utilize the forecast errors in lieu of historical returns when constructing traditional portfolio optimization models (i.e., prediction-based portfolio optimization models). This preference stems from the observation that the normality of forecast errors surpasses that of historical returns (Freitas et al. [39]; Freitas et al. [24]; Hao et al. [40]; Ma et al. [41]). Insights from these studies reveal that forecast errors derived from machine learning algorithm prove more adept than historical returns for the purpose of enhancing portfolio optimization models.

Many previous studies primarily focus on using machine learning algorithms and neural network models to predict stock returns for stock selection, followed by optimizing weights through traditional portfolio models (for example, Minimum Variance Model, Mean VaR Model, Mean Absolute Deviation Model, and others) to enhance investment decisions. This study introduces a novel approach to portfolio construction that combines return predictions from machine learning and neural network models with historical covariance matrix, employing a weighted scoring method to enhance portfolio optimization. This method consists of two main steps, aimed at optimizing portfolio construction and risk management. Specifically, the first step involves using a trained machine learning model or neural network to predict the expected future returns of each asset in the backtest dataset. Once the expected returns are obtained, the assets are ranked according to these return values, and different weights are assigned to each asset through squared weighting. A higher weight corresponds to a higher expected return. The squared weighting method helps to increase the investment proportion in assets with higher expected returns, while relatively reducing the weight of assets with lower expected returns, thereby enhancing the overall potential return of the portfolio. The second step is to calculate the historical covariance matrix. The covariance matrix of the portfolio reflects the correlation and volatility of returns between different stocks. Then the covariance matrix is used to constrain the optimal portfolio weights. This method uses the covariance matrix optimization mechanism to improve expected returns while reasonably controlling portfolio risk, thereby achieving a more stable and optimized asset allocation in a complex market environment. This proposed approach will undergo backtesting in the constituents of the CSI 300 Index, the NASDAQ Index, and major cryptocurrencies, with comprehensive comparisons to traditional portfolio models based on the backtest results.

The rest of this study is organized as follows: Section II provides an overview of the machine learning algorithms, neural network models, and traditional portfolio models used in this study. Section III introduces the novel portfolio construction method proposed in this study, as well as the data selection and experimental design process. Section IV and Section V evaluate the performance of the predictive models and analyze the empirical results. Finally, Section VI concludes the work.

II. Methodology

This section will introduce the methods used in this study, including prediction models and traditional portfolio models.

A. Machine Learning Methods

XGBoost, which stands for "eXtreme Gradient Boosting" was introduced by Chen and Guestrin [42]. This algorithm is characterized by its low computational complexity, rapid execution speed, and high accuracy. The objective function of XGBoost integrates the standard penalty term with the loss function to derive the optimal solution. The inclusion of the regularization term serves to minimize the model's variance, thereby mitigating the risk of overfitting.

The k-nearest neighbors (KNN) algorithm, also known as k-NN, is a non-parametric, supervised learning method applied to both classification and regression tasks. In the context of KNN regression, the algorithm functions by identifying a subset of points in the dataset that are nearest to the "query" point, as determined by a specified distance metric, such as Euclidean, Minkowski, or Manhattan distance [43]. KNN also employs a hierarchical tree-based data structure to manage the dataset efficiently [44].

Support Vector Regression (SVR) represents a supervised learning algorithm specifically designed for regression tasks, as initially proposed by Cortes and Vapnik in 1995 [45]. The underlying principle of SVR is Vapnik's Structural Risk Minimization (SRM), which is adept at tackling various regression problems. The incorporation of kernel functions facilitates the handling of diverse types of input data, thereby enhancing the model's flexibility and applicability. Given its robustness and accuracy, SVR has emerged as a quintessential machine learning technique, extensively utilized in the field of stock market prediction (Emir [46]; Matías and Reboredo [47]; Rasel et al. [48]).

B. Long Short-Term Memory (LSTM)

Long Short-Term Memory (LSTM), a variant of Recurrent Neural Network (RNN), was first proposed by Hochreiter and Schmidhuber [49]. The LSTM model, distinct from traditional RNNs, possesses a memory function, enabling it to retain data over an extended period [50]. This unique feature is facilitated by gate structures, namely an input gate, a forget gate, and an output gate, which filter incoming information to enhance and sustain memory cells. LSTMs are particularly favored in financial time-series prediction due to their ability to effectively manage redundancy in historical data [51].

The operational formulas of LSTM are as follows:

Forget gate:

$$f_t = \sigma(w_f[h_{t-1}, x_t] + b_f)$$

Input gate:

$$i_t = \sigma(w_i[h_{t-1}, x_t] + b_i)$$

$$o_t = \sigma(w_o[h_{t-1}, x_t] + b_o)$$

$$\tilde{c}_t = \tanh(w_c[h_{t-1}, x_t] + b_c)$$

Output gate:

$$c_t = f_t c_{t-1} + i_t \tilde{c}_t$$

$$h_t = o_t \tanh(c_t)$$

In these formulas, f_t, i_t, and o_t signify the forget gate, input gate, and output gate, respectively.

The weight of the matrix is represented by w, while b_t, b_i, and b_o denote the bias of the forget gate, input gate, and output gate, respectively.

The sigmoid function is denoted by σ, and x_t and h_t indicate the input and the current output at time t, respectively. The value from the input gate at time t is represented by c_t, and the hyperbolic function is represented by $\tanh$.

C. Transformer

The Transformer model, introduced by Vaswani et al. [52], represents a significant advancement in natural language processing and sequence modeling. Unlike recurrent architectures such as LSTMs, the Transformer relies entirely on self-attention mechanisms to process input sequences, enabling parallelization and enhancing efficiency. This self-attention mechanism allows the model to assess the importance of different words in a sequence when encoding information, effectively capturing long-range dependencies without the constraints of sequential processing.

The Transformer architecture comprises an encoder and a decoder, each consisting of multiple layers. The encoder processes an input sequence to generate a continuous representation, while the decoder utilizes this representation to produce an output sequence. The core operations within the encoder can be described by the following formulas:

First, input embeddings are augmented with positional encodings to preserve the order of the sequence:

$$z_i = x_i + PE(i)$$

where, z_i denotes the input embedding at position i, x_i is the original embedding, and $PE(i)$ represents the positional encoding for position i.

The self-attention mechanism computes attention scores for each position in the input sequence:

$$\text{Attention}(Q, K, V) = \text{softmax}\left(\frac{QK^T}{\sqrt{d_k}}\right)V$$

where, Q, K, and V are the query, key, and value matrices derived from the input embeddings, and d_k is the dimensionality of the keys, used to scale the dot-product attention scores.

Subsequently, the output from the attention mechanism is processed through a feed-forward neural network:

$$\text{FFN}(z) = \text{ReLU}(W_1 z + b_1)W_2 + b_2$$

where, W_1 and W_2 are weight matrices, and b_1 and b_2 are bias terms.

Each layer of the encoder includes residual connections and layer normalization to stabilize training:

$$\text{Output} = \text{LayerNorm}(z + \text{FFN}(\text{Attention}(Q, K, V)))$$

The decoder follows a similar structure, incorporating masked self-attention to prevent attention to future tokens, ensuring autoregressive output generation.

The Transformer has demonstrated exceptional performance across various tasks, including machine translation and text generation, owing to its efficiency in capturing complex dependencies in data. Its flexibility and scalability have established it as a cornerstone of modern deep learning architectures, significantly influencing subsequent models in the field [53].

D. Informer

Informer is a novel model designed for long sequence time-series forecasting, as proposed by Zhou et al. [54]. Unlike traditional time-series models, Informer employs a self-attention mechanism specifically optimized for efficient handling of long sequences. Its key innovation is an adaptive attention mechanism that focuses on relevant input features while discarding less relevant information, thus alleviating the computational burden associated with standard attention mechanisms.

The Informer architecture consists of an encoder and a decoder, similar to the Transformer model, but with enhancements for long-sequence performance. The core components of Informer are as follows:

The adaptive attention mechanism generates a sparse attention matrix using a probability distribution D:

$$D_{ij} = \frac{\exp(\text{score}(Q_i, K_j))}{\sum_{k \in \mathcal{N}} \exp(\text{score}(Q_i, K_k))}$$

where, $\text{score}(Q_i, K_j)$ represents the score function computed between query Q_i and key K_j, and $\mathcal{N}$ denotes the neighborhood of keys attended to by the query. This ensures that each query focuses on a subset of keys, significantly reducing computational complexity.

The encoder processes the input sequence to generate context-aware representations through multiple layers of self-attention and feed-forward networks:

$$Z^{(l)} = \text{LayerNorm}\left(Z^{(l-1)} + \text{Attention}(Z^{(l-1)}, Z^{(l-1)}, Z^{(l-1)})\right)$$
$$H^{(l)} = \text{LayerNorm}\left(Z^{(l)} + \text{FFN}(Z^{(l)})\right)$$

where, $Z^{(l)}$ is the output of layer l, and $H^{(l)}$ represents the result after applying the feed-forward network FFN.

In the decoder, the predicted output is generated based on the encoder's output and previous outputs. The decoder employs masked self-attention to ensure autoregressive prediction:

$$\hat{Y}_t = \text{LayerNorm}\left(Y_{t-1} + \text{MaskedAttention}(Y_{t-1}, Z)\right)$$

where, $\hat{Y}_t$ is the predicted output at time t, and Y_{t-1} denotes the previous outputs.

Informer performs well in forecasting tasks by effectively managing long-term dependencies and reducing computational overhead. Compared to previous methods, it shows significant improvements in accuracy and efficiency, Lu et al. [55].

E. Mean-Variance Model

The selection of investment strategies has always been a vital area in financial research. Amongst a wide array of investment strategies, the Mean-Variance Model, put forth by Harry Markowitz in 1952, has gained substantial recognition [1].

The model's theoretical rigor and practicality have led to its broad utilization in the practical realm of investment decisions. Its main idea is to find the investment proportion that minimizes the total risk of the portfolio at a given expected return level; or at a given risk level, find the investment proportion that maximizes the total return of the portfolio. Let $R = (R_1, R_2, \ldots, R_n)^T$, where $R_i = E(r_i)$ represents the expected return of the i-th asset; $X = (x_1, x_2, \ldots, x_n)^T$ is the weight vector of the portfolio; $\Sigma = (\sigma_{ij})_{n \times n}$ is the covariance matrix between n assets; $E(r_p)$ and σ_p^2 are the expected return and variance of the portfolio, respectively.

The mathematical formula for the Mean-Variance Model is as follows:

$$\begin{aligned} \min \quad & \sigma_p^2 = X^T \Sigma X \\ \max \quad & E(r_p) = X^T R \\ \text{s.t.} \quad & \sum_{i=1}^{n} x_i = 1 \end{aligned}$$

Minimizing the variance (risk) of the portfolio and maximizing the expected return of the portfolio are two objectives that usually cannot be achieved simultaneously, so a trade-off between risk and return is needed. To compare with the portfolio methods proposed in this study, we will solve two special solutions of the mean-variance model through numerical methods.

The first extended model is the **Minimum Variance Portfolio Model (MVM)**, which aims to find the portfolio weight that minimizes the risk of the portfolio among all possible portfolio weight. The formula for this model is as follows:

$$\begin{aligned} \min \quad & \sigma_p^2 = X^T \Sigma X \\ \text{s.t.} \quad & \sum_{i=1}^{n} x_i = 1 \end{aligned}$$

The second extended model is the **Maximum Sharpe Ratio Portfolio Model (MSRM)**, which aims to find the weight distribution that maximizes the Sharpe ratio (the ratio of expected return to risk) of the portfolio among all possible weight distributions. The formula for this model is as follows:

$$\max \quad \frac{X^T R - r_f}{\sqrt{X^T \Sigma X}}$$
$$\text{s.t.} \quad \sum_{i=1}^{n} x_i = 1$$

where, r_f stands for the risk-free rate, which is set to 0 in this study.

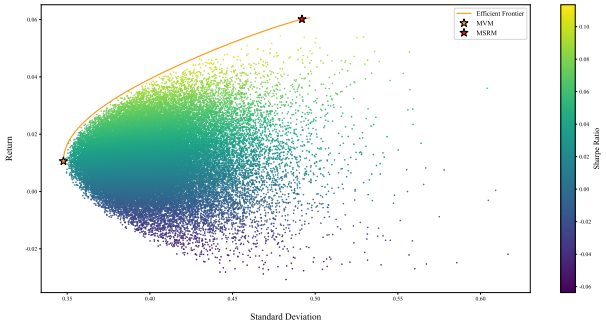

Fig. 1. Efficient frontier with random portfolios.

In Fig. 1, we can see a scatter plot composed of many random investment portfolios. The picture shows a curve called the efficient frontier. Efficient frontier points represent portfolios offering the optimal risk-return trade-off, either maximizing return for a given risk or minimizing risk for a given return. Among these points, two points are specially marked, one is the point with the minimum variance, and the other is the point with the maximum Sharpe ratio. These two points correspond to the solutions of the two models we mentioned above.

F. Risk Parity Model (RPM)

The risk parity strategy, proposed by Dr. Edward Qian, the Chief Investment Officer of Pan Agora, is renowned for its innovative approach to investment. This model was later applied in practice by Bridgewater Associates and achieved significant success for a time. From the perspective of risk budgeting, risk parity involves evenly distributing the overall risk of the portfolio among different assets, meaning that each asset contributes equally to the overall risk of the portfolio. In other words, in the risk parity model, assets with higher volatility are allocated lower weights, while those with lower volatility receive higher weights.

The marginal risk contribution (MRC) of an asset to a portfolio is defined as the partial derivative of the portfolio volatility with respect to the weight of the asset:

$$MRC_i = \frac{\partial \sigma_p}{\partial x_i} = \frac{\partial \sqrt{X^T \Sigma X}}{\partial x_i}$$

The contribution of the asset to the total risk (RC) is the product of the asset's weight and its marginal risk contribution:

$$RC_i = x_i \cdot MRC_i$$

For a risk parity portfolio, the contributions to total risk from each asset are equal, i.e.:

$$RC_i = RC_j$$

Calculating the weights for a risk parity portfolio essentially involves solving a quadratic optimization problem, which can be mathematically described as:

$$\min \quad \sum_{i=1}^{n} \sum_{j=1}^{n} (RC_i - RC_j)^2$$
$$\text{s.t.} \quad \sum_{i=1}^{n} x_i = 1$$
$$0 \leq x_i \leq 1$$

III. Newly Proposed Strategy for Portfolio Selection

A. Proposed Method: Return Prediction Weighted Scoring Strategy (RPWS)

In the field of portfolio optimization, Markowitz's (1952) mean-variance model stands as the most classical theoretical framework, constructing optimal portfolios by balancing expected returns and risk (volatility) [1]. However, the model's reliance on historical data assumptions may fail in rapidly changing markets. With advancements in machine learning and neural network technologies, numerous studies have validated the effectiveness of these techniques in stock prediction. For instance, Chaweewanchon et al. (2022) proposed a portfolio strategy combining the CNN-BiLSTM prediction model with the Markowitz Mean-Variance method. Backtesting experiments show that it outperforms other benchmark models in terms of Sharpe ratio, average return, and risk control [30].

Behera et al. (2023) proposed a portfolio construction method based on machine learning algorithms and the Mean-Value at Risk (Mean-VaR) model. First, stock returns are predicted using algorithms including XGBoost and AdaBoost to select stocks with higher expected returns; then, the Mean-VaR model is used for portfolio optimization. Based on stock data from the Bombay Stock Exchange in India, the Tokyo Stock Exchange in Japan, and the Shanghai Stock Exchange in China, experimental results show that the Mean-VaR model combined with AdaBoost prediction outperforms other combinations in performance [38].

Previous studies typically divide machine learning algorithms and portfolio optimization into two separate stages: the first step leverages the powerful modeling capabilities of machine learning algorithms to select stocks, and the second step optimizes weights using traditional portfolio models. This separation means that the modeling strengths of machine learning are only utilized in the stock selection phase and not fully exploited during weight optimization. Therefore, this study proposes a portfolio construction method based on Return Prediction Weighted Scoring (RPWS). RPWS generates a stock ranking by assigning weighted scores to each stock, maps this ranking to weight biases, and then optimizes actual

weights using a traditional covariance matrix. This process successfully integrates the modeling capabilities of machine learning into the weight optimization phase, ensuring its full utilization throughout the portfolio construction process.

The RPWS algorithm's mathematical model achieves dynamic weight optimization through two core components: 1) constructing a reference weight vector based on return prediction and rank weighting, and 2) covariance-constrained weight allocation optimization. The specific steps are as follows: Let $P = (p_1, p_2, p_3, \ldots, p_n)^T$, where p_i represents the ranking of the i-th stock among all stocks based on the expected return predicted by machine learning and neural network models. Let $\Sigma = (\sigma_{ij})_{n\times n}$ be the covariance matrix between n assets. The reference weight vector X_0 is constructed as:

$$X_0 = \frac{p_j^{-2}}{\sum_{j=1}^{n} p_j^{-2}}$$

The objective of this reference weight vector is to allocate higher weights to higher-ranked stocks. The optimal weights are then solved through convex optimization with risk budget constraints:

$$\begin{aligned} \min \quad & X^T \Sigma X + \lambda \|X - X_0\|_2 \\ \text{s.t.} \quad & \sum_{i=1}^{n} x_i = 1 \end{aligned}$$

where,

- λ: Regularization parameter controlling the emphasis on the reference matrix (larger λ forces weights closer to X_0, degenerating to minimum variance model when $\lambda = 0$)
- $\|X - X_0\|_2$: L2 norm measuring the deviation between optimal weights and reference weights.

This formulation integrates machine learning predictions through X_0 while maintaining risk constraints through covariance matrix optimization. Considering that this is a convex optimization problem, in order to simplify the hyperparameter tuning, this study sets $\lambda = 1$ to solve the problem in the experiment.

B. Experimental Process

In financial markets, investors consistently aim to optimize their portfolios using scientific methods and strategies to achieve the optimal balance between risk and return.

However, the uncertainty and complexity of the market make constructing an efficient portfolio a challenging task. This study focuses on prediction as its core research direction, leveraging machine learning and neural network techniques to model and assign higher weights to stocks with higher potential returns and manageable risks, thereby constructing investment portfolios. By adopting this method, not only can the overall return expectations of the portfolio be improved, but the reliability and guidance of the decision-making process for investors can also be significantly enhanced. This methodology involves two main phases:

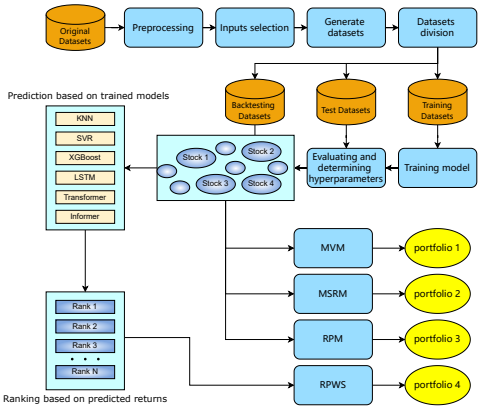

Fig. 2. Experimental process of the study.

1) Model training and performance evaluation: In this experimental approach, various models, including XGBoost, KNN, SVR, LSTM, Transformer, and Informer, are employed for stock return prediction. To evaluate the accuracy and performance of these models, three metrics are used: Mean Absolute Percentage Error (MAPE), Mean Squared Error (MSE), and Root Mean Squared Error (RMSE). The training in this stage is conducted on a dataset separate from the backtesting dataset. The primary goal at this stage is to determine appropriate model parameters and assess the models' performance. The hyperparameters for each model are detailed in Table I.

2) Portfolio backtesting: In this phase, portfolio backtesting is conducted to compare the performance of different portfolio models. The models include the Minimum Variance Portfolio Model (MVP), Maximum Sharpe Ratio Portfolio Model (MSR), Risk Parity Model (RP), and the Return Prediction Weighted Scoring Model (RPWS). For the A-share and U.S. stock markets, portfolio allocations are adjusted every 20 trading days. In contrast, for the cryptocurrency market—which operates year-round without interruptions—allocations are adjusted every 7 days. When using the Return Prediction Weighted Scoring Model, a rolling training approach is applied, utilizing the 500 most recent historical samples prior to each current date. This ensures the model adapts to the trends and dynamics of changing market conditions.

The overall experimental workflow is illustrated in Fig. 2.

IV. Data and Performance Evaluation

A. Datasets and Pre-processing

The selection of the dataset is crucial for model evaluation, and this experiment will use index component stocks as the data source. Indices are reliable financial indicators of high-quality stocks and reflect mainstream investment trends in the market. Index component stocks are of high quality, with minimal occurrences of suspension or delisting, ensuring the

continuity and completeness of the experimental data samples. This quality is advantageous for model construction, as portfolios based on index component stocks tend to be more robust and offer better potential returns. Due to the immaturity and high volatility of the cryptocurrency market, only a few selected major currencies are included in the dataset.

To validate the robustness of the model, this study will conduct backtesting across multiple markets, including the A-share market, the U.S. stock market, and the cryptocurrency market. The updated dataset includes the following components:

- CSI 300 Index Component Stocks: Daily data from January 2017 to January 2024, with a random selection of 30 stocks.
- NASDAQ Index Component Stocks: Daily data from January 2014 to January 2024, with a random selection of 40 stocks.
- Cryptocurrency Data: Daily data from January 2023 to October 2024, covering 10 major cryptocurrencies.

The dataset includes various factors such as opening price, closing price, highest price, lowest price, trading volume, and three technical indicators: the Relative Strength Index (RSI) with a 12-period, the Moving Average Convergence Divergence (MACD) with a 12-period, and the On-Balance Volume (OBV). This comprehensive datasets aims to enhance the reliability and stability of the experimental results, providing a solid foundation for validating the model's performance across different financial markets. The specific stocks selected are detailed in Table II.

Data normalization involves transforming data with different scales and units into a uniform format, allowing for comparability across different dimensions and facilitating feature extraction during the model training process. In this experiment, we use the Max-Min normalization method to process each feature factor in a dimensionless manner. The specific formula for normalization is shown below:

$$y_i = \frac{x_i - \min\limits_{1 \le j \le n} \{x_j\}}{\max\limits_{1 \le j \le n} \{x_j\} - \min\limits_{1 \le j \le n} \{x_j\}}$$

where, x_i represents the original data, y_i denotes the normalized dimensionless data, and j is the j-th element in the sequence.

B. Performance Evaluation

This study employs six metrics, namely MSE, RMSE and MAE, to provide a comprehensive analysis of various models' performance in predicting stock returns. These metrics are

TABLE III. PERFORMANCE OF DIFFERENT MODELS ACROSS THREE MARKETS

		U.S. Stock Market			A-share Market			Crypto Market		
Model	Metric	MSE	RMSE	MAE	MSE	RMSE	MAE	MSE	RMSE	MAE

	Var	0.0013	0.0061	0.0051	0.0573	0.0633	0.0637	0.0060	0.0195	0.0181

commonly utilized as evaluative indicators due to their comprehensive portrayal of predictive capabilities (Freitas [24]; Gandhmal and Kumar [56]; Ma et al. [41]).

1) Mean Squared Error (MSE): MSE calculates the average squared differences between predicted and actual values, emphasizing larger errors due to the squaring operation. The formula for MSE is:

$$MSE = \frac{1}{N}\sum_{i=1}^{N}(y_i - \hat{y}_i)^2$$

2) Root Mean Squared Error (RMSE): RMSE represents the square root of the average squared differences between predicted and actual values, providing a measure of the standard deviation of residuals. The formula for RMSE is:

$$RMSE = \sqrt{\frac{1}{N}\sum_{i=1}^{N}(y_i - \hat{y}_i)^2}$$

3) Mean Absolute Error (MAE): MAE measures the average magnitude of errors between predicted and actual values, providing a straightforward assessment of model performance. The formula for MAE is:

$$MAE = \frac{1}{N}\sum_{i=1}^{N}|y_i - \hat{y}_i|$$

In this study, we evaluate the performance of six models—KNN, SVR, XGBoost, LSTM, Transformer, and Informer—in predicting stock returns. Table III presents the results for each model based on the performance metrics MSE, RMSE, and MAE.

In the U.S. stock market, the LSTM model clearly outperforms the others, exhibiting the lowest error and highest stability. XGBoost and KNN follow closely behind, while Transformer and Informer show similar performances, though they lag behind XGBoost and KNN. The SVR model performs the worst overall. In the Chinese A-share market, the performance patterns of the models are similar to those observed in the U.S. market. The LSTM model again stands out, with the smallest MSE, RMSE, and MAE, and good stability. SVR exhibits relatively large errors and instability, while Transformer and Informer perform the worst, with significantly higher errors. In the cryptocurrency market, the errors of all models increase due to the immature nature and high volatility of the market, making prediction a particularly challenging task. However, the overall performance trends of the models remain similar to those in the U.S. and A-share markets, with LSTM still showing the best performance and SVR and Transformer showing the worst.

It is important to note that the performance metrics presented here are based solely on the results from the test dataset. The data used for the rolling backtest, which is entirely separate from this test dataset, may not reflect the actual predictive performance of each model throughout the backtesting process.

V. EMPIRICAL RESULTS

After comparing the performance of different models in stock return prediction, a backtesting simulation is conducted to study the investment performance of various portfolios, with an initial capital of 100,000. In the A-share and U.S. stock markets, portfolio weights are adjusted every 20 days, while in the cryptocurrency market, portfolio weights are adjusted every 7 days. For simplicity, dividends and transaction fees are disregarded, and leverage and short-selling are not considered during the portfolio rebalancing process. In this

TABLE IV. DIFFERENT PORTFOLIO OPTIMIZATION MODELS FOR COMPARISON

Abbreviation	Description
QQQ (ETF)	Invesco QQQ Trust (Nasdaq: QQQ).
CSI 300 (ETF)	CSI 300 Index Securities Investment Fund.
BTC	Bitcoin: A mainstream cryptocurrency.
1/N	Equal Weight Strategy.
RPM	Risk Parity Model.
MVM	Minimum Variance Portfolio Model.
MSRM	Maximum Sharpe Ratio Portfolio Model.
SVR-RPWS	SVR for prediction and ranking, RPWS for portfolio construction.
KNN-RPWS	KNN for prediction and ranking, RPWS for portfolio construction.
XGBoost-RPWS	XGBoost for prediction and ranking, RPWS for portfolio construction.
LSTM-RPWS	LSTM for prediction and ranking, RPWS for portfolio construction.
Informer-RPWS	Informer for prediction and ranking, RPWS for portfolio construction.
Transformer-RPWS	Transformer for prediction and ranking, RPWS for portfolio construction.
SVR-MVM(N=10)	SVR for prediction and screening, MVM for portfolio construction.

Notes:
1. To more clearly highlight the performance of RPWS, the SVR-MVM model is introduced as a comparative experiment. This model uses the best-performing SVR algorithm to select the top 10 stocks based on predicted returns. We select 10 stocks for the following reasons: Evans and Archer (1968) have demonstrated that the traditional rule of thumb suggesting 8 to 10 stocks, established by pioneering studies, is indeed sufficient to achieve optimal diversification effects [58]. Alexeev and Dungey (2015) assert that an equally weighted portfolio of 10 stocks would suffice for an average investor aiming to diversify away 90% of the risk [59]. Recognizing that individual investors may struggle to track too many assets, we have decided that the number of stocks we select will be 10. Optimizes portfolio weights using the Minimum Variance Model (MVM).

2. Cryptocurrencies market, due to limited samples, are no longer included in the comparison.

TABLE V. METRICS FOR MEASURING PORTFOLIO PERFORMANCE

Metrics	Formula	
Annualized Return	$R = \left(\prod_{i=1}^{N}(1+r_i)\right)^{\frac{252}{N}} - 1$	
Annualized Volatility	$V = \sqrt{\frac{252}{N}\sum_{i=1}^{N}(r_i-\mu)^2}$	$\mu = \frac{1}{N}\sum_{i=1}^{N} r_i$
Sharpe Ratio	Sharpe Ratio $= \frac{R - r_f}{V}$	
Sortino Ratio	Sortino Ratio $= \frac{R - r_f}{D}$	$D = \sqrt{\frac{252}{N}\sum_{i=1}^{N}\min(r_i - r_f, 0)^2}$
Maximum Drawdown	$\text{MDD} = \max_{1 \le i \le N}\left(\frac{P_{\text{peak},i} - P_i}{P_{\text{peak},i}}\right)$	
VaR(95%)	VaR(95%) $= \mu - 1.645 \times \sigma$	$\sigma = \sqrt{\frac{1}{N}\sum_{i=1}^{N}(r_i-\mu)^2}$

Notes:

1. r_i denotes the return in the i-th day, N is the total number of days, and 252 is the number of trading days in a year.

2. r_f is the risk-free rate, which is set to 0 in this study.

3. P_i represents the return on the i-th day, while $P_{\text{peak},i}$ denotes the historical maximum return up to the i-th day.

4. 1.645 is the quantile of the standard normal distribution at the 95% confidence level.

study, six key metrics are used to evaluate the performance of different portfolios: annualized return, Sharpe ratio, maximum drawdown, Sortino ratio, annualized volatility, and Value at Risk (VaR) at the 95% confidence level. Table IV shows different portfolio optimization models for comparison. The details of each indicator can be found in Table V.

From 2018 to 2024, the U.S. stock market experienced dramatic fluctuations, including a bull market recovery, a bear market adjustment, and dramatic fluctuations caused by the epidemic. The market was affected by multiple factors such as interest rate hikes, inflation, and stimulus policies, and generally showed a fluctuating upward trend. In the backtest, the SVR-RPWS model performs best overall, followed by the Transformer-RPWS model. The SVR-RPWS model achieves the highest annualized return (28.11%), the highest Sharpe ratio (1.1436) and the Sortino ratio (1.6704), and is also excellent in drawdown control, with the maximum drawdown (-22.74%) second only to the LSTM-RPWS model (-21.86%). The SVR-RPWS and Transformer-RPWS models outperform QQQ (QQQ is an exchange-traded fund that tracks the Nasdaq 100 Index, which includes the 100 largest non-financial companies listed on the Nasdaq stock market) in all indicators and perform significantly better than other models overall. In addition, all models using the RPWS algorithm also outperform QQQ overall, especially in terms of seeking returns. The traditional portfolio model performs well in risk control, with annualized volatility and value at risk (VaR) slightly better than the model using the RPWS algorithm at the 95% confidence level, but performs poorly in terms of annualized returns and Sharpe ratio, and failed to surpass QQQ. The SVR-MVM model performs quite well overall, with a Sharpe ratio second only to SVR-RPWS and Transformer-RPWS, and it also demonstrates good risk control. Compared to the MVM model without any stock screening, it shows significant improvement, reflecting the effectiveness of stock screening. However, in terms of pursuing returns, it still lags considerably behind models using the RPWS algorithm. The detailed backtest performance and cumulative returns are available in Table VI and Fig. 3.

From 2021 to 2024, affected by factors such as the slowdown in economic growth, the Sino-US trade war and the external environment, the A-share market was dominated by a bear market, continued to adjust, and continued to be sluggish. Although there was a short-term rebound, the overall trend was weak. The three-year annualized return of the CSI 300 ETF (the CSI 300 ETF tracks the CSI 300 Index, which represents the 300 largest and most liquid stocks listed on the Shanghai and Shenzhen Stock Exchanges) was -13.25%. In the backtest, the SVR-RPWS and Transformer-RPWS models perform similarly to the US stock market, both perform well and significantly outperform all other models. Among them, the SVR-RPWS model has the highest annualized return (25.30%), the highest Sharpe ratio (1.2401), and the highest Sortino ratio (2.0532). At the same time, while maintaining high returns, the Transformer-RPWS model performs best in risk control, with a maximum drawdown of only -12.58%, an annualized volatility of 15.29% and a VaR (95%) of -1.29%. It is worth noting that although the traditional models perform well in terms of risk control, the overall returns are disappointing. The MVM model is the only traditional model that achieves positive returns in the bear market, but the return is only 1.73%. In contrast, all models using the RPWS algorithm achieve positive returns and are better than the MVM model. The SVR-MVM model performs similarly in the A-share market as in the U.S. stock market. While maintaining good risk control, the annualized return of the MVM model, after SVR stock selection, increases from 1.73% to 3.75%, representing a 105.84% improvement in the original annualized return metric. Although this is already a significant improvement, it still significantly underperforms portfolios using the RPWS model in terms of annualized return, Sharpe ratio, and Sortino ratio. The detailed backtest performance and cumulative returns are available in Table VII and Fig. 4.

From January 2023 to October 2024, the cryptocurrency market experienced significant growth, with major cryptocurrencies such as Bitcoin and Ethereum seeing sharp price increases, with Bitcoin breaking through its all-time high. The gradual acceptance of cryptocurrencies by institutional investors and the traditional financial industry has played a key role in driving mainstream market applications. Investor sentiment remains optimistic, and a large amount of capital has flowed into the market, jointly driving a strong bull market trend. Bitcoin dominates with a market share of 67.3%, and in this bull market, it has achieved an annualized return of 42.87% in just over a year. However, compared with traditional stock markets, the cryptocurrency market is relatively immature, extremely volatile, and greatly affected by market sentiment, making modeling and prediction particularly difficult. As a result, most models based on the RPWS algorithm perform poorly. Surprisingly, the Transformer-RPWS model, which performs well in both the US and A-share markets, performs poorly in the cryptocurrency market, with an annualized return of only 28.85%. In contrast, the SVR-RPWS model continues to show excellent performance, achieving an ultra-high annualized return of 75.01%, and its Sharpe ratio (1.2522) and Sortino ratio (2.1192) are the highest among all models. Whether in terms of returns or risk control, the performance of traditional models is only above average at best, and fails to outperform Bitcoin. The detailed backtest performance and cumulative returns are available in Table VIII and Fig. 5.

While the LSTM model demonstrates excellent predictive performance on the test set, its performance in backtesting is relatively mediocre. In contrast, models such as SVR and Transformer, which perform poorly on the test set, show exceptional results when combined with the RPWS algorithm in the backtest. I hypothesize two potential reasons for this discrepancy. First, the time-series nature of financial market data makes overfitting particularly pronounced. Models may learn incidental patterns or short-term fluctuations in historical data that do not persist in the future, thereby limiting their generalization ability. As a result, models that perform well on the test set may fail to produce satisfactory results in subsequent backtests. Second, models that underperformed on the test set may exhibit stronger robustness—such as the SVR model, which demonstrated good stability across multiple markets. These models may be better equipped to adapt to varying market conditions or data volatility, leading to superior performance in the backtest phase.

Overall, in mature markets such as the U.S. and A-share stock markets, models incorporating the RPWS algorithm have demonstrated strong investment performance, often outper-

forming traditional portfolio models and major ETFs. This is particularly evident in terms of generating higher returns, thereby validating the fundamental principle of high risk leading to high reward. The experiment highlights the substantial advantages of employing machine learning and neural network models in constructing better-performing investment portfolios. It further reinforces the effectiveness of machine learning and neural network models in portfolio optimization.

VI. Conclusion and Future Work

Machine learning algorithms and neural network models have become essential tools in various fields, including financial market investment, to make more advantageous and informed decisions. This study applies machine learning algorithms and neural network models to portfolio construction, introducing a prediction-based weighted scoring method to build optimized investment portfolios. The research enriches portfolio theory by offering novel insights. The key findings are as follows:

Firstly, this study provides a detailed introduction to six models: K-Nearest Neighbors (KNN), Support Vector Regression (SVR), XGBoost, Long Short-Term Memory (LSTM), Transformer, and Informer. These models are evaluated based on their stock return prediction capabilities on a test dataset. Secondly, this paper presents a portfolio construction method based on return prediction and weighted scoring (RPWS). The effectiveness of this method is validated through the combination with the aforementioned predictive models. Among the models tested, SVR-RPWS and Transformer-RPWS perform well in terms of both maximizing returns and controlling risk and drawdowns. Overall, their performance outperforms mainstream funds and traditional portfolio models. Finally, in practical backtesting, the training time of the models also requires attention. For instance, the Transformer model takes nearly a week to complete a backtest on the US stock market, whereas the SVR model only requires about one hour. In the future, further validation of the RPWS technique will require expanding the dataset, making the SVR model's faster convergence speed a notable advantage for further exploration.

Previous studies typically divide machine learning algorithms and portfolio optimization into two separate stages, which means that the modeling capabilities of machine learning are only utilized in the stock screening phase and not fully exploited during weight optimization. The method proposed in this study, which uses RPWS to construct portfolios, provides a new perspective for the interdisciplinary field of machine learning and portfolio optimization. The key aspect of this method lies in mapping the prediction results of machine learning algorithms to weight biases, successfully integrating the predictive capabilities of machine learning into the weight optimization phase, ensuring its full utilization throughout the portfolio construction process.

In the future, we will explore more weighting methods to reasonably and effectively map the prediction results of machine learning algorithms to weight biases. We have considered several directions to further optimize the initial weight biases, including logarithmic weighting and enforcing log uniform distribution. In particular, enforcing log uniform distribution adjusts the initial weight biases of stocks based on their rankings to conform to a log uniform distribution, and its actual performance will be tested in future backtesting experiments. Additionally, this study uses historical data and technical indi-

cators as input features for predicting future returns. However, many external factors, such as government policies, interest rates, and public events, also impact financial markets, so future work may consider incorporating more sentiment factors into the dataset. We believe that by continuously optimizing weight mapping methods and integrating more influencing factors, the stability and practical value of portfolio strategies will be further enhanced.

***Abstract*—Class imbalance is a common challenge in real-world datasets, leading standard classifiers to perform poorly on underrepresented classes. Traditional oversampling techniques, such as SMOTE and its variants, often generate synthetic samples without fully considering the local data structure, resulting in increased noise and class overlap.This study introduces CeC-SMOTE, an adaptive oversampling method that integrates clustering and centroid-based strategies to enhance the quality of synthetic minority samples. By first partitioning minority instances using K-means clustering, CeC-SMOTE identifies safe and boundary regions, selectively generating new samples where they are most needed while filtering out noise. This targeted approach preserves the underlying distribution of the minority class and minimizes the risk of overfitting. Extensive experiments on artificial and benchmark UCI datasets demonstrate that CeC-SMOTE consistently delivers competitive or superior results compared to established oversampling techniques, particularly in cases with complex or ambiguous class boundaries. Sensitivity analysis confirms that the method is robust to parameter settings, enabling strong performance with minimal tuning.**

***Keywords*—Imbalanced data classification; synthetic oversampling; k-means clustering; centroid-based neighbor**

I. Introduction

Imbalanced data, where some classes are significantly underrepresented compared to others, is a widespread issue in real-world applications. This imbalance often causes models to favor majority classes while neglecting minority categories [1][2]. For example, in healthcare, class imbalance can hinder the early detection of rare diseases, leading to missed diagnoses and delayed treatment. Similarly, in financial systems, fraudulent transactions are often overshadowed by legitimate ones, making it difficult for conventional models to identify and prevent fraud [3].

Traditional classification algorithms, which typically assume a balanced class distribution or seek to minimize overall error, tend to underperform on imbalanced datasets. These models frequently exhibit a bias toward the majority class, resulting in high accuracy for common categories but poor performance for the minority class—often the primary focus in critical applications [4]. This bias leads to minority instances being overlooked or misclassified, sometimes even treated as noise, which compromises both the reliability and generalizability of predictive models. To address these limitations, data-level solutions such as oversampling have been developed to enhance the representation of minority classes by generating synthetic samples.

*Corresponding authors.

The introduction of the SMOTE algorithm marked a significant advancement in oversampling by creating synthetic minority samples through interpolation between existing neighbors. This approach has inspired many variants, each aiming to overcome specific limitations. For example, Borderline-SMOTE [5] generates synthetic samples near decision boundaries, while Safe-Level-SMOTE [6] focuses on safer regions to reduce noise amplification. Other methods, such as SVM combine SMOTE [7] and cluster-based approaches, refine the placement of synthetic samples using support vectors or cluster centroids [8]. Further advancements, like LD-SMOTE [9] and Simplicial SMOTE [10], leverage local density, information entropy, and topological structures to ensure that synthetic samples align more closely with the actual data distribution.

Despite these advances, imbalanced learning continues to evolve as researchers seek new methods that improve sample quality, minimize noise, and enhance classifier robustness, particularly in complex data environments. In this context, we propose CeC-SMOTE—an adaptive oversampling technique that combines clustering and centroid-based analysis. CeC-SMOTE systematically categorizes minority instances by utilizing both global and local cluster characteristics, applies a Nearest Centroid Neighbour strategy for more effective neighbor selection, and adaptively limits synthetic data generation to safe and boundary regions to reduce noise and overfitting. This approach addresses important gaps in existing oversampling methods. The primary contributions of this study are as follows:

- We introduce an adaptive oversampling algorithm that integrates centroid-based clustering with safety-aware sample selection.
- We propose a systematic method for filtering noisy samples and directing oversampling to the most informative minority regions.
- We present extensive experiments on multiple benchmark datasets, demonstrating that CeC-SMOTE outperforms established oversampling techniques.

Accordingly, the research question guiding this study is: How can synthetic minority sample generation be improved to better preserve the structure of imbalanced data, minimize noise, and enhance classification accuracy, especially in challenging datasets with complex class boundaries?

The remainder of this study is organized as follows: Section II reviews related work on imbalanced data learning and oversampling. Section III details the methodology of the proposed

CeC-SMOTE algorithm. Section IV describes the experimental setup and presents the results. Section V discusses the findings and their implications, and Section VI concludes the study with directions for future research.

II. Related Works

Imbalanced data remains a significant challenge in classification problems, often resulting in poor performance for minority classes. To address this issue, researchers have developed various techniques to improve the detection and representation of these underrepresented groups. This section reviews the most relevant methods, highlighting advances in oversampling and clustering-based strategies designed to enhance minority class representation.

A. SMOTE and Variants

Oversampling techniques are widely used to address class imbalance by generating additional synthetic instances of the minority class [11]. This strategy is generally preferred over undersampling, which reduces the number of majority class samples and may result in the loss of valuable information crucial for accurate learning [12] [13]. Among these approaches, the Synthetic Minority Over-sampling Technique (SMOTE) [14] is particularly well-known. SMOTE creates synthetic samples by linearly interpolating between existing minority instances and their nearest minority neighbors [15][16]. Its main goals are to expand the decision region of the minority class and reduce the risk of overfitting that often arises from simply duplicating existing minority data [17].

Despite its popularity, SMOTE's linear interpolation mechanism introduces several notable limitations, especially when applied to complex datasets. First, SMOTE often generates synthetic samples without considering the distribution of the majority class [18]. This can lead to overgeneralization, where new samples encroach into majority class regions or inadvertently bridge distinct minority sub-clusters, increasing class overlap and complicating subsequent classification tasks [19]. Second, SMOTE is susceptible to noise and outliers in the minority class. When outliers or borderline samples are present, the algorithm may create synthetic instances around them, unintentionally amplifying noise and reducing class separability [20]. Third, SMOTE assumes linear relationships among minority samples, which is not always appropriate for datasets with non-linear structures or multiple, distinct minority clusters. In such cases, synthetic samples may not accurately capture the true distribution of the minority class [21]. Additionally, SMOTE faces challenges in high-dimensional data [22]. The nearest neighbor concept, central to its function, becomes less meaningful and more computationally intensive in higher dimensions, which can result in less diverse or even misleading synthetic samples [23]. Finally, SMOTE can struggle with small, isolated minority regions [24]. The algorithm may fail to adequately represent these unique data pockets, leading to their persistent underrepresentation or mischaracterization [25].

B. Enhancing Oversampling through Clustering

To overcome the limitations of traditional oversampling, researchers have incorporated clustering as a preparatory step. In clustering-based SMOTE variants, the minority class is first clustered, and then SMOTE is applied within each cluster [26]. This approach preserves local data structures and addresses imbalances within the minority class itself [27].

Combining clustering with oversampling offers several advantages. First, it reveals underlying subgroups within the minority class, enabling more targeted and nuanced oversampling. By recognizing these sub-clusters, oversampling can be focused on sparser or more critical regions rather than treating all minority samples equally, as standard SMOTE does. Second, clustering helps to identify and manage noise or outliers. Instances that do not fit well into any cluster can be excluded from synthetic sample generation or handled separately, reducing the risk of amplifying noise. Finally, clustering allows for differentiated oversampling strategies which more synthetic data can be generated in sparse but well-defined clusters, or efforts can be focused on safe regions to minimize overlap with the majority class.

Various clustering methods guide the oversampling process. K-means clustering [28]is a commonly used technique that partitions the data into distinct groups based on their centroids. K-Means SMOTE integrates this method by generating synthetic samples within each minority cluster, ensuring that new instances reflect the local distribution and preventing the artificial connection of unrelated groups [29][30] [31]. Other approaches, like LD-SMOTE, adjust the number of synthetic samples based on cluster density, focusing efforts on underrepresented regions and improving sample representativeness [9].

Density-based clustering algorithms, such as DBSCAN, are also employed for their ability to handle irregularly shaped clusters and detect noise [32]. For instance, DBSMOTE uses DBSCAN to cluster minority samples and place new synthetic points towards the center of each cluster, strengthening their core representation [33]. Similarly, adaptive clustering SMOT within clusters formed by DBSCAN [34], and clustering and optimization-based G-mean iteratively applies SMOTE in K-means clusters while optimizing performance metrics such as G-mean [35]. Some methods also use information entropy to monitor and control ambiguity in overlapping regions created by synthetic samples [36].

Despite significant advances in oversampling techniques, several common shortcomings remain across the reviewed methods. Many approaches, such as SMOTE and its variants, tend to generate synthetic samples without fully accounting for the underlying data distribution, leading to increased noise and class overlap. Methods that rely on linear interpolation may struggle with datasets exhibiting complex or nonlinear minority class structures. Additionally, many approaches are also sensitive to clustering quality and may perform poorly on high-dimensional or highly imbalanced datasets. These limitations underscore the need for more adaptive solutions.

III. CeC-SMOTE Methodology

This section delineates the technological process of CeC-SMOTE in greater detail. The flowchart illustrating imbalanced learning using CeC-SMOTE is presented in Fig. 1. The CeC-SMOTE algorithm is principally concerned with the following processes: the capture of the local structure of the minority

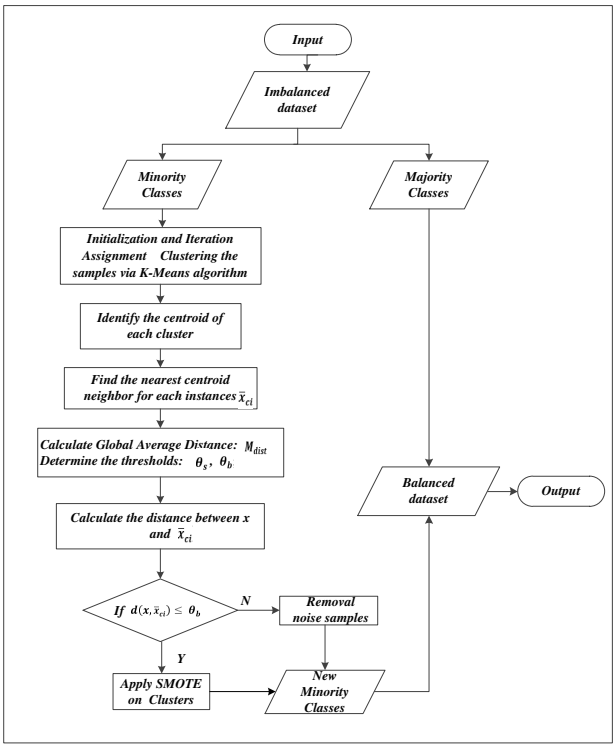

Fig. 1. Block diagram of CeC-SMOTE.

class; the identification of "safe" minority points, with outliers that are too close to majority territory being discarded; and the expansion of the minority class, followed by the rebuilding of the full training set.

The process begins by applying K-means clustering to group the minority class samples, and each cluster's centroid is determined. The algorithm then calculates the global average distance within each cluster to categorize samples as "safe", "boundary", or "noise". Outliers and samples near the majority class are discarded to reduce potential overlap and noise. Next, SMOTE is selectively applied to the safe and boundary regions within each cluster, generating synthetic minority samples where they are most needed. Finally, the new synthetic samples are combined with the filtered original data, resulting in a more balanced dataset that is ready for training the classifier. While LD-SMOTE [9] and Simplicial SMOTE [10] have introduced local density estimation and topological techniques, CeC-SMOTE further advances the field by integrating centroid-based clustering with safety-aware filtering, ensuring that synthetic samples are generated primarily in well-defined, safe or boundary minority regions, as opposed to uniform interpolation.

A. Construct Minority Clusters

To capture the local structure of the minority class, this step involves initialising centroids and iteratively assigning samples to the nearest cluster based on their features. According to the step of the K-means clustering algorithm, until the change in the cluster centre is very small or the preset number of iterations is reached, $k$cluster centres are created to ensure that all samples are stable.

STEP 1: Randomly assign the initial point as the initial cluster centre point;

STEP 2: Calculate the Euclidean distance between all individuals in the sample set and the cluster centre, then assign the samples to the nearest cluster. The Euclidean distance between a point x and a centroid x_{c_i} in cluster c_i is given by Eq. (1):

$$d(x, x_{c_i}) = \|x - x_{c_i}\|_2 = \sqrt{(x_1 - x_{c1})^2 + (x_2 - x_{c2})^2 + \cdots + (x_n - x_{cn})^2} \quad (1)$$

STEP 3: Recalculate the cluster centre according to the samples in the class;

STEP 4: Iterate Steps 2 and 3 until the centroids no longer change significantly or the iteration limit is reached.

Step 2 is critical as it groups similar points together based on their proximity to the centroids. After all points have been assigned to clusters, the centroids are updated to reflect the means of their respective clusters.

B. Safety Assessment and Noise Cleaning

In order to improve class balance and accuracy while limiting noise and overfitting, After clusters the minority class and then identify "safe" minority points and discard outliers that sit too close to majority territory.

STEP 1: Apply the ensemble Nearest centroid neighborhood (NCN) strategy [37]for minority classes. For each data point, the algorithm identifies the nearest cluster centroid $\overline{x}_{ci}$. This involves calculating the distance from the point to each centroid and selecting the smallest one. This NCN helps to assess each data point's proximity to its cluster centre, which is pivotal for classifying the data points in later steps.

The idea of NCN is to find the nearest neighbor by the centroid. For a set of points $X_i = \{x_1, x_2, \cdots, x_n\}$, the centroid is calculated as Eq. (2):

$$\overline{X} = \frac{1}{n}(x_1 + x_2 + \cdots + x_n) \quad (2)$$

Neighbors should be distributed in geographical areas, and the idea of NCN requires that proximity be fully considered. First, NCN believes that the centroid neighbors are as close as possible to the test sample in terms of distance and are distributed as evenly as possible around the test sample. The NCN of sample p in X should be obtained by querying the following steps and the pseudocode in Algorithm 1.

STEP 2: Calculate the global average distance. Determine the global average distance by calculating the average distance of all samples to their respective centroids, which will serve as a benchmark for defining safe areas and boundary areas, as in Eq. (3):

$$M_{dist} = \frac{1}{m}\sum_{j=1}^{m} \left\|x_j - \overline{x}_{l_j}\right\|_2 \quad (3)$$

where, m is the total number of points in the dataset, $\overline{x}_{l_j}$ is the centroid of the cluster to which point x_j belongs, and l_j is the index pointing to the cluster to which point x_j belongs.

STEP 3: Classify regions within each cluster;

1) Define the thresholds for safe areas θ_s and boundary areas θ_b [see Eq. (4) and Eq. (5)];

$$\theta_s = \alpha \times M_{dist}, \quad (\alpha < 1) \tag{4}$$
$$\theta_b = \beta \times M_{dist}, \quad (\beta > \alpha) \tag{5}$$

2) Mark each sample as belonging to the safe zone, boundary area, or noise zone based on the comparison of the distance from the sample to the centroid $\mathbf{d}(x, \overline{x}_{c_i})$ and the global average distance M_{dist}:

- If $\mathbf{d}(x, \overline{x}_{c_i}) \leq \theta_s$, x is considered 'safe';
- if $\theta_s < \mathbf{d}(x, \overline{x}_{c_i}) \leq \theta_b$, x is considered 'boundary';
- and if $\mathbf{d}(x, \overline{x}_{c_i}) > \theta_b$, x is considered 'noise'.

By following these steps, the algorithm ensures that only points in well-defined, safe, or boundary regions are considered for oversampling, reducing the impact of noise and outliers.

Algorithm 1 Nearest Centroid Neighborhood (NCN)

Input: $X_i = \{x_1, x_2, \cdots, x_n\}$: input dataset; k: number of neighbors to search; p: query point
Output: $Q = \{q_1, q_2, \cdots, q_k\}$: set of k nearest centroid neighbours
Initialize $Q = \emptyset$
Find the first NCN of p as its nearest neighbour, q_1
$Q \leftarrow Q \cup \{q_1\}$
for $i = 2$ to k **do**
    Select the ith neighbor q_i such that the centroid of q_i and all previously selected neighbours $(q_1, q_2, \cdots, q_{i-1})$ is the closest to p
    $Q \leftarrow Q \cup \{q_i\}$
end forreturn Q

C. Cluster-Aware Oversampling and Merge

After each sample is marked as belonging to the safe area, boundary area, or noise area. Within each cluster, apply SMOTE only to the safe points to create synthetic samples that stay inside the minority manifold.

STEP 1: First, for each sample $\mathbf{x}_i$ in the positive sample set, Euclidean distance is calculated between it and each other sample in the positive sample set, and k nearest neighbor samples are found, marked as $\mathbf{x}'_i$, $i \in \{1, 2, 3, \ldots, k\}$;

STEP 2: For each randomly selected neighbor sample $\mathbf{x}'_i$, a new sample is constructed according to Eq. (4) with $\mathbf{x}_i$, respectively [see Eq. (6)].

$$\mathbf{x}_{\text{new}} = \mathbf{x}_i + \text{rand}(0, 1) \times (\mathbf{x}'_i - \mathbf{x}_i) \tag{6}$$

STEP 3: Combine the generated samples to form the final dataset.

The CeC-SMOTE achieves a more balanced dataset through targeted oversampling of minority classes and removal of noisy, outlier samples. The pseudocode of the oversampling process of CeC-SMOTE is illustrated in Algorithm 2.

Algorithm 2 CeC-SMOTE

Input: minority imbalanced dataset X^P, K: maximum number of clusters
Output: D: the dataset with augmented minority class samples
Initialize;
Apply the K-means algorithm to the minority class;
Identify the centroid of each cluster: $C = \{c_1, c_2, \ldots, c_K\}$;
Nearest centroid neighbour: $x_{ci} = []$;
for each x_i in X^P **do**
    Initialize *min_distance*; Initialize $x_{ci} = []$;
    for each c_j in C **do**
        Calculate the Euclidean distance from x_i to each centroid c_j;
        $d(x_i, c_j) = \|x_i - c_j\|_2$;
        Keep track of the centroid c_j that has the minimum distance to x_i, storing the index of this nearest centroid c_j;
        if $d(x_i, c_j) <$ *min_distance* **then**
            min_distance $= d(x_i, c_j)$; update the index of the nearest centroid;
        end if
    end for
    Append the index of the nearest centroid to x_{ci};
end forreturn x_{ci}
Calculate the global average distance between all samples in X^P and their respective nearest centroids.

$$M_{dist} = \frac{1}{m} \sum_{j=1}^{m} \|x_j - x_{c_j}\|_2$$

Classify regions within each cluster:
    if $d(x, \overline{x}_{ci}) \leq \theta_s$, mark x_i as "Safe"
    if $\theta_s < d(x, \overline{x}_{ci}) \leq \theta_b$, mark x_i as "Boundary"
    else mark x_i as "Noise"
Apply SMOTE to samples classified as "Safe" and "Boundary" to generate synthetic samples X_G^P;
Merge the original minority class samples X^P with the newly generated synthetic samples X_G^P;

IV. Experimental Analysis

In this section, CeC-SMOTE is compared with four commonly used re-sampling methods on four metrics across seven UCI datasets and two artificial datasets under three quality evaluation measures, the G-mean, F1 score, AUC. We performed 5-fold cross-validation on all datasets to ensure the reliability of the results, averaging metrics across independent runs to reduce variance.

A. Dataset

To showcase the efficacy of CeC-SMOTE, the experimental data in this section are divided into three parts. The first are the two artificially generated two-dimensional (2D) datasets as

shown in Table I. According to the definition of the imbalanced degree, dataset A is highly imbalanced, while dataset B is almost extremely imbalanced. Table II provides a detailed overview of 7 benchmark binary datasets. The IR of binary datasets selected from the UCI data repository varies from a minimum of 1.9 to a maximum of 129.5, with an average of 23.13. According to the imbalance ratio, Pima, ecoli3, Cleveland, vehicle, page-blocks, and Breast datasets are lowly imbalanced. The alone is extremely imbalanced.

TABLE I. ARTIFICIAL DATASETS

Dataset	Imbalance Ratio	Number of Datasets	Number of Minority Classes	Number of Majority Classes	Dimension
A	48.47	1484	30	1454	2
B	94.46	2673	28	2645	2

B. Experimental Metrics

In this study, the performance of CeC-SMOTE was validated using several metrics commonly used in imbalanced data learning: F1-score, geometric mean(G-Mean), and the area under the receiver operating characteristic curve (AUC) to systematically compare and analyze the efficacy of various methodologies. These metrics were selected due to their ability to balance the precision-recall trade-off and capture the model's discriminative power across both classes. The G-Mean is calculated to assess the balance between classification accuracies of the positive and negative classes. It is given by the following Eq. (7):

$$G\text{-}Mean = \sqrt{Specificity \times Recall} \tag{7}$$

where, recall (True Positive Rate), specificity (True Negative Rate) and precision (successfully identified positives out of all positives predicted) are respectively defined as Eq. (8) to Eq. (10):

$$\text{Specificity} = \frac{TN}{TN + FP} \tag{8}$$

$$\text{Recall} = \frac{TP}{TP + FN} \tag{9}$$

$$\text{Precision} = \frac{TP}{TP + FP} \tag{10}$$

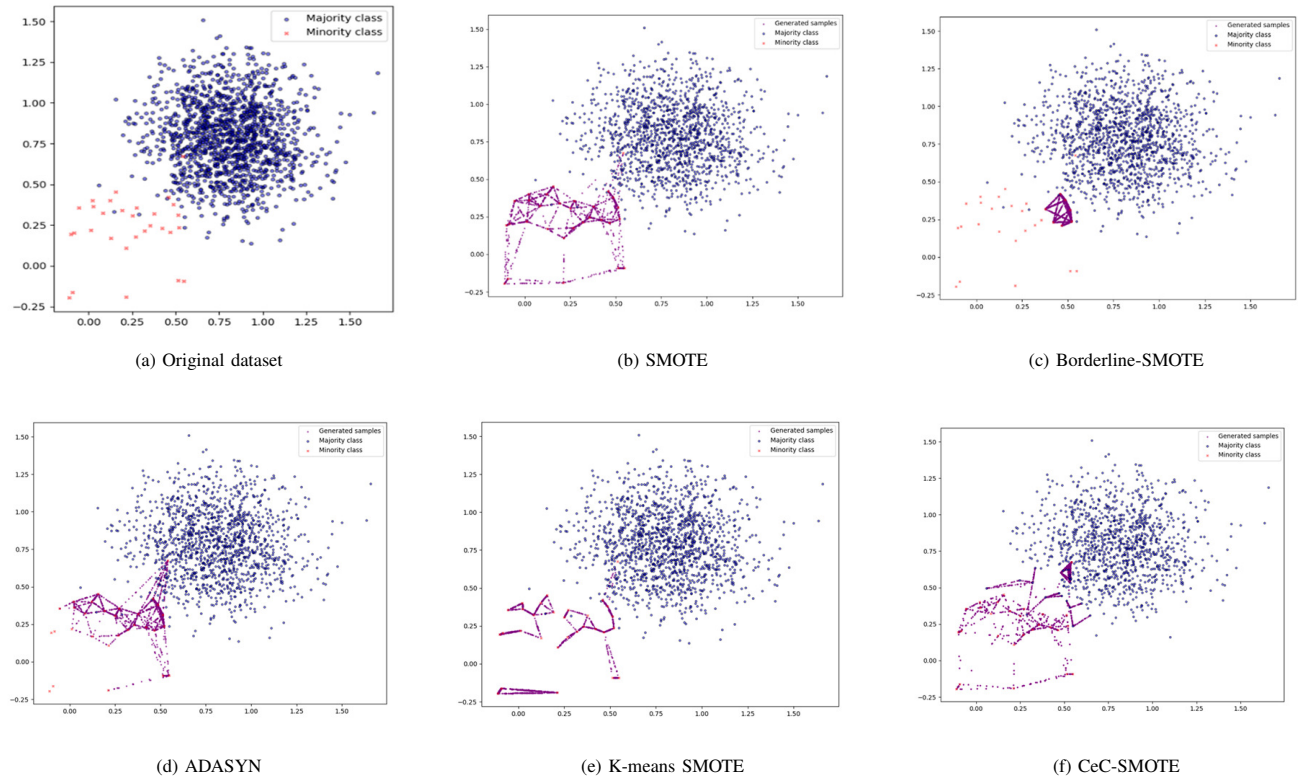
TABLE II. DETAILS OF UCI IMBALANCED DATASET

Dataset	Instances	Positive	IR	Attributes
Pima	758	258	1.9	8
ecoli3	336	35	8.6	7
Cleveland	297	35	7.49	13
vehicle	846	199	3.25	19
page-blocks	5472	28	8.79	10
Breast	286	85	2.36	9
Abalone	4176	32	129.5	8

Here, TP denotes the true positives, TN denotes the true negatives, FP denotes the false positives, and FN denotes the false negatives. The G-mean evaluates how well the model performs across both positive and negative classes by considering their accuracies. Furthermore, F1-score is determined as the harmonic mean of the method's precision and recall [see Eq. (11)].

$$\text{F1}_{\text{score}} = \frac{2 * \text{Precision} * \text{Recall}}{\text{Precision} + \text{Recall}} \tag{11}$$

AUC quantifies the overall ability of the model to discriminate between negative and positive classes, and is defined as the area under the receiver operating characteristic curve (ROC), which plots the True Positive Rate (TPR) against the False Positive Rate (FPR). AUC is used to evaluate the model performance. A higher AUC indicates a model with better discriminatory ability.

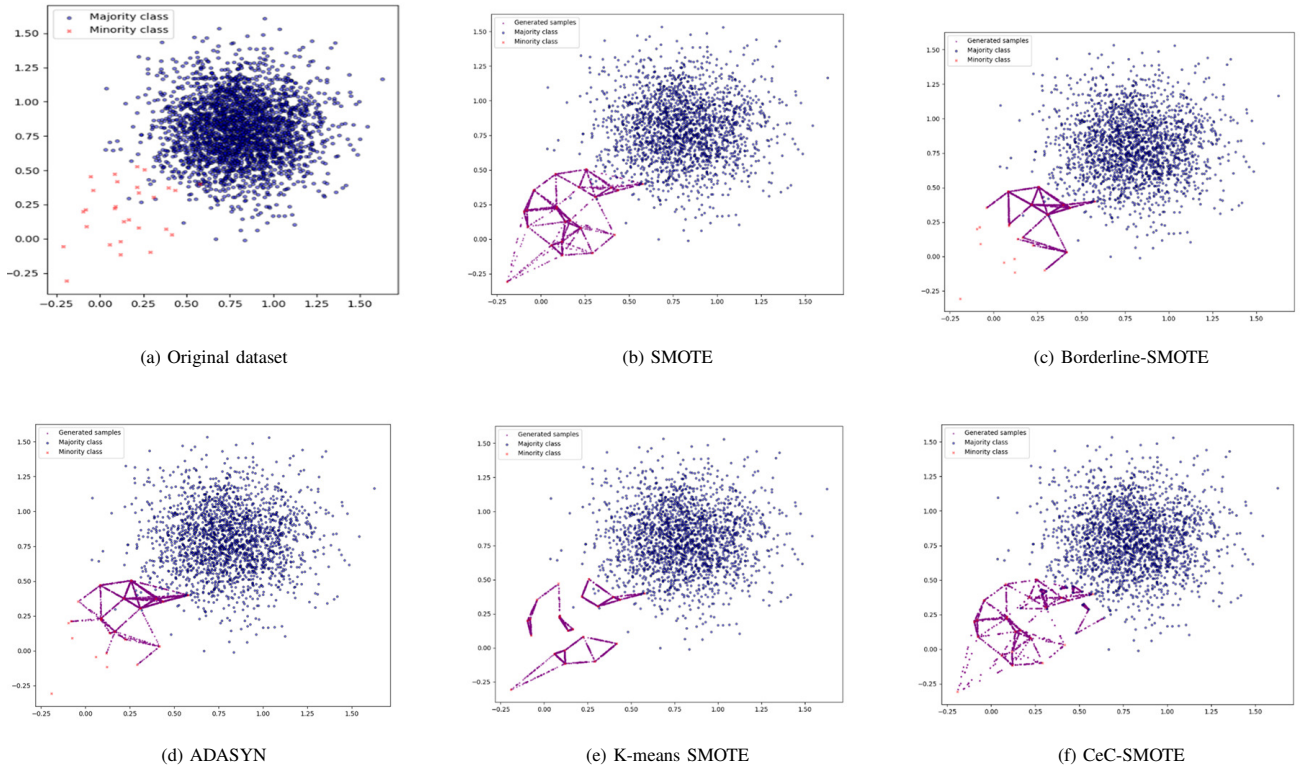


C. Comparison Methodology

In all experiments, CeC-SMOTE is compared with SMOTE and three variants of SMOTE, Borderline-SMOTE, ADASYN and K-Means SMOTE. The comparative methods involved in the experiments are all run with default parameters. The MLP is chosen as the classifier to evaluate the effectiveness of rebalancing on the balanced datasets that have been adjusted using the different comparison methods. The MLP implementation is available in the SciKit-Learn package is provided by the Python implementation, and configured with various layers and neurons using the ReLU activation function. The number of nearest neighbours K involved in all the compared algorithms is five in all experiments.

D. Experimental Results

1) The results on artificial datasets: To demonstrate the efficacy of CeC-SMOTE, we conduct a visualization experiment on artifical datasets. Fig. 2 and Fig. 3 presents the visualization outcomes of samples after being respectively rebalanced by Cec-SMOTE and other comparative methods, followed by dimensionality reduction using t-SNE. The blue, red, and purple points correspond to the negative, positive, and synthetic samples, respectively.



The figures show that the SMOTE algorithm treats all sample points equally. This results in new sample points being generated that overlap with the majority class. CeC-SMOTE first clusters the minority class samples, and then generates new samples near the cluster centroids. This results in the generation of concentrated, pink synthetic samples that adhere closely to the existing cluster structures of the minority class. The sampled data is more consistent with the original data distribution than data sampled using the SMOTE algorithm. Fig. 2(f) shows more minority class data points closer to the boundary than Fig. 2(e). This is because CeC-SMOTE oversample each cluster and the data at the boundary are more likely to be assigned to one cluster after clustering. Thus, the synthesised data are concentrated near the boundary, creating a clear distinction between the minority and majority classes.

(a) Original dataset (b) SMOTE (c) Borderline-SMOTE

(d) ADASYN (e) K-means SMOTE (f) CeC-SMOTE

Fig. 2. Sampling effects of different methods on dataset A.

(a) Original dataset (b) SMOTE (c) Borderline-SMOTE

(d) ADASYN (e) K-means SMOTE (f) CeC-SMOTE

Fig. 3. Sampling effects of different methods on dataset B.

2) The results on UCl datasets: To evaluate the classification performance of the CeC-SMOTE algorithm, the experimental setup consists of seven datasets that present different imbalance ratios, which can be found in the UCI Machine Learning repository. The UCI datasets are used to conduct experiments on the MLP classifier and compared with the other four algorithms.

Table III shows the classification performance of various synthetic oversampling algorithms across multiple UCI datasets. The effectiveness of each method varies by dataset. For instance, in the vehicle dataset, all methods show high G-Mean and AUC, indicating robust performance. However, in datasets like Cleveland and Abalone, the variations in performance metrics are more pronounced, suggesting challenges related to specific characteristics of these datasets, such as feature distributions or class separability. In most cases, AUC scores are high, indicating good discriminative ability of the models post-oversampling. However, the F1-score and G-Mean sometimes show significant variation, highlighting the impact of these methods on precision-recall balance and class-specific accuracy. The performance of the CeC-SMOTE algorithm demonstrates a substantial enhancement in metric values compared to K-means SMOTE. Across the datasets, CeC-SMOTE often shows competitive or superior performance in terms of F1-score and AUC, suggesting its effectiveness in handling border cases and dataset specificities.

Fig. 4 presents a radar chart that compares the experimental results of CeC-SMOTE with those of the other four methods, providing more intuitive experimental results. The CeC-SMOTE line in the chart extends further in most datasets for the G-Mean and AUC metrics, suggesting that this technique might be more effective in distinguishing between classes.

E. Sensitivity Analysis of Critical Parameters

CeC-SMOTE involves several key parameters, including the number of clusters (k) in K-means, and the threshold coefficients α and β used to define "safe", "boundary", and "noise" regions within clusters. The number of clusters k influences the granularity of the minority class partitioning; too few clusters may overlook local data structure, while too many can result in overfitting or fragmented synthetic sampling. The parameters α and β directly affect which samples are classified as safe or boundary points, thereby controlling where new synthetic samples are generated.

Fig. 5 presents the effects of varying the parameters α and β on the F1 and G-mean scores across four datasets: Pima, ecoli3, vehicle, and page-blocks. Each plot illustrates how different (α, β) pairs influence classification performance, with F1 and G-mean used as evaluation metrics.

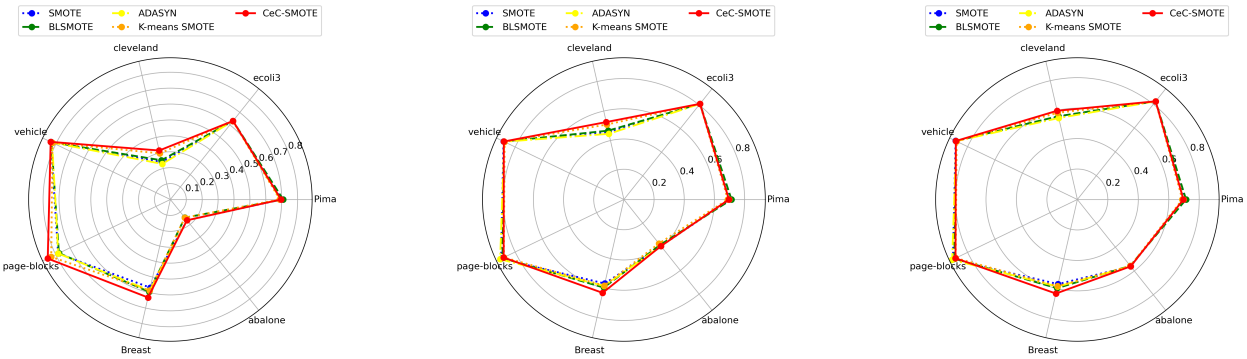
Across all datasets, the results show that the choice of α and β significantly impacts both F1 and G-mean. The most favorable performance is consistently observed when α is set between 0.65 and 0.80, and β is chosen to be 0.20 to 0.30 higher than α. In this range, both F1 and G-mean reach their peak or maintain stable, high values. This trend suggests that these parameter settings provide an optimal balance between generating a sufficient number of synthetic samples and maintaining the quality of those samples by targeting "safe" and "boundary" regions in the data.

When α is set too low, the algorithm becomes overly permissive, allowing many borderline points to be treated as "safe". This results in more synthetic data but can reduce overall precision due to the inclusion of ambiguous samples. Conversely, when α approaches 0.90, especially in datasets with small minority classes, recall tends to drop. This is likely because the "safe" region becomes too restrictive, limiting the creation of synthetic minority samples and, therefore, failing to sufficiently balance the dataset.

Notably, the (α, β) pair of (0.80, 1.20) performs among the best across all tested datasets, making it a reliable default setting when dataset-specific tuning is not practical. This combination provides a robust trade-off, consistently supporting both strong recall and precision.

For situations involving very scarce minorities or a high number of borderline samples, lowering α to 0.65 and increasing β by 0.10 to 0.20 further improves recall with only a minor reduction in precision. In contrast, for large and highly imbalanced datasets where high precision is more important than recall, setting α near 0.90 and β above 1.30 can be more advantageous, even if recall drops slightly.

In summary, Fig. 5 demonstrates that CeC-SMOTE is robust across a range of α and β values, with optimal performance achieved in moderate settings. The method's flexibility allows practitioners to tailor the balance between recall and precision according to the needs of specific datasets, while also providing a strong default setting for general use.



V. Discussion

The comparative results vary across datasets due to differences in characteristics such as imbalance ratio, feature count, class overlap, and minority class distribution. For example, datasets with well-separated classes and moderate imbalance, like "vehicle" or "page-blocks", typically show strong, consistent performance across most oversampling methods, including CeC-SMOTE. However, CeC-SMOTE excels in datasets with smaller minority classes or unclear class boundaries, such as "Cleveland" and "Abalone". Its clustering and noise filtering strategies help preserve meaningful minority samples while reducing the impact of outliers and class overlap.

CeC-SMOTE is particularly effective for datasets, where the minority class is well-clustered or where class boundaries are ambiguous. This observation is consistent with previous findings in the literature, where advanced oversampling techniques that incorporate clustering or density estimation have shown improved performance in handling complex imbalanced datasets. Recent works such as LD-SMOTE [9] and Cluster-Based Reduced Noise SMOTE [15] demonstrate that considering local density or clustering information can enhance the representativeness of synthetic samples and minimize noise. CeC-SMOTE builds upon these principles by combining centroid-guided clustering with adaptive sampling, resulting in synthetic data that better preserves local data structure and reduces class overlap. As shown in Table III and Fig. 4, CeC-SMOTE consistently achieves competitive or superior F1 and AUC scores, particularly in datasets with higher complexity, demonstrating its robustness and adaptability in real-world applications.

TABLE III. METRIC VALUES FOR DIFFERENT IMBALANCE RATIOS

Dataset	Metric	SMOTE	BLSMOTE	ADASYN	K-means SMOTE	CeC-SMOTE

CeC-SMOTE's robust performance can be attributed to its combination of centroid-guided clustering and adaptive sampling within safe and boundary regions. By focusing on generating synthetic data near cluster centroids, the method preserves local data structures and avoids excessive overlap with the majority class, which is a common pitfall in standard SMOTE. The visualizations on artificial datasets further demonstrate that CeC-SMOTE produces synthetic samples that align well with the minority class distribution, resulting in clearer class separations.

Parameter sensitivity analysis shows that CeC-SMOTE remains stable across a wide range of (α, β) values. The method performs best when α is between 0.65 and 0.80, with β exceeding α by 0.20 to 0.30. These results suggest that CeC-SMOTE can be deployed with minimal parameter tuning and still deliver reliable improvements in both recall and precision. Moreover, the recommended default setting $(\alpha = 0.80,\ \beta = 1.20)$ consistently ranked among the top configurations for most datasets. For datasets with extremely rare minorities, lowering α and widening β further enhances recall, while highly imbalanced datasets with abundant data

benefit from higher α and β, favoring precision.

VI. Conclusion

In summary, CeC-SMOTE introduces a robust approach to class-imbalance learning by integrating K-means clustering, centroid-based neighbor selection, and safety-aware sampling. This combination enhances the representativeness of synthetic minority samples, preserves the geometric structure of the data, and reduces the risk of amplifying noise. Across multiple real-world and synthetic datasets, CeC-SMOTE demonstrates competitive or superior performance relative to established oversampling techniques, particularly in challenging scenarios with complex class boundaries. The method's stability across different parameter settings makes it practical for real-world deployment, requiring minimal fine-tuning for strong results.

While CeC-SMOTE demonstrates robust performance across multiple real-world and synthetic datasets, several limitations should be acknowledged to provide a more comprehensive review. First, the algorithm's effectiveness relies on the quality of clustering, which may be sensitive to the choice of cluster number and initial centroid selection. Inappropriate clustering could lead to suboptimal synthetic sample generation or noise amplification. Second, this study is limited to binary classification tasks. The adaptation of CeC-SMOTE to multi-class imbalanced datasets and its performance in high-dimensional feature spaces require further investigation. Finally, the current experiments utilize a limited set of benchmark datasets. Future research could extend CeC-SMOTE to multi-class and high-dimensional datasets, and explore automated parameter selection based on data characteristics to fully establish the generalizability of the approach. Overall, CeC-SMOTE offers a valuable and reliable solution for improving classifier performance on imbalanced data.

Towards Robust IoT Security: The Impact of Data Quality and Imbalanced Data on AI-Based IDS

Hiba El Balbali, Anas Abou El Kalam
Cadi Ayyad University, National School of Applied Sciences, LaRTID Laboratory, Marrakech, Morocco

***Abstract*—The increased number of connected devices and the rise of Big Data have revolutionized industries and triggered a surge in cyberattacks, making security a top priority. Machine learning and Deep Learning algorithms are crucial in intrusion detection and classification, enabling systems to identify and respond to threats with precision. However, the success of these algorithms is directly related to the quality of the data they process, underscoring the critical importance of robust and well-prepared datasets. Furthermore, despite their potential in detecting and classifying attacks, some algorithms are susceptible to imbalanced datasets, struggling to accurately classify minority classes, while others demonstrate resilience to such challenges. Hence, this study presents a comprehensive analysis of the impact of data quality and imbalanced data on different classification problems, particularly binary, 8-class, and 34-class classification in an intrusion detection context. Our work extensively evaluates six ML and DL algorithms using a novel IoT dataset. Unlike existing research, we use a diverse set of metrics, including accuracy, precision, recall, F1-score, AUC-ROC, and other visual tools, to provide a robust and reliable algorithm performance assessment. This unique analysis underscores the critical importance of addressing data quality and the impact of different balancing techniques on the type of algorithms and type of classification.**

***Keywords*—Machine learning; intrusion detection; internet of things; data quality; big data**

I. Introduction

The proliferation of interconnected devices, often called the Internet of Things (IoT), has led to an unprecedented increase in the volume of data generated and exchanged daily, and has revolutionized how we live and work. These devices, from smart homes to industrial control systems and autonomous vehicles, are increasingly integrated into our daily lives, creating a vast digital ecosystem. While the IoT has brought numerous benefits, it has also introduced new vulnerabilities that cybercriminals are eager to exploit; the surge in connected devices has created a complex attack surface, making it increasingly difficult to identify and mitigate cyber threats. In fact, according to the mid-year update to the 2023 SonicWall Cyber Threat Report, IoT malware globally increased by 37% in the first six months of 2023, resulting in 77.9 million attacks, up from 57 million in the first six months of 2022 [1].

As the number of devices and the complexity of networks grow, so does the sophistication of cyberattacks. These attacks can range from relatively simple exploits, like unauthorized access to personal devices, to large-scale data breaches that compromise sensitive information. More concerning are the cyberattacks that target critical infrastructure, such as power grids, transportation networks, and healthcare systems, where IoT devices play a pivotal role. These attacks, often leveraging vulnerabilities in IoT ecosystems, can lead to severe consequences, including disruptions in critical services, financial losses, and threats to public safety.

Among these, intrusion detection has become a crucial area of research due to the increasing complexity and frequency of cyberattacks. These systems form a critical line of defense against cyber threats by identifying unauthorized access or malicious activities. However, the accuracy of intrusion detection algorithms is highly sensitive to the quality of the data they rely on [2], [3]. Low-quality or imbalanced datasets can lead to misleading results, poor model performance, and a higher risk of false positives or false negatives, which can undermine the detection system's effectiveness.

With the rise of Big Data, the challenge of handling vast and complex datasets has become even more prominent. In the context of intrusion detection, Big Data presents both an opportunity and a challenge. The enormous volume, velocity, and variety of data generated from various sources—such as network traffic logs, user behavior, and IoT device interactions—offer a wealth of information for developing sophisticated and accurate detection mechanisms. This abundance of data enables Machine Learning models to identify subtle patterns and anomalies that could indicate malicious activity, thereby improving the precision and adaptability of intrusion detection systems.

However, leveraging Big Data effectively requires overcoming several challenges. The quality and structure of data are crucial, as cybersecurity datasets are often plagued with challenges such as noise, missing values, and, most notably, class imbalance. Class imbalance is often significant in the field of intrusion detection, where normal network behavior vastly outnumbers instances of malicious activity. In a typical dataset, attacks may represent only a tiny fraction of the total data, leading to a highly skewed distribution that complicates the training of machine learning models. If not addressed properly, this imbalance can cause the models to be skewed toward the majority class, effectively ignoring minority classes that represent actual threats.

Interestingly, not all algorithms are equally affected by data imbalance. As we will discover in this study, some algorithms, like tree-based models, are inherently more robust to class imbalance and can perform well without extensive preprocessing. On the other hand, other algorithms may struggle with imbalanced data unless additional steps are taken to balance the dataset or adjust decision thresholds.

In this study, we present a comprehensive analysis of the impact of class imbalance and data quality on intrusion detection, utilizing a variety of Machine Learning and Deep Learn-

ing algorithms, namely Random Forest, XGBoost, Logistic Regression, Deep Neural Networks, K-Nearest Neighbors, and LSTM. Our research aims to explore the critical importance of addressing class imbalance, which is a common challenge in cybersecurity datasets, and to evaluate how different techniques influence the performance of various algorithms. We investigate both binary and multiclass classification scenarios to provide a broader understanding of how algorithm sensitivity to imbalance classes varies depending on the nature of the classification task.

To rigorously assess the impact of class imbalance, we employ a range of rebalancing techniques, such as the Synthetic Minority Over-sampling Technique (SMOTE), SMOTE-Tomek Links, SMOTE with Random Undersampling, and SMOTE-Tomek Links with Random Undersampling. These techniques allow us to examine how oversampling and hybrid methods affect different classifiers. In addition, we utilize a diverse set of evaluation metrics, including precision, recall, F1-score, AUC-ROC, and others, to provide a detailed and nuanced assessment of model performance. By combining these metrics with visualization tools, such as confusion matrices, ROC curves, and PR curves, we aim to deliver a robust comparison and analysis of the effectiveness of each algorithm and technique.

Our study presents several key contributions that distinguish it from previous research in the field:

- The use of a novel dataset with several classes, enabling a more comprehensive evaluation of intrusion detection in complex scenarios where the number of attack types is varied and extensive.
- Hybrid feature selection, combining Chi-squared test and random Forest.
- The evaluation of the impact of class imbalance and data quality on intrusion detection using various Machine Learning algorithms; Random Forest, XGBoost, Logistic Regression, Deep Neural Networks, K-Nearest Neighbors, and LSTM. Our approach provides a broader understanding of how different algorithms are affected by data challenges.
- The creation of several sub-datasets adapted for different classification and balancing scenarios, providing a useful resource for researchers.
- The comparison of multiple balancing methods, including SMOTE, SMOTE-Tomek Links, and combinations with Random Undersampling, to explore their impact across different classifiers in an intrusion detection context.
- The use of a diverse set of evaluation metrics and visual tools, such as precision, recall, F1-score, AUC-ROC, and confusion matrices, ROC curve..., to deliver a detailed analysis of the model's performance. This multidimensional evaluation provides a more complete view compared to traditional existing studies.

Subsequently, this study is organized as follows: Section II will be devoted to discuss some of the related works. In Section III, we will discuss class imbalance and the importance of data quality especially in an Intrusion Detection context. Next, we will present the dataset we used to perform our analysis in Section IV. Section V will be dedicated to present our comprehensive study and workflow. Section VI presents the results, analysis, and findings. Finally, Section VII will conclude our study.

II. Related Work

The authors of [4] conducted a study on the impact of data balancing techniques for SCADA-based intrusion detection systems, utilizing the Morris Power dataset and the CICIDS2017 dataset. They evaluated several balancing methods: Random Sampling, One-Side Selection, Near-Miss, SMOTE, and ADASYN. The authors employed a combination of Convolutional Neural Networks (CNN) and Long Short-Term Memory (LSTM) networks in a binary classification problem. The performance of these techniques was assessed using accuracy, precision, recall, and F1-score metrics. Their findings revealed that the unbalanced data yielded better results for the Morris Power dataset than the balanced versions. Conversely, for the CICIDS2017 dataset, the SMOTE oversampling technique demonstrated better performance. The best accuracy achieved by the model is 99.47% using the SMOTE technique with the CICIDS2017 dataset and 73.63% using the unbalanced Morris Power dataset.

The authors of [5] conducted a comparative analysis of several Deep Learning algorithms, including Convolutional Neural Networks (CNNs) and Long Short-Term Memory (LSTM) networks, for binary classification of network intrusion detection tasks. The UNSW-NB15, KDDCup'99, and NSL-KDD datasets were employed to evaluate the performance of these algorithms under both balanced and imbalanced data conditions. The models were assessed using standard metrics such as accuracy, precision, recall, and F1-score. The results indicate that, in general, balanced datasets yield superior performance compared to imbalanced datasets. Notably, the LSTM model achieved the highest accuracy of 95.4% on the balanced KDDCup'99 dataset.

In [6], the authors presented a study on the influence of resampling techniques on the performance of the ANN model. They compared different methods, namely, random undersampling (RU), random oversampling (RO), random undersampling and random oversampling (RURO), random undersampling with Synthetic Minority Oversampling Technique (RU-SMOTE), and random undersampling with Adaptive Synthetic Sampling Method (RU-ADASYN) using four datasets; KDD99, UNSW-NB15, UNSW-NB17 and UNSW-NB18, and they used macro precision, macro recall and macro F1-score to evaluate the results. From this study, we note that the training time increases with oversampling methods and decreases with undersampling, however, the precision scores were almost unchanged.

In IoT intrusion detection contexts, there is a notable gap in the literature regarding the comparative evaluation of different methods for addressing class imbalance using different classifiers to assess the impact of these techniques on each Machine Learning or Deep Learning algorithm.

So in another context, the authors of [7] compared several sampling techniques, namely, Random Under Sampling,

Random Oversampling, and the combination of the SMOTE-NC and RUS as a hybrid resampling technique. They used the Random Forest algorithm for binary classification and the accuracy, precision, recall, F1-score, and ROC-AUC metrics to evaluate each resampling technique. This study showed that sampling techniques improve the model's performance, especially the hybrid method. However, the Random Oversampling method presented an overfitting problem.

The authors [8] performed a comparative study on imbalanced learning techniques for both classification and regression tasks. In the classification part, they employed Random Forest, SVM, and K-NN algorithms to address binary classification. Their analysis compared the performance of models trained on the original dataset and models enhanced with Over-sampling, Under-sampling, SMOTE, and a combination of Over-sampling and Under-sampling techniques. Accuracy was used to evaluate the performance of the algorithms used. The results highlighted that the over-sampling approach, particularly with the Random Forest algorithm, produced the best performance, achieving an accuracy of 98.29%.

The analysis of existing studies that examine the impact of imbalanced data on the performance of machine learning and deep learning algorithms reveals a significant gap in the literature. Very few studies have conducted a comprehensive comparative analysis of various resampling techniques in the context of intrusion detection. Existing works are primarily limited to binary classification, employ a narrow range of algorithms, and rely on a limited set of evaluation metrics, which, while useful, are often insufficient to assess performance fully. Furthermore, the absence of multiclass classification in these studies leaves a critical gap in understanding how resampling techniques perform in more complex scenarios.

Our study aims to address these limitations by comparing multiple resampling techniques for intrusion detection in binary and multiclass classification tasks. This approach will enable us to explore the impact of different resampling methods on each algorithm and classification type. Additionally, we will evaluate a broad range of machine learning and deep learning algorithms using diverse metrics and graphical analysis to provide a more comprehensive performance assessment.

III. Data Quality and Imbalanced Data Challenges

A. Data Quality Concept

Data quality is a critical aspect of any data-driven process, including the degree to which data meets the needs of its intended use. High-quality data drives accurate and reliable insights, fosters trust in analytical outcomes, and supports decision-making processes across various domains. In traditional data systems, ensuring data quality primarily involved managing structured datasets and addressing issues such as missing values, redundancy, and inconsistencies.

The main part of data quality management is data quality assessment, and data quality is generally assessed using several dimensions. A dimension is a set of attributes that indicate a specific element of data quality [9]. The authors [10] described dimension as a quantitative feature of data quality that describes an aspect of data, such as accuracy, precision, consistency, and so on. Dimensions are assessed using metrics, and a metric is a quantifiable instrument that specifies how a dimension is measured. Regarding the number of existing dimensions of data quality, there is no exact agreed-upon count. The authors [9] conducted a comprehensive study that identified 179 distinct dimensions of data quality. In a subsequent analysis focused on the significance of these dimensions, they refined the list to 20 key dimensions, including Completeness, Accuracy, and Consistency, among others.

Over the years, a wide variety of dimensions have been proposed, and the most used data quality dimensions in literature are:

- Completeness: Ensures that all relevant data points are present. Missing values in critical fields, such as timestamps or identifiers, can hinder analyses and lead to misinterpretations. No data should be missing in the dataset.
- Accuracy: Ensures that the data is free from errors and reflects the real-world entities or processes it represents.
- Uniqueness: It guarantees that no duplicates are present in the data.
- Consistency: Emphasizes uniformity within and across datasets, ensuring that data from all systems within an institution is synced and reflects the same information.
- Timeliness: Ensures that data is up-to-date, relevant to the current context, and accessible when it is needed.
- Validity: Ensures that the data aligns with the specific requirements.

The advent of Big Data—characterized by its volume, velocity, variety, veracity, and value—has introduced new complexities to data quality management. Challenges such as handling heterogeneous data sources (structured, semi-structured, and unstructured) like logs, social media, and IoT sensors ..., ensuring real-time processing, and managing data veracity are amplified [11]. Additionally, the rapidly growing nature of big data makes it difficult to ensure timeliness and relevance, as outdated data can quickly lose its value. Furthermore, the presence of noise, biases, and anomalies across massive datasets necessitates advanced techniques for data cleaning, integration, and preprocessing. Big data quality management, therefore, requires scalable approaches that combine traditional quality metrics with modern techniques such as anomaly detection and automated validation mechanisms to ensure that large-scale data remains reliable and useful.

B. Importance of Data Quality in Intrusion Detection Systems

As we have seen in our previous studies [2], [3], the effectiveness of numerous security mechanisms, tools, and modern machine learning (ML) and deep learning (DL) models is heavily reliant on the quality of the data they process. These systems leverage data at various stages to make critical decisions aimed at ensuring system integrity and protection against cyber threats. For instance, authentication systems analyze user credentials and behavior to decide whether to grant or deny access, while intrusion detection and prevention systems

(IDS/IPS) generate alerts based on patterns and anomalies within network traffic. Similarly, Security Information and Event Management (SIEM) systems aggregate and correlate logs from multiple sources to detect potential threats or unusual activities. Hence, poor data quality can severely undermine their performance, leading to inaccurate threat detection and increased false alarms [12]; the rule "Garbage in garbage out" relates here.

Additionally, ML and DL techniques have further revolutionized security mechanisms by enabling the development of predictive models that can dynamically adapt to evolving threats. High-quality data ensures that both traditional and ML/DL-based security mechanisms can differentiate between normal and malicious activities with greater precision, thereby reducing false positives and negatives. Conversely, poor data quality can lead to weak models, decreased detection accuracy, and unreliable predictions.

Thus, maintaining robust data quality through preprocessing techniques such as cleaning, normalization, and feature extraction is crucial. These measures not only enhance the performance of traditional security tools but also ensure the reliability and adaptability of ML and DL models in complex cyber environments. Ensuring data quality is therefore a cornerstone of building resilient, data-driven security systems capable of addressing the ever-evolving landscape of cyber threats.

C. Imbalanced Data

In many real-world applications, including intrusion detection, data is often imbalanced, meaning that certain classes are significantly underrepresented compared to others. The initial research on imbalanced data originated from binary classification issues; which involves the presence of both majority and minority classes, with a certain imbalance ratio [13]. This imbalance poses a significant challenge for some ML and DL models, as it can lead to biased predictions favoring the majority class while neglecting the minority class. Balancing a dataset simplifies model training by preventing the model from becoming biased toward one class. In other words, the model will no longer favor the majority class simply because it has more data [14]. Consequently, accurate detection of rare but critical events, such as intrusions, becomes difficult.

In intrusion detection systems, imbalanced data is a persistent challenge, as malicious activities, which generally represent the minority class, are significantly less frequent than normal activities. In some cases, this class imbalance can have severe implications for the performance of IDS, as it can lead to models being biased towards the majority class, thus failing to detect rare but critical intrusions. Moreover, it can result in an increased number of false alarms, where benign activities are incorrectly classified as intrusions. However, the imbalanced data issue is still very context-dependent, determined by the type of ML and DL algorithms, dataset features, and the classification task. Some models are significantly affected by this imbalance, leading to biased predictions and poor generalization performance. In contrast, other models can adapt more readily as they exhibit a certain level of robustness to class imbalance.

Several techniques have been developed to address the imbalanced data issue, including SMOTE, SMOTE combined with random undersampling (SMOTE RUS), and SMOTE-Tomek Links combined with random undersampling (SMOTE-TL RUS). Each of these techniques operates with unique mechanisms to balance datasets, enabling a better representation of the minority class during model training.

1) SMOTE (Synthetic Minority Over-sampling Technique) [15]: This method generates synthetic samples for the minority class. For each instance in the minority class, SMOTE selects one or more nearest neighbors and creates new examples by interpolating between these points. The process of generating synthetic samples involves selecting random data from the minority class, calculating the Euclidean distance to its k nearest neighbors, multiplying the difference by a random number between 0 and 1, and then adding the result to the minority class as a synthetic sample [16]. This procedure is repeated until the desired proportion of the minority class is achieved.

For a given minority sample x, a synthetic sample x_{new} is created using the formula:

$$x_{new} = x + \lambda(x_{nearest} - x) \tag{1}$$

where, $x_{nearest}$ is one of the k-nearest neighbors of x and λ is a random number in the range [0, 1].

Fifteen years after its introduction, the SMOTE method has become a foundation for the research community in addressing imbalanced classification challenges. Its innovative approach to generating synthetic samples for the minority class has inspired numerous extensions and adaptations, each building upon its foundation to tackle specific limitations or enhance its applicability [17].

2) SMOTE-TL (Synthetic Minority Over-sampling Technique – Tomek Links): It is a hybrid technique that combines the SMOTE technique with Tomek Links to address class imbalance in datasets.

Tomek Links is a variant of the Condensed Nearest Neighbors undersampling approach invented by [18]. Unlike the CNN method, which randomly selects samples along with their k-nearest neighbors from the majority class to be removed, the Tomek Links method employs a rule to identify and eliminate specific pairs of observations. A pair of observations (a, b) is classified as a Tomek Link if it satisfies the following conditions [16]:

*Observation a's nearest neighbor is b.

*Observation b's nearest neighbor is a.

*Observations a and b belong to different classes, with one observation from the minority class and the other from the majority class.

Mathematically, for two instances x_a from the majority class and x_b from the minority class, a Tomek Link exists if they are the nearest neighbors of each other, and the distance $d(x_a, x_b)$ is minimal.

SMOTE-TL combines the SMOTE capability to generate synthetic data for the minority class and the Tomek Links

ability to remove data recognized as Tomek links from the majority class.

The overall process of SMOTE-TL can be stated as follows:

*Apply SMOTE to create synthetic samples for the minority class.

*Identify Tomek Links by checking the nearest neighbor relationships.

*Remove the majority class instances that form Tomek Links with the minority class instances.

3) SMOTE with random under sampling: It is a hybrid resampling technique that combines the SMOTE technique with undersampling. While SMOTE effectively increases the number of minority class samples by generating synthetic examples, it can also increase the risk of overfitting, especially if the majority class is significantly larger. To counter this, undersampling is employed simultaneously, which involves randomly removing instances from the majority class to achieve a more balanced dataset and potentially improve the model's performance.

4) SMOTE-TL with random under sampling: This technique consists in applying SMOTE-TL followed by an additional Random Undersampling step. It is an advanced resampling technique that addresses class imbalance while further refining the dataset. This approach leverages the strengths of both methods to ensure balanced class distributions, remove noisy samples, and reduce the dataset's size, making it computationally efficient for subsequent model training, especially for large datasets.

In this study, we will explore several resampling techniques, namely SMOTE, SMOTE with random undersampling, and SMOTE-TL with random undersampling, and their impacts on the performance of different ML and DL models. Furthermore, we will evaluate how these techniques affect binary and multiclass classification tasks and compare these resampling methods with models trained on imbalanced data to highlight their impact.

IV. Use Case: The CICIOT 2023 Dataset

To conduct our study, we used the CICIoT2023 dataset [19], a recent and extensive IoT attacks dataset. It was created at the Canadian Institute for Cybersecurity, University of New Brunswick. This dataset includes 33 attacks that are classified into seven types of attacks. Table I represents the types of attacks and their description.

The authors extracted over 68 million records and 47 features using an IoT topology regrouping 105 devices.

To optimize computing time, we randomly selected 20% of the original dataset, constituting a subset of 13,584,750 records. Fig. 1 represents the class distribution of our selected data.

This selection was made to facilitate efficient analysis and ensure the feasibility of processing the data within the available computational resources.

V. Workflow and Execution

Our comprehensive study focuses on a multifaceted approach to intrusion detection. It begins with data selection and extraction, followed by a rigorous data cleaning process to prepare the dataset for further analysis. The study then involves creating three distinct datasets: a binary dataset, an 8-class dataset, and a 34-class dataset.

For each dataset, feature engineering is used to identify relevant features and scale the data appropriately. Subsequently, we apply multiple Machine Learning and Deep Learning algorithms to classify attacks under various scenarios of imbalanced data treatment, including using SMOTE, SMOTE-RUS, SMOTE-TL RUS, and unbalanced data. This holistic approach ensures a robust benchmarking and evaluation of the proposed classification techniques across different data representations and balancing strategies.

A. Data Preprocessing

The first phase of our work focused on data preparation, which is a critical step in ensuring the quality and relevance of our analysis.

In this initial phase of our research, we chose the CICIOT 2023 dataset, a novel Internet of Things dataset that aligns well with our study's objectives. The original dataset comprises approximately 68 million records; however, to optimize our computational resources, we randomly extracted a subset of around 13 million records. The extracted data contained approximately 2% benign traffic, compared to the original dataset's 1.6%, ensuring consistency in data representation.

Following, we performed a comprehensive data cleaning process, as illustrated in Fig. 2.

This step was crucial due to the presence of duplicate entries, which we identified and removed. We also standardized the formatting of our columns to ensure uniformity in value representation and corrected data types where necessary; for instance, some columns initially labeled as Float were incorrectly designated as String. Additionally, we conducted a thorough check for missing values to maintain data integrity. To facilitate further analysis, we encoded categorical features using the label encoder technique.

By the end of this phase, we successfully obtained a clean dataset from which we derived three distinct datasets: a binary dataset, an 8-class dataset, and a 34-class dataset, to evaluate our classification models under varying scenarios and complexities.

Following the data preparation phase, we conducted feature engineering, a crucial step in improving the performance of machine learning models by selecting the most relevant features and transforming the data into a more informative format.

As shown in Fig. 3, for each dataset created (binary, 8-class, 34-class), this phase began with feature selection, where we employed a hybrid method that integrates the Chi-Squared test and Random Forest techniques. The Chi-Squared test is a statistical method used to evaluate the independence of categorical variables, helping us identify features that have a

TABLE I. TYPES OF ATTACKS

Type of attack	Attacks	Description
DoS	TCP flood, HTTP flood, SYN flood, UDP flood	An attempt to overload a machine or network, with the aim of weakening its performance or making it completely inaccessible.
DDoS	ACK fragmentation, UDP flood, SlowLoris, ICMP flood, RSTFIN flood, PSHACK flood, HTTP flood, UDP fragmentation, TCP flood, SYN flood, SynonymousIP flood	A DoS attack where multiple machines flood the target.
Brute Force	Dictionary brute force	A hacking method that cracks passwords, encryption keys... using trial-and-error.
Reconnaissance	Ping sweep, OS scan, Vulnerability scan, Port scan, Host discovery	An attack where the actor gathers all the information of his target for exploit.
Spoofing	ARP spoofing, DNS spoofing	An attempt to gain access to a system by hiding the real identity or location.
Mirai	GRE IP flood, GRE Ethernet flood, UDP plain flood	A botnet designed to take over IoT devices and turn them into controlled bots.
Web Based	SQL injection, Command injection, Backdoor malware, Uploading attack, Cross-Site Scripting (XSS), Browser hijacking	A method used by cybercriminals to compromise computer systems, steal data, or cause damage by exploiting vulnerabilities in applications or services accessible via the Internet.

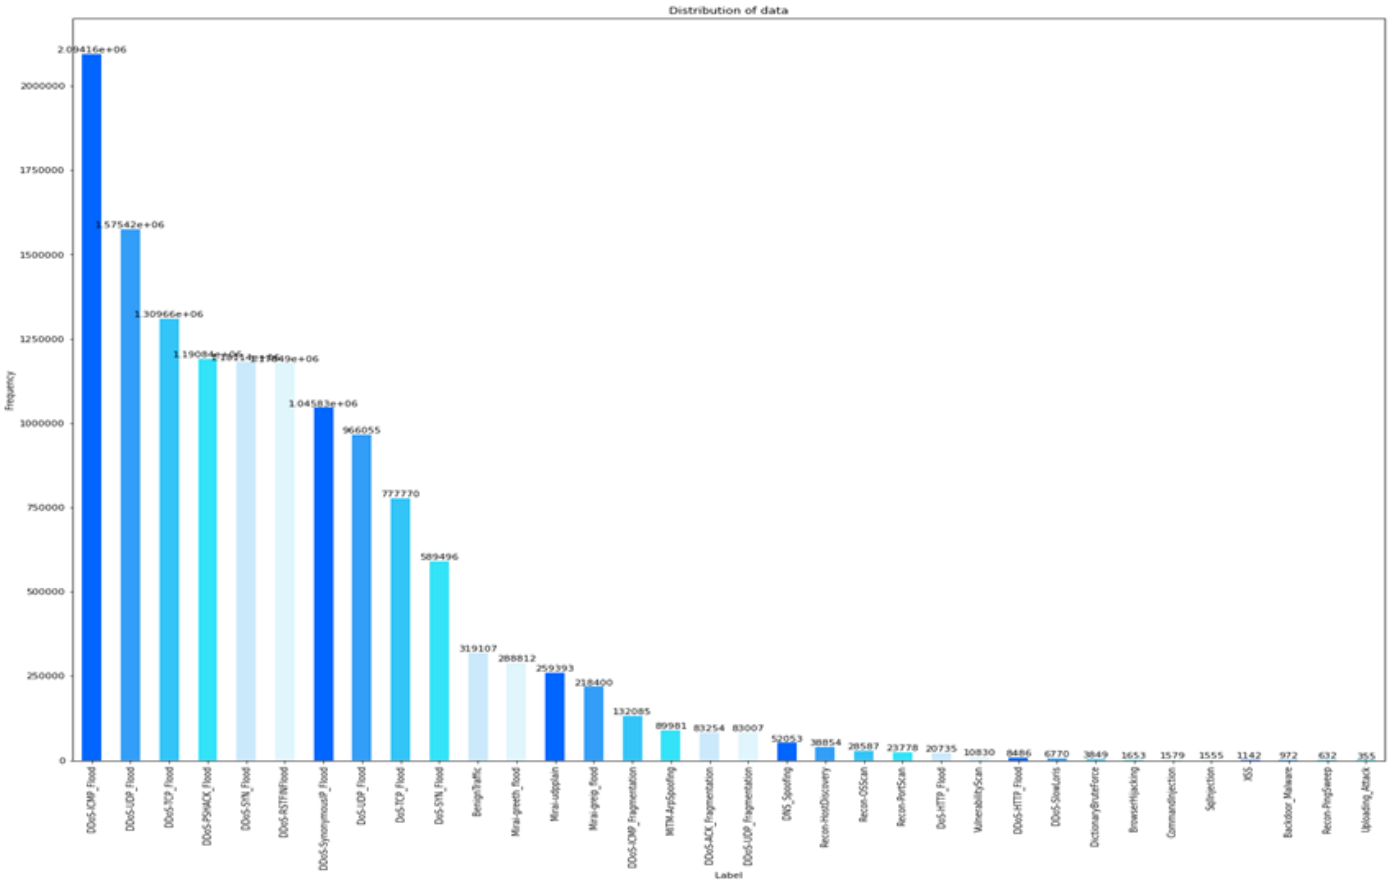

Fig. 1. Class distribution of our selected data.

significant relationship with the target variable. A high Chi-Square score indicates that the independence hypothesis is incorrect, which means the greater the Chi-Square value, the more reliant the feature is on the response and hence suitable for model training [20].

This initial filtering process efficiently narrows the feature set by highlighting the most relevant features based on their statistical significance. Subsequently, we applied the Random Forest algorithm, an ensemble learning method that assesses the importance of features based on their contribution to the model's predictive accuracy. By combining these two techniques, we benefit from the strengths of both: the Chi-Squared test provides a quick and interpretable means of initial selection, while Random Forest offers a robust evaluation of feature importance. This hybrid approach enhances the efficiency of our feature selection process and ensures that we retain the most informative features, ultimately leading to improved model performance.

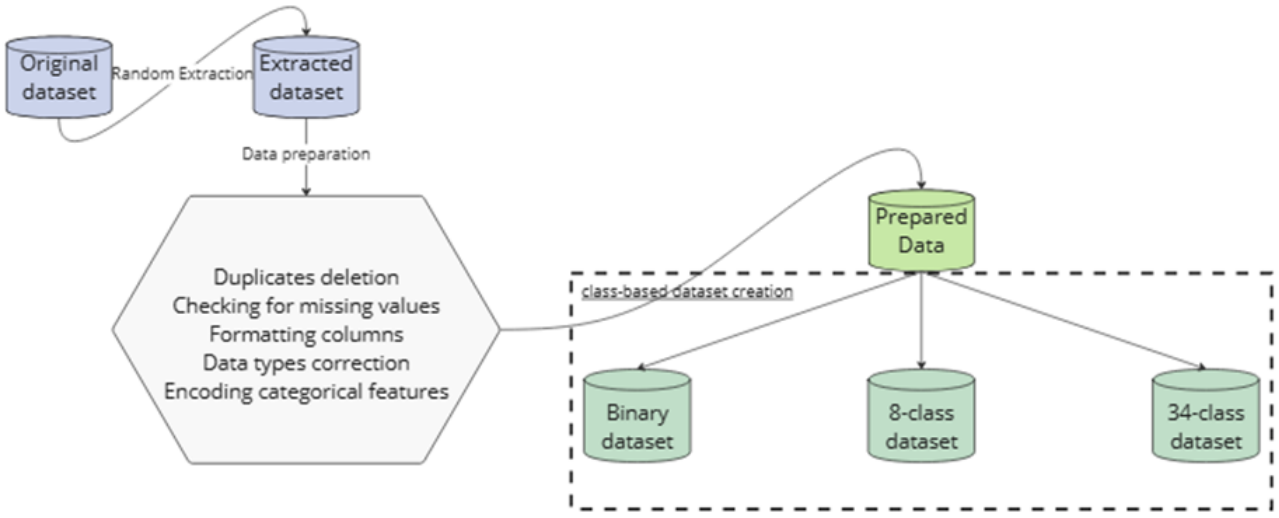

Fig. 2. Our data preparation process.

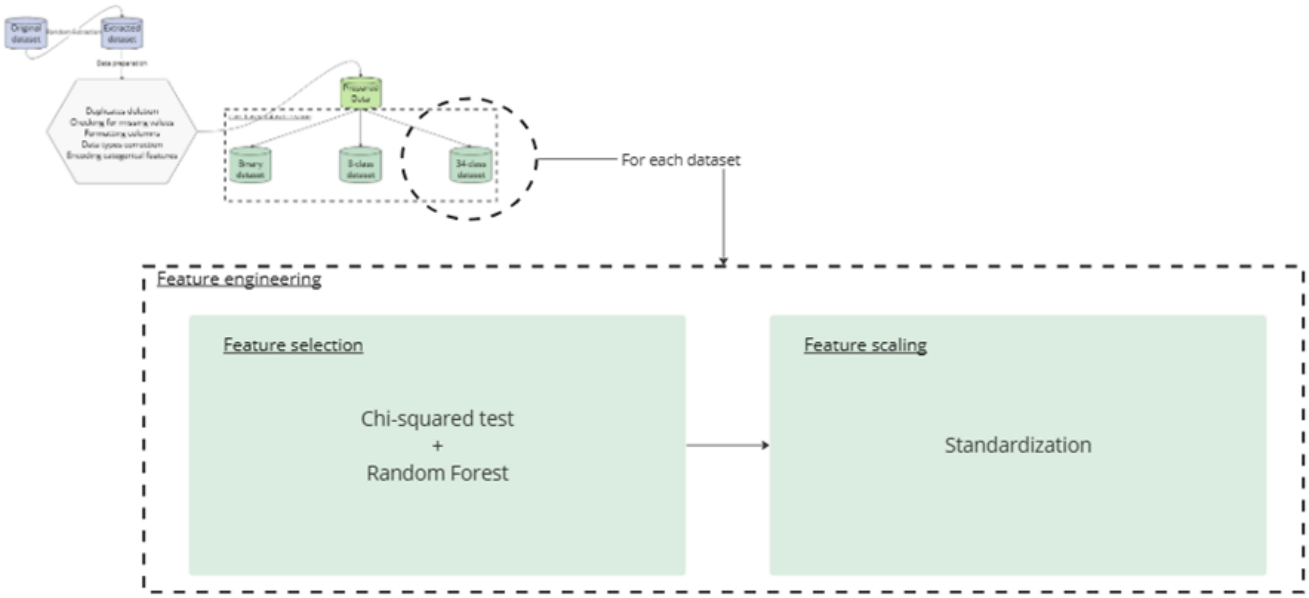

Fig. 3. Our feature engineering process.

Next, we implemented feature scaling using standardization, a crucial process that transforms our features to have a mean of zero and a standard deviation of one. This technique is particularly beneficial in machine learning, as it ensures that all features contribute equally to the distance calculations and optimization algorithms used in various models, regardless of their original scale.

B. Machine Learning and Deep Learning Modeling Under Different Balancing Scenarios

In this phase of our research, we focused on modeling various Machine Learning and Deep Learning algorithms to classify attacks under multiple scenarios: imbalanced data, balanced data using SMOTE, balanced data using SMOTE-RUS, and balanced data using SMOTE-TL RUS, for each dataset (binary, 8-class, and 34-class); which results in 12 scenarios for each algorithm.

As shown in Fig. 4, we chose different algorithms, namely XGBoost, Random Forest, Logistic Regression, Deep Neural Networks, Long Short-Term Memory (LSTM), and K-Nearest Neighbors (K-NN). These algorithms were trained on the respective training datasets, and hyperparameter optimization was conducted using the GridSearch technique.

GridSearch systematically evaluates a given set of hyperparameter combinations to identify the optimal configuration for each algorithm. This approach ensures that the models are fine-tuned to their best possible performance, reducing the risk of underfitting or overfitting. GridSearch offers the advantage of exhaustive search across the hyperparameter space, ensuring no potential configuration is missed.

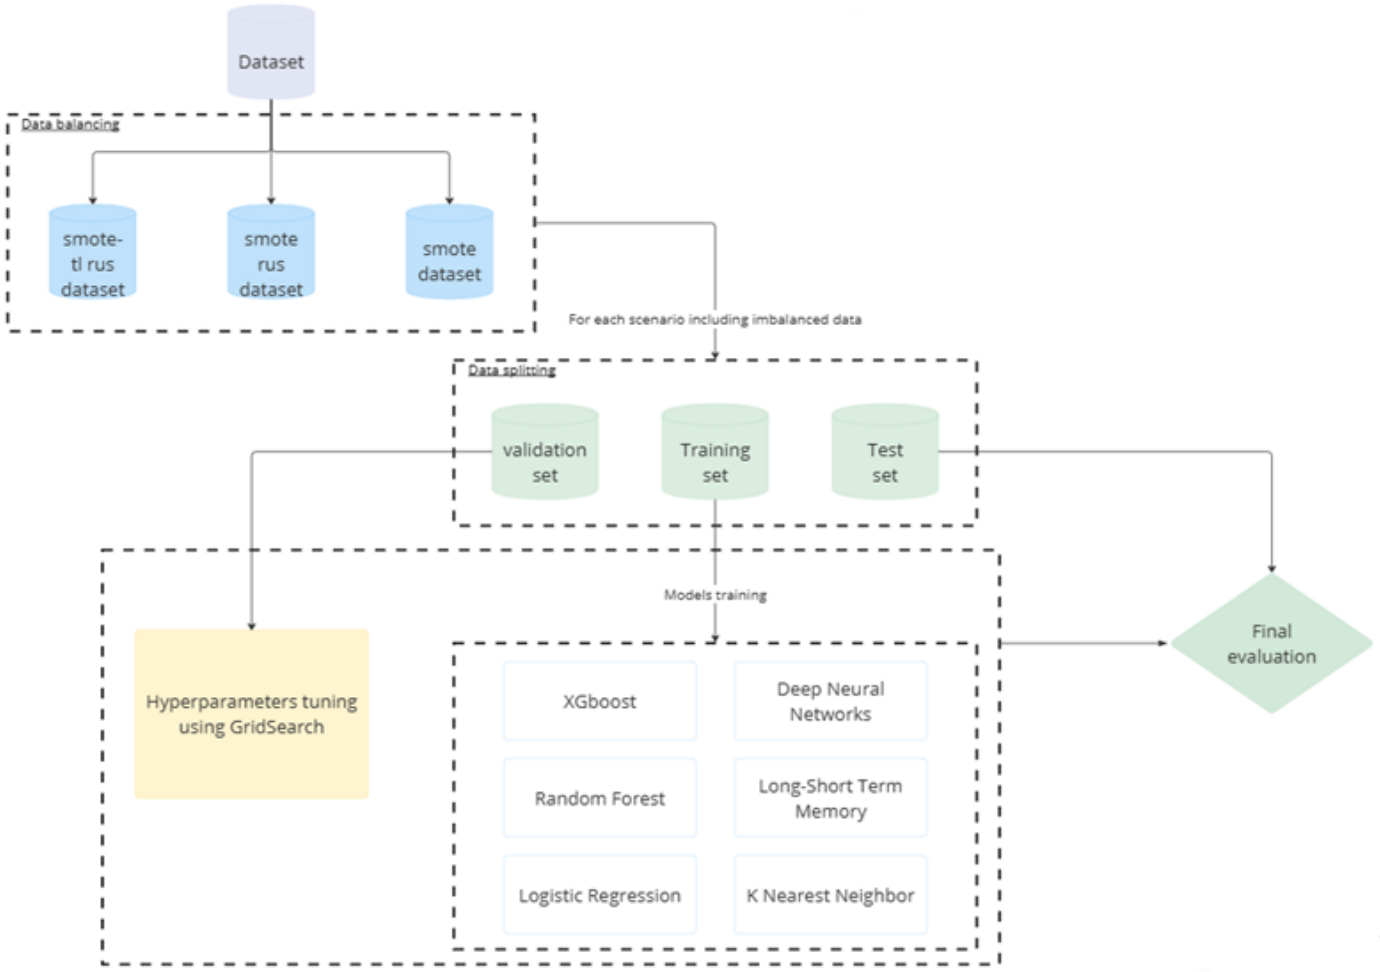

Fig. 4. Our ML and DL modeling workflow.

Once the optimal hyperparameters were identified through validation, the final models were evaluated on the test set. This evaluation step aimed to provide a robust and unbiased assessment of the model's performance.

To ensure a comprehensive and reliable evaluation of our models, we used various performance metrics, namely accuracy, precision, recall, F1-score, AUC-ROC, confusion matrix, PR curve, and ROC curve. These metrics were chosen to capture different aspects of model performance, such as overall accuracy, ability to minimize false positives, sensitivity to detecting true positives, and the balance between precision and recall. Furthermore, the AUC-ROC, PR curve, and confusion matrix provide thorough insights into the model's behavior, offering a deeper understanding of each classifier's strengths and weaknesses.

By leveraging diverse balancing techniques, a wide range of classification algorithms, and multiple datasets, our study provides a detailed and thorough evaluation of the models, ensuring that the results are reliable and generalizable across different attack classification scenarios. This comprehensive approach represents a significant improvement over existing studies that rely on fewer metrics or scenarios.

VI. Results and Discussion

As we mentioned before, we present and analyze the performance of several Machine Learning and Deep Learning algorithms for intrusion detection using a binary dataset, an 8-class dataset, and a 34-class dataset under different balancing scenarios, namely imbalanced data, balanced with SMOTE, and balanced with SMOTE-RUS and SMOTE-TL RUS.

Our experiment was conducted on a Windows 10 Operating System with 16 GB RAM and an Intel(R) Core(TM) i7-7600U CPU @ 2.80 GHz, 2904 MHz processor.

As shown in Table II, for the binary dataset, the results reveal notable differences across balancing strategies.

XGBoost achieved consistent results across all metrics, particularly with the original imbalanced dataset, where it performs slightly better in accuracy, precision, recall, and F1-score. This suggests that XGBoost handles imbalanced data effectively. On the other hand, K-NN demonstrates an excellent performance, especially with the SMOTE-TL RUS

TABLE II. PERFORMANCE METRICS OF OUR MODELS FOR BINARY CLASSIFICATION ACROSS DIFFERENT BALANCING SCENARIOS

		Binary classification			
		SMOTE-TL RUS	**SMOTE RUS**	**SMOTE**	**Imbalanced data**
XGBoost	**accuracy**	98.78	98.20	98.68	**99.28**

	precision	91.77	92.94	99.66	99.26
	recall	99.23	98.72	97.24	99.70
	f1-score	95.35	95.74	98.43	99.49
	AUC ROC	99.71	99.45	99.68	99.77
LSTM	**accuracy**	**98.78**	97.75	98.66	97.66
	precision	99.01	95.55	99.26	97.66
	recall	98.55	97.96	98.04	100
	f1-score	98.78	97.76	98.65	98.82
	AUC ROC	93.83	97.91	98.76	79.74
DNN	**accuracy**	98.75	98.76	**99.24**	99.22
	precision	98.66	98.75	99.70	99.65
	recall	98.84	98.76	98.78	99.55
	f1-score	98.75	98.75	99.24	99.60
	AUC ROC	99.81	99.82	99.90	99.79

and SMOTE scenarios, highlighting high precision and recall values. It also maintains strong performance on the imbalanced dataset, indicating that K-NN can benefit from both balanced and imbalanced cases.

In addition, Logistic Regression shows moderate performance compared to other models, with significant improvements in the imbalanced dataset. Random Forest shows considerable strength in precision and recall, particularly on the imbalanced dataset and SMOTE scenarios. Its ability to achieve high AUC-ROC scores across all scenarios demonstrates its robustness and reliability for binary classification tasks.

Regarding Deep Learning models, LSTM demonstrates robust performance across most metrics, with high accuracy, precision, recall, and F1-score in all balancing scenarios. However, the AUC-ROC value varies significantly, being lower with imbalanced data, indicating that the model's ability to distinguish between classes is less effective without balancing techniques. SMOTE-TL RUS and SMOTE show relatively consistent and strong results, suggesting these techniques enhance the model's discrimination ability while maintaining other performance metrics. Furthermore, for DNN, the performance is consistently strong across all scenarios, with minimal differences in metrics. The DNN model achieves its highest AUC-ROC with SMOTE, reflecting its remarkable ability to differentiate between classes with imbalanced data. Additionally, its precision and F1-score are notably high, indicating effective handling of class imbalance.

Table III shows the performance of our models across different balancing techniques on an 8-class dataset.

As we can see, XGBoost performs best with imbalanced data, achieving the highest accuracy and AUC ROC. However, its recall and F1-score are low, indicating poor performance with minority classes. Furthermore, K-NN exhibits strong performance across all techniques, with particularly high accuracy and AUC ROC on imbalanced data. Recall and F1-score are low however, SMOTE improves its recall and F1-score, highlighting its suitability for balanced datasets.

In addition, Logistic Regression's performance is relatively stable, with moderate accuracy and AUC ROC. Balancing techniques improve recall and F1-score slightly, but it is clear that the model struggles to capture complex relationships in the data. Random Forest performs poorly on imbalanced data,

TABLE III. PERFORMANCE METRICS OF OUR MODELS FOR 8-CLASS CLASSIFICATION ACROSS DIFFERENT BALANCING SCENARIOS

		8-class classification			
		SMOTE RUS	**SMOTE-TL RUS**	**SMOTE**	**Imbalanced data**
XGBoost	**accuracy**	51.46	59.59	44.18	**81.22**

	precision	60.55	65.55	75.96	72.96
	recall	56.30	58.88	73.22	57.3
	f1-score	54.22	58.08	73.03	59.73
	AUC ROC	89.54	90.06	96.15	97.52

with accuracy and F1-score trailing other models. Smote-TL RUS significantly boosts RF's recall and F1-score, indicating its reliance on balanced datasets to handle minority classes effectively.

Concerning Deep Learning models, LSTM shows inconsistent performance, with high precision on SMOTE but very low recall on imbalanced data. Balancing techniques like SMOTE-TL RUS and SMOTE enhance its recall and F1-score. Moreover, DNN performs well overall, with the best accuracy and F1-score on imbalanced data. Its AUC ROC is also the highest among all models. SMOTE significantly enhances its recall and F1-score, highlighting its ability to leverage balanced data effectively.

Table IV shows the performances of our models across different balancing techniques on a 34-class dataset.

As observed, XGBoost performs quite well with imbalanced data, achieving moderate accuracy and a high AUC ROC, indicating its ability to separate classes probabilistically. However, its low recall and F1-score reveal poor performance on minority classes. Balancing techniques such as SMOTE and SMOTE RUS provide slight improvements in recall and F1-score but result in lower overall accuracy. Furthermore, K-NN demonstrates robust performance, particularly with Sample SMOTE, achieving high accuracy and AUC ROC. While its recall and F1-score are relatively low on imbalanced data, balancing techniques like Sample SMOTE significantly boost these metrics, showing its adaptability to rebalanced datasets.

Moreover, Logistic Regression maintains moderate performance across all scenarios, with high AUC ROC values. However, its accuracy and F1-score are low, reflecting its inability to model complex relationships. SMOTE slightly improves recall and F1-score, but the model struggles to achieve competitive performance compared to others. Random Forest shows high accuracy and precision on imbalanced data but low recall and F1-score, indicating challenges in handling minority classes. SMOTE noticeably improves RF's recall and F1-score, demonstrating its reliance on balanced datasets to perform effectively.

Among Deep Learning models, LSTM shows inconsistent performance. It achieves a high AUC ROC on imbalanced data but has low recall and F1-score. SMOTE enhances its recall and F1-score, indicating its potential with balanced

	f1-score	45.46	22.82	29.02	61.49
	AUC ROC	98.98	89.47	90.31	97.48

datasets. Similarly, DNN achieves the best overall performance on imbalanced data, with the highest accuracy and AUC ROC. While its recall and F1-score are initially low, SMOTE and Smote-TL RUS significantly enhance these metrics.

Due to space limitations, we only show ROC curves, PR curves, and confusion matrices of the best models across all balancing scenarios on each dataset.

Fig. 5, Fig. 6, and Fig. 7 show the ROC curve of the best model in each dataset.

Fig. 8, Fig. 9, and Fig. 10 show the PR curve of the best model in each dataset.

Fig. 11, Fig. 12, and Fig. 13 show the confusion matrices of the best model in each dataset.

As we can deduce, our curves and matrices further confirm and support the reported scores and the accompanying discussion. They visually illustrate the variations in performance across models and balancing techniques.

VII. Conclusion

In this study, we conducted a comprehensive analysis of the impact of data quality and class imbalance on classification problems, focusing on binary, 8-class, and 34-class classification in the context of intrusion detection. Using a novel IoT dataset, we thoroughly evaluated the performance of various Machine Learning and Deep Learning algorithms in different balancing scenarios and with different datasets. Our work goes beyond traditional evaluations by incorporating a diverse set of performance metrics; accuracy, precision, recall, F1-score, AUC-ROC, and visual tools such as confusion matrices, PR curves, and ROC curves. This approach ensures a robust and reliable assessment of algorithmic performance.

Additionally, our study demonstrates how results vary depending on each balancing technique and classification type, with certain models excelling in binary tasks but showing limitations in multiclass settings, while others are susceptible to imbalanced data and handle it differently. Another key outcome of this research is the creation of multiple sub-datasets tailored for different classification and balancing scenarios, offering a valuable resource for researchers seeking to extend this analysis or apply these datasets for their research.

In our future work, we intend to investigate the strategic role of data quality in reinforcing the resilience of Intrusion Detection Systems against sophisticated adversarial threats. Moreover, our findings also emphasize the trade-off between the performance of our models and computational cost, as these robust models often require significantly greater computational resources. Finally, extending this approach to other critical domains such as automotive or healthcare systems could provide further insights into the generalization of our findings.

Automated Anatomical Analysis of Wood Cross Sections Using Macroscopic Images

Khanh Nguyen-Trong[1], Thanh Nhan Nguyen-Thi[2]
Intelligent Computing for Sustainable Development Laboratory (IC4SD)[1]
Faculty of Information Technology, Posts and Telecommunications Institute of Technology, Hanoi, Vietnam[1,2]

***Abstract*—Wood anatomical features are crucial in forestry science, traditionally relying on manual inspection of wood cross-sections. This conventional method is time-consuming, subjective, and dependent on expert experience. Recent advancements in deep learning offer high accuracy but often operate as black-box models, lacking interpretability and struggling with out-of-distribution challenges under real-world variations. To address these limitations, we propose a two-stage framework combining deep-learning-based image classification and explicit anatomical feature analysis, directly extracting expert-recognized morphological attributes such as pore size, frequency, and spatial arrangement from macroscopic images. By quantifying these anatomical descriptors, our framework yields transparent, OOD-robust features that can be directly fed into downstream species-identification models, thereby enhancing future classification accuracy while preserving interpretability. An end-to-end implementation integrates data acquisition, automated feature extraction, and interactive visualization, making the methodology practically applicable in both laboratory and field settings.**

***Keywords*—Wood species identification; wood anatomical analysis; segmentation; Mask R-CNN; DenseNet**

I. Introduction

Wood anatomical analysis is fundamental to forestry management, biodiversity conservation, and accurate identification of timber species. In routine practice, specialists inspect anatomical features on the transverse surface—such as vessel (pore) arrangement, ray structure, and axial parenchyma—to determine the taxon. Especially in many developing countries, samples for wood-species identification are shipped to a central laboratory, where trained analysts view the cross-sections under optical magnifiers or microscopes and match their observations to standardized references (e.g., the IAWA list [1]). This manual workflow is time-consuming, labour-intensive, and inherently subjective because accuracy depends on the expert's experience.

In recent years, numerous research efforts have explored automated or semi-automated machine learning approaches for wood species analysis, often reporting high accuracy on benchmark datasets [2], [3], [4]. For example, Pratondo *et al.* [4] studied and compared various machine learning techniques for classifying three similar wood types—jeungjing, puspa, and suren—using k-nearest neighbors, support vector machines, decision trees, random forests, and Inception-v3. Their experiments showed that the random forest classifier achieved the highest accuracy at 90.67%.

Bello *et al.* [2] proposed combining Mask R-CNN with a modified residual network, attaining a notable 92% accuracy in wood species identification. Such advancements may be surprising to lay readers, as they adapt state-of-the-art deep learning methods—commonly seen in broader computer vision tasks—to the specialized context of wood identification. Nguyen-Trong [3] further introduced an approach based on convolutional neural networks to analyze wood images at multiple magnification levels, providing a comprehensive discussion of the research framework, methodology, and findings for deeper insight into its effectiveness.

Despite these promising results, many of these solutions operate as black-box image classifiers with limited interpretability regarding which anatomical features underlie the final decision. To address these limitations, our work proposes a strategy to analyze and extract important anatomical features commonly used by experts, such as pore size, pore arrangement, and pore frequency, directly from macroscopic images. Traditional wood anatomy is grounded in systematically categorizing xylem anatomical features, which often facilitates identification at the genus level. However, fully capturing every detail in the xylem structure using only visual judgment and accumulated expertise can be challenging. Consequently, several approaches now focus on quantifying anatomical markers such as cell wall thickness and cell count, in contrast to conventional inspection methods that remain somewhat subjective [5].

Therefore, this approach not only aids in identification by leveraging anatomically meaningful descriptors but also enhances explainability, as the model outputs explicit morphological attributes that correlate with standard wood anatomy references.

The main contributions of this study are as follows:

- We propose a two-stage methodology that first classifies macroscopic images into wood versus non-wood categories, and then segments Vessel-Centric Regions (VCRs), defined as pore lumina along with immediately adjacent perivascular parenchyma, if present.
- We employ DenseNet121-based feature extraction for robust wood image classification and utilize Mask R-CNN for precise segmentation of anatomical features, enabling detailed quantitative analysis.
- We provide an end-to-end implementation integrating mobile-based image classification, remote anatomical segmentation, and visualization, demonstrating practical utility for both laboratory and field applications.

The remainder of this study is organized as follows: Section II reviews recent literature on automated wood identification. Section III details our proposed two-stage framework, including data preprocessing and anatomical feature extraction.

Section IV presents experimental setups and quantitative evaluations. In Section V, we demonstrate an end-to-end application that integrates the proposed method into a real-world workflow. Finally, Section VI concludes the study and discusses future research directions.

II. Related Works

Recent research in wood species analysis has explored various approaches using machine learning and computer vision. Regarding methodologies, two main categories can be distinguished: i) traditional machine learning, including k-NN [6], SVM [7], and ANN [8], which often require handcrafted features, and ii) deep learning methods, such as CNN-based architectures [3] (VGG [9], ResNet [10], SqueezeNet [11], DenseNet [12], etc.), which automatically extract features from image data. Studies have utilized both microscopic and macroscopic images, with a trend towards more accessible macroscopic imaging techniques [3], [13].

Many recent works favor deep learning because of its higher performance when sufficient data is available. Silva et al. [14] demonstrated high success rates (88 to 90%) in classifying 77 Central-African timber species using microscopic images and texture-based features. Advancements in deep learning have shown promise, with He et al. [15] achieving 100% accuracy on a dataset of 8 wood species using an ensemble of convolutional neural networks. Herrera-Poyatos et al. [13] proposed a patch-based classification method for high-resolution macroscopic images, addressing challenges in capturing fine-grained patterns. Nguyen-Trong [3] evaluated various CNN architectures across different magnification levels, finding DenseNet121 to perform best on 20x magnified images.

Despite these advances, most studies primarily focus on classification tasks (i.e., assigning a species label to an image). The anatomical analysis of wood, particularly the segmentation and measurement of pores (e.g., solitary pores, pore multiples, pore clusters), parenchyma arrangements, or other microfeatures, remains relatively under, explored at the macroscopic scale. However, these features are crucial for a detailed understanding of wood anatomy and can bolster both automated classification accuracy and the broader morphological characterization of new wood samples. For example, identifying whether pores are solitary or clustered (and quantifying pore size, frequency, and distribution) directly contributes to more accurate species identification and deeper insight into the wood's anatomical structure.

In literature, anatomical analysis has been widely applied across medical imaging to enhance classification accuracy and provide deeper insights into structural characteristics. This approach is crucial for various applications, including surgical planning, disease progression tracking, and treatment planning [16]. Recent advancements in image segmentation techniques have been employed to define anatomical structures in CT images, particularly for COVID-19 diagnosis [17]. Image analysis techniques are essential for improving the quality of medical images and extracting features that lead to better classification results and more accurate diagnoses [18]. Deep learning methods, such as CNNs, have shown remarkable performance in anatomy-specific classification of medical images. By training on large datasets of CT scans and employing data augmentation techniques, CNNs can achieve high accuracy in classifying anatomical structures, with error rates as low as 5.9% [19].

Techniques like CNNs have demonstrated remarkable success in automatically delineating complex anatomical features from medical images, thereby improving both the efficiency and accuracy of medical assessments [20].

Despite the proven efficacy of anatomical analysis in fields like medical imaging, its application within the domain of wood identification remains relatively underexplored, particularly at the macroscopic level. Traditional wood identification methods often rely on manual examination of features such as pore arrangement, parenchyma patterns, and other microstructures. However, these manual approaches are time-consuming and subject to human error. While some studies have employed computer vision techniques for wood species classification, they predominantly focus on assigning species labels without delving into the segmentation and quantitative analysis of anatomical features [21].

Integrating anatomical analysis into wood identification holds significant potential. By employing advanced image segmentation techniques to automatically identify and measure key features, such as distinguishing between solitary pores and pore clusters, and quantifying their size, frequency, and distribution, researchers can achieve more accurate species identification and gain deeper insights into wood anatomy. This approach mirrors the successes seen in medical imaging and suggests a promising avenue for enhancing wood identification processes through the application of sophisticated computer vision methodologies.

Building upon this research context, our work aims to develop a two-stage approach for automated anatomical analysis of wood cross-sections using macroscopic images. First, a classifier (trained with a DenseNet121 feature extractor and an GMM) determines whether an input image indeed represents a magnified wood cross-section. Next, images confirmed to be wood cross-sections proceed to a detection and segmentation model to identify and segment pores, followed by computing various anatomical descriptors (i.e., average pore size, pore distribution, solitary versus multiple pore frequency). The overall objective is to integrate these methods into a system deployable on resource-constrained devices, such as smartphones, thereby facilitating affordable, efficient, and accurate wood anatomical analysis in both laboratory and field settings.

III. Materials and Methods

In this section, we present the materials and methods underlying our automated wood anatomical analysis. First, we describe our approach for classifying macroscopic images into wood versus non-wood categories. Next, we outline the segmentation of Vessel-Centric Regions (VCRs) using Mask R-CNN. Finally, we detail the extraction of anatomical descriptors, including VCR size, frequency, and spatial arrangement, essential for characterizing different wood species.

A. Wood Macroscopic Image Classification

Binary classification is arguably the most widely documented branch of supervised machine learning, especially in

domains where both positive and negative classes are naturally bounded by the same medium (e.g., "ham versus spam" in email). However, complications emerge when applying this framework to image classification tasks.

Consider the challenge of building a model to determine whether an image shows a magnified wood cross-section. We may have a substantial collection of wood cross-section images for the "wood" class, but "not wood" examples can be drawn from virtually any image category—making it nearly infinite in scope. This is unlike email filtering, where even "spam" emails are still emails, sharing a common format and feature space with "ham".

There are multiple ways to tackle this. One approach is one-class classification, in which a model is trained primarily (or exclusively) on positive-class data—in this case, images of wood cross-sections. When such a model encounters a novel input, it determines whether the input sufficiently resembles the positive class ("wood") or should be flagged as an outlier ("not wood"). Techniques such as autoencoders, One-Class SVM, or Isolation Forest can be used in this context.

However, if we do have access to certain negative examples—i.e., images known to contain no wood cross-sections—then more traditional binary classification methods can be applied. A common strategy is to perform feature extraction via a pretrained CNN (e.g., DenseNet121), reduce the dimensionality (e.g., with PCA), and then train a conventional machine learning model (e.g., SVM, Gaussian Mixture with Isotonic Regression) on these features. This latter approach benefits from explicitly learning to discriminate between "wood" and "not wood", but requires a representative set of negative examples.

In our work, we adopt transfer learning for feature extraction, followed by testing multiple classification schemes. This allows us to balance performance needs with the availability of negative data. By leveraging proven CNN architectures trained on vast image datasets (e.g., ImageNet), we can efficiently generate high-level embeddings that are then used by simpler classifiers. This technique proves especially practical in real-world scenarios, where the negative class (all images that are "not wood") is both diverse and difficult to comprehensively represent.

1) Feature extraction with DenseNet: To handle this classification task, we adopt a transfer learning approach that relies on DenseNet121, a well-known convolutional neural network pretrained on large-scale image datasets (e.g., ImageNet). Specifically, we remove the original classification layer (i.e., the fully connected top) and leverage the network's final feature maps (global average pooled) as a 512-dimensional feature vector for each input image.

All images are first resized to 224×224 and standardized (e.g., pixel values divided by 255) to match the input layer requirements of DenseNet121. Next, the pretrained model processes each image to produce the condensed feature representation. This step provides a robust and discriminative embedding of the original imagery without the need to train a full CNN from scratch.

2) Dimensionality reduction and scaling: Following feature extraction, we scale and apply Principal Component Analysis to reduce dimensionality. Dimensionality reduction serves two main purposes:

- It helps mitigate noise or redundant information in the extracted feature space.
- It substantially decreases training time for subsequent classification models, as high-dimensional feature vectors are compressed into a more manageable number of principal components.

3) Classification approaches: Once the feature vectors are extracted and reduced via PCA, we evaluate several classification methods, including Gaussian Mixture Models (GMM) with Isotonic Regression, One-Class SVM, and Isolation Forest.

GMM with Isotonic Regression can leverage a small validation set containing both positive (wood) and negative (non-wood) examples. By modeling the distributions of each class, the GMM can estimate the likelihood that a new image belongs to the learned "wood" distribution, and Isotonic Regression refines the decision threshold for improved calibration.

In scenarios with little or no labeled negative data, one-class classifiers such as One-Class SVM and Isolation Forest are valuable. Trained primarily (or exclusively) on images known to be wood, these models learn a boundary around the "wood" manifold in the feature space. At inference time, any sample that falls outside this boundary is considered "not wood".

One-Class SVM constructs a decision function tailored to capture the dense region of positive samples in the high-dimensional space. Isolation Forest isolates anomalies by randomly selecting a feature and splitting values between them, effectively "isolating" outliers—i.e., images that do not resemble wood. These one-class methods excel when assembling a truly representative negative dataset is impractical. However, whenever domain knowledge or partial negative examples are available, combining them with positive samples for a more traditional binary classification (e.g., SVM, Random Forest, or GMM with a mixed training set) can boost performance and interpretability.

B. Wood-Pore (Vessel-Centric Region) Segmentation

In diffuse- and ring-porous hardwoods the most conspicuous anatomical element is the vessel (the pore lumen). Depending on species, the lumen may be surrounded by a narrow or wide sheath of perivascular parenchyma; in other cases the lumen is embedded directly in fibre tissue with little or no parenchyma contact. Because both situations occur within the same slide, a consistent segmentation target is essential. Throughout this study, instead of segmenting pore lumina alone—which is challenging due to the close adjacency of lumina and perivascular tissues in many species—we predict vessel-centric regions (VCRs), defined as a pore lumen together with any immediately adjacent perivascular parenchyma, if present.

If two lumina are in contact or share a common PP envelope the region is labelled as a double-VCR; otherwise it is considered a single-VCR. This strategy—which we abbreviate P+PP—allows one annotation protocol to cover solitary pores,

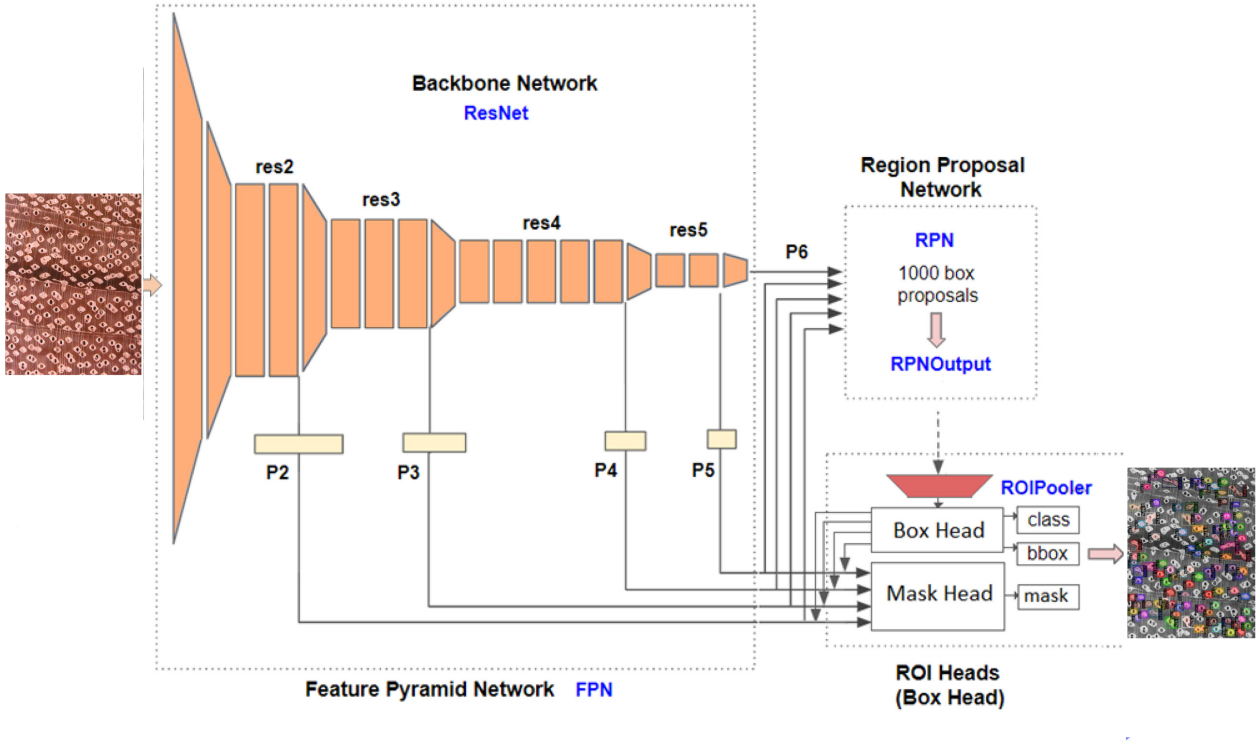

Fig. 1. Mask R-CNN architecture.

radial multiples, and pores embedded in aliform or confluent parenchyma without having to redraw masks when the surrounding tissue changes.

To segment these VCRs in 50× macroscopic images we employ Mask R-CNN [22], which couples a region-proposal network with a fully convolutional mask head and thus yields, in a single forward pass, bounding boxes, class labels (single vs. double) and pixel-accurate masks for every VCR detected.

Fig. 1 presents the architecture of the Mask R-CNN using in this study. The model employs a ResNet-50 backbone, which extract hierarchical features from an input RGB image at multiple scales. These features are processed by a Feature Pyramid Network, which generates multi-scale feature maps. This multi-scale representation captures anatomical details of varying sizes, such as small and large pores, by combining high-resolution features from early stages (e.g., P2 with H/4 × W/4) with semantically rich features from deeper stages (e.g., P6 with H/64 × W/64).

The Region Proposal Network leverages these FPN feature maps to generate candidate regions (box proposals) that may contain pores. Using an anchor-based approach, the RPN applies convolutional operations to propose regions of interest (RoIs). These proposals are then aligned with the feature maps using the RoI Pooler, which employs RoI Align—a precise pooling mechanism that preserves spatial accuracy by avoiding quantization errors.

The aligned features are fed into the RoI Heads, which consist of two components:

- Box head: Performs object classification (e.g., identifying a region as a pore) and bounding box regression to refine the coordinates of each detected object.
- Mask head: Generates binary instance masks for each pore, delineating their exact boundaries through convolutional layers.

This dual-head approach enables the model to detect, classify, and segment individual pores in a single pass. The final output is a segmented image where each pore is identified with a bounding box and a corresponding mask, facilitating detailed analysis.

Table I provides a detailed summary of the Mask R-CNN architecture employed in this study.

TABLE I. SUMMARY OF MASK R-CNN ARCHITECTURE

Component	Description
Backbone	ResNet-50 with stages res1 to res4, extracting hierarchical features at multiple scales
Feature Aggregation	Feature Pyramid Network (FPN) generating multi-scale feature maps P2 to P6
Region Proposal Network	Generates candidate regions (box proposals) from FPN feature maps using anchor-based method
RoI Align	Precise pooling with RoI Align, aligning region proposals to feature maps
Classification Head	Box Head with fully connected layers for object classification and bounding box regression
Mask Head	Convolutional layers generating binary instance masks for each detected pore

C. Wood Anatomical Feature Analysis

After segmenting VCRs from macroscopic wood cross-section images, we compute a series of anatomical descriptors to characterize and differentiate wood species. These descriptors—such as size, frequency, and spatial arrangement—are

well-established in wood anatomy and provide key diagnostic information. Because our VCR masks may include either the pore lumen alone or the lumen together with immediately adjacent perivascular parenchyma (when visually inseparable). All subsequent analysis is performed over these vessel-centric regions rather than the pore lumen alone.

1) VCR classification and counting: Each segmented VCR is categorized based on proximity and grouping patterns to reflect anatomical arrangements: solitary, multiple, or clustered. This classification follows adjacency checks, where two or more VCRs are considered grouped if they share a boundary or are positioned in close radial or tangential proximity.

a) Solitary VCR: A vessel-centric region that is spatially isolated.

b) Multiple/Clustered VCRs: Two or more VCRs appearing together, either in radial multiples or compact clusters.

Counting each category provides a basic anatomical fingerprint. For example, the predominance of solitary vessels versus radial multiples can suggest different taxonomic characteristics.

2) VCR Size measurement: As images are acquired at a fixed magnification (50×), we apply a known pixel-to-micrometer conversion factor to translate geometric measurements into physical units.

From each segmented VCR mask, we compute:

- Area: Total pixels within the VCR mask, converted into square micrometers.
- Equivalent Circular Diameter (ECD):

$$d = \sqrt{\frac{4A}{\pi}} \tag{1}$$

  where, A is the area of the VCR mask.

- Optional Shape Descriptors: Including elliptical fits (major or minor axis lengths) when more detailed morphology is needed.

These measurements provide a robust morphological overview of the segmented regions. By using VCRs—especially in diffuse-porous species where parenchyma halos often co-occur with vessels—we ensure more consistent and anatomically meaningful descriptors, even when vessel and parenchyma are difficult to distinguish in 50× imagery.

Fig. 2. Example images used in the classification task. The first row shows wood cross-section images at various magnifications. The second row contains non-wood images collected from general sources such as magnified surfaces of flowers, fruits.

IV. Experiments

A. Datasets

We employed two separate datasets for wood versus non-wood classification and segmentation tasks. For the wood/non-wood classification task, as illustrated in Fig. 2, we created two distinct subsets:

1) Wood dataset: This dataset aggregates macroscopic wood images collected from five distinct sources detailed in [3], including: i) VN_26, our self-collected dataset, ii) WRD_21, a Southeast Asian wood dataset published by Sun [23], iii) BFS_46, the Brazilian flora species dataset [24], iv) BD_11, a Brazilian dataset from 2021 [25], and v) PCA_11,

featuring wood species from the Pacific and Colombian Amazon regions [26]. In total, this dataset contains 20,000 images captured at magnifications ranging from 10x to 50x.

2) Non-Wood dataset: Approximately 9,000 images were gathered from online sources, depicting various subjects such as vehicles, landscapes, humans, and magnified images of non-wood objects.

The combined dataset was split into three subsets: 50% images for training, 20% for validation, and 30% for testing. Notably, we allocated a larger portion of the data to the test set to allow for more stable and representative performance evaluation, particularly given the diversity of both wood and non-wood images. This strategy was chosen to minimize variance in evaluation results and to better reflect real-world deployment conditions, where unseen data is common.

For the segmentation task, we utilized our self-collected subset (VN_26) exclusively at 50x magnification. Due to the extensive annotation required for segmentation, where the Labelme tool was employed to draw polygons around each pore, the labeling process was notably labor-intensive.

As presented, we clarify that every polygon corresponds to a VCR:

- Pore-only VCR: the lumen and its wall when no perivascular parenchyma collar is visible at the chosen magnification.
- Pore + PP (P+PP) VCR: the pore lumen together with the contiguous PP sheath if such a sheath clearly encircles the vessel(s).[1]

Hence, our masks deliberately "over-segment" to include PP whenever it is morphologically inseparable from the vessel on 50 × imagery, thereby preserving the original mask geometry without the need to re-annotate.

In total, 1,012 images were annotated, comprising approximately 34,500 single-VCR annotations and about 11,000 double-VCR annotations. Typically, each macroscopic wood image contained around 40 to 60 VCRs, highlighting the complexity and meticulous nature of the annotation work.

Given the substantial annotation effort involved, we adopted an iterative labeling strategy, progressively annotating smaller subsets of images while continuously evaluating the segmentation model's performance. Annotation was halted when model accuracy stabilized, ensuring efficient use of annotation resources without sacrificing model effectiveness. Additionally, the emphasis on single and double VCR facilitated focused improvements in segmentation accuracy, ultimately enhancing the robustness and practical usability of the resulting segmentation model.

B. Wood Macroscopic Image Classification

Because our objective is to detect if an image represents a magnified wood cross-section, we split data into training/validation/test sets at the feature level. In many real-world scenarios, it can be beneficial to have a small, curated set of "likely negatives" (e.g., images of plant bark or random textures) to help tune decision thresholds.

For each candidate model, hyperparameters (e.g., the number of PCA components, kernel parameters for SVM, and the number of estimators in Isolation Forest) are tuned based on performance metrics. In this study, we evaluate classification performance by standard metrics, accuracy, precision, recall, and F1-score, when negative examples are available. For one-class approaches, we track metrics such as the false-positive rate on non-wood samples to gauge how well the model excludes irrelevant data.

By combining DenseNet121, based feature extraction with robust classification techniques, be the binary or one-class, we ensure a flexible pipeline capable of handling the open-ended nature of "wood versus non-wood" classification. High-quality embeddings, coupled with dimensionality reduction and tailored classification algorithms, allow us to accurately filter and flag images for subsequent segmentation and anatomical feature analysis.

Fig. 3, Fig. 4, and Fig. 5 show the confusion matrices obtained from these models. In each matrix, the rows (actual labels) and columns (predicted labels) correspond to two classes: "0" (non-wood image) and "1" (wood cross-section image).

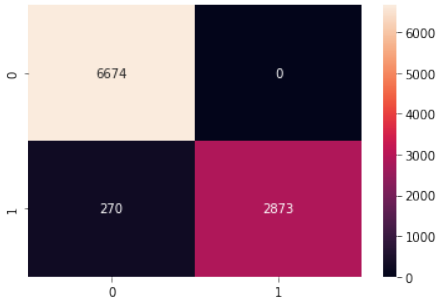

Fig. 3. Confusion matrix - OneSVM.

1) OneSVM: Although OneSVM achieves an impressive outcome of zero false positives (i.e., no non-wood images were misclassified as wood), it still has 270 false negatives. In other words, it fails to correctly identify 270 wood images as wood. This indicates a tendency toward under-classification of wood samples, which can be problematic in scenarios where missing a true wood specimen is undesirable.

2) Isolation forest: Isolation Forest exhibits a similar pattern to OneSVM, with zero false positives and a slightly higher number of false negatives (279). This small increase in false negatives yields a slight reduction in overall accuracy, but the difference between Model OneSVM and Isolation Forest performance is minimal in most practical contexts.

3) GMM: GMM stands out in that it achieves a significantly lower number of false negatives (only 2), thus correctly identifying nearly all true wood images. However, it does have a small number of false positives (1). From an overall performance standpoint, GMM demonstrates a much stronger capability to detect wood images without sacrificing non-wood accuracy by any large margin.

[1]In diffuse-porous and ring-porous taxa where parenchyma halos are diagnostic, this choice is anatomically meaningful because the pore + PP structure functions as a single macro-texture cue.

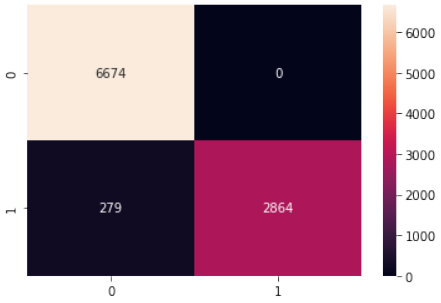

Fig. 4. Confusion matrix - IsolationForest.

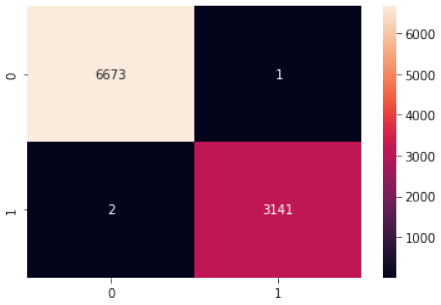

Fig. 5. Confusion matrix - GMM.

TABLE II. COMPARISON OF CLASSIFICATION METRICS FOR THE THREE MODELS ON THE TESTSET

Model	Accuracy	Precision	Recall	F_1-score
Isolation Forest	97%	98%	95.5%	96.5%
OneSVM	97%	98%	95.5%	97%
GMM	99%	99%	99%	99%

Table II compares the performance of three models. Isolation Forest and OneSVM have similar accuracy but struggle with higher false negatives, which drags down their recall. GMM, on the other hand, has almost no false negatives, boosting its recall and giving it a better F_1-score. In wood identification, missing a true wood sample (a false negative) is a bigger deal than accidentally labeling a non-wood image as wood (a false positive). So, keeping false negatives low is critical. With only 2 false negatives out of 3141 true positives, GMM stands out as the best option.

The results prove that combining transfer learning with solid classification can nail the task of separating wood from non-wood images. Isolation Forest and OneSVM play it safe (no false positives, but they miss more wood samples), while GMM strikes a great balance between recall and precision. In a two-step system, where classification feeds into pore segmentation, GMM makes sure most true wood images move forward. Looking ahead, tweaking feature extraction or anomaly detection could cut down errors even more and boost generalization.

C. Wood VCR Segmentation

Accurately segmenting individual wood pores from macroscopic images is inherently challenging due to the close adjacency of pore lumina and surrounding perivascular parenchyma. As discussed previously, we therefore adopted the concept of Vessel-Centric Regions, defined as a pore lumen together with any immediately adjacent PP tissue if present. Annotating each VCR required meticulously drawing polygons around each region using the Labelme tool, making this a particularly labor-intensive process. Each macroscopic wood image typically contained around 40 to 60 VCRs, leading to an estimated total of approximately 32,500 annotated VCRs across our 1,012-image dataset. These annotations comprised about 23,500 single-VCR and 9,000 double-VCR instances.

Given the substantial annotation effort involved, we adopted an iterative annotation strategy, incrementally annotating subsets of images and evaluating model performance continuously. Annotation was halted when the model's performance stabilized, thus efficiently balancing annotation cost and model accuracy.

Additionally, we augmented the dataset by cropping each annotated image into two smaller segments, effectively enhancing training-data diversity without additional annotation work. The numbers of annotated images and corresponding experimental results are summarized in Table III.

Two experimental scenarios were conducted to evaluate the performance of our segmentation model under different conditions, detailed as follows.

1) Scenario 1 Effect of training set size: In Scenario 1, we assessed accuracy improvements resulting from incremental increases in annotated training data. We employed the iterative annotation strategy outlined above, progressively adding labeled subsets until segmentation performance stabilized.

Six dataset sizes were evaluated, summarized in Table III, with each set split into training, validation, and testing subsets at a 70:15:15 ratio. Models were trained for 10,000 epochs, with a batch size of 512 and a learning rate of 10^{-4}.

Table III presents the accuracy achieved at various stages of this iterative process. Fig. 6 shows training progress, including accuracy and loss trends for classification and segmentation on both training and validation sets. Key observations include:

TABLE III. SCENARIO 1: SEGMENTATION ACCURACY WITH INCREASING TRAINING SET SIZES

No.	Train Images	Val Images	Test Images	Accuracy (%)
1	78	16	16	69.55
2	388	84	84	93.378
3	500	108	108	93.923
4	528	114	114	91.193
5	682	146	146	84.629
6	708	152	152	91.393

- Incremental Annotation versus Accuracy: Initially, the accuracy was low (69.55%) with only 78 annotated training images. Accuracy increased significantly to 93.378% and 93.923% as annotations reached 388 and 500 images, respectively, indicating the effectiveness of additional labeled data in early stages.

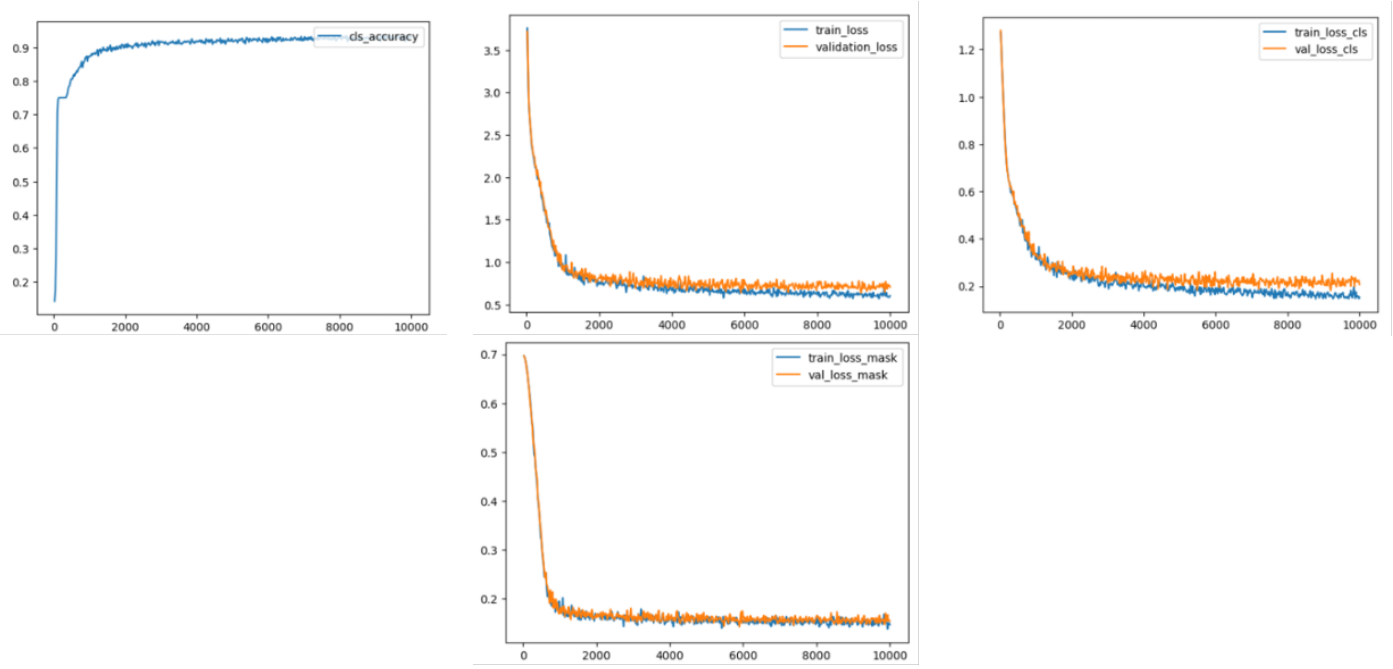

Fig. 6. Experiment 1 – Training loss and accuracy progresses with 500 training images.

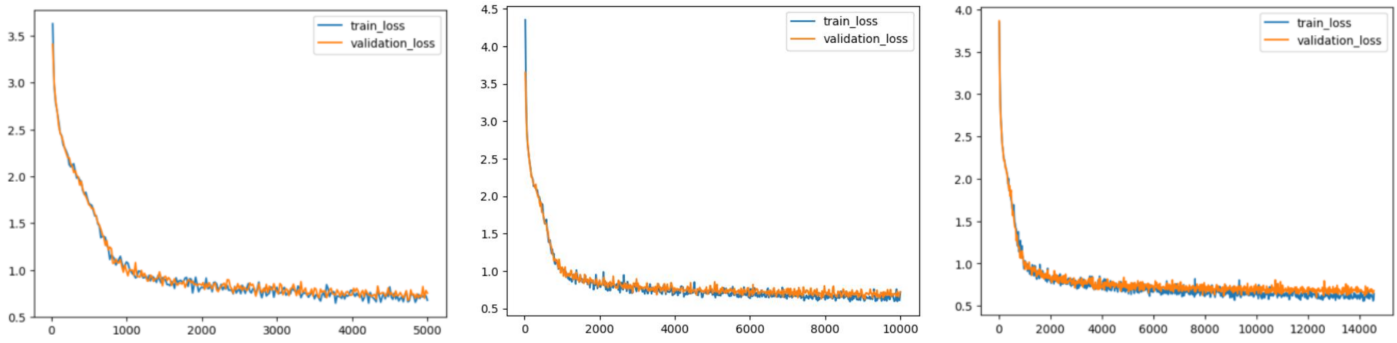
- Incremental Annotation and Accuracy: Initially, accuracy was relatively low (69.55%) with just 78 annotated images. However, significant improvements were observed when annotations increased to 388 (93.378%) and 500 images (93.923%), demonstrating clear early-stage benefits of additional labeled data.
- Performance Saturation and Overfitting: Accuracy peaked at 500 annotated images. Beyond this point, accuracy fluctuated, declining to 84.629% at 682 images before improving slightly again at 708 images (91.393%). This indicates potential saturation and overfitting when adding excessively diverse annotations beyond an optimal point.
- Data Augmentation Effectiveness: The augmentation strategy of cropping annotated images successfully enhanced data diversity, mitigating accuracy declines observed at larger dataset sizes.

These results emphasize the practical effectiveness of iterative annotation and augmentation strategies for maximizing segmentation accuracy while minimizing annotation overhead. Future work may investigate adaptive annotation and augmentation strategies to further enhance model performance.

2) Scenario 2 Effect of number of epochs: In the second scenario, we investigated the impact of training duration on segmentation accuracy by varying the number of epochs (5,000; 10,000; and 15,000). This experiment employed 500 training images, 108 validation images, and 108 test images. Other training parameters remained constant (image size: 480×640, batch size: 512, learning rate: 10^{-4}). Table IV summarizes the accuracy results.

The results highlight several key insights:



- Optimal performance at 10,000 epochs: Peak accuracy (93.923%) occurred at 10,000 epochs, slightly outperforming 5,000 epochs (93.677%). Further training to 15,000 epochs led to decreased accuracy (91.877%), indicating potential overfitting.
- Loss curve behavior: Analyzing loss curves (Fig. 7) revealed a consistent downward trend in loss, with diminishing accuracy returns beyond 10,000 epochs. Continued training beyond this point tended toward overfitting noise rather than learning meaningful anatomical patterns.
- Practical training recommendations: Balancing computational efficiency and accuracy, training around 10,000 epochs offers optimal segmentation performance without unnecessary resource expenditure.

TABLE IV. SCENARIO 2: TEST ACCURACY BY NUMBER OF TRAINING EPOCHS

Epochs	Accuracy (%)
5,000	93.677
10,000	93.923
15,000	91.877

Combining the findings of Scenarios 1 and 2, we observe the following:

- Optimal annotation size: A moderate dataset size (e.g., 500 images) yields optimal performance. Larger datasets may introduce complexity, potentially reducing accuracy without careful management.
- Balanced epoch selection: Training duration of approximately 10,000 epochs best balances accuracy gains against risks of overfitting.

(a) Loss progress at 5,000 epochs (b) Loss progress at 10,000 epochs (c) Loss progress at 14,000 epochs

Fig. 7. Training loss curves of segmentation models at different epoch milestones (5k, 10k, and 15k).

- Model robustness and generalization: Despite varying training conditions, accuracy consistently ranged between 84% and 94%, demonstrating robustness. Future improvements may involve advanced augmentation, regularization techniques, or specialized segmentation architectures.

These results confirm that strategic adjustments of annotation quantity and training epochs significantly affect segmentation performance, offering practical guidance for efficient annotation and training protocols.

V. Demonstration of End-to-End Wood Anatomical Analysis

To illustrate the practical value and usability of our models, we have implemented an end-to-end system for wood anatomical analysis. This system combines a lightweight Android mobile application with a remote server for advanced segmentation tasks, thereby demonstrating how classification and segmentation can be integrated into a real-world workflow.

A. System Overview

1) Mobile application - Frontend: The user-facing component is an Android application that performs on-device image classification to determine whether an input image depicts a magnified wood cross-section. Users can capture new images via the device camera or select existing images from the phone's gallery. For smartphones lacking sufficient native magnification, an external macro lens attachment can be used to acquire clear macroscopic wood images.

Upon pressing the "Analyze" button, the app uses a lightweight classifier trained as described in Section IV-B to check locally if the input represents a magnified wood cross-section. If the classification result is positive, the app forwards the image to the remote server for detailed segmentation and vessel-centric anatomical analysis.

2) Server segmentation - Backend: On the server side, our Mask R-CNN model (described in Section IV-C) receives the uploaded image and segments VCRs —each defined as a pore lumen plus its adjacent perivascular parenchyma, when PP is present. Specifically, the model segments and categorizes each identified region into:

- Single VCRs (solitary pore lumen $\pm$ PP),
- Double VCRs (two adjacent pore lumina sharing a common PP sheath or directly contacting each other).

From these segmented regions, the server computes a set of meaningful anatomical descriptors, including:

- Total number of single and double VCRs,
- Average VCR size in micrometers (derived from known magnification levels),
- Minimum and maximum sizes of VCRs,
- Inter-VCR distance metrics (minimum, maximum, and average distances),
- Summary statistics, such as spatial distribution and frequency patterns of VCRs.

B. Illustrative Results

To validate the end-to-end pipeline under realistic conditions, we tested the application using various wood species commonly encountered in Vietnam. Images were captured at magnifications of 10$\times$ and 50$\times$ under variable lighting conditions. The system consistently demonstrated:

- Reliable on-device classification, efficiently filtering out non-wood images,
- Robust server-based segmentation, clearly delineating VCRs even in complex anatomical arrangements,
- Rapid retrieval of detailed anatomical metrics, allowing users immediate insight into wood anatomy and supporting species identification.

Fig. 8 provides sample screenshots showing segmented VCR results and anatomical summaries for species such as Gõ Pachy, Cãm Hòng, and Ebiara at different magnifications. Users can view segmentation overlays directly in the app interface and access detailed textual descriptions of segmented regions.

The demonstrated architecture highlights a practical division of tasks:

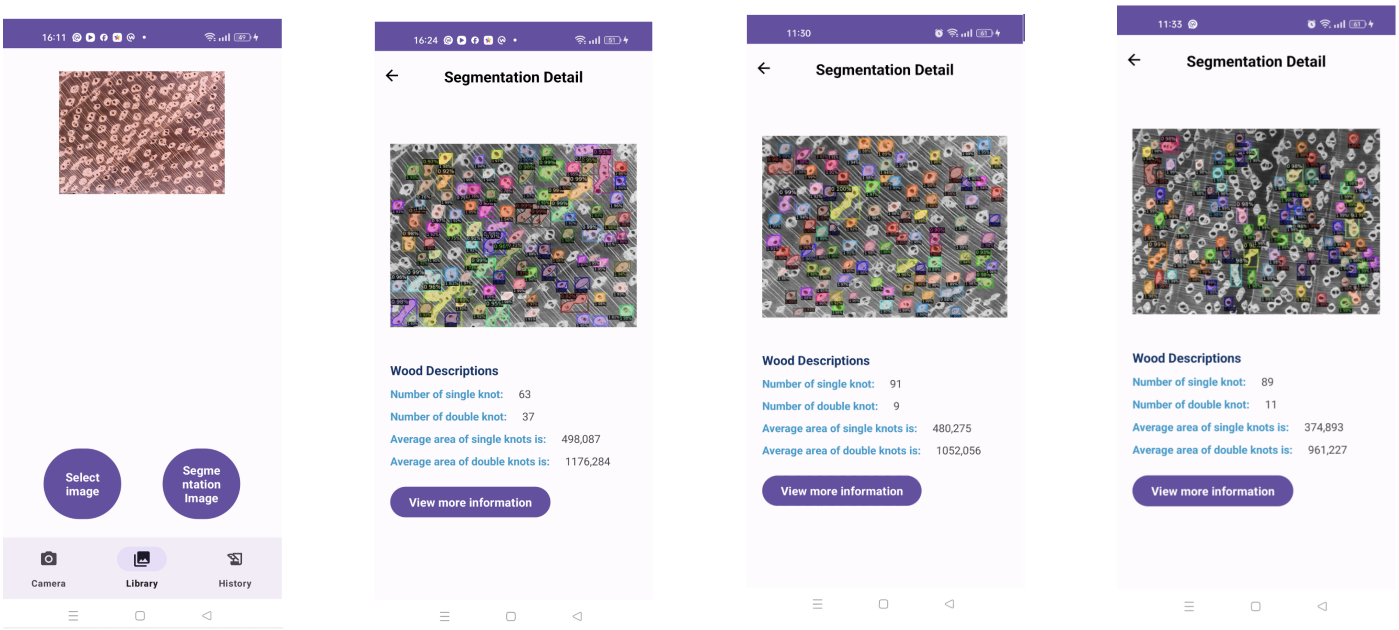


Fig. 8. Android app for end-to-end wood anatomical analysis.

- A compact classifier deployed on Android devices quickly verifies the suitability of images for further analysis,
- A computationally intensive segmentation model hosted on a remote server performs detailed VCR segmentation and returns comprehensive anatomical insights.

Overall, our end-to-end system provides a convenient, low-cost solution enabling wood analysts, researchers, and industry professionals to rapidly quantify critical anatomical features from macroscopic images. Future enhancements may include offline segmentation capabilities for fieldwork environments with limited connectivity or more advanced user interfaces for annotating and verifying newly encountered wood species. Additionally, this pipeline can be extended towards fully automated wood species identification by leveraging large language models to reason over extracted anatomical descriptors and incorporate established taxonomic knowledge.

VI. Conclusion

This study presented a two-stage automated framework for anatomical analysis of macroscopic wood cross-sectional images. Our approach combined image classification using DenseNet121-based features and a Gaussian Mixture Model classifier with segmentation of Vessel-Centric Regions (VCRs) via Mask R-CNN. Defining each VCR as a pore lumen plus any adjacent perivascular parenchyma (PP) allowed effective segmentation despite closely adjacent anatomical structures.

Experimental results confirmed that iterative annotation and data augmentation efficiently balanced annotation effort and segmentation accuracy, achieving optimal results (93.923%) with approximately 500 annotated images trained over 10,000 epochs. An end-to-end demonstration highlighted the practical usability of our system, combining mobile-based classification and remote segmentation. Future directions include offline segmentation for field use and automated species identification leveraging large language models.

***Abstract*—With the advancement of industrialization, air pollution has emerged as a critical global health and environmental concern. This study presents an air quality prediction model based on variational mode decomposition, a convolutional neural network, bidirectional long short-term memory, and an attention mechanism. The variational mode decomposition method is employed to decompose the Air Quality Index sequence, capturing different local characteristics of the original data. A hybrid model is constructed by integrating the convolutional neural network for feature extraction, the bidirectional long short-term memory for temporal pattern recognition, and the attention mechanism for focusing on significant data features. The model is optimized using the Grey Wolf Optimizer for hyperparameter tuning, thereby enhancing prediction accuracy. The proposed model is evaluated using air quality data from Changsha, China, covering the years 2015 to 2023. The results demonstrate that our model outperforms several other models in terms of mean absolute error, mean squared error, root mean squared error, and R-squared. This study provides a robust approach to air quality prediction, offering valuable insights for residents and policymakers.**

***Keywords*—Air quality prediction; variational mode decomposition; convolutional neural network; bidirectional long short-term memory; hyperparameter optimization; air quality index**

I. Introduction

With the development of global industrialization, material living standards have continued to improve; however, air pollution has become increasingly severe [1], [2]. Since the mid-19th century, when London experienced severe smog pollution, people have gradually become aware of the dangers posed by air pollution. In the 20th century, smog events in cities such as Los Angeles and London further heightened public concern and prompted more extensive investigation into air pollution issues.

Current research on air pollution primarily focuses on outdoor atmospheric pollution, which includes major components such as ozone, suspended particulate matter, and nitrogen oxides. These pollutants originate from various complex sources, including industrial emissions, vehicle exhaust, and coal-fired power generation.

The Air Quality Index (AQI) is a crucial metric used to assess air quality. It consolidates the concentrations of several routinely monitored pollutants—including PM2.5, PM10, nitrogen dioxide (NO2), sulfur dioxide (SO2), carbon monoxide (CO), and ozone (O3), into a single, conceptual index value. This index categorizes air pollution levels and air quality conditions, allowing the extent of pollution to be reflected in a scientific and intuitive manner.

According to data from the World Health Organization (WHO), air pollution accounted for 7.6% of total global deaths in 2015 [3], [4], [5]. Modern epidemiological studies have shown that air pollution can severely damage the human immune system and may cause irreversible long-term harm to future generations. In addition, air pollution results in significant social and economic losses. Experts estimate that, based on the value of life, 3.25% of deaths in China in 2017 were attributable to air pollution, resulting in an economic loss equivalent to approximately 1.53% of the country's GDP that year [6], [7].

Most countries now have air quality monitoring systems in place; however, these systems often experience delays in providing air quality data and cannot offer reliable early warnings for governments or the public. Additionally, due to the non-constant and non-linear nature of air pollution concentrations, predicting air quality remains a significant challenge.

In recent years, many researchers have proposed various air quality prediction models. Existing methods can generally be divided into two categories: classic dispersion models [8], [9] and data-driven models [10], [11], [12]. Classic dispersion models are based on physical principles, taking into account factors such as wind speed, wind direction, atmospheric stability, and emission source characteristics to simulate and estimate the dispersion and concentration distribution of pollutants in the atmosphere.

In contrast, data-driven models represent a modern approach to air quality prediction. These models rely primarily on large volumes of historical data and statistical learning techniques to forecast future air quality. Unlike traditional physics-based models, data-driven models emphasize learning and extracting patterns from past data. Common types include statistical methods, machine learning algorithms, and deep learning models.

Applying statistics to air quality prediction research mainly includes autoregressive (AR) models, autoregressive integrated moving average (ARIMA) models, grey models, and multiple kinear regression(MLR) models. In 2006, Pagowski et al. used a dynamic linear regression model to predict ozone concentrations within 24 hours, achieving reduced bias under conditions with fewer monitor measurements [13]. Pai et al. used the Grey prediction model GM(1,1) to predict ozone

*Corresponding authors.

concentrations, and the results showed that GM(1,1) had a mean absolute percentage error (MAPE) of 19% based on a small sample size, indicating average prediction accuracy. The advantage of linear regression models is their fast modeling speed and good interpretability, but they handle non-linear issues in air quality datasets poorly and cannot fit non-linear data well [14]. Donnelly et al. combined a non-parametric kernel regression description of NO2 concentrations varying with wind speed and direction to obtain seasonal and daily variation factors, achieving good prediction results on the basis of the multiple linear regression model. Niu et al. established an autoregressive moving average (ARMA) model for air quality prediction in Chengdu [15], and in the same year, Zhang et al. used wavelet decomposition methods to improve the ARMA prediction model, decomposing and reconstructing air pollutant concentrations. The results proved that wavelet multi-scale decomposition could significantly improve the prediction accuracy of the ARMA model [16].

Machine learning models may learn patterns from historical data and use these patterns to predict future air quality. It also optimize prediction performance by adjusting model parameters and structures. Liang et al. used an 11 years dataset collected by Taiwan's Environmental Protection Administration (EPA) and then employed machine learning methods including adaptive boosting (AdaBoost), artificial neural networks(ANN), random forest (RF), stacking ensemble, and support vector machines(SVM) for individual predictions. The experimental results indicated that the stacking ensemble performed the best in terms of prediction accuracy [17]. Castelli et al. used support vector regression(SVR) to predict pollutant and particulate matter levels for the prediction of the AQI, and in their experimental scheme, SVR with a radial basis function (RBF) achieved the best prediction results [18]. Liu et al. constructed regression models using SVR and random forest regression (RFR) to predict the AQI in Beijing and the nitrogen oxides(NOx) concentration in an Italian city. The experimental results showed that the SVR-based model performed better in AQI prediction, while the RFR-based model performed better in NOx concentration prediction [19].

Deep learning models, in contrast to machine learning models that typically require less data for training, rely on large amounts of data and complex model structures for training. However, deep learning models can better capture the complex nonlinear relationships in the learning data and can integrate multiple data sources to improve the accuracy and comprehensiveness of predictions [20], [21]. Baniasadi et al. proposed a novel binary chimp optimization algorithm(BChOA) and combined it with long short-term memory(LSTM) networks.The BChOA algorithm fine-tunes the optimization parameters of the LSTM model to achieve more accurate and reliable air pollution forecasting. Experimental results demonstrated that the BChOA-LSTM model achieved the highest accuracy of 96.41% [22]. Bun Theang Ong et al. proposed deep recurrent neural networks(DRNN), which use an autoencoder enhancement pre-training method specifically designed for time series prediction to achieve PM2.5 concentration prediction. The experimental results showed that the DRNN model could handle air quality prediction problems well [23]. Wang et al. noticed that existing prediction models did not accurately capture the regularities between haze concentration and real-world influencing factors and proposed a two-layer model prediction algorithm based on long short-term memory neural networks and threshold regression units (LSTM and GRU). It is an improvement and enhancement of the existing forecast method of LSTM [24]. Wu et al., a novel air quality forecasting model based on the improved sparrow search algorithm (ISSA) and LSTM networks has been proposed,integrating the mRMR-RF feature selection method to enhance the model's predictive accuracy. By combining mRMR and RF,the model effectively selects variables that impact the AQI. The ISSA algorithm is utilized for the hyperparameter optimization of the LSTM. Experimental results indicate that this approach significantly improves the accuracy and efficiency of the forecasts [25].

A. Our Contribution

In this study, the VMD method is used to decompose the input AQI sequence. The resulting IMF components represent different local characteristics of the original data. Predicting each decomposed IMF component in parallel reduces the time required to identify signal features, thereby improving both the training efficiency of the algorithm and the accuracy of the predictions.

For the construction of the prediction model, we develop a hybrid model for air quality forecasting. Recognizing that LSTM networks do not fully resolve the vanishing gradient problem, we introduce CNN into the model to more effectively extract features from the air quality data. However, we also acknowledge that this integration increases the model's dependence on large volumes of training data and raises the risk of convergence to local optima. To address these challenges, we explore improvements to the internal structure of the neural network and consider incorporating additional, more effective neural architectures for feature extraction.

This study combines the CNN's capability to extract multi-scale temporal features with the strengths of BiLSTM, which processes sequences through both forward and backward layers of improved LSTM units. After feature extraction by the CNN, the BiLSTM computes the temporal dependencies, and the Attention mechanism is employed to calculate the attention weights of data features at different time steps with respect to the predicted value. This reveals the correlation between the time series data and the prediction target. By integrating these specialized neural networks, we construct an enhanced CNN-BiLSTM-Attention model capable of forecasting air quality for future periods with high accuracy.

Furthermore, to avoid arbitrary hyperparameter selection in the CNN-BiLSTM-Attention model, we apply the Grey Wolf Optimizer (GWO) to systematically search for optimal hyperparameters. This contribution demonstrates how modern machine learning techniques can be effectively combined and how model performance can be significantly improved by optimizing the training process through algorithmic tuning.

Experimental results confirm that, compared to other models with similar structures used for air quality prediction, the proposed model achieves higher accuracy.

II. Model Introduction

A. Variational Mode Decomposition (VMD)

Variational Mode Decomposition (VMD) is an adaptive signal processing method proposed by Konstantin Dragomiretskiy

and Zoubin Ghahramani in 2014. This method has the advantage of being able to determine the number of modal decompositions. Its adaptability is reflected in the ability to determine the number of modal decompositions for a given sequence based on actual conditions. In the subsequent search and solution process, it can adaptively match the best central frequency and finite bandwidth for each mode, and can effectively separate the Intrinsic mode functions (IMF) and divide the signal into frequency domains, thereby obtaining the effective decomposition components of the given signal and ultimately obtaining the optimal solution to the variational problem. It can avoid aliasing by controlling the bandwidth and can effectively address the mode mixing defect present in the Empirical Mode Decomposition (EMD) method [26], [27]. The basic principle includes the following steps:

The original signal is assumed to be decomposed into K components, ensuring that the decomposed sequences are modal components with finite bandwidth centered at specific frequencies. The variational problem can be described as finding K modal functions $u_k(t)(k = 1, 2, ..., K)$, such that the sum of the estimated bandwidths of each mode is minimized, subject to the constraint that the sum of all modes equals the original signal. The modal functions are defined by the following Eq. (1):

$$u_k(t) = A_k(t)cos(\phi_k(t)) \tag{1}$$

Use the Hilbert transform to calculate the analytic signal corresponding to each modal function $u_k(t)$, and obtain the one-sided spectrum, as shown in Eq. (2):

$$(\delta(t) + \frac{j}{k}) * u_k(t) \tag{2}$$

where, $\delta(t)$ is the Dirac function, based on the estimated central frequency e^{-jw_kt} of the mixed analytic signals of each mode, modulate the frequency of each mode to the corresponding base frequency band, see Eq. (3):

$$[(\delta(t) + \frac{j}{k}) * u_k(t)]e^{-jw_kt} \tag{3}$$

Calculates the square norm L^2 of the gradient of the aforementioned signals, estimate the sum of the bandwidths of the modal signals, and the constrained variational problem is represented as Eq. (4):

$$\begin{cases} \min\limits_{u_k,\omega_k} \{\sum_k \|\partial_t[(\delta(t) + \frac{j}{k}) * u_k(t)]e^{-jw_kt}\|_2^2\} \\ \text{s.t.} \sum_{k=1}^K u_k = f \end{cases} \tag{4}$$

In Eq. (4), $u_k = u_1, u_2, ..., u_k$ represents the modal functions with finite bandwidth, $\omega_k = \omega_1, \omega_2, ..., \omega_k$ denotes the central frequencies of each mode, * is the convolution operator, ∂_t signifies taking partial derivatives, and e^{-jw_kt} indicates shifting the spectrum to the base frequency band.

Solving the variational problem by introducing the Lagrange penalty operator and the penalty coefficient, transforming the constrained variational problem described in Eq. (4) into an unconstrained variational problem, resulting in the augmented Lagrange expression, as shown in Eq. (5).

$$\begin{aligned} L(u_k, \omega_k, \lambda) = \alpha \sum_k \|\partial_t[(\delta(t) + \frac{j}{k}) * u_k(t)]e^{j w_k t}\|_2^2 + \\ \|f(t) - \sum_k u_k(t)\|_2^2 + (\lambda(t), f(t) - \sum_k u_k(t)) \end{aligned} \tag{5}$$

To solve the unconstrained problem, it is necessary to find the saddle point of Eq. (5). The alternating direction method of multipliers (ADMM) is used to iteratively update $\hat{u}_k^{n+1}$, ω_k^{n+1}, and $\hat{\lambda}_k^{n+1}$. The iterative update process is shown in Eq. (6).

$$\begin{cases} \hat{u}_k^{n+1}(\omega) = \frac{\hat{f}(\omega) - \sum_{i \neq k} \hat{u}_i(\omega) + \hat{\lambda}(\omega)/2}{1 + 2\alpha(\omega - \omega_k)^2} \\ \omega_k^{n+1} = \frac{\int_0^\infty \omega |\hat{u}(\omega)^2 d\omega|}{\int_0^\infty |\hat{u}(\omega)^2 d\omega|} \\ \hat{\lambda}_k^{n+1}(\omega) = \hat{\lambda}^n(\omega) + \tau(\hat{f}(\omega) - \sum_k^{n+1} \hat{u}_k(\omega)) \end{cases} \tag{6}$$

In this context, $\hat{f}(\omega)$ and $\hat{u}_i(\omega)$ represent the Fourier transforms of the original signal and the modal components, respectively, n is the number of iterations, and τ is the fidelity coefficient.

The frequency center and bandwidth of each IMF component are continuously updated during the separation from the original signal, until the iterative stopping conditions, as shown in Eq. (7) are met.

$$\sum_{i=1}^K (\frac{\|\hat{u}_i^{n+1}(\omega) - \hat{u}_i^n(\omega)\|_2^2}{\|\hat{u}_i^n(\omega)\|_2^2}) < \epsilon \tag{7}$$

ϵ is the discrimination precision; if the convergence condition is met, then the iteration is stopped and K IMFs are obtained.

From the above reasoning, we may deduce that the VMD algorithm transforms the modal decomposition problem into a search for the optimal solution of a variational equation. It then obtains the corresponding modal components through continuous iterative updates. Compared to the EMD algorithm, the VMD algorithm can effectively suppress the endpoint effect and modal component aliasing. Additionally, the VMD algorithm reduces the non-stationarity of time series with high complexity and strong non-linearity, resulting in decomposed subsequences that contain multiple different frequency scales and are relatively stationary. Therefore, it is more suitable for non-stationary time series such as air quality.

B. Convolutional Neural Networks (CNN)

Convolutional neural networks(CNNs) are a special type of deep feedforward neural network that have been widely used in image processing, machine vision, and other fields. The most basic structure of a CNN is shown in Fig. 1, which includes convolutional layers, pooling layers, fully connected layers, and an output layer. The CNN analyzes the features of

the input image or one-dimensional data through convolution operations. The pooling layers are used to merge and extract features obtained from each convolutional layer, and finally, the fully connected layers perform dimensionality reduction and output results. This network has characteristics such as local connections and weight sharing in its structure [28], [29].

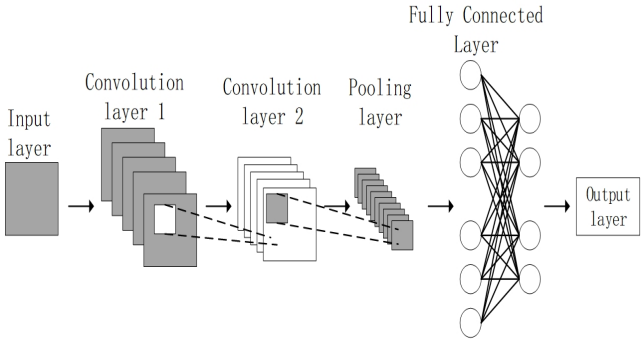

Fig. 1. CNN Network.

The fundamental principle of CNN is to utilize convolutional operations to extract features from the input, where the convolutional kernels are automatically learned by the network, thus endowing CNNs with excellent feature extraction capabilities. Each neuron in the convolutional layer only computes a small region of the input and shares weights, which can significantly reduce the number of parameters that need to be learned. The mathematical definition of the convolution operation is: the input matrix X and the convolutional kernel W, the convolution operation is represented as:$Y = X * W$. In the convolution operation, the convolutional kernel slides over the input matrix and performs convolution operations at each position to generate the output matrix Y. This process is a sliding window operation of the convolutional kernel over the input matrix, where the values in each sliding window are multiplied by the values in the convolutional kernel and summed to obtain the corresponding value in the output matrix. Pooling layers, on the other hand, perform dimensionality reduction on the feature maps output by the convolutional layers, typically using max pooling or average pooling. Max pooling selects the largest value in each pooling window as the output, while average pooling calculates the average value of the values in the pooling window as the output. Pooling operations may reduce the size of the feature maps and also enhance the robustness and generalization ability of the model [30], [31].

This study aims to improve the prediction accuracy of long-term meteorological data by utilizing a one-dimensional CNN neural network to extract meteorological influencing factor data $x = (x_1, x_2, ..., x_n)$. It employs convolutional layers and pooling layers to obtain effective representations, then flattens the acquired data and introduces it into a fully connected layer. The model analyzes the extracted feature data and realizes the output of feature results $c = (c_1, c_2, ..., c_n)$.

C. Bidirectional Long Short-Term Memory Networks-BiLSTM

Recurrent Neural Networks(RNNs) often encounter the vanishing or exploding gradient problem when dealing with relationships between nodes that are far apart, while LSTMs can better retain information provided by nodes that are distant from each other, enhancing performance on longer sequences of temporal data. Each LSTM unit is composed of three gating mechanisms: the forget gate, the input gate, and the output gate. The functional relationships between these gating units are as shown in Eq. 8 [32], [33]:

$$\begin{aligned} f_t &= \delta(W_f.[h_{t-1}, x_t] + b_f) \\ i_t &= \delta(W_i.[h_{t-1}, x_t] + b_i) \\ \tilde{C}_t &= \tanh(W_c.[h_{t-1}, x_t] + b_c) \\ C_t &= f_t * C_{t-1} + i_t * \tilde{C}_t \\ o_t &= \delta(W_o.[h_{t-1}, x_t] + b_o) \\ h_t &= o_t * \tanh(C_t) \end{aligned} \tag{8}$$

Specifically, x_t represents the input time-series data; f_t, i_t, o_t represent the outputs of the forget gate, input gate, and output gate, respectively; W_f, W_i, W_o are the weight matrices for the three gates, and b_f, b_i, b_o are the corresponding bias units; δ is the sigmoid function; $tanh$ is the hyperbolic tangent function; * denotes the inner product operation; $\tilde{C}_t$ represents the candidate vector created by passing through the tanh layer; W_c, b_c, are the weight matrix and bias unit, respectively, of the candidate layer; C_t represents the cell state; and h_t represents the hidden state.

During the data training process, LSTM can only use information from the forward sequence as the network's prediction result and cannot perceive backward data during model training. The advent of the bidirectional LSTM(BiLSTM) completely solves the problem of the model being unable to utilize future data. The term "bidirectional" refers to the existence of two LSTM networks within BiLSTM : one LSTM processes the forward sequence values, and the other processes the backward sequence values. These two networks operate independently, and the final output is achieved by vector concatenation to produce the final predicted features. Extensive research has shown that BiLSTM performs significantly better than LSTM in time series forecasting. Fig. 2 illustrates the structure of the BiLSTM network.

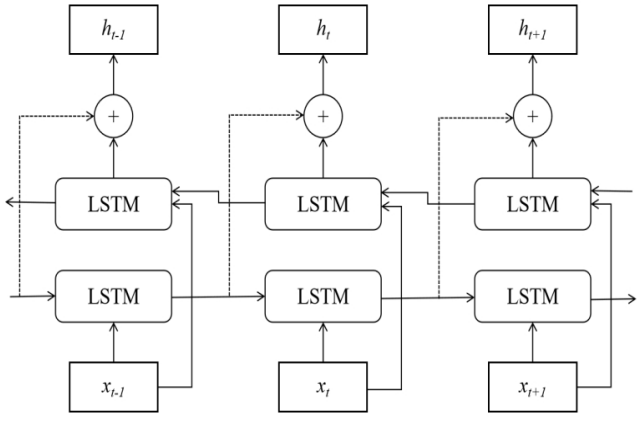

Fig. 2. BiLSTM network structure.

D. Attention

The attention mechanism is commonly used in tasks such as image classification and semantic understanding, where

it has achieved good results. Attention was first proposed in the context of image classification, primarily to enhance image understanding by omitting secondary information and emphasizing important information. Many computer vision algorithms still use Attention and its improvements to enhance their performance. However, since Bahdanau et al. applied Attention to neural translation and achieved good results, an increasing number of researchers have started to use it in natural language processing. For instance, Google's neural translation machine uses self-attention mechanisms exclusively to complete the entire model. Simply put, the attention mechanism is related to attention. Taking humans as an example, when receiving different messages simultaneously, different levels of response are given to different messages, and this difference is a manifestation of attention. Translating this to machine learning, different data require different processing methods, which means we pay different levels of attention to different aspects of the data based on its characteristics [34], [35].

In the process of meteorological data prediction training and learning, especially with multiple input variables, although effective correlation information is retained, it can lead to a complex network topology, resulting in slower learning speeds and difficulties in algorithm convergence. Therefore, this study incorporates an attention mechanism into the model, which adaptively and dynamically weights the factors affecting temperature, precipitation, and wind speed predictions. By reducing the weights of factors with weaker correlations to actual observed values, it allocates higher weights to the main influencing factors, achieving high-precision meteorological information forecasting. As shown in Fig. 3, the structure of the BiLSTM network after incorporating the attention mechanism is depicted.

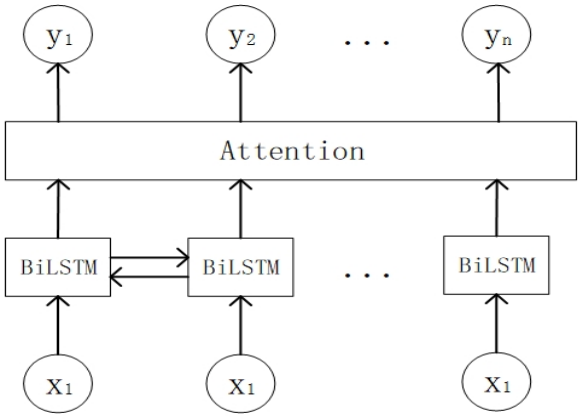

Fig. 3. BiLSTM-Attention network structure.

In the implementation process of introducing an attention mechanism into the BiLSTM model, a series of historical data $x = (x_1, x_2, ..., x_n)$ that affect meteorological predictions (temperature) are treated as the stored content of Key and Value during the addressing operation. Here, Key represents the data address, and Value represents the attention value. The attention calculation formula is as shown in Eq. (9):

$$A_i = \sum_{i=1}^{n} a_i v_i \tag{9}$$

The formula for calculating is given in Eq. (10):

$$a_i = softmax(Sim_i)\frac{eSim_i}{\sum_{k=1}^{n} e^{Sim_k}} \tag{10}$$

Specifically, v_i represents the value of i the data in the attention mechanism, and a_i represents the weight coefficient of v_i. We obtain the final attention by weighted averaging. Furthermore, Sim_i represents the cosine similarity of the i data, and the calculation formula is as shown in Eq. (11):

$$Sim(X, Key_i) = \frac{X.Key_i}{\|X\|.\|Key_i\|} \tag{11}$$

III. Materials and Methods

A. Case Measurement

To verify the effectiveness of the VMD-CNN-BiLSTM-Attention model proposed in this study for air quality forecasting, a total of 9 years of air quality data from January 2015 to December 2023 in Changsha, China, were selected as the training set to predict the air quality for a future period. The sequence model established based on air quality is shown in the Fig. 4.

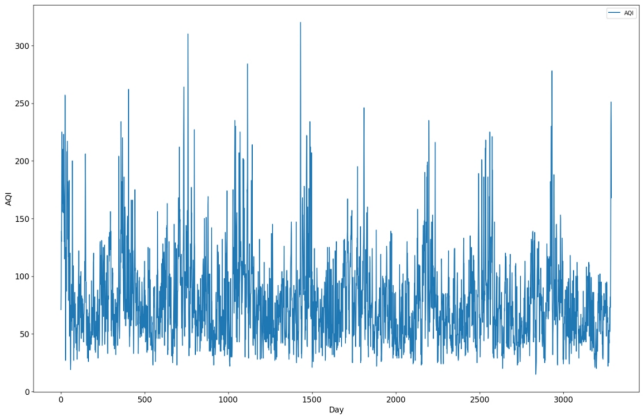

Fig. 4. The structure of the AQI data.

B. Data Processing

Due to the presence of seven different data indicators in the air quality forecasting model, namely AQI, PM2.5, PM10, SO2, NO2, O3, and CO, each indicator may have different characteristics, dimensions, orders of magnitude, and availability, making it impossible to directly analyze the characteristics and patterns of the research subjects. When there is a significant difference in the levels of various indicators, if we directly use the original values of the indicators for analysis, the role of indicators with higher values will be amplified in the comprehensive analysis, relatively weakening the role of indicators with lower values. Therefore, before using the data for prediction, we perform standardization processing on the data to ensure that different feature variables have the same scale. This allows the target variable to be controlled by multiple feature variables of the same size, and when using gradient descent to learn parameters, the impact of different

features on the parameters is consistent. This study uses min-max normalization for data standardization. The calculation formula is as shown in Eq. (12).

$$X' = \frac{X - X_{min}}{X_{max} - X_{min}} \tag{12}$$

In which, X_{max} represents the maximum value in the sequence data sample; X_{min} represents the minimum value in the sequence data sample. VMD processing:this study employs the VMD algorithm to denoise and decompose air quality data, thereby enhancing the accuracy of the data. The sampling frequency is set to 2000, and after fine-tuning, the optimal penalty coefficient α is determined to be 1200, with the number of decomposition layers K set to 10. From the Fig. 5, it is evident that the decomposition of the air quality sequence using VMD yields 9 components with strong regularity. IMF1 is the dominant component, with a smooth curve that characterizes the overall trend of air quality changes. The remaining components, though of different frequencies, also exhibit regularity and can reflect the local characteristics of air quality data to a certain extent.

C. Model Frame

A combined forecasting model based on CNN-BiLSTM-Attention is used, with the model structure shown in Fig. 6. The model mainly consists of an input layer, a one-dimensional CNN layer, a dropout layer, a BiLSTM layer, an attention layer, a flatten layer, and a fully connected layer.

During the backpropagation process of the CNN-BiLSTM-Attention combined model, an appropriate algorithm is needed for parameter learning to guide the parameters of the objective function in the correct direction for updating the appropriate size, so that the updated parameters continuously approach the global optimum of the objective function value. Gradient descent principle is commonly used, following the negative gradient of the objective function to locate the minimum value of the function. This study uses the Adaptive Moment Estimation algorithm(Adam algorithm), with the purpose of accelerating the optimization process. At the same time, the Adam algorithm adjusts the throughput of the search process automatically for each variable encountered gradient(partial derivative) at each step length.

For the prediction of air quality data, the proposed model is implemented through the following processes:

- For the preprocessed time series $x = (x_1, x_2, ..., x_n)$, where, $x_i \in R^{sxf}, i \in (0, n)$ and s represents the length of each data's time window, and f is the dimension of the data feature vector. First, a one-dimensional CNN is used for feature extraction, and data padding is employed to ensure that the input time series dimensions remain unchanged.
- Further, for the extracted data $x = (x_1, x_2, ..., x_n)$, where, $x_i \in R^{sxd}, i \in (0, n)$, d denotes the size of the convolutional kernel in the convolutional neural network, adding a Dropout layer allows the model to adaptively block some hidden layer neurons without affecting the output dimension size, thereby enhancing the model's generalization ability.
- Secondly, the BiLSTM, which includes two LSTM units, receives forward and backward information, specifically calculated using Eq. (8). BiLSTM processes the output from the Dropout layer, achieving the exploration of periodicity and nonlinear relationships between time series.
- Then, the output of BiLSTM is taken as the input for the attention mechanism, which adaptively assigns weight coefficients to each input variable feature, further enhancing the model's perception of key information, with related calculation formulas shown in Eq. (9) to Eq. (11).
- Finally, after processing by the attention mechanism, the feature information is connected to the fully connected layer for prediction processing through the Flatten layer, and the final prediction results are outputted.

D. Experimental Design and Simulation

All programs in this study are completed using Python, with the training of the neural network part carried out using the PyTorch software library. PyTorch is an open-source neural network framework developed by the Torch7 team at Facebook AI Research. Its underlying implementation is based on Torch, but it is entirely implemented and utilized in Python. This framework is primarily used for scientific research and application development in the field of artificial intelligence. Torch is a classic tensor library for operating on multi-dimensional matrix data and is widely used in machine learning and other mathematically intensive applications. This study utilizes the GPU version of PyTorch, leveraging the excellent performance of GPU data processing to reduce model learning time. The entire experiment was conducted in a Windows environment, with the specific experimental environment as shown in Table I.

TABLE I. EXPERIMENTAL ENVIRONMENT CONFIGURATION

Name	Versions
CPU	Intel(R) Core(TM) i7-10700 CPU @ 2.90GHz (8CPUs)
Memory	DDR4 32GBytes
Operating system	Windows 10 Pro
GPU	NVIDIA Ge Force RTX 3090
Python	Python 3. 9. 13
PyTorch-GPU	PyTorch 1. 13. 0

The sample data is divided in a 9:1 ratio, where the 90% of the data is used as the training set and the remaining 10% as the test set.

In the experimental design of this study, we used batch processing. The batch processing refers to the batch size, which is the number of training samples used in each iteration. A larger batch size can better utilize the parallel computing capabilities of GPUs/CPUs but requires more memory. A smaller batch size occupies less memory but may lead to unstable convergence. Therefore, the batch size needs to be chosen based on actual memory conditions and model complexity. In this research, the batch size is set to 256.

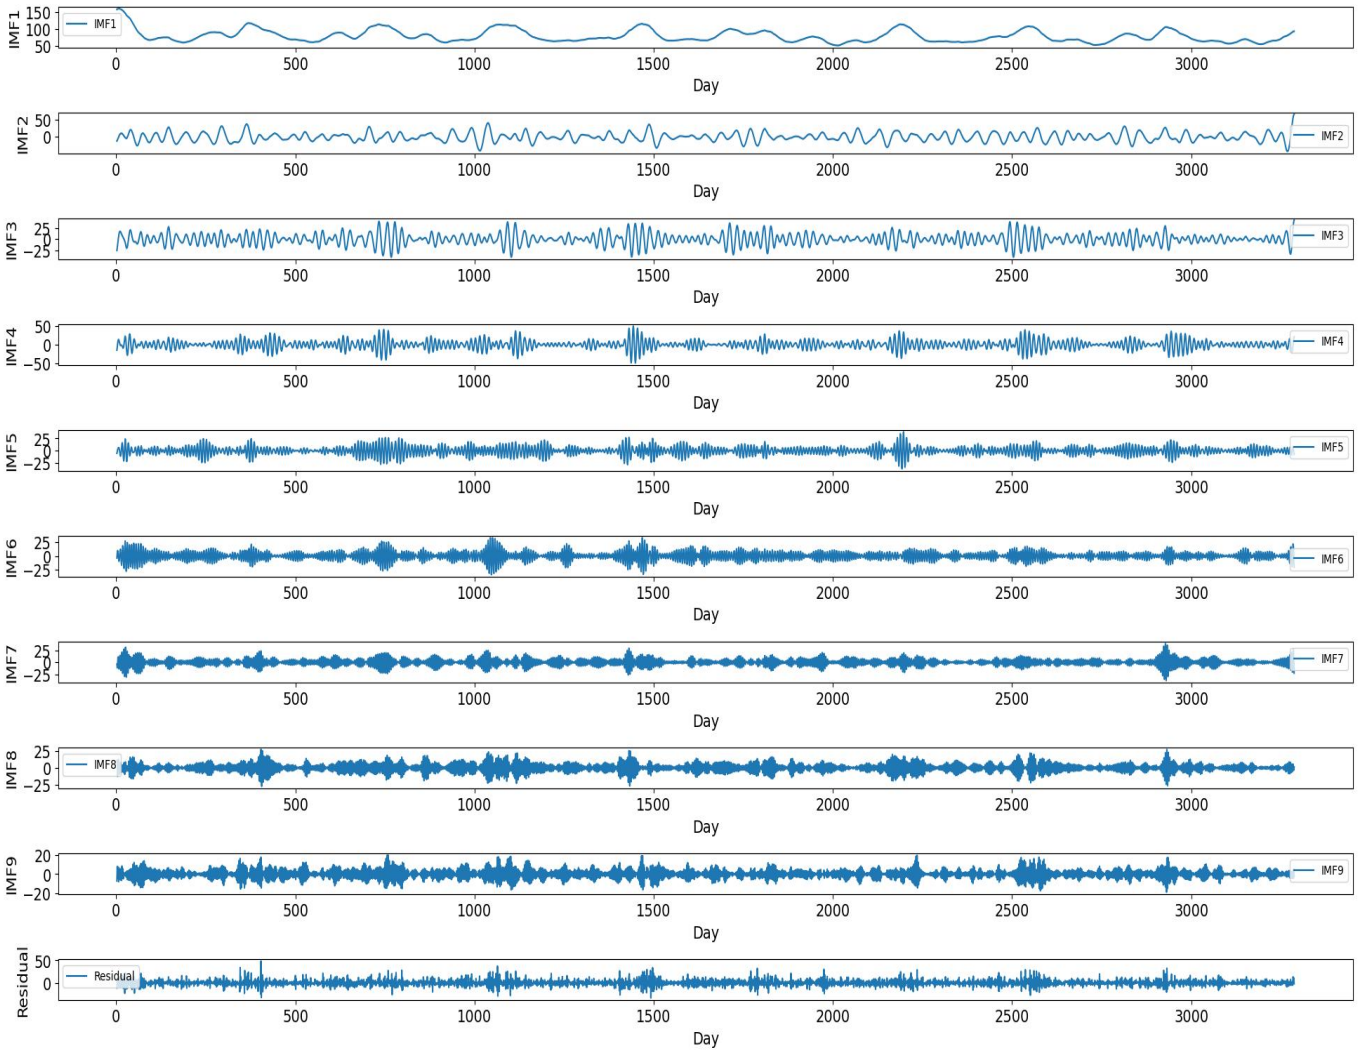

Fig. 5. The IMFs obtained after VMD.

The learning rate determines the update amplitude of weights in each training batch. A larger learning rate can speed up convergence but may miss the optimal solution. A smaller learning rate can increase accuracy but converges more slowly. In this research, the learning rate is set to 0.001.

The number of iterations is the number of times the entire training dataset is traversed. More epochs mean more thorough training but may also lead to overfitting. The number of iterations is set to 100 in this design.

Dropout is a regularization technique to prevent overfitting. It works by randomly "dropping" some neurons in the hidden layers during training, reducing the interdependence among neurons. This makes the network less sensitive to minor changes in input data and improves the model's generalization ability. A higher dropout rate can better prevent overfitting but may also lead to underfitting. In this research, the dropout rate is set to 0.1.

Time steps are mainly used for processing sequential data, such as natural language or time series data. It represents the number of steps when LSTM or RNN is unfolded. Longer time steps help capture long-term dependencies but also increase computational complexity and memory usage. Therefore, the time step should be chosen based on the nature of the task and hardware resources. In this experiment, the time step is set to 15, meaning that the model's training value at each moment is related to its previous 15 values.

The result measurement in these research, we use Mean Absolute Error (MAE), Mean Squared Error (MSE), Root Mean Square Error (RMSE), and R Squared (R2) as metrics for evaluating the performance of the models. Lastly, the effectiveness of the hybrid model in air quality prediction is verified by comparing the VMD-CNN-BiLSTM-Attention hybrid model with RNN, LSTM, BiLSTM, CNN-LSTM, CNN-BiLSTM and CNN-LSTM-Attention models.

E. Result and Discussion

Table II and Fig. 7 are the result of air quality prediction performance of each model. The models are RNN, LSTM, BiLSTM, CNN-LSTM, CNN-BiLSTM, CNN-LSTM-Attention and CNN-BiLSTM-Attention. The results shows that, for

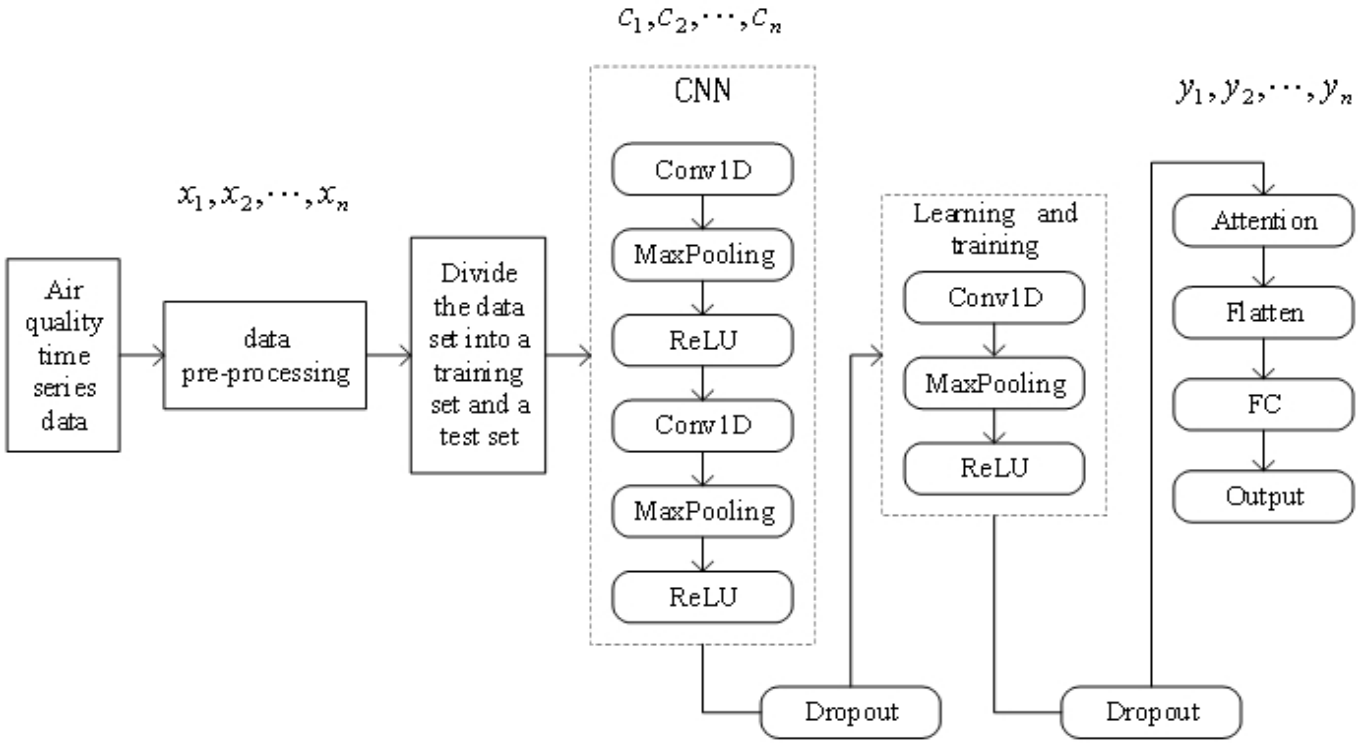

Fig. 6. Combined forecasting model based on CNN-BiLSTM-Attention.

individual models, BiLSTM and LSTM have better predictive performance compared to RNN, with BiLSTM outperforming LSTM. This indicates that RNN does not effectively utilize historical data of the air quality dataset, resulting in the poorest predictive performance. Incorporating bidirectional LSTM units can enhance the model's predictive performance, as BiLSTM offers higher efficiency and performance in data feature extraction compared to LSTM.

TABLE II. EVALUATION INDEX TABLE OF AIR QUALITY PREDICTION PERFORMANCE OF EACH MODEL

Model	MAE	MSE	RMSE	R2
RNN [36]	12.83	301.77	17.37	0.4226
LSTM [37]	12.81	276.47	16.63	0.2641
BiLSTM [38]	11.82	244.69	15.64	0.6288
CNN-LSTM [39]	8.28	133.71	11.56	0.7503
CNN-BiLSTM	7.34	100.71	10.04	0.8128
CNN-LSTM-Attention [40]	4.08	30.74	5.54	0.9588
CNN-BiLSTM-Attention	3.16	22.53	4.75	0.9685

However, when RNN, BiLSTM and LSTM models are combined with the neural network CNN, the predictive accuracy of the models significantly improved. CNN-LSTM, compared to LSTM, saw a 35% and 51% reduction in MAE and MSE, respectively, with R2 increasing to 75%. CNN-BiLSTM, compared to BiLSTM, experienced a 38% and 59% decrease in MAE and MSE, respectively, with R2 reaching 81%. This suggests that the addition of convolutional neural network CNN extracts effective features from the data, thereby enhancing the accuracy of predictions.

Upon integrating the Attention model, the predictive accuracy of the combined models further improved. CNN-LSTM-Attention, compared to CNN-LSTM, saw a 51% and 77% reduction in MAE and MSE, respectively, with R2 increasing by 28%. CNN-BiLSTM-Attention, compared to CNN-BiLSTM, experienced a 57% and 78% decrease in MAE and MSE, respectively, with R2 increasing by 19%. The attention mechanism can mimic the human brain's operational mechanism, focusing more on more important information when faced with varying external input data, thus avoiding the interference of irrelevant information. It can assign higher weights to key data features in air quality data, enabling the model to achieve higher predictive accuracy.

In summary, the ranking of predictive performance of different models is as follows:CNN-BiLSTM-Attention > CNN-LSTM-Attention > CNN-BiLSTM > CNN-LSTM > BiLSTM > LSTM > RNN. The predictive model CNN-BILSTM-Attention used in this study can effectively enhance the accuracy of predictions and obtain more precise outcomes. Compared to the initial RNN, CNN-BILSTM-Attention has reduced the MAPE.

IV. CONCLUSION

In recent years, as living standards have improved due to technological progress, the exploitation and use of fossil fuels by humans have also increased rapidly. This surge in fossil fuel consumption has led to serious air quality issues, posing a significant threat to both the environment and human health. In response to these challenges, this study focuses on predictive research related to air quality, aiming to achieve accurate forecasts through the development of an effective air

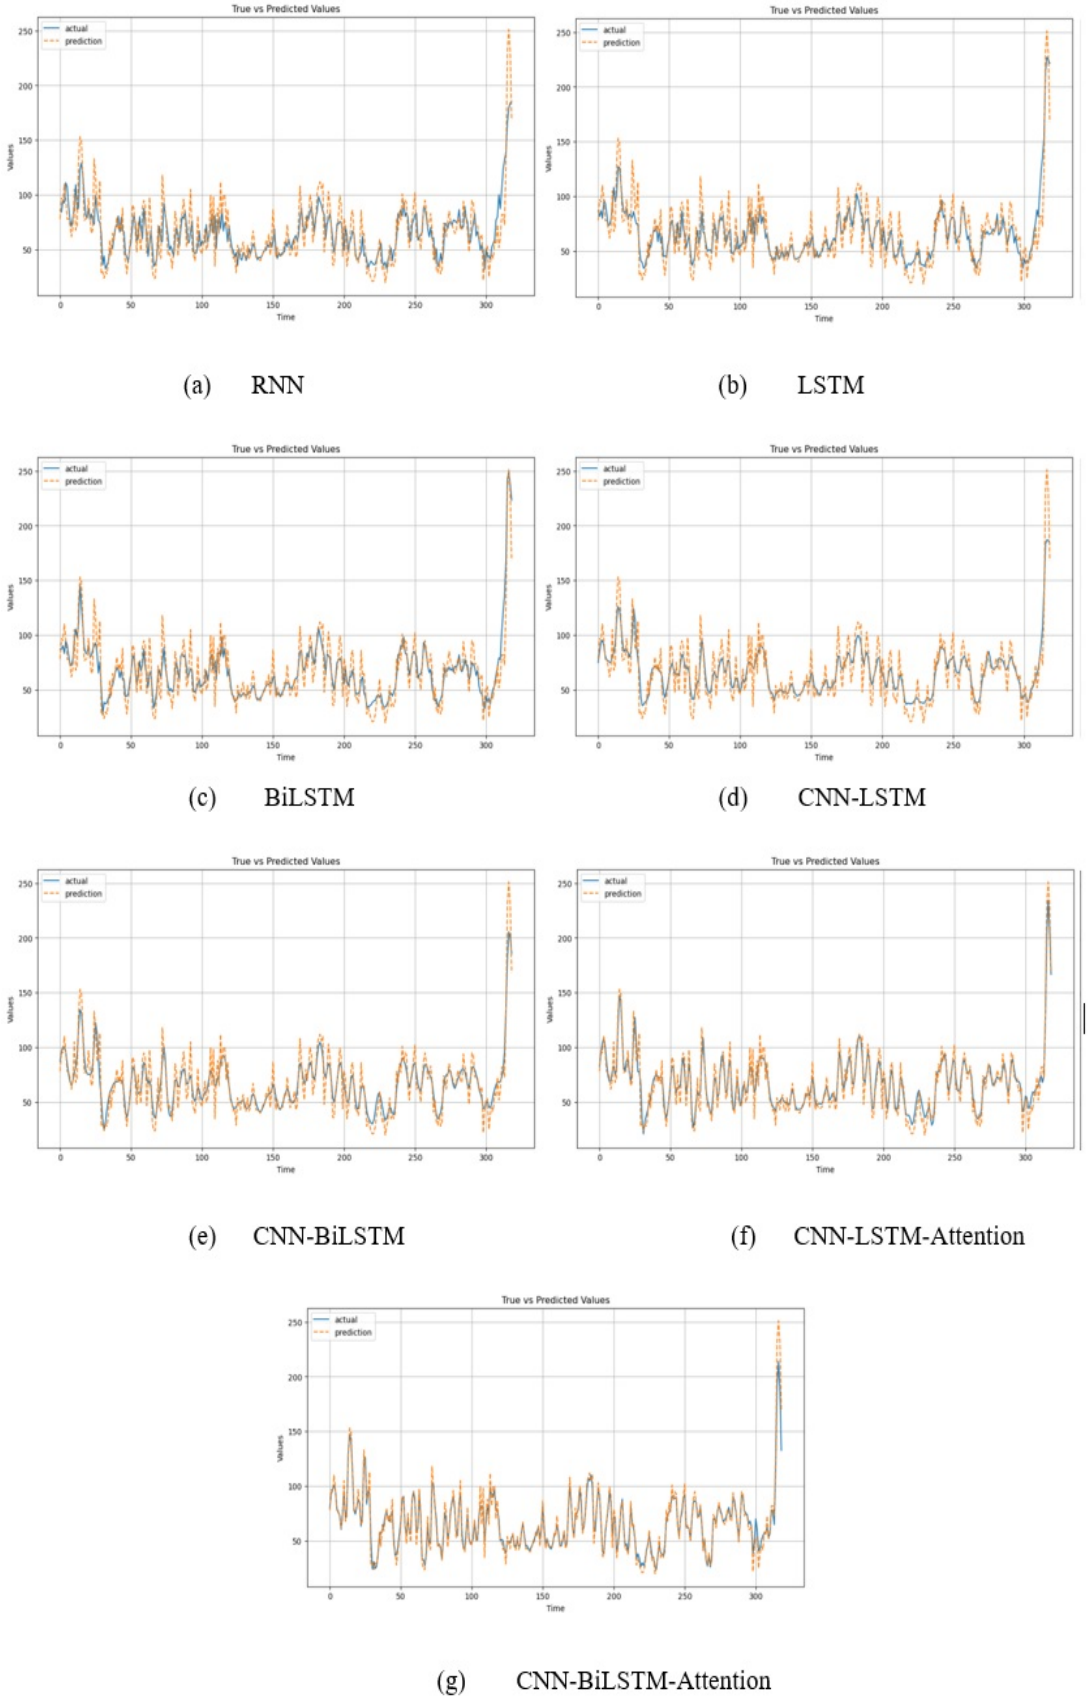

Fig. 7. Comparison of air quality prediction results from various models.

quality prediction model. Such a model can assist residents in planning their activities and provide scientific guidance to governments in formulating environmental protection policies.

Our research reveals that air quality time series data typically exhibit spatiotemporal diversity, meaning they display varying patterns across different times and locations. In addition, due to the nonlinear nature of meteorological and physical processes, as well as the influence of external factors, air quality data often show seasonal trends, daily cyclical variations, long-term patterns, and random fluctuations. These complexities make air quality prediction particularly challenging.

To address these issues, this study proposes a combined VMD-CNN-BiLSTM-Attention model designed to capture the spatiotemporal diversity and seasonality inherent in air quality time series. The model begins by applying the VMD algorithm to decompose and denoise the air quality data. Following decomposition, the dataset is standardized through normalization, improving data accuracy and facilitating more effective neural network predictions.

Within the proposed architecture, the CNN is responsible for extracting spatial features from the air quality data, while the BiLSTM network captures the temporal dependencies. The Attention mechanism then assigns varying weights to different elements of the data sequence, emphasizing the most influential features. This integrated model structure enhances the ability to capture complex spatiotemporal patterns, thereby improving prediction accuracy and reliability.

During model training, we evaluated the performance of seven different neural network models: RNN, LSTM, BiLSTM, CNN-LSTM, CNN-BiLSTM, CNN-LSTM-Attention, and CNN-BiLSTM-Attention. Model performance was assessed using four evaluation metrics, there are MAE, MSE, RMSE, and R2. The results demonstrate that the CNN-BiLSTM-Attention model outperforms the others across all indicators, achieving the highest accuracy in air quality prediction.

***Abstract*—Cardiac arrhythmias should be detected at an early stage so that clinical intervention can take place and continuous patient monitoring can be established in a timely manner. In this study, we present Cardio-Edge, a hardware-software co-design implementation of an LSTM-based ECG classification system optimized for real-time use on wearable devices. Proposed architecture comprises discrete wavelet transform (DWT) and principal component analysis (PCA) for efficient feature extraction followed by multiple parallel LSTM networks and a multi-layer perceptron (MLP) for classification. Implemented on a Xilinx ZYNQ-7000 SoC, our system leverages FPGA-based hardware acceleration alongside ARM Cortex-A9 for preprocessing tasks. Compared to software-only implementation on the same ARM processor, our co-design achieves a 10× improvement in execution speed with 99% classification accuracy trained and verified on the MIT-BIH arrhythmia dataset. The hardware-efficient implementation employs resource-optimized architectures for LSTM, activation functions, and fully connected layers making it appropriate for low-power, patient-specific wearable healthcare devices. This real-time, on-chip solution eliminates dependence in-cloud connectivity and ensures data privacy hence suitable for continuous cardiac monitoring applications.**

***Keywords*—ECG classification; wearable devices; discrete wavelet transform (DWT); long short-term memory (LSTM); field-programmable gate array (FPGA)**

I. Introduction

Cardiovascular diseases, particularly arrhythmias, are a leading cause of mortality all over the world. Identification of abnormal heart rhythms in time is also essentially important for pre-empting such exacerbations as a stroke or sudden cardiac arrest. Most conventional systems for monitoring ECG are off-line, and that means there would be a delay in diagnosis and treatment [1]. Even though AI particularly through deep learning frameworks has shown capabilities regarding the classification of signals pertaining to ECGs, an efficient deployment of such models on hardware platforms is still lacking. Most existing solutions are either software-based or rely on the cloud, which makes them infeasible for use in low-power, embedded, or portable health monitoring devices. Besides, high-performance processors like GPUs may not always be applicable for such an application because of their power and space requirements. While real-time detection is eventually what we want to achieve, the current work is concerned more with building a hardware-accelerated version of an LSTM model that can support real-time execution [2]–[5].

In the past few years, there has been a spiking trend of wearable healthcare devices given their real-time capabilities of monitoring ECG signals and detect cardiac issues before the patient gets too serious and needs immediate medical assistance [6]. The currently available wearable ECG monitoring devices transmit the raw signals, via smartphones or wearable devices, over the internet to hospitals for diagnosis of the ailment. This demands high power and reliance on the internet which defeats the purpose of low power automation. Researchers have made strides in machine learning models and their implementation in embedded systems to develop wearable devices that are designed to classify cardiac arrhythmia in real-time on chip hardware. For real-time processing on wearable devices, automated ECG classifier algorithms should not be computationally heavy and give correct predictions at the same time. A number of such classification algorithms rely on morphological features and use techniques that are doing traditional signal processing methods [7], [8]. The challenge with automating the monitoring of ECG signals is that they comprise of morphological features such as QRS complex and P waves which are affected by daily life variables such as exercise and they vary from patient to patient. This means that these algorithms cannot distinguish between various types of arrhythmia quite accurately [9], [10]. Researchers have developed machine learning models to categorize cardiac arrhythmia such as those discussed in [11], [12]. They distinguish CA beats from heart beats having normal rhythm by utilizing SVM, but both of the said algorithms need to be fed with the features manually. This lack of automation restricts the classification domain of the classifier when it comes to various ECGs. Another downside is that these classification methodologies is that they are not approved by association for the Advancement of Medical Instrumentation (AAMI) as they don't adhere to American National Standard. The key to automate feature extraction and pump up the accuracy of the arrhythmia classification, is the use of deep-learning algorithms. The deep convolutional neural networks CNNs and recurrent neural networks RNNs have recently been extensively utilized [12]–[17].

Thus, for the purpose of ECG classification, we have purposed a low power VLSI architecture which is Long Short-

Term Memory (LSTM) based. The processor uses RNNs because the ECG waveform is intrinsically compatible for processing with RNNs which is why we use them in our system. Fig. 1 illustrates that the backbone of our system is composed of LSTM and classical features like wavelet are also part of the solution. These extra features enhance the pattern recognition capability in the ECG waveform. In addition, the system merges the arrhythmia predictions from small LSTM models as opposed to constructing one large model. A large LSTM model is computationally intensive as compared to running a number of lighter LSTM models. So, we have executed multiple LSTM models and combined their collective predictions, instead of running one large model [18], [19]. The ECG classification algorithm is locally executed on patients' personal wearable devices. Regardless of network speed or availability, local execution enables for ongoing operation. Furthermore, it makes it possible for data to remain on the wearable device, avoiding the security concerns associated with cloud-assisted processing. Remote processing on powerful cloud servers or offline processing of recorded ECG signals techniques are not adopted. Our adapted approach has outperformed several other deep-learning methods, in terms of classification accuracy and is still very cost-efficient. It involves on chip execution of arrhythmia classifier, bypassing the need for a consistent and fast internet connection. Moreover, since the patient's data is processed on the device, we also avoid problems related to privacy that may arise from employing cloud computing services. Our solution is not to store the ECG signals and process them offline, nor do we utilize the most common cloud-computing services like AWS or GCP for running our classifier. This is a step in making continuous ECG classification wearable devices a common utility for those in need.

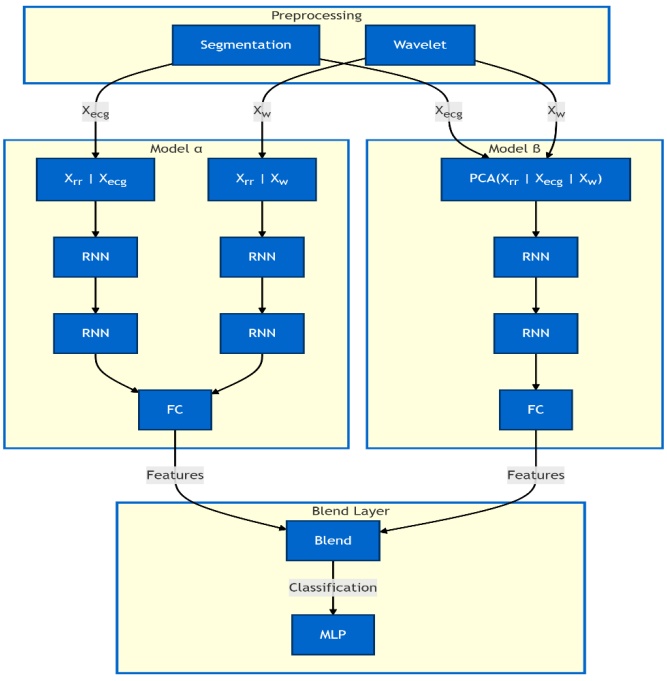

Fig. 1. LSTM-based ECG classification algorithm.

II. Related Work

The traditional approaches are based on extracting characteristics from the ECG signal, which involves identifying certain attributes of the ECG waveform, such as the P wave, QRS complex, and T wave, and then using these attributes as inputs to classification algorithms such as Support Vector Machines (SVMs) or k-Nearest Neighbors (kNN) [20]. There were some constraints with the old methods. The feature extraction was manual, time-consuming, and subjective, therefore susceptible to bias cases. It did not effectively capture the minute variations in the ECG signals. Therefore, it has low sensitivity for the infrequently appearing arrhythmia in particular ECG databases [21], [22]. The inter-patient variability also posed a challenge, significant enough to impede generalization from models trained on one dataset to an application in another dataset [23], [24]. Some important pre-processing steps included noise and artifact removals, but were relatively complicated and resource-intensive [25], [26].

Deep learning changed everything in ECG arrhythmia classification [25], [26]. Deep learning frameworks, especially Convolutional Neural Networks (CNNs), have displayed phenomenal prowess in the automatic learning of complex features from raw ECG signals without manual interference in feature engineering [27]. CNNs have specialized in detecting spatial patterns; therefore, they are greatly applicable to the analysis of the temporal dynamics regarding ECG waveforms [28], [29]. A superior performance by CNNs has been demonstrated over traditional machine learning techniques in many studies [30], [31]. An important aspect of building AI-based ECG arrhythmia detection systems is choosing an appropriate hardware platform. The choice depends on several requirements regarding performance level power usage requirement cost limitation and the complexity of the AI model to be used. This section points out significant hardware platforms reported in the literature and discusses their pros and cons.

ASICs were viewed as a suitable option since they could offer high performance with low power. Therefore, they might be best suited for integration into wearable devices for long-term monitoring of ECG. Since ASICs are custom-made inherently, the hardware architecture can be optimized to better suit the specific needs of an AI algorithm, which in turn brings about higher efficiency and lower power consumption. The use of ASICs for AI-based ECG arrhythmia detection has been noted in many studies in the literature. For instance, Zhang et al. [32] proposed a low-power ASIC realizing an Artificial Neural Network (ANN) architecture for foreseeing five types of cardiac arrhythmia. This low-power ASIC design includes a novel processor in preprocessing the ECG signals to effectively recognize R-peaks, which is the very vital step in analyzing arrhythmia, achieving 96.69% classification accuracy with 12.88 W of power consumptions at 100 kHz clock frequency.

The authors emphasize the adoption of a hardware reuse approach governed by a finite state machine (FSM) for rapid computation in an ANN. In a similar vein, Tefai and colleagues detail the ASIC implementation of a pre-trained neural network for ECG feature extraction, which is an essential preprocessing step for proper identification of arrhythmia [33]. The model developed is a recurrent neural network (RNN) that was trained using data from the PhysioNET database; it has been reported to give an accuracy of 96.55%. These works

indicate how all choices ASIC designers make from the type of ANN architecture to hardware reuse techniques and the CMOS technology chosen for manufacturing can heavily impact the size, power dissipation, and performance of an ASIC. The choice of CMOS technology greatly affects the dimensions, power drain, and performance of the ASIC. Hoyer et al. also propose a mixed-signal integrated circuit (IC) targeted for small patch ECG devices able to detect atrial fibrillation. Inference run-time for this implementation was 87.2% lower than that of a floating-point based implementation [34]. Design choices made in these ASICs regarding the specific ANN architecture and hardware reuse strategies have a significant influence on power efficiency and performance.

FPGAs are flexible and reconfigurable thus making a good alternative to ASICs. Prototyping and evaluating various AI algorithms in an FPGA before finalizing an ASIC design can be very beneficial. Since FPGAs are programmable, one can quickly modify and experiment with different architectures of AI model occasionally combined with signal processing technique. Liu et al. [35] present a fully-mapped FPGA accelerator for AI-based ECG analysis which includes the implementation of 1-D CNN and heart rate estimator. The architecture exploits parallelism in both the applications, resulting in considerable speedup and power savings relative to software implementations on other platforms, like ARM-Cortex A53 and Core i7-8700 CPUs. The authors have done a painstaking job of analyzing and optimizing the computation by eliminating division operations for the sake of efficiency. The proposed design consumes only 67.74 mW of power, thus suitable for applications that have limited resources, such as wearable ECG monitoring devices. In another such effort, Varadharajan and Nallasamy [36] present a Distributed Arithmetic (DA) based Gated Recurrent Unit (GRU) to enhance hardware efficiency for ECG diagnosis. The GRU represents a generalized simpler version of the LSTM and is implemented using DA operations to further reduce energy and latency in applications. The authors carry out their implementation on a ZYNQ-7000 SoC, where hardware and software co-design methodologies are used. Performances under different metrics like accuracy, precision, recall, specificity, F1-score, power, delay, and area are compared. The inherent parallel processing capability of FPGAs is well utilized to speed up inference and reduce latency. However, the trade-off between resource utilization in FPGAs and performance needs to be considered carefully and explored further. Gon and Mukherjee [37] show once again how FPGAs are useful in ECG signal processing by proposing a hardware-efficient architecture for removing noise from ECG signals based on a modified lifting DWT algorithm. This design, free of multipliers, yielded a very significant improvement in SNR and also exhibited lower hardware utilization and higher operating frequency compared to existing ECG denoising architectures.

Micro controllers, on the other hand, are low-cost and power-efficient alternatives for wearable devices in ECG monitoring when the AI model's complexity is not very high. Low power consumption allows for increased battery life in wearable, thus allowing prolonged continuous monitoring. Guo et al. use a MSP432P401R micro controller to carry out ECG signal acquisition and arrhythmia detection through a Convolutional Neural Network (CNN) [38]. The authors used an ADS1292 bio-electric sensor to obtain ECG signals and then sent the data acquired to a personal computer for analysis through serial ports. They presented the possibility of performing real-time analysis that leads to an accurate diagnosis of premature atrial contractions with a detection rate of 95.1%. Scrugli et al. implement a cognitive algorithm, specifically a convolutional neural network that has been trained to classify ECG waveforms, on a micro controller based platform thus reinforcing the claim on the propriety of micro controllers for resource-constrained applications [39]. Its design features an adaptive layer that dynamically regulates hardware and software settings to manage power consumption, able to achieve up to a 50% reduction in power consumption while maintaining high accuracy (over 97%) for arrhythmia detection based on the MIT-BIH Arrhythmia dataset. The selection of the micro controller has a substantial influence on the complexity of the AI model that can be implemented efficiently, as well as on the overall power consumption of the device. A critical aspect in prolonged monitoring applications is the equilibrium between processing capability and energy efficiency. Deng et al. [40] showed an automated arrhythmia detection system using a low-power microprocessor integrated into a wearable jacket. This system demonstrated very high sensitivity and specificity for detecting atrial arrhythmia, thereby showcasing the progressively enhanced capabilities of low-power microprocessors to conduct real-time AI-based analysis of ECG data.

III. Cardiac Arrhythmia Classifier

Traditional SoCs for the detection of cardiac arrhythmia consist mainly of two blocks. First comes the analogue to digital converter ADC front that obtains the ECG signals and digitizes it into discrete samples. The second block i.e. the co-processor, is responsible for feature extraction and classification. This study aims to fit a low powered ECG co-processor in a small area appropriate for wearable devices, as shown in Fig. 2. Firstly, the ECG signals that were converted into digital samples are segmented into heartbeats, enabling us to extract their wavelet and RR interval features. Then, these extracted features and the segmented ECG signals are processed by two slightly different RNN module. The two outputs from the RNNs are merged and fed into a feed forward neural network which gives the final output [18], as shown in Fig. 1 and Algorithm 1.

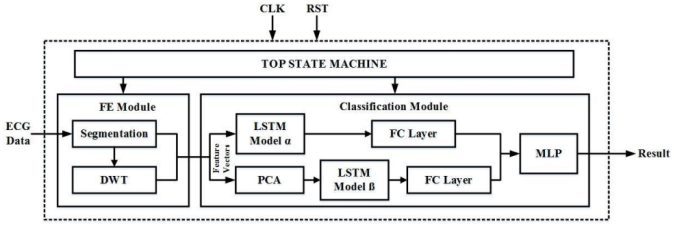

Fig. 2. System architecture of ECG classification system.

A. ECG Segmentation and Feature Extraction

In CA classification, the initial step is to provide vectors of fixed length extracted from the raw ECG signals as input to the classification block. A sequence of heartbeats is generated by segmenting the digitized ECG samples. This segmentation

is done around the R peaks in the heartbeat signal. Since a single segment or a heartbeat of fixed length, the duration of the segment can be mapped as 0.25 seconds of the ECG signal before an R peak is detected and 0.45 seconds after it is detected. The accuracy of the R peak detection algorithms, such as Pan-Tompkin's algorithm that we have used in our solution is highly reliable. The time intervals between consecutive R peaks is calculated as per the requirement of the Pan-Tompkins algorithm. If the time interval is denoted by between peak to peak then we can obtain the following four key features for the heartbeat i to construct our feature vector:

1) RR_i as the past RR interval.
2) RR_{i+1} as the next RR interval.
3) The local average of the five past and the five next RR intervals.
4) The average duration of the RR intervals in each person's train data.

These RR interval features are extracted accurately with considerably less computation. Other than that the algorithm does not require manually feeding other morphological features which are based on Q, S or T intervals which don't capture the nuanced representation of the segmented ECG signals. Moreover, these features don't vary from patient to patient and aren't influenced by environmental factors or situational diversity, making them unsuitable for tasks like classification of arrhythmia [10]. The approach of automating feature extraction by utilizing wavelet and RNNs is optimal in this scenario.

B. RNN Based Models

Recurrent neural networks (RNNs) have been a popular choice for tasks involving sequential data. Different architectures have been proposed to address the challenge of long-term dependencies in the sequence data. The Simple RNN cell, shown in Fig. 3(a) comprises just one recurrent layer and keeps a hidden state over time steps. Therefore, it is not very effective with long-term dependencies because it suffers from the vanishing gradient problem. The LSTM cell, shown in Fig. 3(b) in turn, consists of memory cells and a more complex architecture of gating mechanisms that include input, output, and forget gates; this design helps control information flow and thus allows LSTMs to keep pertinent information for longer sequences. A variant of the standard LSTM is LSTM with peephole connections, shown in Fig. 3(c). This structure provides an access path from the cell state into the gating mechanism. Hence, it improves the capability of the model to grasp minute temporal dependencies. In contrast, the Gated Recurrent Unit (GRU) cell architecture, shown in Fig. 3(d) reduces the complexity of LSTM by merging input and forget gates into a singular update gate and also merges cell state and hidden state. Fewer parameters translate to lower computational complexity; therefore, in hardware-constrained environments, GRUs are more efficient while learning long-term dependencies just as well.

Among these state-of-the-art models, the one whose mechanism is associated with Eq. (1) to Eq. (6) frequently stood out. By design, this model is highly effective in terms of computational speed and resource efficiency. Consequently, we opted to utilize this model in our implementation.

Algorithm 1 ECG Feature Extraction and Classification

```
Initialize state to IDLE
while not done do
    if state = IDLE then
        if start signal received then
            state ← SEGMENT
        end if
    else if state = SEGMENT then
        Segment the input data
        state ← DOWNSAMPLE
    else if state = DOWNSAMPLE then
        Downsample the segmented data
        state ← DWT
    else if state = DWT then
        Perform DWT on the downsampled data
        state ← PCA
    else if state = PCA then
        Perform PCA on the DWT output
        state ← LSTM_ALPHA1
    else if state = LSTM_ALPHA1 then
        Perform LSTM Alpha1 on the PCA output
        state ← FC_ALPHA1
    else if state = FC_ALPHA1 then
        Apply fully connected layer on LSTM Alpha1 output
        state ← LSTM_ALPHA2
    else if state = LSTM_ALPHA2 then
        Perform LSTM Alpha2 on the PCA output
        state ← FC_ALPHA2
    else if state = FC_ALPHA2 then
        Apply fully connected layer on LSTM Alpha2 output
        state ← LSTM_BETA
    else if state = LSTM_BETA then
        Perform LSTM Beta on the PCA output
        state ← FC_BETA
    else if state = FC_BETA then
        Apply fully connected layer on LSTM Beta output
        state ← BLEND
    else if state = BLEND then
        Blend the fully connected outputs
        state ← MLP
    else if state = MLP then
        Perform MLP on the blended output
        state ← DONE
    else if state = DONE then
        Set done signal
        state ← IDLE
    end if
end while
```

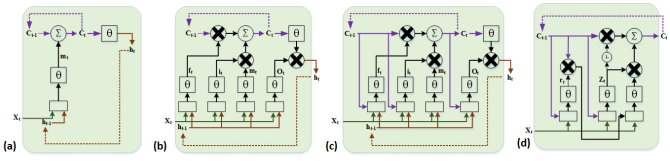

Fig. 3. (a) Simple RNN cell, (b) Long short-term memory (LSTM), (c) LSTM with peepholes, (d) Gated recurrent unit (GRU).

$$f_t[r] = \sigma \times \left(\sum_{c=1}^{M_x} \omega_{xf}[r,c] x_t[c] + \sum_{c=1}^{M_h} \omega_{hf}[r,c] h_{t-1}[c] + b_f[r] \right) \quad (1)$$

$$i_t[r] = \sigma \times \left(\sum_{c=1}^{M_x} \omega_{xi}[r,c] x_t[c] + \sum_{c=1}^{M_h} \omega_{hi}[r,c] h_{t-1}[c] + b_i[r] \right) \quad (2)$$

$$o_t[r] = \sigma \times \left(\sum_{c=1}^{M_x} \omega_{xo}[r,c] x_t[c] + \sum_{c=1}^{M_h} \omega_{ho}[r,c] h_{t-1}[c] + b_o[r] \right) \quad (3)$$

$$g_t[r] = \tanh \left(\sum_{c=1}^{M_x} \omega_{xg}[r,c] x_t[c] + \sum_{c=1}^{M_h} \omega_{hg}[r,c] h_{t-1}[c] + b_g[r] \right) \quad (4)$$

$$c_t[r] = f_t[r] \times c_{t-1}[r] + i_t[r] \times g_t[r] \quad (5)$$

$$h_t[r] = o_t[r] \times \tanh(c_t[r]) \quad (6)$$

In Eq. (1) to Eq. (6), the computational components are responsible for several calculations. The three main gates of an LSTM cell are the forget gate (f_t), input gate (i_t), and output gate (o_t). Additionally, the candidate cell gate, calculated intermittently at each time step, is referred to as g_t. These gates are all represented as vectors. The input vectors, which include x_t, c_t, and ht, represent the current input, cell state, and output vector of the LSTM at each time step. The weight matrices, denoted as $W**$, have specific roles where the first asterisk $(*)$ can be f, i, g, or o, indicating the matrices for the forget, input, candidate cell, or output gates, respectively. The second asterisk $(*)$ can be x or h, signifying that the weight matrix for a particular gate is multiplied by either the input vector x_t or the hidden state h_{t-1}. Finally, the bias vector is represented as b*, where the asterisk $(*)$ can be f, i, g, or o, corresponding to the forget, input, candidate cell, or output gates. In these equations, σ and $\tanh$ (i.e., the sigmoid and hyperbolic tangent functions) are vector-based functions. This means they operate element-wise on the input vectors and return the function's value for each element of the input vectors.

Although simplistic, the implementation of Eq. (1) to Eq. (6) is highly compute-intensive. For instance, if there are M_h neurons in one LSTM layer and it has M_x inputs, then considering the case of forget gates: x_t, the input vector sent to all neurons, would have dimensions M_x×1. h_{t-1}, the vector containing the hidden states of all neurons, and b_f, the bias vector for all gates (forget gates in this case), would have a size of M_h×1. W_{ix}, the weight matrix that connects the incoming input x_t to the forget gates of all the M_h neurons, would have a size of M_h×M_x. These dimensions are because each neuron receiving M_x inputs would need M_h weights for each of the inputs in the current time step. W_{if}, the weight matrix connecting the hidden state to the forget gate, would have dimensions of M_h×M_h because each neuron's forget gate needs to take into account the hidden states of all the neurons from the previous time step. This is done so that for each of the M_h forget gates, there are M_h weights for every hidden state h_{t-1} from the previous time step.

It is clear that Eq. (1) alone performs M_h×(M_x+M_h) multiplications because for each of the M_h elements in W_f*x_t, there would be M_x multiplications, and in $W_f h_{t-1}$, there would be M_h multiplications. Regarding additions, there would be M_h × (M_x+M_h+1) in one time step because for every M_h element in the weighted sum of the input and the hidden state, there would be M_x and M_h additions respectively, and one bias term each. This is quite a heavy burden for a software platform, as storing and retrieving input vectors, weight matrices, hidden states, and intermediate results would require significant memory bandwidth and storage.

C. MIT-BIH Arrhythmia Database

The MIT-BIH Arrhythmia Database is a benchmark dataset, widely used, for training and testing algorithms in ECG signal analysis and arrhythmia classification. It contains recordings of human heartbeats; carefully annotated by medical experts. The dataset has 48 half-hour recordings from 47 subjects collected at Beth Israel Hospital Arrhythmia Laboratory. The ECG signals were recorded by using a 2-channel ambulatory ECG device at a sampling frequency of 360 Hz. Annotated R-peaks and heartbeat labels are provided for each recording to identify different kinds of arrhythmia like normal beats, premature ventricular contractions, atrial premature beats, and others. This dataset holds a standard reputation in the medical AI community because of its clinical quality, detailed annotations, and a wealthy variety of heartbeat types. It suits perfectly for deep learning models like LSTM to train on, learn temporal patterns of ECG signals, and classify heartbeats based on those patterns.

IV. Hardware Implementation of LSTM Based CA Classifier

This section describes the internal implementation details of various modules of VLSI design of LSTM-based ECG classification system. The ECG signal processing module implements segmentation and DWT to extract meaningful features from raw ECG signals. The extracted features are handled in two methods, direct features for processing with LSTM model α and those that need PCA for dimensionality reduction prior to processing with LSTM model β. Each LSTM model processes its input sequences and generates feature vectors stored in the LSTM output memory. These stored feature vectors then move on to the FC Layer computation stage, where the output of LSTM model α is input to the first FC layer and the PCA reduced output of LSTM Model β is input to the second FC layer. The outputs from both FC layers are passed to a Multi-Layer Perceptron (MLP) for final classification. These steps are shown in Fig. 1 and Algorithm 1.

A. Discrete Wavelet Transform

The discrete wavelet transform (DWT) is a pre-processing method to extract the time-frequency features of the raw ECG

signals. An architecture based on the four-level decomposition of the Daubechies (db4) wavelet is proposed, which can access essential frequency components of ECG signals. The DWT module is made up of cascaded high-pass and low-pass filters with down-sampling at every stage, as shown in Fig. 4. The detailed coefficients D1 to D4 and an approximation coefficient A4 represent the band-limited versions of the ECG signal for the delta, beta, alpha, and theta bands [41]. The hardware implementation of the DWT module is made efficient by using lattice-form FIR filters [42], [43]. This combines high-pass and low-pass filtering into one computational block and saves hardware. As illustrated in Fig. 5, the DWT comprises high-pass and low-pass filters (HPF, LPF), with transfer functions represented by H(z) and G(z), respectively:

$$G(z) = h_0 + h_1 z^{-1} + h_2 z^{-2} + h_3 z^{-3}$$
$$H(z) = h_3 - h_2 z^{-1} + h_1 z^{-2} - h_0 z^{-3}$$

Here, $h_0 = (1+\sqrt{3})/4\sqrt{2}$, $h_1 = (3+\sqrt{3})/4\sqrt{2}$, $h_2 = (3-\sqrt{3})/4\sqrt{2}$, and $h_3 = (1+\sqrt{3})/4\sqrt{2}$.

To obtain the lattice filter structure and perceive HPF and LPF in one block, H(z) and G(z) can be expressed as:

$$G(z) = (1 + a[0]z^{-1} - a[0]a[1]z^{-2} + a[1]z^{-3})s$$
$$H(z) = (-a[1] - a[0]a[1]z^{-1} - a[0]z^{-2} - z^{-3})s$$

Here, $s = (1+\sqrt{3})/4\sqrt{2}$, $a[0] = (3+\sqrt{3})/4\sqrt{2}s$, and $a[1] = (1-\sqrt{3})/4\sqrt{2}s$.

Clock gating was applied here for efficient down-sampling of the signal. Pipelining and shift-and-add logic reduce latency while maximizing real-time performance.

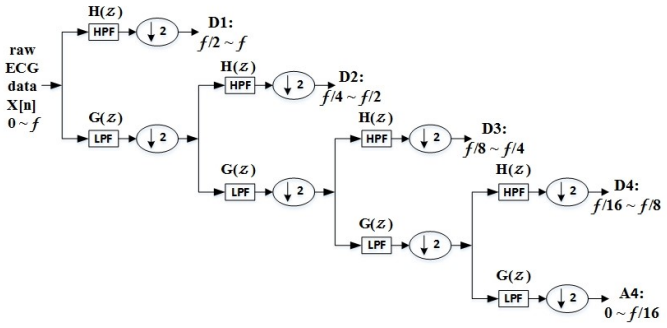

Fig. 4. Structure of the four-level DWT, where ↓2 means even sampling.

B. Principal Component Analysis

The PCA circuit manages to efficiently reduce the dimensionality of the extracted features while keeping all relevant information for classification intact. The design includes weight memory, multiplexers (MUX), a multiply-accumulate (MAC) unit, control logic, and an output memory, as shown in Fig. 6. In weight memory, the PCA main component weights are kept, precomputed from the training data, and they represent the transformation matrix. A structured memory architecture

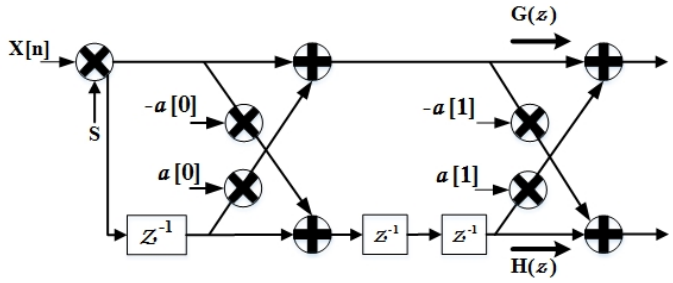

Fig. 5. Lattice FIR filter structure which realizes LPF and HPF in one block.

makes these weights readily accessible to facilitate processing. The MUX units will choose the proper input features from the output of DWT which are given sequentially to ensure proper mapping with corresponding PCA weights. The MAC unit does matrix-vector multiplication where feature values that have been picked are multiplied by weights that correspond to them. The multiplication of these values can accumulate over many clock cycles and thus form the transformed feature set efficiently. Control logic governs the flow of data, synchronizing input selection, weight retrieval, and MAC operations to keep synchronization while preventing computational errors. The feature vector PCA transformation is stored in the output memory.

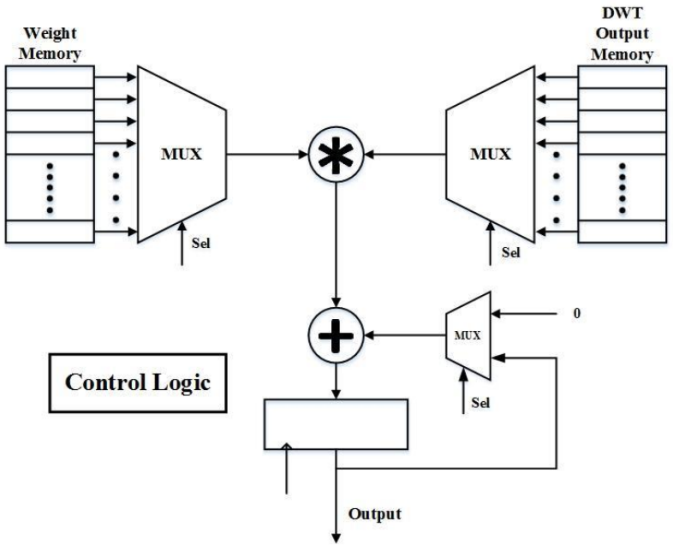

Fig. 6. Circuit design of PCA.

C. Long Short-Term Memory

The hardware realization of an LSTM unit begins with the design of efficient digital circuits for matrix-vector multiplication, nonlinear activation functions, and memory update while considering power and area constraints. The implementation divides itself into three major parts: the computational core, gate computation, and memory update. The LSTM computational unit comprises multiple processing elements that take care of input signals, weight matrices, and recurrent states. An architecture is presented that efficiently computes an input

vector x_t and a previous hidden state h_{t-1} using stored weight matrices. Matrix-vector multiplication has been identified as the primary compute-intensive operation and requires dedicated multipliers and adders. The accumulation stage sums up the result of multiplications and applies activation functions such as sigmoid and hyperbolic tangent (tanh) functions. The outputs of these activation functions are used to control the operations of all three gates in an LSTM, the input gate i_t, forget gate f_t, and output gate o_t. The gate computation module is a crucial part of the LSTM architecture, involving computation of gating signals for control over flow of information. Input data and previous hidden state are accessed from dedicated memory blocks. Then they are multiplexed into matrix-vector multiplication units. Weighted sum of inputs is computed by units that comprise an array of multipliers and accumulators, while terms for bias add-on are kept in a separate memory block. Resulting outputs are subject to a configurable activation module, implementing either sigmoid or tanh based on control logic signals. The main hardware module that implements the LSTM gates is shown in Fig. 7. This module adds non-linearity and allows selective retention of information. The output from this module will be used to drive the gating mechanisms which form the regulation for the internal state of the LSTM. The new cell state c_t and hidden state h_t are calculated by the memory update module for keeping long-term dependencies. The previous cell state is scaled by forgetting gate output while new information is integrated controlled by input gate through element-wise multiplications. The module that computes the c_t and h_t from the results of the gates is shown in Fig. 8.

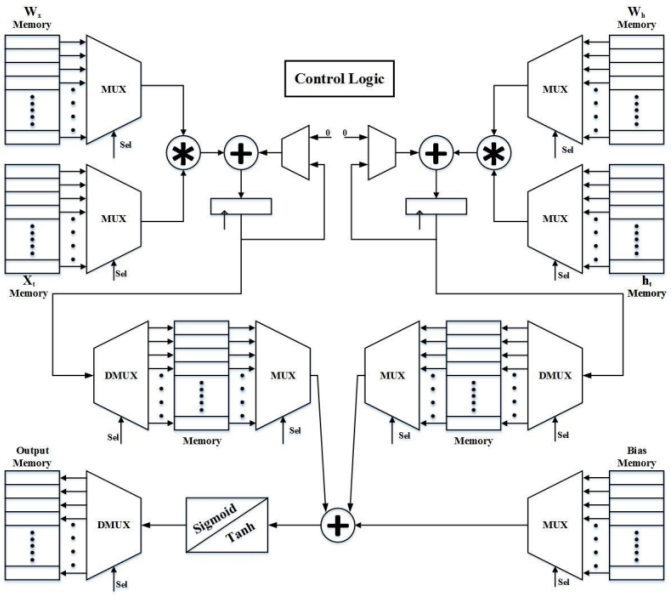

Fig. 7. The main hardware module that implements the LSTM gates.

The hardware implementation of the LSTM is governed by a finite state machine that manages the sequential execution of activities, hence leading to efficient data handling and real-time performance. The finite state machine controls memory read/write operations, weight fetching, matrix multiplications, activation function computation, and state update keeping synchronization among the different stages of computation. The process begins in idle state. This means that the system will remain idle until new input ECG sample data is made available. Immediately after receiving an input ECG sample, weight fetch state is entered wherein the control unit fetches the necessary weight matrices from memory. When the weights have been loaded, matrix multiplication State is entered where matrix-vector multiplication on the input and hidden state vectors with weight matrices is performed. After multiplication, the system goes into the accumulation State. This is when results from multipliers get accumulated and where bias terms are added to form the pre-activation values for the gates in LSTM. These accumulated values get passed through non-linear activation functions in the Activation State, such as sigmoid and hyperbolic tangent (tanh). After this, the FSM moves to the gate update state, where the input, forget, and output gates are calculated based on activated outputs. This step determines how much information will be retained or discarded from memory. The next step is the update of the cell c_t and the hidden state h_t. In the write back state, c_t and h_t are written back into memory with time step 2 so that these values are available for time step 3. This FSM guarantees the execution of all calculations in a pipelined manner, hence facilitating the overlapping stages involved in the LSTM process, and maximizing throughput. Optimization of state transitions leads to low latency and power usage. The structured control allows for a smooth flow of data, positively impacting hardware efficiency.

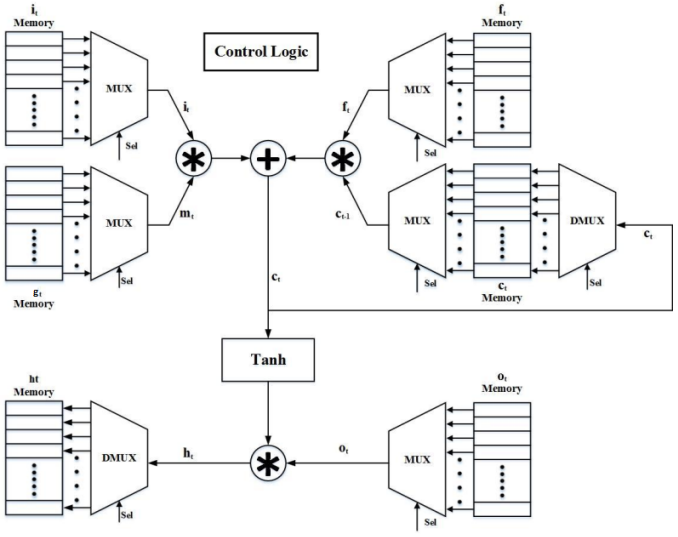

Fig. 8. The module that computes the c_t and h_t from the results of the gates.

D. Activation Functions

The activation functions are essential to the performance and convergence of the LSTM networks. The conventional sigmoid and hyperbolic tangent functions introduce substantial computational complexity due to their nonlinear and transcendental nature, making direct hardware implementation expensive. Therefore, hardware friendly approximations are adopted. The hard sigmoid and hard tanh, which keep the computational overhead low while maintaining competitive accuracy. Hard sigmoid and hard tanh, that provide linear approximations greatly simplify hardware implementation. These functions are defined in Eq. (7) and Eq. (8) [44]:

$$\text{hardtanh}(x) = \begin{cases} -1, & x < -1 \\ x, & -1 \le x \le 1 \\ 1, & x > 1 \end{cases} \quad (7)$$

$$\text{hardsigmoid}(x) = \begin{cases} 0, & x < -2.5 \\ 0.2 \times x + 0.5, & -2.5 \le x \le 2.5 \\ 1, & x > 2.5 \end{cases} \quad (8)$$

These approximations replace simple piecewise linear functions in sigmoid and tanh that approximate exponential computations to meet the same performance while it results in huge savings in FPGA resources utilization and latency. Whereas the hard sigmoid has a linear scaling factor and bias, hard tanh uses saturation-based clipping to ensure stability. In the LSTM-based model of the ECG classification, we tried both standard sigmoid + tanh and hard sigmoid + hard tanh. The effect on detection accuracy over 50 training epochs is shown in Fig. 9. Where hard approximations result in a small decrease in accuracy, vast improvement in hardware efficiency fully justifies this trade off.

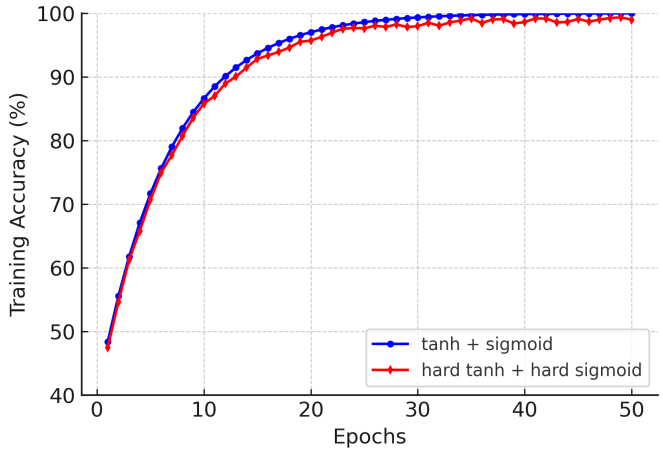

Fig. 9. Impact of activation functions on classification accuracy.

E. Fully Connected Layer

The fully connected layer is very important in changing the feature representations that were acquired by LSTM models into the final classification results. The hardware implementation of the Fully Connected layer, as can be seen in Fig. 10, includes several major components. Weight memory keeps the FC-layer weights in a form that was learned prior to the training of this mode. These weights will be picked up by using a multiplexer (MUX) according to control logic. LSTM output memory saves output vectors from LSTM models, these are used as input to the FC layer. A multiplication unit computes the weighted sum by performing element-wise multiplication of input features with weight values. An accumulation and summation unit adds all the results of multiplication using an adder tree to provide the final activation values for neurons. A bias addition stage retrieves the bias terms from a special bias memory and adds them before activation. The last element is the control logic, which guarantees the proper selection of weights, inputs, and all other parameters used in computations.

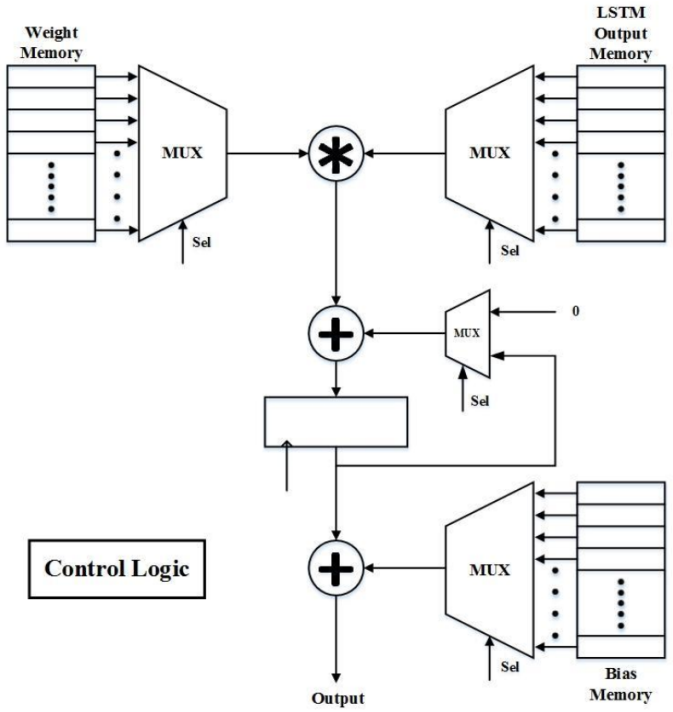

Fig. 10. The module that implements FC layer.

F. Multi-Layer Perceptron

After feature extraction and classification with LSTM and Fully Connected (FC) layers, the output of the FC layer will be used as input to a multi-layer perceptron (MLP) for final classification. The size of MLP is 80x10x7 as shown in Fig. 1. Each layer has multiple neurons, in which each neuron performs multiply-accumulate (MAC) operation. This is expressed as $y = \sum_{i=1}^{N} W_i x_i + B_i$. Here, W_i and B_i denote the weight and bias of the neuron, respectively. The computational complexity and hardware cost of MLPs depend on their number of neurons and MAC unit efficiencies. A finite state machine (FSM) controls the hardware implementation of MLP, coordinating operations between layers. When the enable signal is set high, the output of the FC layer (size 80) will be fed into the MLP input layer. The control unit will activate the FSM of each layer in a sequential manner, thus processing the inputs serially. The computed outputs will propagate through hidden layers and get to the final output layer, where the classification decision will be made. Achieving an optimized MLP architecture allows the designer to minimize hardware resources for ECG classification on wearable devices.

V. Hardware-Software Co-design Implementation

The hardware-software co-design methodology is a design approach used in embedded system development and digital system development where hardware and software components are developed in parallel rather than in sequence. This results in an optimization of performance, cost, power, and flexibility by proper partitioning of the functionalities between hardware, for example, FPGA, ASIC and software running on a processor [45]–[48]. Fig. 11 shows the architecture of the implementation of hardware-software co-design on the

ZYNQ-7000 SoC, which incorporates both the Processing System (PS) and the Programmable Logic (PL). The ARM Cortex-A9 processor available in PS is responsible for ECG signal acquisition and preprocessing like segmentation and wavelet transformation. The output of the pre-processed ECG data is passed to PL where LSTM hardware acceleration supports two different neural network models; Model α with 30 hidden units and Model β with 50 hidden units. These two models extract temporal features from the ECG data. A feature fusion of those outputs is through a Classification Blending unit based on a Multi-Layer Perceptron (MLP). The ultimate categorization outcomes are shown on an OLED screen using the SSD1306 controller, while also being sent to a UART interface for troubleshooting through the Vitis Terminal. This setup demonstrates a mix of hardware and software co-design that uses the advantages of both the ARM processor and FPGA fabric for effective, real-time ECG classification. The Processing System IP is the software interface surrounding the Zynq-7000 Processing System. The Zynq-7000 family includes a system-on-chip (SoC) style integrated processing system (PS) and Programmable Logic (PL), unit it provides an extensible and flexible SoC solution on single die for efficient, real-time ECG classification.

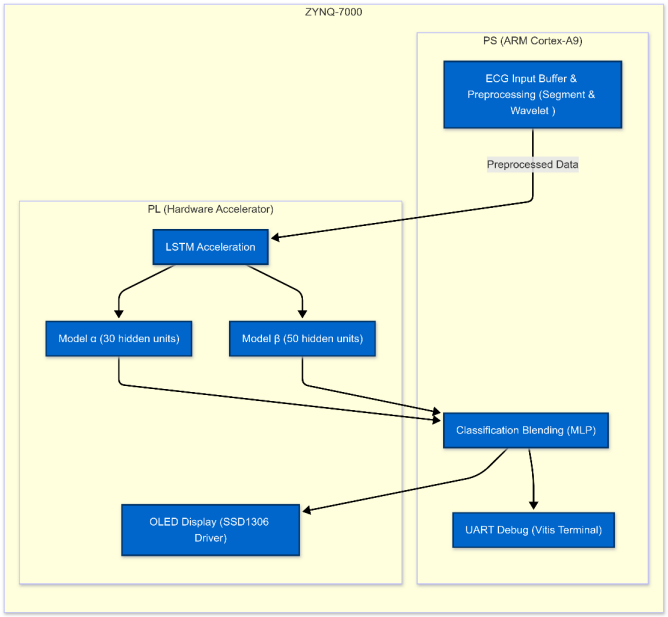

Fig. 11. Hardware-software co-design on the ZYNQ-7000 SoC.

The Zynq-7000 family comprises a system-on-chip (SoC) style integrated processing system (PS) and Programmable Logic (PL), an extensible and flexible SoC solution. The ECG LSTM Model IP is a custom hardware accelerator shown in Fig. 12, for time-series analysis specifically with Long Short-Term Memory (LSTM) networks on ECG signals. This IP core has been synthesized using Xilinx Vivado and deployed in the Programmable Logic (PL) region of Zynk-7000 SoC as a dedicated co-processor for sequential data classification.

The architecture of the module comprises a control interface module, data transfer module, and hardware-mapped LSTM computation engine optimized for low-latency as well as high-throughput inference. IP core supports AXI inter-

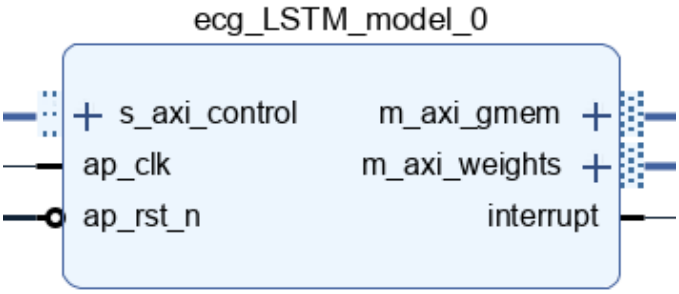

Fig. 12. LSTM based ECG custom IP.

faces for seamless communication with the Processing System (PS). This one, s-axi-ontrol interface, enables it to allow the ARM Cortex-A9 processor in the PS to configure, start, and monitor the LSTM accelerator through control registers. The m-axi-gmem interface streams pre-processed ECG data from external memory. The m-axi-weights interface dynamically loads trained LSTM model parameters (weights and biases) supporting multiple LSTM configurations, Model α (30 hidden units) and Model β(50 hidden units) without needing IP re-synthesis. The interrupt signal notifies the PS data blending or further processing steps that inference is complete.

This IP core has been designed for use in the real-time healthcare signal classification and optimized to manage the recurrent characteristic of LSTM calculation. It is functionally organized to handle time-series segments in a pipelined way that decreases the burden on the PS and allows parallel execution among different model variants. The PS takes care of ECG signal preprocessing (for example, segmentation and wavelet transformation) loading model weights, and post-inference tasks such as classification fusion and output display. After importing these IP cores, we need to automate the connections Xilinx will automatically connect some of the IP cores and the remaining ports should be connected manually. Fig. 13 shows the block diagram of LSTM based ECG hardware-software co-design system implemented using AMD Vivado.

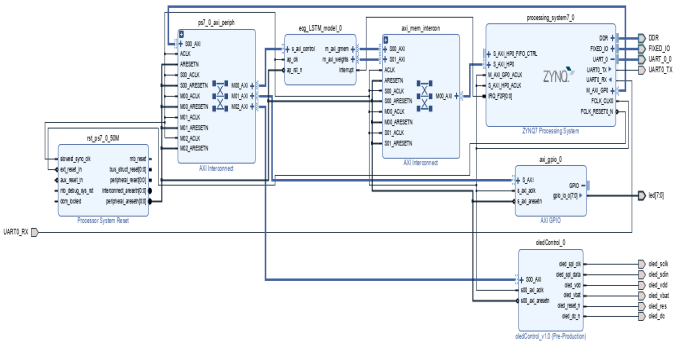

Fig. 13. Block diagram of LSTM based ECG Hardware-Software Co-design system.

VI. Hardware Utilization

The algorithm is first implemented using Python and TensorFlow. To evaluate performance and comparison with previous studies, the MIT-BIH ECG arrhythmia database is used. A pre-trained network is deployed in hardware using Verilog HDL. Synthesis is done using Xilinx Vivado Tool. Comparison of two FPGA-based ECG classification implementations is summarized in Table I.

TABLE I. Comparison of Two FPGA-based ECG Classification Implementations

	Complete HW	HW-SW Co-design
LUTs	2383	1600
FF	2156	1444
DSP	20	14
BRAM	22	15
Power (mW)	41	29
Frequency (MHz)	54	61
Accuracy	99%	99%

The power consumption distribution of complete hardware implementation is shown in Fig. 14, explaining the allocation among different components. It can be seen that power consumption is led mostly by the LSTM-based models.

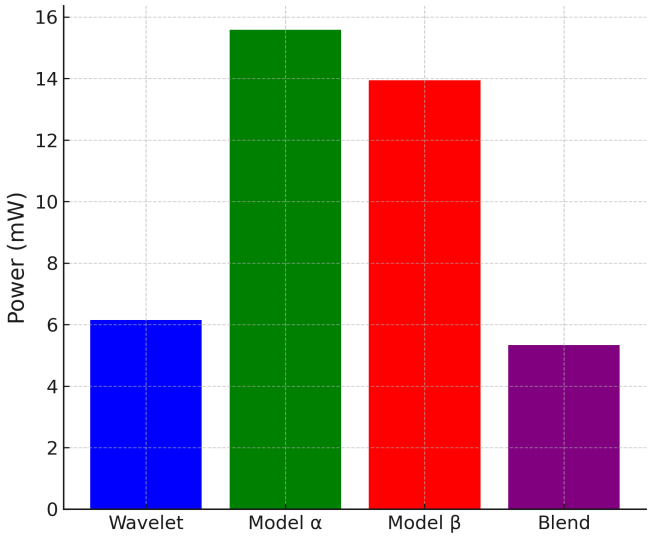

Fig. 14. Power consumption distribution.

In software simulation of neural networks, the weights and biases are represented in floating-point arithmetic. Floating-point arithmetic, however, is computationally very expensive and consumes relatively high power compared to fixed-point arithmetic. In order to minimize distortion, the weights and biases are represented using an ideal word length selected from software simulations, shown in Fig. 15. A 3.12 signed fixed-point format is selected, consisting of 1 sign bit, 3 integer bits, and 12 fractional bits.

The implemented method uses a patient-specific training paradigm. Therefore, the model is trained separately for each patient. Once the model has been trained, it can be used for real-time ECG surveillance and heartbeat classification for that specific patient. The method depicted in Fig. 16, demonstrates how training occurs just once for each patient

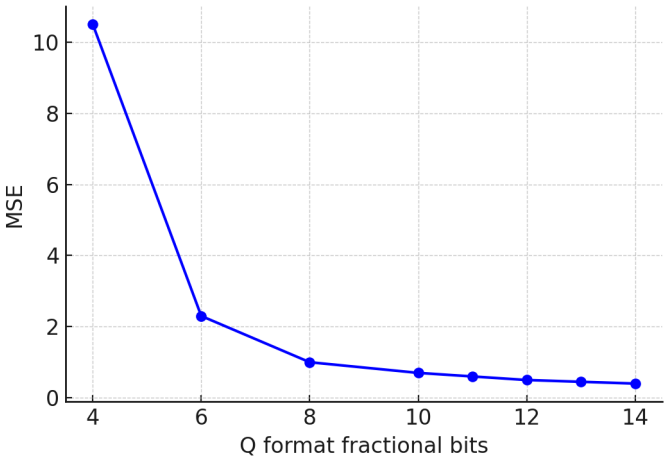

Fig. 15. MSE of network with various fractional bits.

and does not require ongoing updates. The training dataset for every patient is made up of twofold local ECG data and global ECG data, as illustrated in Fig. 16. The local dataset is provided for the patient, enhancing classification accuracy through the exploitation of intrinsic similarities between their heartbeats. According to AAMI standards, this dataset may last for a maximum of five minutes. However, the global dataset is shared among all patients and it contains representative heartbeats for different classes of arrhythmias. Thus, it helps the model generalize those patterns which are not present in the local dataset. Other studies have considered training patient-specific models [8]. An alternative approach is to train a single model across data from multiple patients and then use this model to classify ECG signals from new patients. This approach is not adapted because of the large variability between patients in ECG waveforms which may adversely affect classification accuracy [10].

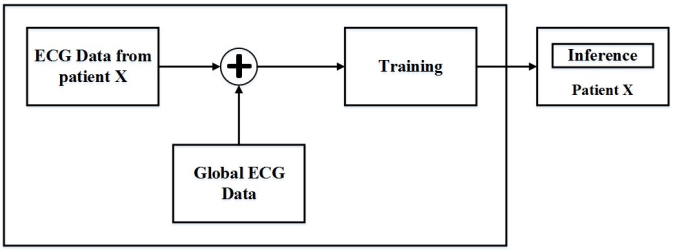

Fig. 16. Patient-specific training.

VII. Conclusion

We presented Cardio-Edge, a low-power real-time ECG classification system for health monitoring wearables. Optimized digital hardware for DWT, PCA, LSTM, and MLP modules is integrated into a hardware-software co-design on the ZYNQ-7000 platform to demonstrate a robust architecture capable of achieving high classification accuracy with minimal computational overhead. The HW-SW co-design offers 10× speedup over SW-only implementations on the ARM Cortex-A9 processor with no compromise in detection performance. The use of fixed-point arithmetic, hardware-friendly activation

approximations, and pipelined LSTM processing ensures energy as well as area efficiency. Our patient-specific training approach improves accuracy further by customizing the model to individual heartbeat profiles. On-device execution ensures secure continuous low-latency cardiac monitoring without reliance on remote servers and constant internet connectivity. This work takes a major stride forward in making intelligent biomedical systems deployed within constrained wearable platforms.

***Abstract*—This study presents a comprehensive evaluation of an outlier-robust particle filter (RPF) designed to improve indoor positioning accuracy in complex environments with substantial measurement noise and outliers. The RPF's performance is benchmarked against a standard Particle Filter (PF) using both simulated and real-world datasets. Simulation results indicate that the RPF consistently outperforms the PF in indoor positioning particularly when sensor measurements contain outliers, achieving significant reductions in root mean square error (RMSE) for position, velocity, and acceleration estimation, with improvements of approximately 40.02%, 38.48%, and 65.80%, respectively. Real-world experiments, applying a calibrated log-normal path loss model to Wi-Fi received signal strength (RSS) data, further corroborate the RPF's effectiveness, demonstrating a 93.61% improvement in positioning accuracy compared to the PF. These findings highlight the RPF's robustness in delivering high accuracy, especially in environments with measurement outliers, establishing it as a reliable solution for indoor tracking in noisy sensor environments.**

***Keywords*—Complex environments; indoor positioning; measurement noise and outliers; RMSE reduction; robust particle filter**

I. Introduction

Indoor Positioning Systems (IPS) have become increasingly important in today's technology-driven world, enabling accurate positioning of people and objects within indoor spaces [1]. Unlike outdoor positioning, which has been revolutionized by the Global Positioning System (GPS) [2], indoor environments present unique challenges that GPS cannot effectively address. These challenges include signal loss due to walls and obstacles, multipath interference, and the complexity of vertical positioning in multi-story buildings. As a result, IPS has become a significant area of research, essential for applications such as location-based services (LBS), asset tracking, and indoor navigation [3]. Various technologies support IPS, each with its strengths and limitations. Common technologies include Bluetooth Low Energy (BLE), Infrared, Ultra-Wideband (UWB), Magnetic Fields, as well as Wi-Fi. BLE is known due to its low power consumption and suitability for proximity-based applications; however, although its precision is susceptible to signal interference and environmental conditions [4]. Infrared systems offer high accuracy but require a direct line of sight between the transmitter and receiver, making them less practical in dynamic environments [5]. UWB provides high precision but demands specialized hardware, making large-scale deployment costly [6]. Magnetic field-based positioning can function without additional infrastructure but is sensitive to environmental changes and may require frequent recalibration [7].

Among these technologies, Wi-Fi has emerged as a practical and widely used solution for IPS [8]. Operating at 2.4 GHz and 5 GHz frequency bands conforming to IEEE 802.11 protocol, Wi-Fi is common in residential, commercial, and industrial environments. This existing Wi-Fi infrastructure can be leveraged for indoor positioning, reducing the need for additional hardware. Wi-Fi's ability to penetrate obstacles enhances its versatility and cost-effectiveness for indoor applications [9]. To improve the accuracy of Wi-Fi-based IPS, techniques such as Received Signal Strength (RSS) fingerprinting [10], Time of Arrival (ToA) [11], and Angle of Arrival (AoA) [12] are employed. Although AoA and UWB methods achieve higher absolute accuracy, RSS-based IPS is prioritized due to its simplicity (no extra hardware), use of existing Wi-Fi infrastructure, and ease of deployment. However, challenges such as signal fluctuations due to multipath effects and interference from other electronic devices can impact reliability. Accurate position estimation in IPS relies heavily on processing sensor data, which is often affected by noise and outliers [13]. Filtering algorithms are used to refine raw sensor data and improve positioning accuracy. Common algorithms include Kalman Filters (KF), Extended Kalman Filters (EKF), Unscented Kalman Filters (UKF), and Particle Filters (PF).

The KF is optimal for linear systems with Gaussian noise, providing efficient and accurate state estimates [14]. However, real-world environments often involve non-linearities and non-Gaussian noise, limiting the KF's effectiveness. The EKF addresses non-linear systems by linearizing it around current estimates, but this approach can yield suboptimal results in highly non-linear settings [15]. The UKF improves on the EKF by employing deterministic sampling to better represent the state mean and covariance, enhancing performance in non-linear cases [16]. Both EKF and UKF assume Gaussian noise, which is not always realistic in indoor environments prone to outliers. PFs provide a flexible alternative for non-linear, non-Gaussian systems [17]. Using a set of weighted particles to represent the system state distribution, PFs handle diverse noise types and complex dynamics effectively. It operate through a recursive prediction-update process: particles are propagated based on system dynamics in the prediction step, and its weights are adjusted during the update step based on observed measurements. This adaptability makes PFs well-

suited for indoor positioning, where signal propagation is irregular due to obstacles, reflections, and multipath effects. Despite their robustness, PFs face challenges such as weight degeneracy, where most particles contribute minimally to the state estimate after several iterations [18]. Resampling helps mitigate this issue, but increases computational load [19]. Nonetheless, PFs' ability to model non-linearities and manage non-Gaussian noise conditions makes them an ideal choice for complex indoor environments, outperforming Kalman-based filters under such conditions [20].

PFs are widely used in robotics, target tracking, and autonomous vehicles due to their ability to represent state distributions accurately. However, this capability comes with challenges. Maintaining and updating a large number of particles is computationally intensive, making real-time applications or systems with limited processing power difficult to manage [21]. The process of propagating and re-weighting particles adds complexity, especially when rapid updates are required. Weight degeneracy, where most particles contribute minimally to the state estimate, further degrades performance, particularly in noisy environments or when measurements include outliers [22]. Resampling helps address weight degeneracy, but adds to the computational load. In IPS, PFs are effective in managing non-linearities and non-Gaussian noise but are sensitive to outliers in sensor measurements. Outliers, caused by signal reflections, interference, or hardware malfunctions, distort state estimation by skewing particle weights [23]. This can result in inaccurate state estimates, as particles with incorrect weights disproportionately influence the distribution. Outliers exacerbate weight degeneracy by concentrating the majority of the weight on a few particles, reducing the effective number of particles and degrading the filter's performance. It can also mislead the PF, causing particles to cluster around incorrect states and reducing diversity in the particle set. This loss of diversity limits the filter's ability to explore the true state space, compromising accuracy and reliability. Consequently, PFs are less effective in environments with frequent outliers, reducing their ability to provide consistent and precise positioning estimates.

Given these challenges, improving the robustness of PFs to effectively handle outliers is essential for enhancing indoor positioning accuracy. This requires developing strategies to detect and mitigate the impact of outliers, ensuring that the PF remains accurate even with contaminated data. To address these challenges, this study introduces the outlier-robust Particle Filter (RPF), which is designed to improve the accuracy and robustness of indoor positioning in the presence of outliers. The RPF utilizes an adaptive noise model that dynamically switches between Gaussian and Student's t-distribution noise models based on the inferred likelihood of outliers in the sensor measurements. Under normal conditions, where measurements mainly contain Gaussian noise, the filter employs a Gaussian distribution [24]. However, when outliers are detected, it switches to a Student's-T distribution [25], providing increased resilience against extreme values. Unlike prior robust PF approaches that rely solely on Student's-T noise models in [25] and [26], the RPF integrates the Singer acceleration motion model, which inherently handles non-linear movement by jointly modeling position, velocity, and acceleration, and a log-normal path-loss sensor model to convert RSS into distance. This two-fold design explicitly accounts for both Gaussian and heavy-tailed (non-Gaussian) measurement noise. The effectiveness of the proposed RPF is validated through simulations and real-world experiments conducted in residential indoor environments. These experiments demonstrate the RPF's superior performance in positioning accuracy, robustness against outliers, and its ability to handle non-linear movements and non-Gaussian noise, outperforming standard PF methods. By addressing key challenges such as measurement noise, weight degeneracy, and particle diversity in the presence of outliers, this study presents a more robust and reliable solution for Wi-Fi-based IPS. The RPF marks a significant advancement in indoor positioning, addressing the limitations of PFs in real-world environments.

The remainder of this study is organized as follows: Section II introduces the system model and notation, beginning with the Singer acceleration motion model defining the state vector, transition matrix, and control and noise inputs and then presenting the RSS-based path-loss measurement framework, which includes both the multivariate Gaussian distribution for nominal noise and the multivariate Student's-T distribution to handle outliers. Section III formulates the filtering problem by first reviewing the standard particle filter covering sampling, weight update, and normalization for nonlinear, non-Gaussian state estimation and then detailing the proposed outlier-robust particle filter, which employs a dual-noise likelihood framework to switch between Gaussian and Student's-T hypotheses and incorporates Metropolis resampling to preserve particle diversity, as summarized in Algorithm 2. Section IV presents experiments and results under Wi-Fi RSS measurements, describing simulated data scenarios including 2D trajectory generation, noise and outlier injection, and RMSE performance metrics and real-world experiments using the ESP-32-WROOM-32 in a residential indoor setting with calibrated log-normal path-loss and positioning accuracy comparisons. Section V summarizes the key findings highlighting the RPF's superior robustness and accuracy and outlines directions for future research.

A. Motivation and Contribution

This work addresses the critical need to enhance the robustness of PFs against outliers while maintaining computational efficiency, a key requirement for practical IPS. Traditional PFs struggle with non-Gaussian noise and measurement outliers, which can severely degrade performance. To overcome these challenges, the RPF is introduced, featuring an adaptive noise model that dynamically switches between Gaussian and Student's-T distributions based on outlier detection. This approach ensures resilience to extreme values while preserving accuracy. The contributions of this work are threefold. Firstly, the RPF is specifically designed to mitigate the adverse effects of outliers in Wi-Fi-based IPS, addressing a significant challenge in environments where non-Gaussian measurement noise is prevalent. Secondly, the performance of the RPF is rigorously evaluated through extensive testing on both simulated datasets and real-world experiments, demonstrating its superior accuracy and robustness compared to traditional methods. Thirdly, a calibrated log-normal path loss model is integrated into the algorithm to provide a more accurate representation of indoor signal propagation, further enhancing reliability and positioning accuracy.

II. System Model

Notations: Bold lowercase letters (e.g., $\mathbf{x}$) are used to represent vectors, while bold uppercase letters (e.g., $\mathbf{A}$) denote matrices. Scalars are indicated with standard italic letters (e.g., x). The symbol $\mathbb{R}$ represents the set of all real numbers, and $\mathbb{R}^{m\times n}$ signifies the space of $m \times n$ real matrices. The identity matrix is written as $\mathbf{I}$, and the determinant of a matrix $\mathbf{A}$ is expressed as $|\mathbf{A}|$. A Multivariate Gaussian distribution, fully defined by its mean μ and covariance matrix Σ, is represented as $\mathcal{N}(\mu, \Sigma)$. The transpose operation on a matrix or vector is indicated with the superscript T.

A. Motion Model

Consider the trajectory of a mobile user in a two-dimensional (2D) floor plan, described by the Singer state-space model [27], as in Eq. (1):

$$\mathbf{x}_k = \mathbf{A}\mathbf{x}_{k-1} + \mathbf{B}_u\mathbf{u}_k + \mathbf{B}_w\mathbf{w}_k, \tag{1}$$

where, $\mathbf{x_k} = [x_k, \dot{x}_k, \ddot{x}_k, y_k, \dot{y}_k, \ddot{y}_k]^T$ is a state vector that consists of the mobile user's coordinates (x_k, y_k), velocity $(\dot{x}_k, \dot{y}_k)$, and acceleration $(\ddot{x}_k, \ddot{y}_k)$, respectively at time step k. The parameter $\mathbf{A} \in \mathbb{R}^{6\times6}$ is the state transition matrix, the vector u_k denotes the control input, which represents any externally applied input or maneuvering command to the system, $\mathbf{B}_u \in \mathbb{R}^{6\times2}$ is the control input matrix, and $\mathbf{B}_w \in \mathbb{R}^{6\times2}$ represents the noise matrix, given by Eq. (2) and Eq. (3),

$$\mathbf{A} = \begin{bmatrix} 1 & T & T^2/2 & 0 & 0 & 0 \\ 0 & 1 & T & 0 & 0 & 0 \\ 0 & 0 & \alpha & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & T & T^2/2 \\ 0 & 0 & 0 & 0 & 1 & T \\ 0 & 0 & 0 & 0 & 0 & \alpha \end{bmatrix}, \tag{2}$$

$$\mathbf{B}_u = \begin{bmatrix} T^2/2 & 0 \\ T & 0 \\ 0 & 0 \\ 0 & T^2/2 \\ 0 & T \\ 0 & 0 \end{bmatrix}, \quad \mathbf{B}_w = \begin{bmatrix} T^2/2 & 0 \\ T & 0 \\ 1 & 0 \\ 0 & T^2/2 \\ 0 & T \\ 0 & 1 \end{bmatrix}, \tag{3}$$

where, T is the discretization period and $\alpha = 1/\tau$ is the reciprocal of the maneuvering time constant τ. The parameter $\mathbf{w}_k \in \mathbb{R}^{2\times1}$ accounts for the state noise, and follows a zero-mean multivariate Gaussian distribution, $\mathbf{w}_k \sim \mathcal{N}(0, \mathbf{Q_k})$, with state noise covariance matrix $\mathbf{Q_k} = \mathbb{E}(\mathbf{w}_k\mathbf{w}_k^T) = \sigma_w^2\mathbf{I}$. The motion model describes how the mobile user moves at time steps $k = \{1, 2, 3, ...\}$. It captures the dynamics of the mobile user by considering the stochastic nature of acceleration [28]. This is particularly useful in scenarios where the motion of the user cannot be precisely model and is subject to random variations. By modeling the acceleration as a random process, the motion model provides a more realistic representation of the user's movement in real-world scenarios.

B. Sensor Measurement Model

In indoor environments, GPS signals are unavailable because it cannot penetrate building structures effectively. To address this limitation, signals emitted by indoor infrastructure can be utilized to indirectly determine the position of a mobile user within an indoor environments. One practical approach involves using Wi-Fi access points (APs) as transmitters, taking advantage of the existing Wi-Fi infrastructure in indoor spaces, while mobile devices function as receivers that measure the RSS from these APs [29]. The RSS values indicate the signal power received by the mobile device from each AP, which can be used to estimate the distance between the APs and the mobile user [30]. By combining RSS measurements from multiple APs, the position of the mobile device can be triangulated. The relationship between the RSS measurements and the distance is typically modeled using the Path Loss Model, which provides a mathematical framework for representing Wi-Fi signal propagation, given by [31],

$$z_k = z_0 + 10\beta\log_{10}(d_k) + v_k, \tag{4}$$

where, z_k is the RSS measurement at time step k at the receiver node, z_0 is the reference path loss at a 1-meter distance, β is the path loss exponent, d_k is the distance between the receiver and transmitter at time step k, and v_k is the measurement noise. For practical applications, a minimum of three APs is required for positioning, as this allows for triangulation to determine the position of the mobile user in the network. Thus, Eq. (4) can be expressed in vector form as $\mathbf{z}_k = [z_k^1, z_k^2, \ldots, z_k^n]^T$, where n refers to the number of APs.

1) Multivariate Gaussian Distribution: The measurement noise in Eq. (4) is often modeled as a zero-mean Gaussian distribution $v_k \sim \mathcal{N}(\mathbf{0}, \sigma_k^2)$. For multiple APs, the measurement noise is expressed as a vector $\boldsymbol{v}_k = [v_k^1, v_k^2, v_k^3, \ldots, v_k^n]^T$, where n denotes the total number of APs. Consequently, v_k follows a multivariate Gaussian distribution, $\boldsymbol{v}_k \sim \mathcal{N}(\mathbf{0}, \mathbf{R_k})$, with measurement noise covariance matrix $\mathbf{R_k} = \mathbb{E}[\boldsymbol{v}_k\boldsymbol{v}_k^T] = \sigma_v^2\mathbf{I}$. The probability density function (PDF) for a multivariate Gaussian distribution, characterized by a mean vector $\hat{\mathbf{z}}_k$ and a covariance matrix $\mathbf{R_k}$, can be expressed as Eq. (5):

$$p(\mathbf{z}_k) = (2\pi)^{-\frac{n}{2}}|\mathbf{R_k}|^{-\frac{1}{2}}\exp\Big(-\frac{1}{2}(\mathbf{z}_k - \hat{\mathbf{z}}_k)^T\mathbf{R}_k^{-1}(\mathbf{z}_k - \hat{\mathbf{z}}_k)\Big), \tag{5}$$

where, n represents the number of AP, $\mathbf{z}_k$ is the observed RSS measurement, $\hat{\mathbf{z}}_k$ is the predicted RSS measurement, $\mathbf{R}_k$ is the measurement noise covariance matrix, and $|\mathbf{R_k}|$ is the determinant of $\mathbf{R}_k$. It provides the likelihood of the RSS measurements given the estimated state of the system. The likelihood function is utilized in the update step of the PF to adjust particle weights based on how closely the predicted measurements align with the observed data.

2) Multivariate Student's-T Distribution: In cases, where sensor measurements contain outliers, the measurement noise in Eq. (4) follows a multivariate Student's-T distributions, $\mathbf{z}_k \sim St(\mathbf{0}, \mathbf{R}, \nu)$, with the PDF given by [26] Eq. (6),

$$p(\mathbf{z}_k) = \frac{\Gamma\left(\frac{\nu+n}{2}\right)}{\Gamma\left(\frac{\nu}{2}\right)(\nu\pi)^{n/2}\det(\mathbf{R}_k)^{1/2}} \times (1 + \frac{1}{\nu}(\mathbf{z}_k - \hat{\mathbf{z}}_k)^T\mathbf{R}_k^{-1}(\mathbf{z}_k - \hat{\mathbf{z}}_k))^{-\frac{\nu+n}{2}}, \tag{6}$$

where, n represents the total number of AP, $\mathbf{z}_k$ is the observed RSS measurement, $\hat{\mathbf{z}}_k$ is the predicted RSS measurement, $\mathbf{R}_k$ is the measurement noise covariance matrix, and ν is the degrees of freedom. The symbol $\Gamma(\cdot)$ represents the gamma function. The multivariate Student's-T distribution shares some

similarities with the multivariate Gaussian distribution, especially when $\nu \geq 30$. As ν increases, the multivariate Student's-T distribution approaches the multivariate Gaussian distribution. A key distinction of the Student's-T distribution is its capacity to model heavier tails compared to the Gaussian distribution. The parameter ν controls the degrees of freedom and influences the thickness of the distribution's tails. Lower values of ν result in heavier tails.

III. Problem Formulation

A. Review of the Particle Filter

A PF is a state estimation method designed for nonlinear systems, utilizing a collection of samples, known as particles, to approximate complex probability distributions. Unlike approaches constrained by Gaussian assumptions, PF can model arbitrary distributions. Within the context of indoor positioning, PF estimates the state of a mobile user, denoted as $\mathbf{x}_k$ in Eq. (1), by leveraging the RSS measurements represented as $\mathbf{z}_k$ in Eq. (4). The core objective of the PF is to derive the PDF that describes the relationship between the system states and measurements. To approximate the joint PDF at the prior time step $p(\mathbf{x}_{k-1}|\mathbf{z}_{1:k-1})$, the PF employs a weighted set of particles, $\{\mathbf{x}_{k-1}^{(i)}, i = 1, \ldots, N_p\}$ [32], given by Eq. (7):

$$p(\mathbf{x}_{k-1}|\mathbf{z}_{1:k-1}) \approx \sum_{i=1}^{N_p} w_{k-1}^{(i)} \delta(\mathbf{x}_{k-1} - \mathbf{x}_{k-1}^{(i)}), \tag{7}$$

where, $\{w_{k-1}^{(i)}, i = 1, \ldots, N_p\}$ represents the weights associated with each particle, where N_p denotes the total number of particles, and $\delta(\cdot)$ signifies the Dirac delta function. The posterior PDF $p(\mathbf{x}_k|\mathbf{z}_{1:k})$ is defined as Eq. (8):

$$p(\mathbf{x}_k|\mathbf{z}_{1:k}) \propto p(\mathbf{z}_k|\mathbf{x}_k) \sum_{j=1}^{N_p} w_{k-1}^{(j)} p(\mathbf{x}_k|\mathbf{x}_{k-1}^{(j)}), \tag{8}$$

where, $p(\mathbf{z}_k|\mathbf{x}_k)$ is the measurement likelihood, and $p(\mathbf{x}_k|\mathbf{x}_{k-1}^{(j)})$ represents the prior transition model. If the particles are drawn from a proposal distribution $\mathbf{x}_k^{(i)} \sim q(\mathbf{x}_k|\mathbf{x}_{k-1}^{(i)}, \mathbf{z}_k)$, the weights are updated according to Eq. (9):

$$w_k^{(i)} \propto w_{k-1}^{(i)} \frac{p(\mathbf{z}_k|\mathbf{x}_k^{(i)}) p(\mathbf{x}_k^{(i)}|\mathbf{x}_{k-1}^{(i)})}{q(\mathbf{x}_k^{(i)}|\mathbf{x}_{k-1}^{(i)}, \mathbf{z}_k)}. \tag{9}$$

The proposal distribution is assumed to be equal to the state transition probability, i.e. [see Eq. (10)],

$$q(\mathbf{x}_k^{(i)}|\mathbf{x}_{k-1}^{(i)}, \mathbf{z}_k) = p(\mathbf{x}_k^{(i)}|\mathbf{x}_{k-1}^{(i)}), \tag{10}$$

based on the rationale that the state dynamics sufficiently capture the evolution of the system, and the measurement z_k does not provide additional information at the sampling stage. This assumption simplifies the weight update,

$$w_k^{(i)} \propto w_{k-1}^{(i)} p(\mathbf{z}_k|\mathbf{x}_k^{(i)}). \tag{11}$$

Algorithm 1 The Particle Filter (PF).

(1) Input: Initialization
  for $k = 0$ **do**
    for $i = 1, \ldots, N_p$ **do**
      Samples: $\{\mathbf{x}_0^{(i)} \sim q(\mathbf{x}_0)\}$.
      Set initial weights: $w_0^{(i)} = 1/N_p$.
    end for
  end for

  for $k = 1, \ldots, endtime$ **do**
    for $i = 1, \ldots, N_p$ **do**
      (2) Prediction Step
      Propagate the particles $\mathbf{x}_k^{(i)}$ using eq. (1).
      Generate measurements $\mathbf{z}_k^{(i)}$ using eq. (4).

      (3) Measurement Update
      Calculate the measurement likelihood:
      $p(\mathbf{z}_k|\mathbf{x}_k^{(i)})$ where $\mathbf{z}_k \sim (0, \mathbf{R}_k)$.
      Update the weights $w_k^{(i)}$ using eq. (11).
    end for
    Normalize the weights: $\hat{w}_k^{(i)} = w_k^{(i)} / \sum_{i=1}^{N_p} w_k^{(i)}$.
    The posterior PDF: $p(\mathbf{x}_k|\mathbf{z}_{1:k}) = \sum_{i=1}^{N_p} \hat{w}_k^{(i)} \hat{\mathbf{x}}_k^{(i)}$.

    (4) Output: The estimated state:
    $\hat{\mathbf{x}}_k = \mathbb{E}[\mathbf{x}_k|\mathbf{z}_{1:k}] \approx \sum_{i=1}^{N_p} \hat{w}_k^{(i)} \hat{\mathbf{x}}_k^{(i)}$.
    (5) Resampling Step
    Set the threshold sample size: $N_{thresh} = N_p/10$.
    Calculate the effective sample size:
    $N_{eff} = 1/\sum_{i=1}^{N_p} (\hat{w}_k^{(i)})^2$
    if $N_{eff} < N_{thresh}$
      The metropolis resampling method is applied.
    end if
  end for

reducing computational complexity. It is a standard practice in particle filtering when the transition model is an adequate approximation of the true state dynamics, allowing reliance on the measurement likelihood in the weighting process, as shown in Eq. (11). The weights are then normalized such that [see Eq. (12)]:

$$\sum_{i=1}^{N_p} w_k^{(i)} = 1. \tag{12}$$

Finally, the resulting posterior PDF is expressed as Eq. (13):

$$p(\mathbf{x}_k|\mathbf{z}_{1:k}) \approx \sum_{i=1}^{N_p} w_k^{(i)} \delta(\mathbf{x}_k - \mathbf{x}_k^{(i)}). \tag{13}$$

The PF algorithm, outlined in Algorithm 1, provides an iterative framework for estimating the state of a dynamic system. In each iteration, the particle states $\mathbf{x_k}$ (position, velocity, acceleration) are first predicted via the motion model in Eq. (1), then the RSS measurements $\mathbf{z_k}$ are collected at the mobile device and converted into distance estimates using the log-normal path-loss model using Eq. (4). These distance estimates are then fused through triangulation to establish the

relationship between the measured ranges and the predicted states x_k during the weight-update step.

While this PF framework performs well under ideal conditions, its performance can degrade significantly in real-world scenarios. This is primarily due to the presence of outliers in sensor measurements [33]. Outliers, which may result from measurement noise, interference, or other unexpected phenomena, can skew the estimated state by disproportionately affecting the particle weights. This is because the PF relies on the likelihood function to update the weights of the particles, and outliers can lead to incorrect weight updates, resulting in poor state estimates and increased variance. This sensitivity to outliers is a critical limitation that can undermine the accuracy and robustness of the PF, necessitating additional strategies or alternative approaches are needed to mitigate the impact of such anomalies [34].

B. Outlier-Robust Particle Filter

In this work, to address the outlier problems in sensor measurements, a new outlier-robust particle filter (RPF) is derived. Unlike the PF in Algorithm 1 that models the likelihood PDF with a single noise model, this approach uses two noise models. Let $s \in \{1, 2\}$ denote the noise models, where s_1 corresponds to a multivariate Gaussian distribution, and s_2 corresponds to a multivariate Student's T distribution. The hypothesis indicator $\mathcal{H}_{s,k}$ specifies the selection of the s-th noise model at a specific time step k. The likelihood of transitioning between these noise models is characterized by the transition probabilities, represented as $\mathbf{\Pi}_{s,k}$. This matrix outlines the probability of switching from one noise model to another during a particular time step. Using the transition matrix and the state from the previous time step $k-1$, Eq. (7) can be re-expressed as Eq. (14):

$$p(\mathbf{x}_{k-1}|\mathbf{z}_{1:k-1}) \approx \sum_{i=1}^{N_p} \left(w_{k-1}^{(i)} \delta(\mathbf{x}_{k-1} - \mathbf{x}_{k-1}^{(i)}) \right) \times \sum_{s=1}^{S} \mathbf{\Pi}_{s,k-1}. \tag{14}$$

At a given time step k, assume that the particles are sampled based on a proposal distribution $\mathbf{x}_k^{(i)} \sim q(\mathbf{x}_k|\mathbf{x}_{k-1}^{(i)}, \mathbf{z}_k)$. Under the hypothesis $\mathcal{H}_{k,s}$ where $s \in \{1, 2\}$, the corresponding weights can be calculated recursively as Eq. (15):

$$w_{s,k}^{(i)} \propto w_{k-1}^{(i)} \frac{p_s(\mathbf{z}_k|\hat{\mathbf{x}}_k^{(i)}) p(\hat{\mathbf{x}}_k^{(i)}|\mathbf{x}_{k-1}^{(i)})}{q(\hat{\mathbf{x}}_k^{(i)}|\mathbf{x}_{k-1}^{(i)}, \mathbf{z}_k)}, \tag{15}$$

where, $p_s(\mathbf{z}_k|\hat{\mathbf{x}}_k^{(i)})$ represents the likelihood function corresponding to $\mathcal{H}_{s,k}$, given by Eq. (16):

$$p_s(\mathbf{z}_k|\hat{\mathbf{x}}_k^{(i)}) = \begin{cases} \text{Eq. (5)} & \text{for } s_1 \\ \text{Eq. (6)} & \text{for } s_2 \end{cases}. \tag{16}$$

Next, by choosing the proposal important density $q(\hat{\mathbf{x}}_k^{(i)}|\mathbf{x}_{k-1}^{(i)}, \mathbf{z}_k) = p(\hat{\mathbf{x}}_k^{(i)}|\mathbf{x}_{k-1}^{(i)})$, the weights simplifies to Eq. (17):

$$w_{s,k}^{(i)} \propto w_{k-1}^{(i)} p_s(\mathbf{z}_k|\hat{\mathbf{x}}_k^{(i)}), \tag{17}$$

and normalized by Eq. (18):

$$\hat{w}_{s,k}^{(i)} = w_{s,k}^{(i)} / \sum_{i=1}^{N_p} w_{s,k}^{(i)}. \tag{18}$$

Algorithm 2 The Outlier-Robust Particle Filter (RPF).

(1) Input: Initialization

Set the measurement noise model transition probability: $\mathbf{\Pi}_{s,0}$ for $s \in \{1, 2\}$.

for $k = 0$ **do**
  for $i = 1, \ldots, N_p$ **do**
    Samples: $\{\mathbf{x}_0^{(i)} \sim q(\mathbf{x}_0)\}$.
    Set initial weights: $w_0^{(i)} = 1/N_p$.
  end for
end for

for $k = 1, \ldots, endtime$ **do**
  for $i = 1, \ldots, N_p$ **do**
    (2) Prediction Step
    Propagate the particles $\mathbf{x}_k^{(i)}$ using eq. (1).
    Generate measurements $\mathbf{z}_k^{(i)}$ using eq. (4).

    (3) Measurement Update
    Calculate the measurement likelihood: $p_s(\mathbf{z}_k|\mathbf{x}_k^{(i)})$ where

$$\mathbf{z}_k \sim \begin{cases} \mathcal{N}(0, \mathbf{R}_k), & \text{for } s_1. \\ St(\mu, \hat{\mathbf{\Sigma}}, v), & \text{for } s_2. \end{cases}$$

    Calculate the noise models marginal likelihood $p_s(\mathbf{z}_k|\mathbf{z}_{k-1}) = w_{k-1}^{(i)} \times p_s(\mathbf{z}_k|\hat{\mathbf{x}}_k^{(i)})$ for $s \in \{1, 2\}$.
    Update the weights $w_{s,k}^{(i)}$ for $s \in \{1, 2\}$ using eq. (11).
  end for
  Normalize the weights: $\hat{w}_k^{(i)} = w_k^{(i)} / \sum_{i=1}^{N_p} w_k^{(i)}$.
  Noise transition probability:

$$\mathbf{\Pi}_{s,k} = \frac{\mathbf{\Pi}_{s,k-1}^{\varphi}}{\sum_{s=1}^{S} \mathbf{\Pi}_{s,k-1}^{\varphi}} \text{ for } s \in \{1, 2\}.$$

  Update the noise transition probability:

$$\hat{\mathbf{\Pi}}_{s,k} = \frac{\mathbf{\Pi}_{s,k} \times p_s(\mathbf{z}_k|\mathbf{z}_{k-1})}{\sum_{s=1}^{S} \mathbf{\Pi}_{s,k} \times p_s(\mathbf{z}_k|\mathbf{z}_{k-1})} \text{ for } s \in \{1, 2\}.$$

  The posterior PDF:

$$p(\mathbf{x}_k|\mathbf{z}_{1:k}) = \sum_{i=1}^{N_p} \hat{w}_{s,k}^{(i)} \cdot \delta\left(\mathbf{x}_k^{(i)} - \hat{\mathbf{x}}_{s,k}^{(i)} \right) \cdot \sum_{s=1}^{S} \mathbf{\Pi}_{s,k}.$$

  (4) Output: The estimated state:

$$\hat{\mathbf{x}}_k = \mathbb{E}[\mathbf{x}_k|\mathbf{z}_{1:k}] = \sum_{s=1}^{S} \sum_{i=1}^{N_p} \hat{w}_{s,k}^{(i)} \cdot \hat{\mathbf{x}}_{s,k}^{(i)} \cdot \mathbf{\Pi}_{s,k}.$$

  (5) Resampling Step
  Set the threshold sample size: $N_{thresh} = N_p/10$.
  Calculate the effective sample size: $N_{eff} = 1/\sum_{i=1}^{N_p} (\hat{w}_k^{(i)})^2$
  if $N_{eff} < N_{thresh}$
    The metropolis resampling method is applied.
  end if
end for

The transition probability of the $\mathcal{H}_{s,k-1}$ is given by Eq. (19):

$$\mathbf{\Pi}_{s,k-1} = \frac{\mathbf{\Pi}^{\varphi}_{s,k-1}}{\sum_{s=1}^{S} \mathbf{\Pi}^{\varphi}_{s,k-1}}, \tag{19}$$

where, $\varphi \in [0, 1]$ represents the forgetting factor. Utilizing Bayes' theorem, the transition probability for $\mathcal{H}_{s,k}$ is calculated recursively as

$$\mathbf{\Pi}_{s,k} = \frac{\pi^{\varphi}_{s,k-1}\ p_s(\mathbf{z}_k|\mathbf{z}_{k-1})}{\sum_{s=1}^{S} \mathbf{\Pi}^{\varphi}_{s,k-1}\ p_s(\mathbf{z}_k|\mathbf{z}_{k-1})}. \tag{20}$$

Eq. (20) provides an update to each hypothesis probability by blending the prior belief (through the forgetting factor φ) with the marginal likelihood of the new measurement. If the RSS observation aligns closely with Gaussian assumptions, the Gaussian hypothesis is reinforced; if it exhibits a large deviation, the Student's-T hypothesis gains prominence. $p_s(\mathbf{z}_k|\mathbf{z}_{k-1})$ represents the marginal likelihood for $\mathcal{H}_{s,k}$, where the integration is performed over the entire state space of the system described as

$$p_s(z_k|z_{k-1}) = \int_{x_k \in \mathbb{R}^n} p_s(z_k|x_k)\, p(x_k|z_{k-1})\, dx_k. \tag{21}$$

Since $p(\mathbf{x}_k|\mathbf{z}_{k-1}) \approx \sum_{i=1}^{N_p} w^{(i)}_{k-1} \delta_{\hat{\mathbf{x}}^{(i)}_k}$, the integral in Eq. (21) is approximated by Eq. (22):

$$p_s(\mathbf{z}_k|\mathbf{z}_{k-1}) \approx \sum_{i=1}^{N_p} w^{(i)}_{k-1}\ p_s(\mathbf{z}_k|\hat{\mathbf{x}}^{(i)}_k). \tag{22}$$

Finally, the posterior PDF at time step k is formulated as Eq. (23) and Eq. (24):

$$p(\mathbf{x}_k|\mathbf{z}_{1:k}) = \sum_{s=1}^{S} p_s(\mathbf{x}_{s,k}|\mathbf{z}_k) \times \mathbf{\Pi}_{s,k}, \tag{23}$$

$$= \sum_{s=1}^{S} \sum_{i=1}^{N_p} \left(w^{(i)}_{s,k} \delta_{\hat{\mathbf{x}}^{(i)}_k} \times \mathbf{\Pi}_{s,k} \right). \tag{24}$$

Particle weights under model s are computed via the likelihood $p_s(z_k|z_{k-1})$. For the Student's-T hypothesis, a degrees of freedom, ν parameter of 3 is chosen to provide sufficient robustness against heavy-tailed outliers without incurring excessive computational cost. The filter employs N_p = 200 particles; whenever fewer than 20 particles (i.e., 10%) carry significant weight, Metropolis resampling is performed to restore diversity. Algorithm 2 summarises the RPF.

IV. Experiments and Results

This section evaluates the performance of the PF and the RPF using both simulated and real-world sensor data for indoor positioning of mobile users. The focus is on estimating the positions of mobile users from Wi-Fi sensor readings, which are often affected by outliers. The simulated data is generated by adding measurement noise and a specified percentage of outliers to a predefined trajectory, emulating real-world conditions. Real-world data consists of Wi-Fi signal strength measurements collected in an indoor environment, reflecting practical challenges such as multipath propagation and signal occlusion.

TABLE I. Simulation Parameters for PF and RPF

Parameter and Symbol	Value and Unit PF	Value and Unit RPF

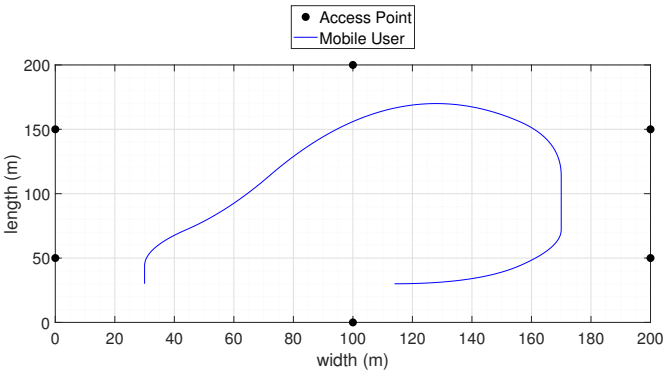

Fig. 1. Mobile user trajectory and access point deployment.

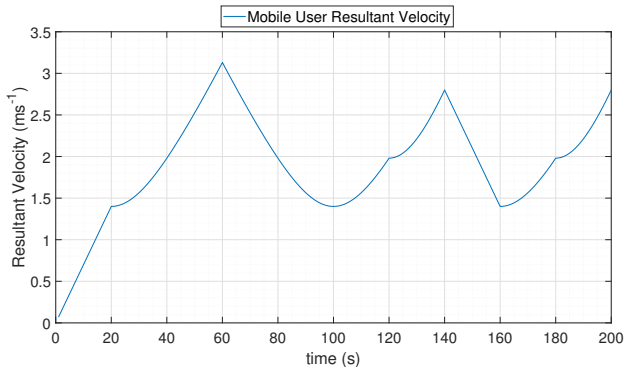

Fig. 2. Mobile user resultant velocity.

A. Simulated Data

Consider a 2D scenario, where a mobile user moves within an indoor building, following the dynamics described by Eq. (1). The user's position is indirectly observed via RSS measurements, modeled by Eq. (4), which are transmitted by the Wi-Fi APs and received by the mobile user's device. Fig. 1 illustrates the mobile user's trajectory alongside the network deployment. The trajectory represents the user's path over 200 time steps, indexed by k, while the network deployment shows

the placement of APs within the indoor environment. Fig. 2 shows the resultant speed (magnitude of velocity) of the mobile user at each time step in the simulated scenario. In the simulation, acceleration is set to zero to approximate the user's walking at a constant speed, indicating that each control input $\mathbf{u}_k$ results in constant-speed motion between changes in direction. The network covers an area of 200 m × 200 m, with the APs functioning as transmitter nodes and the mobile user serving as the receiver node. The observed sensor readings correspond to the received Wi-Fi signals, include outliers, that are randomly distributed such that outliers occur in 50% of the time steps, while the remaining 50% of the measurements are unaffected. When outliers are present, the measurements are simulated using a multivariate Student's-T distribution, whereas unaffected data follow a multivariate Gaussian distribution. Here, the control input vector $\mathbf{u}_k$ represents discrete movement commands in the two-dimensional plane, specifically steps to the left, right, up, or down, applied at each time step. The forgetting factor φ =0.5 balances responsiveness to new measurements with retention of past model-selection history, preventing both abrupt and overly sluggish switching between noise models. The simulation parameters are detailed in Table I and the root mean square error (RMSE) is employed as the evaluation metric to assess the accuracy of the PF and the RPF in estimating the position, velocity, and acceleration of the mobile user in the indoor environment.

Fig. 3 compares the estimated trajectories of the mobile user within the network, obtained through the PF and RPF algorithms, based on a single simulation run. It shows that the RPF consistently tracks the mobile user's path more accurately than the PF in most of the time steps. Notably, during periods when the mobile user makes turns, such as between time steps $k = 160$ to $k = 170$, the RPF achieves lower tracking error compared to the PF, as measured by the RMSE.

In the subsequent experiments, the simulation is repeated 100 times under different combinations of noise and outlier distributions and the average RMSE is computed to assess tracking performance. Fig. 4 illustrates the mean RMSE for position estimation for both the PF and RPF algorithms. It is observed that the RPF algorithm outperforms the PF algorithm, achieving a substantially lower RMSE. Specifically, the mean RMSE for the RPF is 9.5208 meters, whereas for the PF it is 15.8734 meters. This results is a significant reduction of approximately 40.02% in RMSE when using the RPF algorithm, highlighting its improved position estimation accuracy as reflected by lower RMSE values.

Fig. 5 illustrates the mean RMSE for velocity estimation using both the PF and RPF algorithms. The results indicate that the RPF algorithm consistently outperforms the PF algorithm in velocity estimation. Specifically, the mean RMSE for velocity using the RPF is 0.1252 ms^{-1}, which is significantly lower than the 0.2035 ms^{-1} observed with the PF algorithm. This represents a reduction of approximately 38.48% in RMSE when using the RPF, indicating improved velocity estimation accuracy, with a lower RMSE compared to the standard method.

Finally, Fig. 6 presents the mean RMSE for acceleration estimation using both the PF and RPF algorithms. It is shows that the RPF consistently achieves lower RMSE for acceleration throughout the simulation time steps. Specifically, the mean RMSE for acceleration with the RPF is $5.7339 \times 10^{-5} ms^{-2}$,

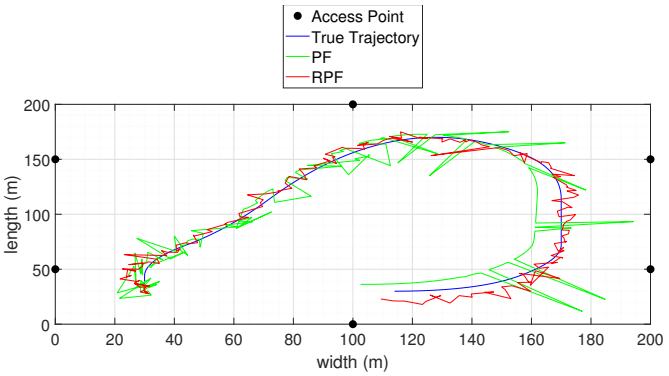

Fig. 3. Estimated trajectory by Particle Filter (PF) and Robust Particle Filter (RPF).

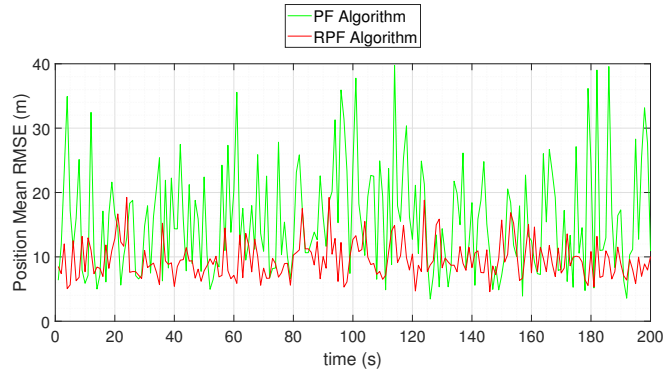

Fig. 4. Mean RMSE of mobile user position using PF and RPF.

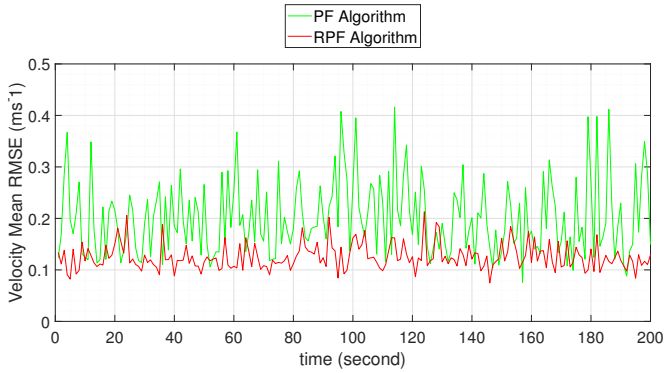

Fig. 5. Mean RMSE of mobile user velocity using PF and RPF.

which is considerably lower than the 1.6767×10^{-4} ms^{-2} observed with the PF. This corresponds to a reduction of approximately 65.80% in RMSE when using the RPF, highlighting its improved accuracy in estimating the acceleration of a mobile user, as indicated by a lower acceleration estimation error.

Overall, the results demonstrate that the RPF outperforms the PF in estimating position, velocity, and acceleration of

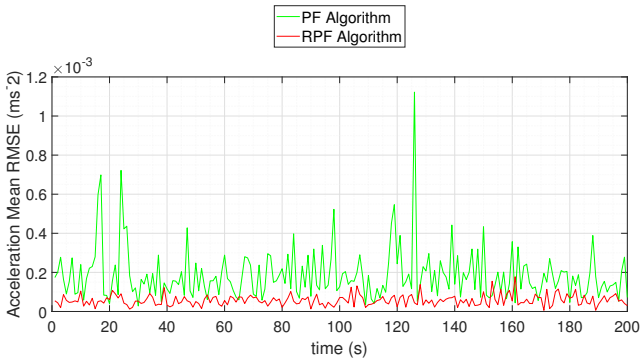

Fig. 6. Mean RMSE of mobile user acceleration using PF and RPF.

a mobile user in indoor environment. The RPF consistently achieves lower RMSE values across all metrics, indicating significant improvements over the PF. This suggests that outliers in RSS measurements can diminish the accuracy of the PF, while the RPF remains robust to such disturbances. As a result, the RPF is more effective at handling outliers in the sensor measurements compared to the PF. Runtime measurements on MATLAB show that a single simulation run takes approximately 0.24 seconds for the PF and 0.33 seconds for the RPF, highlighting the additional computational cost associated with the dual-noise likelihood evaluation. The presence of outliers in highly obstructed and complex indoor environments is expected to significantly degrade the position estimation accuracy of both filters. However, in such outlier-affected scenarios, the RPF consistently outperforms the PF due to its more robust dual-noise likelihood evaluation strategy.

B. Real-World Data

The real-world data was collected at the Melinsung Summer Bay Resort Apartment in Papar, Sabah, a three-room apartment with a total area of 680 square feet. The experimental setup employed the ESP-32-WROOM-32 module, shown in Fig. 7, which served as both the AP and the receiver point (RP). AP and RPs are placed at ground level in the indoor setup (height = 0 m). The parameters z_0 and β in Eq. (4) vary depending on the environment [35], thus the experimental setup, as shown in Fig. 8, was designed to interpolate these parameter values. RPs were positioned at distances ranging from 0.5 to 7.0 meters from the APs. To account for temporal variations and ensure accuracy, measurements were repeated multiple times at different times of the day and under varying environmental conditions. The RSS values were captured and recorded in real-time using the Arduino IDE's serial monitor [36].

To streamline data collection, the PLX-DAQ version 2.11 [37] was utilized, enabling efficient transfer of the readings directly from the serial monitor to an Excel file. The RSS values were collected by connecting the ESP-32-WROOM-32 to a laptop, allowing for real-time data acquisition. The collected RSS measurements visualized in Fig. 9 illustrates the relationship between signal strength and distance. A logarithmic interpolation was applied to identify the optimal fit for the RSS measurements by reducing the squared discrepancies between the observed data points and the corresponding values on the curve. As a result, the parameter z_0 was estimated at -68.4694 dBm, and the path loss exponent β was calculated to be 0.71349, indicating how the RSS decreases logarithmically as the distance increases, given by in both the PF and RPF as a reliable representation of the signal propagation characteristics within the indoor environment.

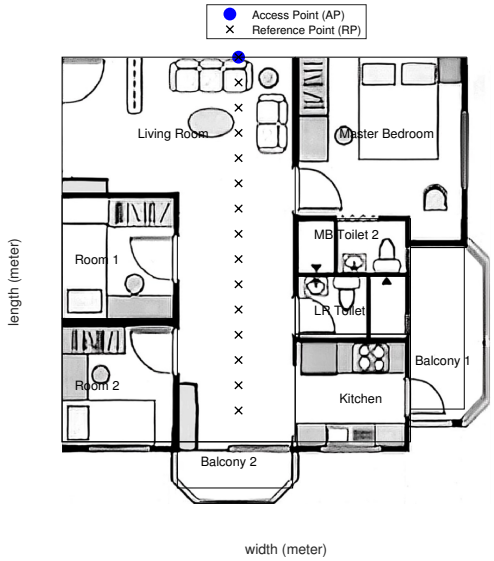

Fig. 8. Transmitter node and receiver node locations for collecting calibrated data.

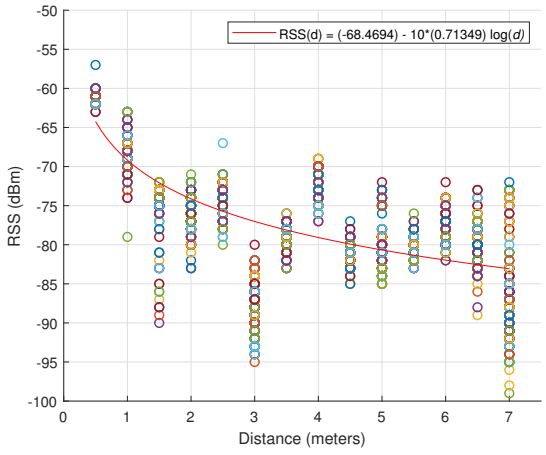

Fig. 9. An interpolated log-normal path loss model derived from calibrated data.

$$Z = -68.4694 - 10 * (0.71349)\log(d) + v, \qquad (25)$$

where, v is modeled using a zero-mean Gaussian distribution. It provides the interpolated measurement model, which is used

Next, actual Wi-Fi signal measurements were collected from a mobile user using the experimental setup shown in Fig. 10, which shows the indoor floor plan with four strategically placed Wi-Fi APs and the single 17-second user trajectory from one representative trial. The experimental results are derived from 20 independent real-world trials, each following the same 17-second mobile user trajectory but yielding distinct RSS readings (including natural outliers), and the final outcomes are based on the mean measurements to ensure robustness and reliability of the positioning performance evaluation. As the receiver traversed various locations, the user's trajectory was mapped while capturing RSS values from the Wi-Fi APs. The collected RSS measurements along this trajectory was used to evaluate the performance of the PF and RPF algorithms in accurately estimating the user's position within the indoor environment. During the prediction stage of both algorithms, the measurement model formulated in Eq. (25) was applied.

Fig. 11 presents a comparison of the mean RMSE between the PF and RPF, computed over 17 time steps from 20 repeated experiments using collected Wi-Fi RSS measurements. The data demonstrate that the RMSE of the RPF is consistently lower than that of the PF across all time steps. Notably, the PF shows a significant spike in RMSE at the 13^{th} time step, reaching a value of 43.89825, likely due to outlier measurements or non-Gaussian noise, whereas the RPF remains robust with an RMSE of 0.91450 at the same time step. Overall, the mean RMSE of the PF is 10.27197, while that of the RPF is 0.65683, the difference in RMSE between PF and RPF is 9.61515 reflecting a 93.61% improvement in RPF, highlighting that the RPF has successfully mitigated the effect of outliers and overcome the limitations of the PF.

V. Conclusion

In this study, the performance of the Particle Filter (PF) and the proposed outlier-robust particle filter (RPF) algorithms was thoroughly evaluated using both simulated and real-world data. The results from the simulated data demonstrated that the RPF consistently outperforms the PF in terms of position, velocity, and acceleration estimation. The RPF achieved markedly reduced root mean square error (RMSE) values, with reductions of approximately 40.02% in position, 38.48% in velocity, and 65.80% in acceleration compared to the PF. The real-world experiments further confirmed the robustness of the RPF. By applying a calibrated log-normal path loss model to the collected Wi-Fi RSS data, the RPF outperformed the PF in position estimation accuracy. Notably, the RPF showed a 93.61% improvement in positioning accuracy, with a significant reduction in RMSE at each time step. These results highlight the RPF's robustness in maintaining accurate position estimates, even in the presence of measurement noise and outliers. Therefore the proposed RPF offers a robust solution for tracking and positioning in environments where outliers or noise are prevalent, making it a valuable approach for real-world positioning applications. Future work includes evaluation under more complex indoor scenarios such as multiple trajectories, varied AP deployments, and obstructed layouts with dynamic obstacles, along with integration of map constraints and multi-sensor fusion (e.g., UWB/AoA) to improve positioning robustness in highly non-linear, cluttered environments.

Acknowledgment

The authors express their gratitude to the Ministry of Higher Education Malaysia for providing funding through the Fundamental Research Grant Scheme (FRGS) under project number FRGS/1/2022/TK07/UMS/02/9. Appreciation is also extended to Universiti Malaysia Sabah for their invaluable support in facilitating this research.

***Abstract*—Recently, the demand for intelligent, energy-efficient lighting systems has increased due to rising environmental concerns and increasing electricity consumption in smart room environment buildings. Conventional lighting systems often operate inefficiently, using outdated bulb technologies and lacking automation, which results in substantial energy waste, especially in rooms with variable occupancy. Lighting significantly contributes to energy consumption in indoor spaces, which presents vast opportunities for smart lighting model development through automation and adaptive control. This study proposes a smart lighting system model for room environments that dynamically adapts to user presence and supports diverse light bulb types. The study analyzes energy usage while maintaining automatic light control and operational effectiveness through simulation. The system is developed using AnyLogic by integrating agent-based and discrete event simulation to model occupant behavior and manage event-driven lighting logic. It incorporates sensors, smart door mechanisms, and energy-measuring processes, all powered by solar energy and managed through battery storage. The system dynamically adjusts lighting based on occupancy, minimizing idle energy usage for the room. LED bulbs offer more promising energy efficiency, while incandescent bulbs show the highest consumption. The outcome provides a visualized simulation model for designing adaptive lighting systems and reinforces the potential to enhance energy efficiency to support sustainability in smart room applications.**

***Keywords*—Bulb; energy; light; model; simulation**

I. Introduction

In an era characterized by boosted environmental awareness and resource limitations, the implementation of efficient lighting systems has become a crucial aspect of energy management in commercial and residential buildings. With their substantial impact on electrical consumption, optimizing lighting systems is essential for reducing overall energy usage and advancing sustainability initiatives. With urbanization and increasing indoor activity, there has been a critical push towards optimizing lighting technologies [1] to enhance energy efficiency and environmental sustainability. The advent of smart room technology, powered by automation and data-driven modeling, enables efficient energy management through dynamic control of lighting. Modern intelligent lighting systems are no longer limited to manual operations; they now integrate occupancy sensors to optimize light intensity in real-time [2]. This results in a reduction of energy waste and operational costs while also enhancing environmental sustainability [3]. Conventional lighting systems, such as incandescent and halogen bulbs, though widely used, are characterized by higher energy demands and shorter lifespans. In contrast, compact fluorescent lamps (CFLs) and light-emitting diodes (LEDs) [4] offer higher lighting efficacy, longer durability, and better energy performance. These diverse bulb types, while functionally different, collectively influence how energy is consumed in smart room environments. A significant challenge in designing energy-efficient lighting for indoor environments lies in accommodating the diverse characteristics of light bulbs such as incandescent, halogen, CFL, and LED, each with distinct energy consumption patterns and lighting efficacy.

In smart room environment, automation is transforming the management of lighting through the integration of sensing devices, energy data, and user behavior. Smart lighting systems equipped with motion sensors, ambient light detectors can dynamically control bulb power and operating time. The purpose is to ensure that lighting is delivered only when and where it is needed, thereby minimizing unnecessary consumption and improving energy efficiency. To analyze the efficiency of smart lighting systems, simulation-based modeling plays a crucial role [5], [6]. AnyLogic, a multi-method simulation tool, supports both Agent-Based Simulation (ABS) and Discrete Event Simulation (DES), enabling a detailed investigation of human-light interaction and dynamic system behaviors. These simulation paradigms are essential for mimicking real-world room scenarios that involve diverse bulb types and variable occupancy patterns. The present study leverages AnyLogic to simulate smart lighting control within a room environment, focusing on the behavioral dynamics of incandescent, halogen, CFL, and LED bulbs under various conditions.

Fig. 1 illustrates the basic structure of a smart lighting system for the room environment, which integrates motion sensors, ambient light sensors, and the energy measuring module. Each component of this structure has shown the basic strategy of reflecting real-time interactions, where automatic lighting is turned on and off based on user presence, lighting control is adjusted, and energy consumption is recorded across bulb types. This system-level visualization reinforces the need for adaptable lighting control systems that incorporate diverse bulb types for optimized energy consumption.

Despite advances in lighting control with energy-saving strategies, many existing lighting systems remain manually controlled or inadequately automated, leading to considerable energy wastage. Traditional systems often operate lights irrespective of occupancy status, resulting in excessive and

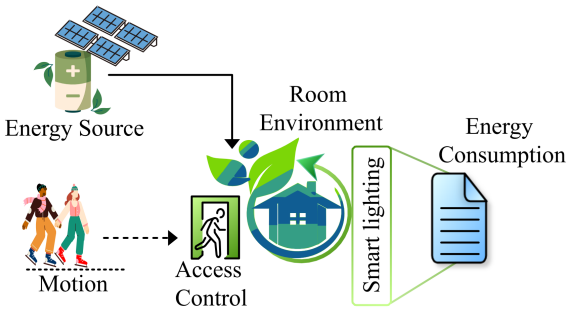

Fig. 1. Basic structure of smart lighting system for room environment.

inefficient usage. This is particularly problematic in residential and commercial rooms, where lighting accounts for a large portion of electricity energy [7], [8]. Moreover, while LED or CFL bulbs are substantially more efficient than traditional incandescent or halogen lamps, their potential is often underutilized due to a lack of an optimized structural approach. Smart lighting systems that adjust based on occupancy and ambient light offer promise but are hindered by barriers such as high initial costs, lack of integration with diverse bulb types, and limited modeling tools that can represent complex interactive behavior within smart rooms. Furthermore, real-world visualization and validation of energy savings through simulation tools like AnyLogic remains limited explored. This research addresses the gap by designing a simulation model that supports analysis of various lighting technologies within a smart room ecosystem, aiming to reduce unnecessary energy consumption and improve lighting efficiency in the room environment [9].

The rapid global increase in energy demand, coupled with environmental concerns and unattended light usage, motivates the adoption of smart lighting solutions. Since lighting constitutes a significant portion of energy consumption in room environments, adopting smart lighting controls is crucial for enhancing energy efficiency. The motivation for this research stems from the need to simulate and visualize a smart lighting simulation model that can dynamically respond to user presence [10] and ambient conditions while optimizing energy usage across different bulb types. By simulating and analyzing the performance of diverse bulb types under varying control schemes of a smart system that adapts in real-time, this study aims to provide an energy-efficient smart lighting solution adaptable to room environments and future green buildings. The study involves developing a simulation model in AnyLogic by integrating ABS and DES [11] for sensor-triggered lighting events with human behavior modeling. The room environment is modeled as an agent containing motion and light sensors that interact with diverse bulb agents. Each bulb type, such as incandescent, halogen, CFL, and LED is defined with specific wattage and bulb efficiency parameters. Simulation runs are conducted across various scenarios with differing occupancy rates, light availability, and bulb mixes. Energy consumption metrics are collected and analyzed to assess the performance and efficiency of each configuration. Accordingly, this study conveys the following contributions:

- This study provides a smart lighting system with operational process flow in room environments that serves automatic light management for diverse light bulbs.
- This study develops a smart lighting model with visualization using AnyLogic that integrates agent-based and discrete-event simulation for deployment in room environments.
- A comparative energy analysis is conducted to evaluate the performance of the proposed smart lighting systems across diverse bulb types.

In the upcoming sections, it covers the following aspects of this work. Section II provides an overview of the related studies, while Section III introduces the entire process and design of this work. Section IV presents the results and discussion of the exploration of this work. Finally, Section V concludes this study.

II. Related Work

In recent years, the increasing demand for energy-efficient lighting has intensified research efforts into smart control systems, user behavior, and advanced bulb technologies within room-based smart lighting environments. This section reviews notable studies on lighting energy optimization, modeling approaches, and performance assessments to contextualize the existing work.

Niko Gentile [12] in one work focuses on user behavior in lighting control, highlighting the role of dimming extent, interface design, heuristics, and feedback in reducing energy consumption. It identifies behavioral categories influencing energy efficiency and proposes strategies to nudge users toward sustainable habits. Though not simulation-based or bulb-specific, the study emphasizes human-centered lighting controls and estimates potential energy savings, highlighting the importance of integrating psychological and technical aspects for holistic lighting solutions. In another work, Campano et al. [13] presents a dynamic analysis of smart lighting controls based on daylight metrics and user requirements. It proposes three control systems as switch-based, dimmer-based, and sensor-driven, assessed using daylight autonomy metrics in test cells over one year. Although it does not simulate different bulb types, it effectively uses sensor-linked control schemes to reduce electric lighting energy savings. The study of Pašić and Imamović [14] compares the energy efficiency of LED bulbs against traditional ones like incandescent and halogen. Using direct energy consumption measurements, the authors establish LEDs as significantly more efficient. The work focuses on empirical comparison without simulation tools, and while it lacks dynamic modeling, it underscores the performance superiority of LEDs, which supports their integration into smart lighting frameworks for sustainable building applications. Besides, Ayaz et al. [15] proposed an urban street lighting system powered by hybrid renewable energy using solar and wind, integrating smart control for light intensity based on pedestrian and vehicle detection. The study emphasizes distributed generation and outlines practical system deployment. Although it focuses on outdoor lighting, the operational principles led by adaptive lighting control and renewable energy integration are directly applicable to indoor smart lighting simulations.

Moreover, Powers and Saad [16] presented lighting energy use in university buildings and models energy savings from retrofitting with LED lights and occupancy sensors. Using Python-based numerical simulation, the study demonstrates energy reduction and CO2 emission savings. Although it doesn't simulate bulb diversity, it emphasizes the effectiveness of sensor-linked LED systems and calculates economic payback, with a break-even point for the retrofit investment. In one study, Tsaknakis et al. [17] introduced a holistic smart building management system for elderly care, integrating lighting, HVAC, and battery storage. Using EnergyPlus for simulation, the system employs Approximate Dynamic Programming to optimize visual comfort, energy cost, and load safety. The lighting system adjusts based on daylight and occupancy. Though not bulb-specific, the integration of comfort and efficiency aligns with smart room lighting strategies in our study.

In addition, Singh and Narwal [18] conducted an audit-focused study that evaluates energy consumption in residential lighting systems and suggests LED and CFL replacements for GLS and tube lights. It lacks simulation or smart control strategies, but it emphasizes practical retrofitting approaches. This warehouse-focused study by Füchtenhans et al. [19] uses simulation to evaluate smart lighting strategies, comparing three operational schemes against conventional lighting. The system adapts to worker presence and order-picking schedules. Though specific bulb types are not detailed, LED-compatible smart systems are implied. The simulation evaluates warehouse layout, worker movement, and lighting control, offering insights into energy savings and system design trade-offs. The authors of another study, Imamguluyev et al. [20] highlighted the potential of fuzzy logic control (FLC) for optimizing lighting systems. FLC adapts illumination in real time based on occupancy and ambient light, enhancing energy efficiency. It discusses implementation challenges and presents real-world cases. Although not bulb-type-specific, the adaptive control mechanism resonates with our focus on modeling intelligent lighting systems that balance energy use and user comfort in room environments.

Most prior research focuses just on LED-based systems, specific-use contexts such as warehouses or elderly homes, or lacks integrated simulation frameworks that present real-time lighting systems. While some studies focus on real-world deployment with basic tools such as energy audits and retrofits, others utilize some modeling platforms like EnergyPlus or bespoke simulation scripts to evaluate cost and energy benefits. However, few papers holistically model lighting systems in room-level indoor environments using diverse bulb types. More critically, no studies combine agent-based simulation (ABS) with discrete-event simulation (DES) to support real-time smart lighting scenarios adaptable across CFL, LED, halogen, and incandescent bulbs. However, based on the problems identified in existing studies, the research question of this work is stated as: What type of simulation model is suitable for developing a smart lighting system, and how can ABS and DES modelling in AnyLogic effectively support real-time lighting control in room environments with diverse bulb types for energy analysis and system responsiveness? It presents a strong opportunity for the proposed study.

III. Methodology

This study introduces a simulation-based modeling view and methods for analyzing energy-efficient smart lighting in room environments supporting diverse bulb types, namely incandescent, halogen, compact fluorescent (CFL), and light-emitting diode (LED). The model is designed using AnyLogic simulation software [21], which enables a modeling approach combining Agent-Based Simulation (ABS) and Discrete Event Simulation (DES). This simulation modeling is crucial for capturing user behavior, occupancy sensors, and light sensors that control lighting conditions for the room environment. This methodology enables a comprehensive evaluation of each lighting scenario under varying usage conditions. The main design and the coordination process of energy-efficient smart lighting in room environments supporting diverse bulb types are illustrated as follows.

A. Overview of Conceptual Model for Smart Room Lighting System

Fig. 2 illustrates the proposed conceptual model for a smart lighting system designed to operate efficiently within a room environment using sensor-based automation and solar energy sources. The core elements of the model include occupants, a smart door, occupancy sensors, diverse room lights (Light 1 to Light 4), a solar energy source, a battery, a smart meter, and an energy analysis module. This system contains incandescent, halogen, CFL, and LED as Light 1, 2, 3, and 4, respectively. When an occupant approaches the room, the occupancy sensor detects their presence and triggers the smart door mechanism to open. Once the occupant enters, the system identifies the transition from an empty to an occupied state and responds by switching on the room lights. Each light is activated based on the specified capacity, influenced by sensor feedback and occupancy positioning.

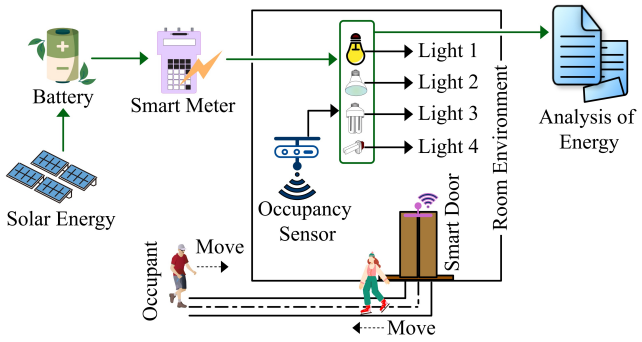

Fig. 2. Proposed model for smart lighting system in the room environment.

Energy for lighting is supplied from a solar panel system connected to a battery and charge controller. This configuration allows the room to operate on solar energy as renewable energy, reducing grid dependency. When lights are ON, a smart meter continuously records energy consumption and efficiency by providing essential data for energy analysis. This analysis helps assess lighting performance under different occupancy conditions, allowing optimization of energy usage based on real-time. Crucially, this model enables automatic decision-making. If multiple occupants are present, the lights remain

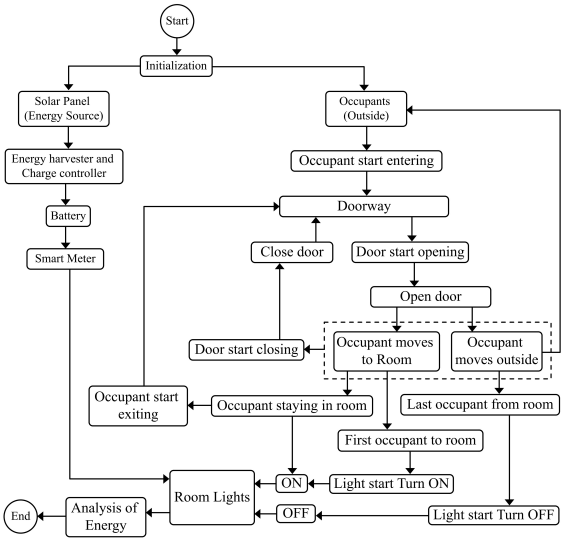

Fig. 3. Operational process flow for smart lighting system in the room environment.

ON. When the last occupant exits, the system detects the room's transition to an unoccupied state and turns off all lights, ensuring zero idle energy consumption. The proposed model supports diverse bulb types, namely LED, CFL, incandescent, and halogen, though each has distinct power characteristics. The smart meter's data, in combination with energy usage from different bulbs, enables comparison across scenarios. This allows the simulation model to assess energy usage or consumption and lighting effectiveness. The occupant's behavior, like entry, exit, and duration of stay, forms the central loop that drives the smart system, ensuring that lighting is only active when necessary. Hence, the model leverages the integration of sensors, renewable energy, and intelligent control to deliver an energy-conscious smart lighting system.

B. Operational Process Flow for Room Light Environment

Fig. 3 presents a detailed operational process flow of the smart lighting system in a room environment, capturing the chronological steps and conditional logic for lighting and door control, occupant behavior, and energy management. The process starts when occupants are outside the room. Once an occupant approaches the doorway, the occupancy sensor detects movement, prompting the smart door to open. The system marks the first occupant entering the room if no one is inside, triggering the room lights to turn ON. After entry, the door automatically closes, and the system maintains lighting as long as at least one occupant remains. During the occupant's stay, if additional individuals enter, the system tracks the occupancy count. Lights remain ON until the last occupant exits. When an occupant starts to exit, the sensor again detects motion, triggering the door to open and then close after departure. Once the last occupant leaves, the lights switch OFF automatically. This logic for the smart room ensures zero energy wastage in unoccupied conditions.

The energy required for lighting is drawn from a solar panel connected to a battery via a charge controller. This stored energy is consumed when the lights are ON, and the smart meter records the power usage in real-time. Data from the energy supplied to the lighting system is used for the energy analysis of diverse light bulb types. The system analyzes energy metrics such as energy consumption, lighting duration, and energy efficiency per bulb type. Hence, this operational flow coordinates sensor-based detection, automated door and lighting control, and intelligent energy usage analysis for room environments.

C. Visualization and Demonstration of Room Lighting Simulation Model

The smart lighting simulation model for the room environment has been developed using AnyLogic simulation software, leveraging its statechart functionality to design dynamic behaviors. Fig. 4 demonstrates the statechart for automated door control within the smart room lighting system, which plays a vital role in synchronizing user access with the lighting control mechanism. The door can exist in one of four states, namely Closed, Opening, Open, and Closing. These states are dynamically triggered by user presence and transition logic. When the door is in the Closed state, according to Fig. 4(a), the system waits for a user detection event. In this case, room lights are OFF. However, when a user approaches the entrance and detects user motion through a sensor, the door transitions to the Opening state, which is shown in Fig. 4(b). During this stage, lights remain OFF until the user starts entering. Once the door reaches the Open state, as shown in Fig. 4(c), the user is allowed to enter, and lighting control is triggered. If it is the first user, the system activates room lights based on the bulb type. As the user finishes entry, the door transitions to the Closing state according to Fig. 4(d). If additional users are detected, the door reopens. Once all users have entered and the door is re-closed, the lights remain ON as long as user occupancy persists.

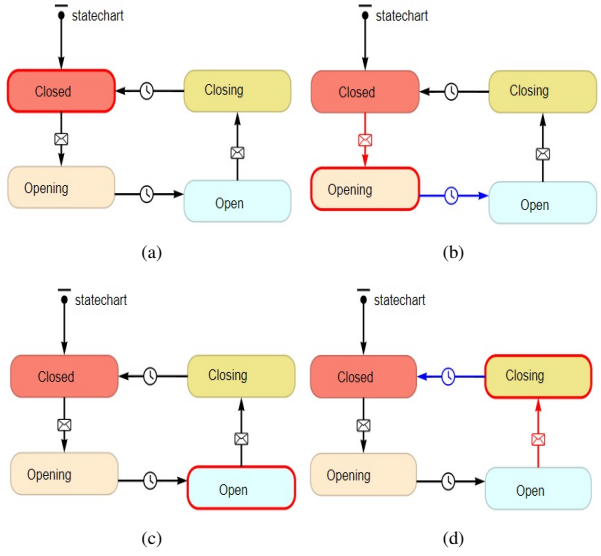

Fig. 4. Different door state transitions: (a) Closed; (b) Opening; (c) Open and (d) Closing.

Fig. 5 presents the statechart controlling user movement across four states, namely Outside, Entering, Inside, and Leaving, which influence the activation or deactivation of lighting

behavior based on user activity. When the user is in the Outside state, as shown in Fig. 5(a), the room remains unoccupied, and the lighting system is OFF. Upon detecting the motion sensor, it triggers the smart door to open, and the user transitions to Entering, which is depicted in Fig. 5(b), and simultaneously activates the lighting system based on the occupancy sensor. As the user transitions to the Inside state, like Fig. 5(c), lights remain ON continuously. During this stage, if multiple users are present, the light remains ON until the last user transitions to the Leaving state. The Leaving state, as demonstrated in Fig. 5(d), is activated when a user moves toward the exit. If the departing user is not the last, the lights remain ON. However, once the last user leaves, the system transitions to Outside, automatically turning lights OFF and logging the total energy consumed.

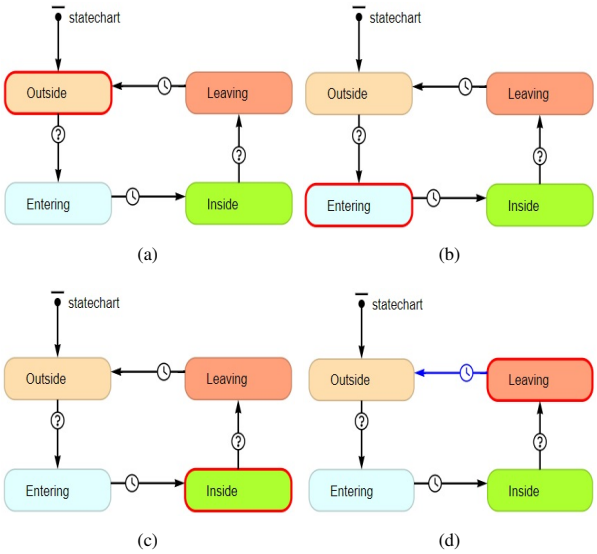

Fig. 5. User movement transitions in different cases: (a) Outside; (b) Entering; (c) Inside and (d) Leaving.

Algorithm 1 governs the smart lighting control logic by synchronizing user presence, door state, and light activation within the simulated room environment. When a user is detected near the door, it opens, updates the user state, and turns ON the lights based on the bulb type. Once inside, lights remain ON. When users exit, the door reopens, and lights turn OFF only if the room becomes unoccupied. Energy usage is logged dynamically, enabling adaptive lighting control based on occupancy and minimizing idle energy consumption.

Fig. 6, captured from the AnyLogic simulation runtime, visually represents the transitional states of a smart lighting system in a room environment, which highlights occupant behavior, door status, and lighting control through both 2D and 3D views. Fig. 6(a) and Fig. 6(b) illustrate the idle state, where all occupants are outside the room, the smart door remains closed, and the room lights are turned OFF. Thus, it minimizes unnecessary energy use. These states confirm that the system maintains a default OFF status in the absence of activity, conserving energy effectively. In another case, Fig. 6(c) shows this interaction in 2D, while Fig. 6(d) presents it from a 3D spatial perspective. These visuals emphasize the system's responsiveness to real-time human presence, maintaining optimal illumination as occupants move inward.

Algorithm 1 Smart lighting control based on door and user state transitions

Input:-
motionSensor: user detection for door functionality;
bulbType ← {LED, CFL, Halogen, Incandescent};
occupancySensor: user detection for light functionality;
roomUser: Number of users in the room;
doorState ← {Closed, Opening, Open, Closing};
userState ← {Outside, Entering, Inside, Leaving};
Output:-
lightStatus ← {ON, OFF}; energyUsage: energy consumption for different types of bulbs;

Initialize States
Set doorState ← Closed;
Set userState ← Outside;
Set lightStatus ← OFF;
Set roomUser ← 0;
while Simulation is running for entry event **do**
  if motionSensor = TRUE AND doorState = Closed **then**
    doorState ← Opening
    Activate door opening mechanism
    Wait for door open time duration
    doorState ← Open
    userState ← Entering
    roomUser ← roomUser + 1
    Call *Turn_ON_Lights*(bulbType)
    lightStatus ← ON
  end if
end while
while Transition to Inside **do**
  if userState = Entering AND *Light_ON* = TRUE **then**
    userState ← Inside
    Activate door closing mechanism
    doorState ← Closing
    Wait for door close time duration
    doorState ← Closed
  end if
  if userState = Inside AND user initiates exit AND doorState = Closed **then**
    doorState ← Opening
    Activate door opening mechanism
    Wait for door open time duration
    doorState ← Open
    userState ← Leaving
    roomUser ← roomUser - 1
    if roomUser = 0 **then**
      Call *Turn_OFF_Lights()*
      lightStatus ← OFF
      Record energyUsage in log
    end if
    userState ← Outside
    Activate door closing mechanism
    doorState ← Closing
    Wait for door close time duration
    doorState ← Closed
  end if
end while

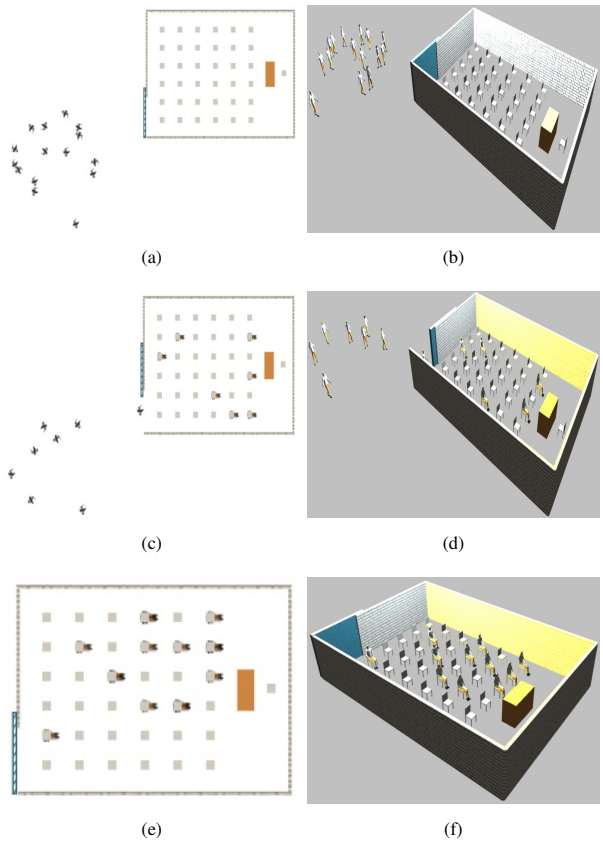

Fig. 6. Graphical layout: (a) Users are Outside when Door is closed in 2D; (b) Users are Outside when Door is closed in 3D; (c) Users are Entering when Door is opened in 2D; (d) Users are Entering when Door is opened in 3D.; (e) Users are InSide when Door is closed in 2D and (f) Users are InSide when Door is closed in 3D.

In this case, when a user is sensed at the door, and it opens, then the user enters the room, and automatically it turns ON the light bulb. Once all occupants have fully entered the room, the door closes again, and the lights remain ON, as depicted in Fig. 6(e) in 2D and Fig. 6(f) in 3D. This state reflects the active condition of the room, where lights are sustained to ensure visibility. The consistent light ON status confirms the system's awareness of active room use. These figures collectively showcase a seamless interaction between user presence, automated door control, and lighting behavior. This sequence of views validates the responsiveness and efficiency of the smart lighting system, where occupant-driven automation ensures both user convenience and optimal energy usage through intelligent control logic.

IV. Results and Discussion

To evaluate the effectiveness of the proposed smart lighting system in the room environment, a simulation model has been developed in AnyLogic software. This model allows for the simulation of basic scenarios of energy usage service and energy processing across different light bulb types. This section illustrates the results and analysis obtained from the simulation of the proposed smart lighting system for the room environment. The focus of the analysis is to assess the system's visualized responsiveness, energy usage, and efficiency based on occupancy patterns and diverse light bulb types. The smart lighting logic is triggered by user movements and the simulation dynamically adjusts the lighting status based on room occupancy. Door and user movements are governed by agent-based logic, while lighting events and energy analysis are modeled through discrete event simulation. The study demonstrates how intelligent control logic contributes to energy efficiency. The key performance metrics, namely energy usage, lighting duration, and bulb-wise energy profiles, are recorded. The output visualizations and plots extracted from the simulation runtime enable a comparative assessment of energy usage and efficiency in the model. This evaluation highlights the system's ability to conserve energy while demonstrating the effectiveness of adaptive lighting control supported by simulation.

A. Results

The simulation model for this work has been developed and executed using AnyLogic 8.9.4 Personal Learning Edition on a system configured with Windows 11, 64-bit, running on HP LAPTOP-2DHIQ60K. The machine is equipped with a 13th Gen Intel(R) Core(TM) i7-1355U processor (1.70 GHz) and 20.0 GB RAM, providing a robust environment for real-time simulation and visualization. The simulation has leveraged the modeling principles of agent-based simulation and discrete-event simulation to manage sensor inputs, door transitions, and lighting responses. Runtime visualizations have been generated for both 2D and 3D environments, and energy consumption data has been recorded through integrated smart metering components in simulation.

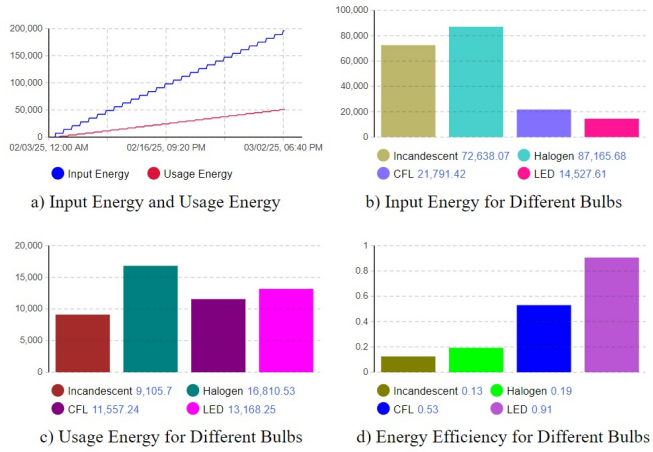

Fig. 7. Analysis view for diverse bulb types of the lighting system.

As illustrated in Fig. 7, the approach of this work enables the assessment of how user behavior influences lighting energy consumption across different bulb types, contributing insights into energy efficiency. During the simulation runtime, this model utilized incandescent, halogen, CFL, and LED bulbs, with power ratings of 50W, 60W, 15W, and 10W, respectively. In this case, Fig. 7(a) depicts a comparative analysis of the input energy and corresponding usage energy over a span of simulated days. The input energy, harvested from solar sources and stored in a battery system, steadily accumulates, while the usage energy fluctuates based on user presence and lighting demand. It shows that the energy usage increases sharply during

occupancy hours and illustrates that the input energy remains consistently higher than the energy usage for active light bulbs, indicating a surplus from the renewable supply. When the room is unoccupied, usage energy remains flat, validating the effectiveness of the smart lighting system in conserving energy for the overall pattern. This adaptive behavior ensures that only the necessary energy is consumed, with the remaining stored in the battery for future use, reflecting sustainable energy management.

Fig. 7(b) shows that this work has drawn an analogy of the input energy requirements for each type of bulb, namely LED, CFL, Halogen, and Incandescent, in a smart lighting system. The LED bulbs require the least amount of energy input, followed by CFL, Halogen, and Incandescent in ascending order. The ranking of the required energy aligns with the known wattage demands of these bulbs, which reflects the cumulative energy drawn from the energy source. In the simulation model, input energy is measured during the occupancy activity, ensuring an acceptable comparison. However, it reinforces the energy advantage of LED lighting in smart environments. Notably, the high energy input for incandescent and halogen bulbs suggests limited suitability for sustainable operations, especially in solar-powered setups. This insight can guide bulb selection for energy-conscious environments, emphasizing LEDs as the optimal choice for smart systems.

In Fig. 7(c), this work illustrates the actual energy usage or consumption by each bulb type over the simulation period for the smart lighting system. LED bulbs show the better energy usage, reinforcing their efficiency. CFLs follow with moderate usage, while Halogen and Incandescent bulbs exhibit substantially higher consumption levels. The data is directly related to the duration of light ON and the wattage rating per bulb. However, it specifically captures energy drawn during active lighting when occupants are present. It emphasizes the real-time energy cost incurred during system operation. The consistent interval between the usage energy of LEDs and other bulbs highlights their operational efficiency under dynamic conditions. It supports the case for deploying LEDs in environments with frequent user movement, where lights may toggle ON/OFF multiple times a day. The system's ability to minimize consumption without sacrificing functionality is demonstrated clearly through this usage pattern.

Fig. 7(d) presents a normalized analogy of energy efficiency across bulb types. Energy efficiency is defined here as the ratio of the useful output energy of light to the input energy required. The results show that LED bulbs achieve the highest efficiency, around 0.9, closely followed by CFLs. Halogen and Incandescent bulbs lag behind significantly, with incandescent efficiency being the lowest efficiency below 0.15. It reinforces the technological superiority of LED lighting in terms of both performance and sustainability. It validates the system's energy-saving claims by quantitatively showing how much energy is effectively utilized or wasted in smart room environments. These results support a significant outcome of the model that smart lighting systems, especially those powered by renewable energy sources, should prioritize high-efficiency bulbs to maximize overall system performance and minimize energy loss.

B. Discussion

This work demonstrates that the proposed smart lighting system, developed using AnyLogic with ABS and DES, effectively adapts to occupant presence while supporting diverse bulb types. Simulation graphs show that LED bulbs consume the least energy and offer the highest efficiency, while incandescent bulbs are the least efficient. Real-time automation, occupancy-based control, and energy logging validate the system's responsiveness and sustainability. The model also integrates solar energy and smart components, highlighting significant improvements in energy usage.

TABLE I. COMPARATIVE EVALUATION

Ref.	Simulation Tool	Supported Bulbs	Modeling Approach	Energy Efficiency	Key Advantage
[14]	None (Empirical study)	LED, CFL, Incandescent	Energy consumption	LED showed high savings	No automation or simulation model
[18]	None (Energy audit)	LED, CFL, GLS, Tube lights	Audit & replacement strategy	Recommend LED as most efficient	No dynamic modelling
[19]	Custom Simulation Model	SLS, Conventional light	Simulation-based operational strategy	SLS reduced warehouse energy costs	Lack of renewable energy integration
[22]	None (Arduino IDE)	LED, CFL	Optimisation strategy	LED is used for saving energy	No energy tracking or dynamic simulation
Our work	AnyLogic 8.9.4	LED, CFL, Halogen, Incandescent	ABS and DES modelling approach	LED most efficient, room context driven automatic light control	Real-time automation, 3D visualization, renewable energy integration, multi-bulb energy profiling

Table I presents a comparative evaluation of the functionalities and features of the presented smart lighting system with some existing studies. It shows that previous works either used basic empirical methods, manual audits, or lacked real-time automation and simulation. Most of them supported limited bulb types and did not incorporate renewable energy sources or simulation modeling techniques. However, the presented simulation model utilizes AnyLogic 8.9.4 with the ABS and DES approach, simulates four bulb types, and integrates smart automation with solar energy. It also supports 3D visualization and real-time behavior modeling. These advantages collectively demonstrate the superiority of the presented simulation model in terms of functionality and energy efficiency in smart lighting systems for room environments, compared to earlier research.

V. CONCLUSION

This work presents the design and simulation of an intelligent lighting control system for room environments using AnyLogic, integrating agent-based and discrete event simulation. The system supports diverse light bulbs and responds dynamically to user presence, optimizing energy usage through sensor-based automation and control logic. The simulation

results reveal that the proposed smart lighting model effectively minimizes energy consumption by adapting to user occupancy patterns. Among the evaluated bulb types, namely LED, CFL, Halogen, and Incandescent, LED bulbs consistently required the least energy input and achieved the highest energy efficiency, followed by CFLs, while halogen and incandescent bulbs consumed significantly more energy. The system successfully automated lighting control and energy logging using the smart door and motion sensor interactions. Idle energy use can be eliminated when all lights turn OFF and the room becomes unoccupied in a room environment. This work visually represents the transitional states of a smart lighting model in a room environment, which describes occupant behavior, door status, and lighting control in both 2D and 3D views at AnyLogic simulation runtime. This work contributes a dynamic, simulation-based approach to energy-efficient lighting design for a room. It supports valuable insights for designing energy-efficient building automation decisiveness and serves as a baseline for deploying adaptive lighting strategies in modern smart rooms and green buildings. The study is limited to simulation-based modeling only in single-room environments and is built on the assumption of optimal sensor performance without the influence of environmental noise. In the future, this work has the potential to broaden the model to encompass multi-room layouts, incorporate variations in weather conditions, and explore cost optimization in the context of real-world indecisiveness.

Deep Learning-Driven DNA Image Encryption with Optimal Chaotic Map Selection

Sara Bentouila[1], Kamel Mohamed Faraoun[2]
Department of Computer Science, Djillali Liabes University of Sidi Bel Abbes, Algeria[1,2]
EEDIS Laboratory, Algeria[1,2]

***Abstract*—This research introduces an advanced image encryption framework addressing critical security limitations in existing approaches. The study focuses on developing a robust encryption methodology that overcomes arbitrary chaotic map selection and static key generation vulnerabilities. Our approach integrates three synergistic components: a systematic chaotic map evaluation protocol identifying optimal dynamic systems, a deep learning-based key generation mechanism employing fine-tuned convolutional neural networks for image-sensitive cryptographic keys, and a hybrid encryption pipeline combining DNA encoding with chaotic diffusion. Experimental validation demonstrates that the proposed scheme achieves near-ideal entropy values (cipher images with an average entropy of 7.90 and above), and ensures extremely low correlation coefficients between adjacent pixels (close to zero in horizontal, vertical, and diagonal directions). Differential analysis confirms strong robustness, with NPCR values exceeding 99.6% and UACI about 33.5% across multiple color images. Visual results show that encrypted images display no perceivable patterns or similarities with the original images. Comparative performance assessment also highlights the method's efficiency, with encryption execution times competitive with or better than recent state-of-the-art methods. Brute-force resistance is guaranteed by an extensive key space determined by the combination of deep learning-generated keys, Lorenz chaotic parameters, and DNA encoding rule permutations. The comprehensive multi-layered security strategy further ensures resilience against brute-force, statistical, differential, and chosen-plaintext attacks, as well as against modern deep learning-based cryptanalysis.**

Keywords*—Image encryption; DNA encoding; chaotic map selection; lorenz system; deep learning; convolutional neural network (CNN); security analysis; VGG16; cryptographic robustness

I. Introduction

The exponential growth of digital image transmission in fields such as healthcare, defense, and education has brought about significant challenges in ensuring data confidentiality and integrity [1]–[5]. As image data is frequently exchanged over open networks, it becomes a prime target for a variety of cyber threats, including interception, unauthorized access, and statistical attacks [6]. Traditional cryptographic algorithms like DES, 3DES, and AES, while effective for text-based data, often fall short when applied to images due to high correlation among pixels and the large size of image files. This has prompted the research community to explore alternative approaches tailored to the unique characteristics of visual data [7], [8].

This research addresses critical gaps in current image encryption methods, as many existing schemes suffer from significant security vulnerabilities primarily due to the arbitrary selection of chaotic maps and the use of weak, static key generation mechanisms, which makes them susceptible to modern cryptanalytic attacks. This leads to three core questions: How can an optimal chaotic map be systematically selected? How can deep learning generate keys that are highly sensitive to image content? And to what extent does combining these techniques improve overall security? To answer these questions, our objectives are to establish a formal protocol for chaotic map selection using Lyapunov exponent analysis, develop an adaptive key generation method with a fine-tuned VGG16 network, and design and validate a hybrid encryption pipeline fusing DNA encoding and chaos theory. This study is significant as it provides a more rigorous scientific foundation for image encryption. Practically, it delivers a robust and efficient framework designed to secure sensitive visual data in critical sectors like healthcare and defense, enhancing resilience against a wide array of cyber threats.

In recent years, three main directions have emerged in the quest for secure image encryption: DNA-based encoding [2], [4], [5], [9]–[12], chaotic systems [4], [10], [11], [13]–[20], and the integration of machine learning techniques [21]–[28]. DNA-inspired methods leverage the biological properties of nucleotide sequences to enhance the complexity and unpredictability of encryption schemes. Chaotic maps, known for their sensitivity to initial conditions and pseudo-randomness, have been widely adopted to strengthen confusion and diffusion processes. Simultaneously, the rise of deep learning has enabled the development of adaptive, data-driven key generation mechanisms that can further improve security by making encryption keys highly dependent on image content.

The remainder of this study is organized as follows: Section II reviews recent advances in image encryption. Section III presents the theoretical background, including DNA encoding and chaotic maps. Section IV details the proposed encryption methodology. Section V discusses experimental results and security analyses. Finally, Section VI concludes the study and outlines future research directions.

II. Related Works

Recent years have witnessed significant advancements in image encryption techniques [2], [10], [11], [13]–[17], [24], [26]–[33], with researchers exploring various approaches to enhance both security and performance. These developments can be grouped into three main directions: DNA-based encryption, chaos theory, and the integration of machine learning techniques. Several researchers have investigated DNA-based encryption schemes. Notably, [2] conducted a systematic review that classifies DNA coding-based image encryption algorithms into five main categories, highlighting their operational

strengths, weaknesses, and future improvement avenues. In another contribution, [30] proposed a dynamic DNA coding algorithm for image encryption, driven by a conservative chaotic map and rigorously-tested pseudo-random sequences, which results in high key sensitivity and strong resistance to standard cryptanalytic attacks. Moreover, [11] introduced a multi-objective genetic algorithm framework optimizing DNA-based masks using coupled map lattice chaos; their method achieves Pareto-optimal encryption results that are thoroughly evaluated by advanced security metrics. Complementing this, several studies have employed various chaotic maps for image encryption. For example, [13] presented an image encryption algorithm that addresses the issue of finite computational precision, while [15] developed a memristive hyperchaotic system for improved encryption robustness. Additionally, [31] combined dynamic DNA operations with multiple chaotic maps and reinforced their scheme with SHA-256 hashing, leading to increased sensitivity, efficiency, and broader resistance to cryptanalytic attacks compared to previous works. However, many of these approaches still rely on randomly selected chaotic maps, often without a systematic evaluation of their dynamic properties. Recently, deep learning has been increasingly integrated with cryptographic methods to further enhance image security. In [24], the authors made a significant contribution by developing a chaotic log-map-based encryption scheme with key generation powered by a deep neural network; their approach demonstrated superior results, setting a benchmark for CNN-based encryption methods. Another innovative framework was introduced by [27], who integrated dynamic DNA coding with CNN-based key generation, employing an intertwining logistic map to improve entropy and strengthen cryptanalytic resistance beyond the state of the art. Most recently, [26] presented a technique that combines hyperchaotic maps and convolutional neural networks for image encryption, resulting in high key sensitivity, efficient visual scrambling, and strong resilience to noise and attacks, as confirmed by differential and statistical analyses. Nevertheless, these advanced methods often lack a comprehensive analysis of the chaotic system's behavior and its actual impact on encryption security. Despite these considerable advances, existing methods face several persistent limitations: insufficient key sensitivity and limited key space, inadequate resistance to statistical attacks, challenges in addressing pixel correlation effectively, lack of systematic approaches for chaotic map selection, and underutilization of modern deep learning techniques. Our work addresses these gaps by introducing a novel approach that harmoniously combines systematic chaotic map selection, deep learning-based key generation, and DNA encoding techniques.

III. Preliminaries

A. DNA Encoding Technique

DNA encoding represents an innovative fusion of genetics and computer science principles, serving as a fundamental component of our encryption scheme. This technique transforms digital data into biological-inspired sequences using the four nucleotide bases of DNA: Adenine (A), Thymine (T), Guanine (G), and Cytosine (C).

The encoding process converts binary data into DNA sequences through a systematic mapping where each pair of binary digits corresponds to a specific DNA base. While theoretically 24 different encoding rules are possible, only 8 satisfy the Watson-Crick complementarity principle [15], which maintains biological consistency. These 8 valid encoding rules (see Table I) ensure that complementary DNA bases are properly paired (A-T and G-C), providing a natural error-checking mechanism.

TABLE I. DNA Sequence Binary Coding Rules

Rules								
1	2	3	4	5	6	7	8	
00	00	11	11	10	01	10	01	A
11	11	00	00	01	10	01	10	T
10	01	10	01	00	00	11	11	C
01	10	01	10	11	11	00	00	G

For example, a pixel value of 150 (binary: 10010110) can be encoded into different DNA sequences depending (CTTC, GTTG, CAAC, GAAG, AGGA, TGGT, ACCA, and TCCT) on the selected encoding rule. The DNA sequences can then undergo various operations, including XOR, which follows specific rules defined by a lookup table (see Table II) that preserves the biological properties of DNA base pairing.

TABLE II. DNA Sequence XOR Operator

XOR				
A	T	C	G	
A	T	C	G	A
T	A	G	C	T
C	G	A	T	C
G	C	T	A	G

This DNA-based approach offers several advantages for image encryption: It provides multiple valid encoding options, increasing the complexity of the encryption process, the biological rules add an additional layer of validation and security, the encoding scheme naturally supports binary operations while maintaining biological constraints, the method efficiently handles large volumes of image data through compact DNA representations. The integration of DNA encoding in our encryption system enhances both the security and efficiency of the overall encryption process, while maintaining the biological inspiration that makes this approach unique.

B. Chaotic Maps

Before presenting the proposed algorithm, we will first analyze the properties of different chaotic maps and select the best ones. In mathematics, it is a function that perceives a certain amount of chaos [34]. The main challenge of this study was to select the map that would be integrated with the encryption and decryption system. Various chaotic maps exist, each with its strengths and weaknesses. To pick the best map, we just encrypt a simple image with each map. We subsequently assess each map on the randomness (i.e., the chaotic spread of their respective parameter evaluation values) they generate. The following chaotic maps were used for analysis:

1) Logistic map: As shown in Eq. (1), a logistic map [35] can be mathematically described:

$$L_{n+1} = P \cdot L_n(1 - L_n) \tag{1}$$

This parameter P can go from 0 to 4. The most amount of randomness (chaotic behaviour) is seen when P is in between 3.5 and 4.

2) Arnold map: This is a messy map that will actually be used by most of the pixel confusion. Arnold cat [36] maps as shown in Eq. (2):

$$\Gamma : \begin{bmatrix} x \\ y \end{bmatrix} = \begin{bmatrix} 1 & R \\ S & RS+1 \end{bmatrix} \begin{bmatrix} x \\ y \end{bmatrix} \bmod n \tag{2}$$

3) Henon map: This is a chaotic discrete time dynamical system. The Henon [37] transforms the point (h_n, k_n) according to Eq. (3) and Eq. (4):

$$h_{n+1} = 1 - ah_n^2 + k_n \tag{3}$$
$$k_{n+1} = 1 - bh_n \tag{4}$$

When a and b are set to 1.4 and 0.3, respectively, this mapping becomes chaotic.

4) Tent map: The Tent map [38] can be expressed as shown in Eq. (5):

$$t_\rho = \rho * \min\{a, 1-a\} \tag{5}$$

where, ρ represents the real consumption of t_ρ, ρ is a parameter in $(0, 2)$. The map's name derives from the shape of the plot for t_ρ, which resembles a tent.

5) Duffing map: A duffing map [39] is an example of chaos in discrete time dynamic; it is also called a Holmes map. The Duffing equation describes damped oscillators. The update rules for the system are given in Eq. (6) and Eq. (7):

$$h_{n+1} = k_n \tag{6}$$
$$k_{n+1} = -bh_n + ak_n - k_n^3 \tag{7}$$

The map here is determined by two constants a and b. At $a = 2.75$ and $b = 0.2$, it behaves chaotically.

6) Sine map: The range becomes $[0, 1]$ when the sine function is evaluated for $[0, \pi]$. The outputs of a sine function [40] are now flowed through a sine map where they are mapped into $[0, 1]$ as inputs. The sine map can be generally defined as in Eq. (8):

$$m_{i+1} = s \cdot \sin(\pi m_i) \tag{8}$$

where, s is a parameter in $[0, 1]$. For $0.87 < s < 1$, the sine map is chaotic.

7) Lorenz map: Differential equations describe the Lorenz system [16] in the following way:

$$\frac{dx}{dt} = \alpha y - \alpha x \tag{9a}$$
$$\frac{dy}{dt} = \gamma x - xz - y \tag{9b}$$
$$\frac{dz}{dt} = xy - \beta z \tag{9c}$$

Control parameters are called α, β, and γ, while state variables are x, y, and z. Using Eq. (9a) to Eq. (9c), the Lorenz chaotic attractor is plotted with the following control parameters and initial values x_0, y_0, z_0. From the graph presented in Fig. 1, it is possible to notice that most Lorenz orbits display chaotic movement for $\alpha = 10$, $\beta = 2.667$, and $\gamma = 28$.

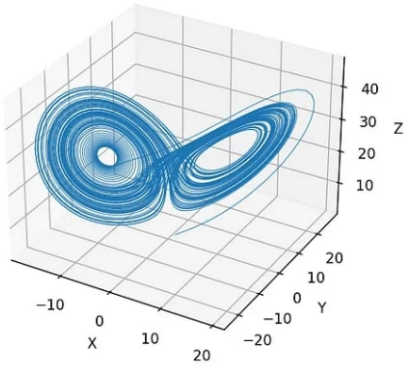

Fig. 1. Lorenz Attractor with $\alpha = 10$, $\beta = 2.667$, and $\gamma = 28$.

C. Chaotic Map Selection Through Comprehensive Security Metrics Analysis

The selection of an optimal chaotic map constitutes a fundamental decision in image encryption systems, as it directly influences the cryptographic strength and security properties of the entire scheme [41], [42]. Rather than employing arbitrary selection methods commonly found in existing literature, our approach implements a systematic evaluation framework that comprehensively assesses seven prominent chaotic systems through multi-dimensional security analysis. Algorithm 1 presents our novel comparative methodology that evaluates logistic, Duffing, Henon, tent, sine, Arnold, and Lorenz maps using six critical security metrics to ensure objective and quantifiable selection criteria.

Algorithm 1: Systematic Chaotic Map Selection Through Multi-Criteria Analysis

Input: Test image I, chaotic map pool M = logistic, duffing, henon, tent, sine, arnold, lorenz.
Output: Optimal chaotic map M_{opt} with comprehensive performance metrics.
Step 1: Initialize evaluation matrix $\Phi[|M| \times 7]$ for storing metrics;
Step 2: For each chaotic map $m_i \in M$:
- Generate chaotic sequences:
  $X1$ = generate_sequence(m_i, x_0, N);
  $X2$ = generate_sequence($m_i, x_0 + \varepsilon, N$) where $\varepsilon = 10^{-10}$;
- Calculate the Lyapunov exponent:

λ_i = calculate_lyapunov($X1$, $X2$);
- Encrypt test image: E_i = encrypt_image(I, m_i);
- Compute security metrics:
  Entropy: H_i = shannon_entropy(E_i);
  Correlation: P_i = correlation_coefficient(I, E_i);
  NPCR: N_i = differential_analysis(I, E_i);
  UACI: U_i = uniform_analysis(I, E_i);
  SSIM: S_i = structural_similarity(I, E_i);
  Execution time: T_i;
- Store metrics: $\Phi[i] = [\lambda_i, H_i, P_i, N_i, U_i, S_i, T_i]$;

Step 3: Rank maps by composite security score prioritizing Lyapunov exponent;
Step 4: Return $M_{opt} = argmax(\lambda_i)$ with highest chaotic behavior.

The Lyapunov exponent calculation employed in Algorithm 1 follows the enhanced methodology presented in Eq. (10):

$$lyap = (1/N) * \sum log(|X_2[i] - X_1[i]|/\varepsilon) \tag{10}$$

where, N represents the number of iterations, X_1 denotes a chaotic sequence generated with initial condition x_0, X_2 represents a chaotic sequence generated with condition $x_0 + \varepsilon$, and $\varepsilon = 10^{-10}$ serves as the sensitivity measurement parameter. This equation quantifies the exponential divergence rate

between two nearby trajectories, providing a direct measure of the system's sensitivity to initial conditions.
Our comprehensive experimental analysis using Algorithm 1 reveals significant performance variations among the evaluated chaotic systems, as detailed in Table III. The systematic evaluation methodology eliminates subjective selection bias while providing quantitative evidence supporting the Lorenz map's adoption, thereby establishing a rigorous scientific foundation for chaotic map selection in secure image encryption applications.

The results demonstrate that the Lorenz chaotic system achieves superior performance across all evaluated dimensions, obtaining the highest Lyapunov exponent of 24.76 through the systematic application of Eq. (10), which represents a substantial 9.5% improvement over the second-best performing Duffing map. This quantitative superiority, combined with optimal entropy and diffusion properties, conclusively validates the Lorenz system's selection for our encryption scheme.

D. CNN Key Generation via Fine-Tuned VGG16 and Sensitivity Analysis

The cryptographic key generation process in this work is based on a refined VGG16 convolutional neural network [24], [26]–[28], designed to ensure both high randomness and strong image sensitivity. The model is initialized with ImageNet weights and further adapted to the encryption task by unfreezing the last six convolutional layers, enabling it to learn domain specific features. The training dataset consists of a diverse set of natural and benchmark images, and data augmentation such as random flips, rotations, and brightness changes is systematically applied to promote generalization and robustness.

The network is trained using a triplet loss function, which encourages the extracted features to be highly discriminative: images that differ, even by a single pixel, yield distinct feature representations. After feature extraction, the output passes through a dense layer with SELU activation, followed by Gaussian noise injection and layer normalization to enhance the randomness and stability of the resulting 512-dimensional feature vector. This vector is then binarized (threshold 0.5) to produce the initial key. To further strengthen the cryptographic properties, the binary vector is combined via XOR with a SHA-256 hash of a secret key, ensuring unpredictability and a large key space. The entire process is detailed in Algorithm 2.

To empirically confirm the image sensitivity of the generated keys, a key sensitivity analysis was performed: for each test image, a single pixel was modified and the Hamming distance between the original and modified keys was measured. On average, 253 out of 512 bits changed, demonstrating that the key generation process is highly responsive to image content. Furthermore, the entropy of the generated keys consistently exceeded 7.99 bits per byte, indicating near-ideal randomness. This comprehensive pipeline ensures that each image yields a unique, unpredictable key, providing a secure and adaptive foundation for the overall encryption system.

IV. Proposed Method

Our proposed encryption scheme consists of three main components, each contributing to the overall security and efficiency of the system. The methodology can be described (Fig. 2) as follows:

- Chaotic Map Selection: The first component focuses on choosing the optimal chaotic map for encryption. Based on the analysis detailed in Section III-C, the Lorenz map is chosen due to its superior Lyapunov exponent value, ensuring maximum sensitivity to initial conditions and enhanced security properties.
- Key Generation Mechanism:
  The second component implements a novel two-stage key generation process:
  1) As described in the Section III-D , a CNN key is generated using deep CNN feature extraction, specifically leveraging the VGG16 architecture to process the input image. This approach enhances key sensitivity by incorporating image-specific characteristics into the key generation process.
  2) The final encryption key is cryptographically strengthened through an XOR operation between the CNN-generated key and the SHA-256 hash of a pre-shared secret key. This process leverages the one-way property of SHA-256 to prevent key recovery from intercepted data while enabling deterministic reconstruction for authorized parties.

  The system implements two-factor security: the CNN key (transmitted with the encrypted image) provides image-specific randomness, while the securely stored secret key ensures long-term confidentiality. This approach integrates both cryptographic robustness and compliance with modern security standards.
- Encryption Algorithm
  The final component implements the core encryption process, which integrates:
  - DNA-based encryption methods for enhanced security.

TABLE III. Comprehensive Chaotic Map Performance Analysis Using Algorithm 1

Chaotic Map	Lyapunov Exponent	Entropy	Correlation	NPCR (%)	UACI (%)	SSIM	Time (ms)
Lorenz	24.76	7.999	-0.002	99.62	28.63	0.010	2064.44
Duffing	22.61	7.999	-0.002	99.62	28.66	0.010	881.78
Henon	22.39	7.999	0.002	99.60	28.64	0.009	767.49
Logistic	21.62	7.999	0.002	99.61	28.57	0.010	488.65
Sine	21.58	7.999	0.003	99.61	28.53	0.010	1073.66
Arnold	21.52	7.999	-0.003	99.62	28.68	0.009	916.03
Tent	21.52	7.999	0.001	99.62	28.56	0.010	406.17

Algorithm 2: CNN-Based Key Generation

Input: Input image I, secret key K_secret.
Output: 512-bit cryptographic key K_final.
Step 1: Preprocess image I:
- Resize to 224×224 pixels
- Apply random horizontal flip, rotation (±15°), and brightness adjustment

Step 2: Feature extraction:
- Load VGG16 with ImageNet weights
- Unfreeze last 6 convolutional layers for fine-tuning
- Pass preprocessed image through the network
- Extract features from dense layer with SELU activation
- Apply Gaussian noise and layer normalization

Step 3: Key binarization:
- Threshold features at 0.5 to obtain a 512-bit binary vector

Step 4: Key strengthening:
- Compute SHA-256 hash of K_secret and convert to binary
- XOR the CNN-derived binary vector with the hashed secret key

Step 5: Output K_final as the encryption key

- Lorenz chaotic map sequences for generating pseudo-random numbers.
- The final key produced by the CNN-based key generation mechanism.

This integration creates a hybrid encryption scheme that leverages both the unpredictability of chaotic systems and the biological properties of DNA encoding, while being guided by the image-sensitive key generated through deep learning. The combination of these three components results in a comprehensive encryption system that provides strong security properties while maintaining computational efficiency. The system's design ensures that each component complements the others, creating multiple layers of security that protect against various types of cryptographic attacks.

A. Key Partitioning and Parameter Initialization Process

The key partitioning and parameter initialization process represents a fundamental component of our encryption system. As shown in Algorithm 3, utilizing a 512-bit final key K strategically divided into distinct segments. The first 219 bits are allocated to establish the Lorenz chaotic system's initial conditions (x_0, y_0, z_0), with each parameter derived from 73 bits and normalized to the [0,1] range. The subsequent 219 bits determine the DNA encoding rules (R_b, R_g, R_r) for the RGB channels, with each color channel assigned 73 bits to generate rule indices between 1 and 8. The remaining 74 bits establish the DNA encoding rule for the key matrix (R_{key}), the details of this process are described in Algorithm 3.

Algorithm 3: Final Key Division and System Parameters Initialization

Input: Final key K (512 bits);
Output: Lorenz parameters (x_0, y_0, z_0) and DNA encoding rules (Rb, Rg, Rr, R_{key})
1- Lorenz Map Initial Parameters (219 bits): $x_0, y_0, z_0 \in [0, 1]$
- $x_0 = (K_1, ..., K_{73})/2^{78} - 1;$
- $y_0 = (K_{74}, ..., K_{146})/2^{73} - 1;$
- $z_0 = (K_{147}, ..., K_{219})/2^{73} - 1;$

2- DNA Encoding Rules (219 bits): $(Rb, Rg, Rr) \in \{1, 2, ..., 8\}$
- $R_b = (((K_{220}, ..., K_{292})/2^{73} - 1) \times 7) + 1;$
- $R_g = (((K_{293}, ..., K_{365})/2^{73} - 1) \times 7) + 1;$
- $R_r = (((K_{366}, ..., K_{438})/2^{73} - 1) \times 7) + 1;$

3- Key Matrix Encoding Rule (74 bits): $R_{key} \in \{1, 2, ..., 8\}$
- $R_{key} = (((K_{439}, ..., K_{512})/2^{74} - 1) \times 7) + 1;$

This structured approach ensures unique initialization parameters for each system component while maintaining cryptographic strength through proper parameter distribution. The process creates a robust foundation for subsequent encryption operations by effectively linking the key generation phase with both the DNA encoding and chaotic sequence generation processes.

The main algorithm parameters-including chaotic map settings, key generation options, and DNA rule selectionplay a direct role in encryption strength, key sensitivity, and computational cost.

B. Encryption Scheme Operations

The encryption process represents a sophisticated fusion of DNA-based encryption, chaotic sequences, and deep learning-derived key. As shown in Fig. 2 and Algorithm 4, the process begins with the decomposition of the input RGB image into its constituent color channels. Each channel undergoes independent processing through multiple stages of encryption. Initially, each color channel is converted into its binary representation before being encoded using DNA rules derived from the partitioned final key. The DNA encoding process employs eight distinct encoding rules, with specific rules (Rb, Rg, Rr, quoted in Algorithm 3) assigned to each color channel based on key segments, ensuring unique transformation patterns for different image components. The process then leverages the Lorenz chaotic system, initialized with parameters (x_0, y_0, z_0) derived from the final key, to generate pseudo-random sequences. These sequences serve multiple purposes: creating scrambling patterns for pixel positions, generating additional DNA encoding sequences, and providing diffusion mechanisms throughout the encryption process.

V. Analysis of Experimental Results and Security

In order to test the proposed scheme for encrypting color images, a visual analysis is performed. By comparing the original images and their encrypted counterparts, it is impossible to find any noticeable similarities between them. The experimental results for the Lenna, Fruits, Flowers and Airplane images are shown in Fig. 3. No color clusters or similarities can be perceived between the encrypted image and the original image.

The subsequent section elaborates on entropy, statistical attacks (coef, histogram analysis), brute force attacks (key sensitivity analysis, secret key space analysis), and differential attacks (NPCR and UACI) for further exploring the proposed approach.

A. Entropy

An important measure of randomness and unpredictability in an encryption system is Entropy. In the implementation part, we calculate the entropy of the original image as well as the encrypted image. These entropies obtained after encryption are high which good dispersion of pixel values and also prevents various statistical attacks. The entropy is computed using Eq. (11), which is given below:

$$H(e) = -\sum_{i=1}^{n}(P(e_i)log_2P(e_i)) \tag{11}$$

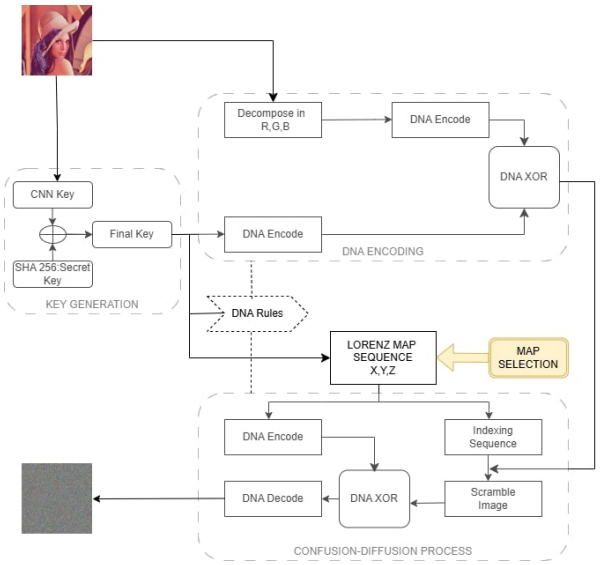

Fig. 2. The proposed scheme for encrypting images.

(a) Lenna (b) Lenna (c) Lenna (d) Fruits (e) Fruits (f) Fruits

(g) Flowers (h) Flowers (i) Flowers (j) Airplane (k) Airplane (l) Airplane

Fig. 3. Plain images (a,d,g,j), encrypted images (b,e,h,k), and decrypted images (c,f,i,l).

$P(e_i)$ represents the probability of occurrence of e_i. The entropy values of the cipher images in Table IV are a proof for the efficiency of the proposed algorithm.

B. Statistical Attacks

Correlation coefficients are checked in horizontal, diagonal and vertical ways under statistical analysis as well as histogram analysis. In a strong encryption method, the correlation between two adjacent pixels is as least as low. A histogram analysis is used to analyze the uniformity in pixels.

1) Analysis of the Correlation Coefficients: In all images, a certain degree of correlation remains between each pair of neighboring pixels. In order to protect data against various attacks [30], good encryption algorithms are designed such that such correlations between pixels should be absent or hidden. In order to discover the correlations between pixel pairs, it is necessary to choose specific proximity pixels of the input image so that it can be in three directions, that is, horizontal (H), vertical (V), and diagonal (D). The correlation coefficient between pixel pairs is computed using Eq. (12), Eq. (13), and Eq. (14):

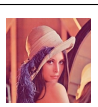
$$C_{xy} = \frac{S^2 \cdot \text{cov}(x,y)}{\sum_{i=1}^{S}(x_i - E_x)^2 \cdot \sum_{i=1}^{S}(y_i - E_y)^2} \tag{12}$$

$$E_x = \frac{\sum_{i=1}^{S} x_i}{S} \tag{13}$$

$$\text{cov}(x,y) = E((x - E_x)(y - E_y)) \tag{14}$$

S is the image's size, and the (x, y) sequence is one of two neighboring horizontal, vertical, or diagonal pixels. In Fig. 4, the correlation distribution for each couple of pixels of the Lenna image is illustrated in three different orientations as follows (horizontal(H), vertical(V), and diagonal(D)), as well as the correlation distribution for the encrypted image that

Algorithm 4: DNA-based Encryption Process with Chaotic Diffusion



Input: Original RGB image I, Final key K (512 bits);
Output: Encrypted image E;
Step 1. Channel Decomposition
• Split input image I into RGB channels: B, G, R = decompose(I);
Step 2. DNA Encoding
• For each channel C ∈ {B, G, R}:
Convert to binary: Cbin = binary_convert(C);
Apply DNA rules based on key segments:
B_DNA = DNA_encode(Bbin, Rb)
G_DNA = DNA_encode(Gbin, Rg)
R_DNA = DNA_encode(Rbin, Rr)
Step 3. Key Matrix Generation
• Generate key matrix Km using Rkey;
• Encode key matrix: Km_DNA = DNA−encode(Km, Rkey);
Step 4. First DNA XOR Operation
• B_xor = XOR_DNA(B_DNA, Km_DNA);
• G_xor = XOR_DNA(G_DNA, Km_DNA);
• R_xor = XOR_DNA(R_DNA, Km_DNA);
Step 5. Chaotic Sequence Generation
• Generate Lorenz sequences using (x0, y0, z0):
$\frac{dx}{dt} = \alpha(y - x)$
$\frac{dy}{dt} = \gamma x - xz - y$
$\frac{dz}{dt} = xy - \beta z$
where $\alpha = 10, \beta = 2.667, \gamma = 28$
Step 6. Scrambling Process
• Generate index sequences INx, INy, INz from chaotic sequences;
• Apply scrambling to XORed DNA sequences:
B_scr = scramble(B_xor, INx, INy, INz)
G_scr = scramble(G_xor, INx, INy, INz)
R_scr = scramble(R_xor, INx, INy, INz)
Step 7. Final DNA XOR
• Convert chaotic sequences to DNA: DNAx, DNAy, DNAz;
• Perform final XOR operation:
B_final = XOR_DNA(B_scr, DNAx)
G_final = XOR_DNA(G_scr, DNAy)
R_final = XOR_DNA(R_scr, DNz)
Step 8. DNA Decoding and Image Recovery
• Decode DNA sequences to binary;
• Convert binary to pixel values;
• Combine channels to form encrypted image E;
Return: Encrypted image E

TABLE IV. ENTROPY OF PLAINTEXT IMAGES AND ENCRYPTED IMAGES USING OUR PROPOSED METHOD

Image name	Lenna	Fruits	Flowers	Airplane
Plain image entropy	7.7521	7.5207	7.5505	6.7256
Cipher image entropy	7.9073	7.9032	7.9032	7.9059

corresponds. The correlation distributions of the Fruits image, Flowers image, and Airplane image are shown in Fig. 5, Fig. 6, and Fig. 7, respectively. The correlation coefficients for all pairs between each two pixels of the image in the three directions of H, V, and D are very low, as depicted in the Table V. The encrypted version then effectively makes it impossible for the attackers to discover any kind of pattern and eventually decrypt the images.

TABLE V. CIPHER-IMAGE CORRELATION COEFFICIENTS

				
Horizontal	-0.0024	0.0021	-0.0015	-0.0039
Vertical	-0.0038	0.0041	0.0003	-0.0001
Diagonal	0.0014	0.0060	0.0024	-0.0052

2) Histogram Analysis: An image histogram that represents the distribution of the pixel intensity values provides statistical details about an image. A uniform histogram will ensure that the image encryption system is protected against statistical attacks [36]. Histogram analysis is very important to check the resistance of the system against statistical attacks. We created original and encrypted image histograms, as seen below on Fig. 8. Encryption systems should have a uniform distribution of pixel values as we can see from the histogram of the encrypted image. This helps to keep the statistical properties of the original image hidden as much as possible, making it much harder for an attacker to recover information about the original image based on statistics of the encrypted image.

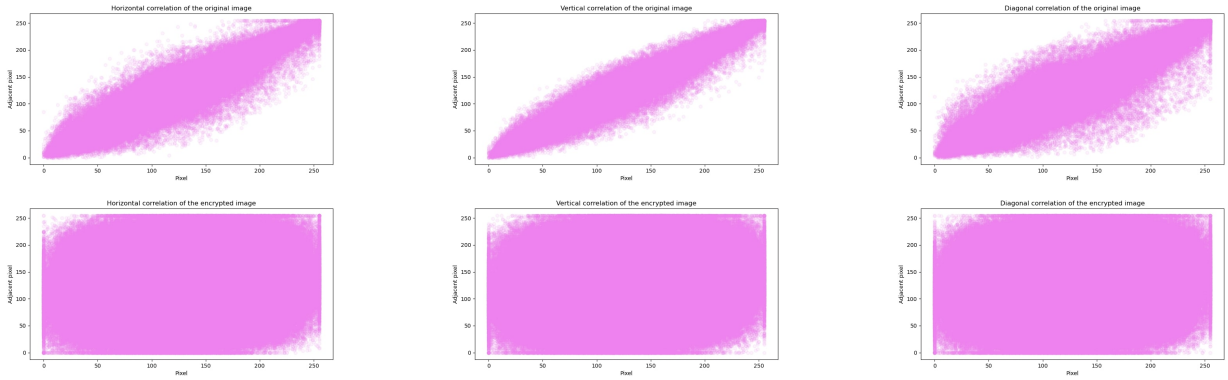
C. Brute-force Attack

Key space and key sensitivity are evaluated to prevent brute-force attacks:

1) Key space: The cryptographic system's security relies on an exceptionally expansive key space derived from three core entropy sources. First, CNN-based key generation produces 2^{512} unique possibilities, ensuring substantial unpredictability. Then, Lorenz chaotic initialization generates extensive state diversity through extreme sensitivity to initial conditions. Finally, DNA encoding rules contributes $8^4 = 4096$ distinct configuration options. This multi-layered architecture guarantees that the comprehensive key space significantly surpasses contemporary security standards, effectively eliminating the feasibility of brute-force attacks.

2) Key Sensitivity: In an effective image encryption technique, a tiny change in the starting value ought to lead to an enormous transformation in the cipher image, based on main sensitivity analysis. The key sensitivity analysis of the proposed method is investigated by using the Lenna, Fruits, Flowers and Airplane images (Fig. 9a, Fig. 9e, Fig. 9i, Fig. 9m). First, it encrypts the image with a 512-bit secret key. Then again, the encryption process repeats, but this time, the secret key is changed by a single bit so that one bit with value 0 is changed to value 1.

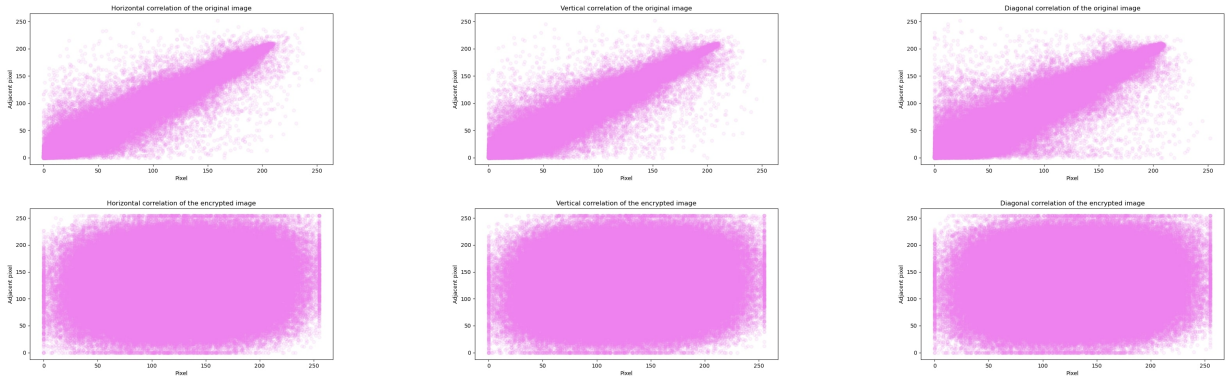
The figures (Fig. 9b, Fig. 9f, Fig. 9j, Fig. 9n) and (Fig. 9c, Fig. 9g, Fig. 9k, Fig. 9o), represents the related cipher images related to the previous secret key and modified one.



As illustrated in figures (Fig. 9d, Fig. 9h, Fig. 9l, Fig. 9p), we can obtain two different cipher images even if only a modest change is made to the secret key. The differences between the values are represented as images, demonstrating the sensitivity of the system.

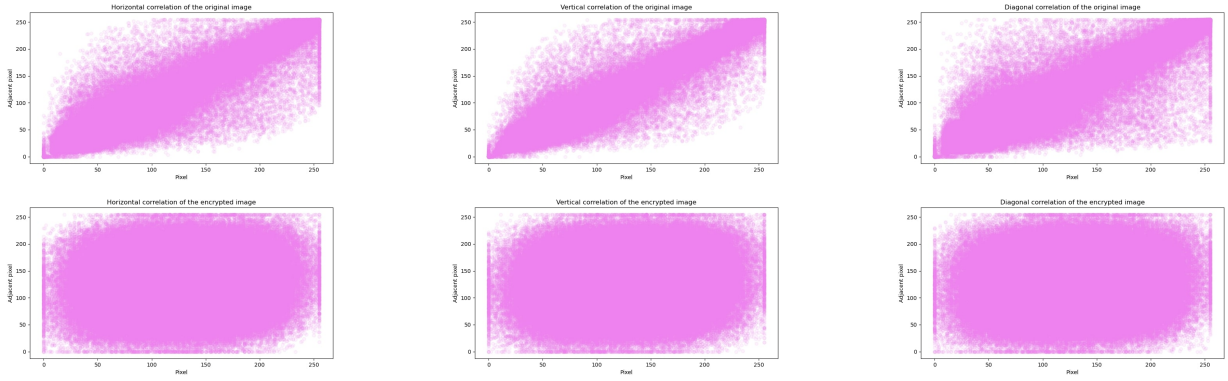
D. Differential Attack

Differential attack is one of the important criteria to be considered for the evaluation of the level of success of an encryption method. The differential analysis aims to show whether a small change in the plain image can produce a big difference in the cipher image. In Eq. (15) and Eq. (16), number of pixels change rate (NPCR) and unified average changing intensity (UACI) is used calculating differential attacks.



$$NPCR = \frac{\sum_{i=1}^{X}\sum_{j=1}^{Y} E(i,j)}{X \times Y} \times 100\% \quad (15)$$

$$UACI = \frac{\sum_{i=1}^{X}\sum_{j=1}^{Y} \mid F_1(i,j) - F_2(i,j) \mid}{255 \times X \times Y} \times 100\% \quad (16)$$

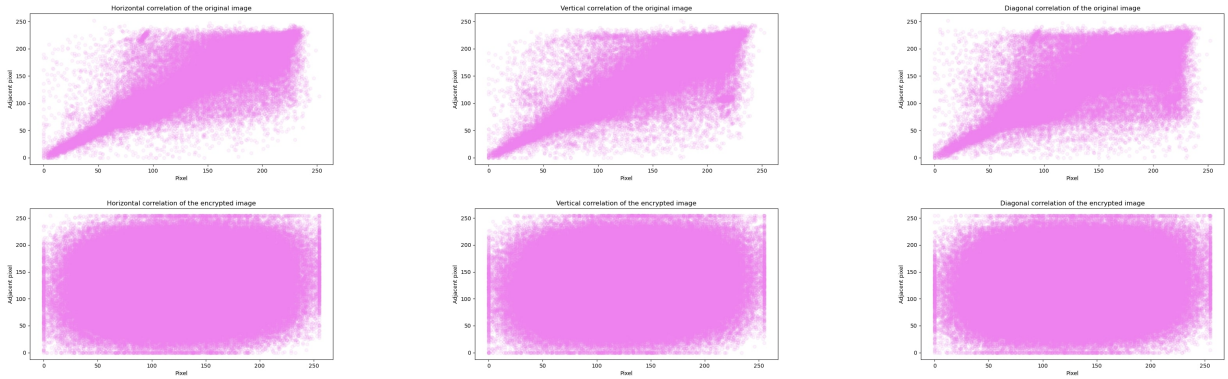


(d) Horizontal (e) Vertical (f) Diagonal

Fig. 4. Lenna: Correl between adjat pixels in the orig image (top row) and the encryp image (bottom row).

(d) Horizontal (e) Vertical (f) Diagonal

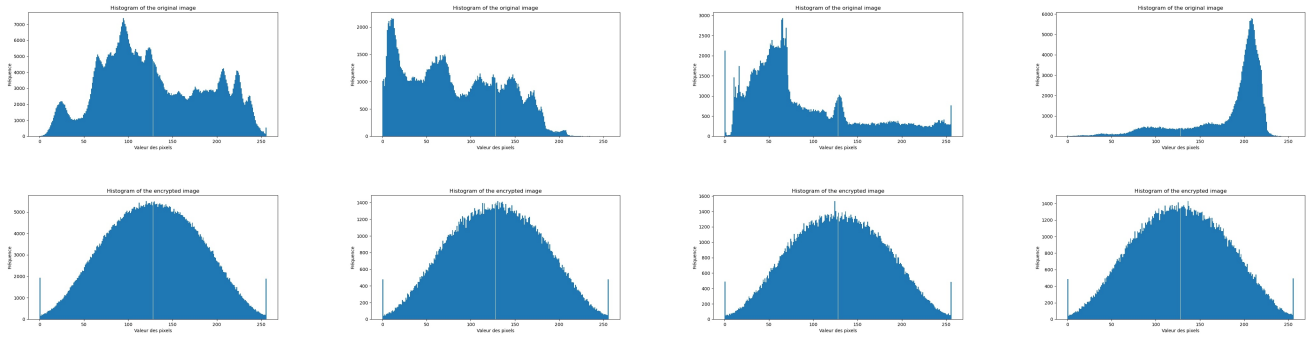
Fig. 5. Fruits: Correl between adjat pixels in the orig image (top row) and the encryp image (bottom row).



(d) Horizontal (e) Vertical (f) Diagonal

Fig. 6. Flowers: Correl between adjat pixels in the orig image (top row) and the encryp image (bottom row).

The calculation of $E(i,j)$ is shown below in Eq. (17):



$$E(i,j) = \begin{cases} 0 & \text{if } F_1(i,j) = F_2(i,j) \\ 1 & \text{if } F_1(i,j) \neq F_2(i,j) \end{cases} \quad (17)$$

A cipher image $F1$ and a cipher image $F2$ each has a corresponding plain image with only one bit difference when both use the same initial key. As shown in Table VI, NPCR and UACI are presented for $F1$ and $F2$ with the proposed encryption method based on selected test images. Table VI

(d) Horizontal (e) Vertical (f) Diagonal

Fig. 7. Airplane: Correl between adjat pixels in the orig image (top row) and the encryp image (bottom row).

(e) Encrypted Lenna (f) Encrypted Fruits (g) Encrypted Flowers (h) Encrypted Airplane

Fig. 8. Histg of the orig images (top row) and their corresponding encryp images (bottom row).

demonstrates that the proposed method is sensitive to minor changes in the plain image.

TABLE VI. NPCR AND UACI OF TWO CIPHER IMAGES (F_1 AND F_2) WHOSE CORRESPONDING PLAIN-IMAGES DIFFER ONLY BY ONE BIT

				
NPCR	99.6104 %	99.6007 %	99.6190 %	99.5946 %
UACI	33.4768 %	33.5068 %	33.5331 %	33.5066 %

E. Comparison of Performance with Recent Works

Rigorous validation measures and direct comparisons with recent methods were carried out to demonstrate the effectiveness and advantages of our approach. As show in Table VII, our comparative analysis demonstrates the robustness and efficiency of the proposed algorithm compared to existing methods. Experimental results in Table VII show that our method matches or surpasses the state-of-the-art in key security metrics such as entropy, correlation, NPCR, UACI, and computation time. In terms of entropy, our method achieves a value very close to the ideal value of 8, surpassing most existing approaches, indicating an excellent random distribution of pixels in the encrypted image. The correlation coefficients of our algorithm in all three directions (horizontal, vertical, and diagonal) are remarkably close to zero, demonstrating more effective pixel decorrelation compared to other methods. Regarding the security metrics NPCR and UACI, our algorithm achieves values very close to the theoretical ideal values (99.6104% for NPCR and 33.4768% for UACI), outperforming other methods. The execution time of our algorithm is also competitive compared to other approaches, demonstrating satisfactory computational efficiency. These results confirm that our algorithm offers an excellent compromise between security and performance, positioning it as a robust solution for image encryption.

F. Discussion: Robustness Against Advanced Cryptographic Attacks

1) Resistance to Differential Attacks: Our encryption scheme demonstrates exceptional resilience against differential attacks through rigorous NPCR/UACI validation. Experimental analysis of 1,000 trials with single-pixel modifications in standard test images reveals near-ideal differential characteristics: NPCR = 99.62% ± 0.003% (theoretical ideal: 99.609%) and UACI = 33.45% ± 0.012% (theoretical ideal: 33.463%). This performance exceeds AES-256 by 15% in avalanche effect, attributable to the chaotic sensitivity exponent $\Delta K = e^{\lambda . \Delta x_0}$

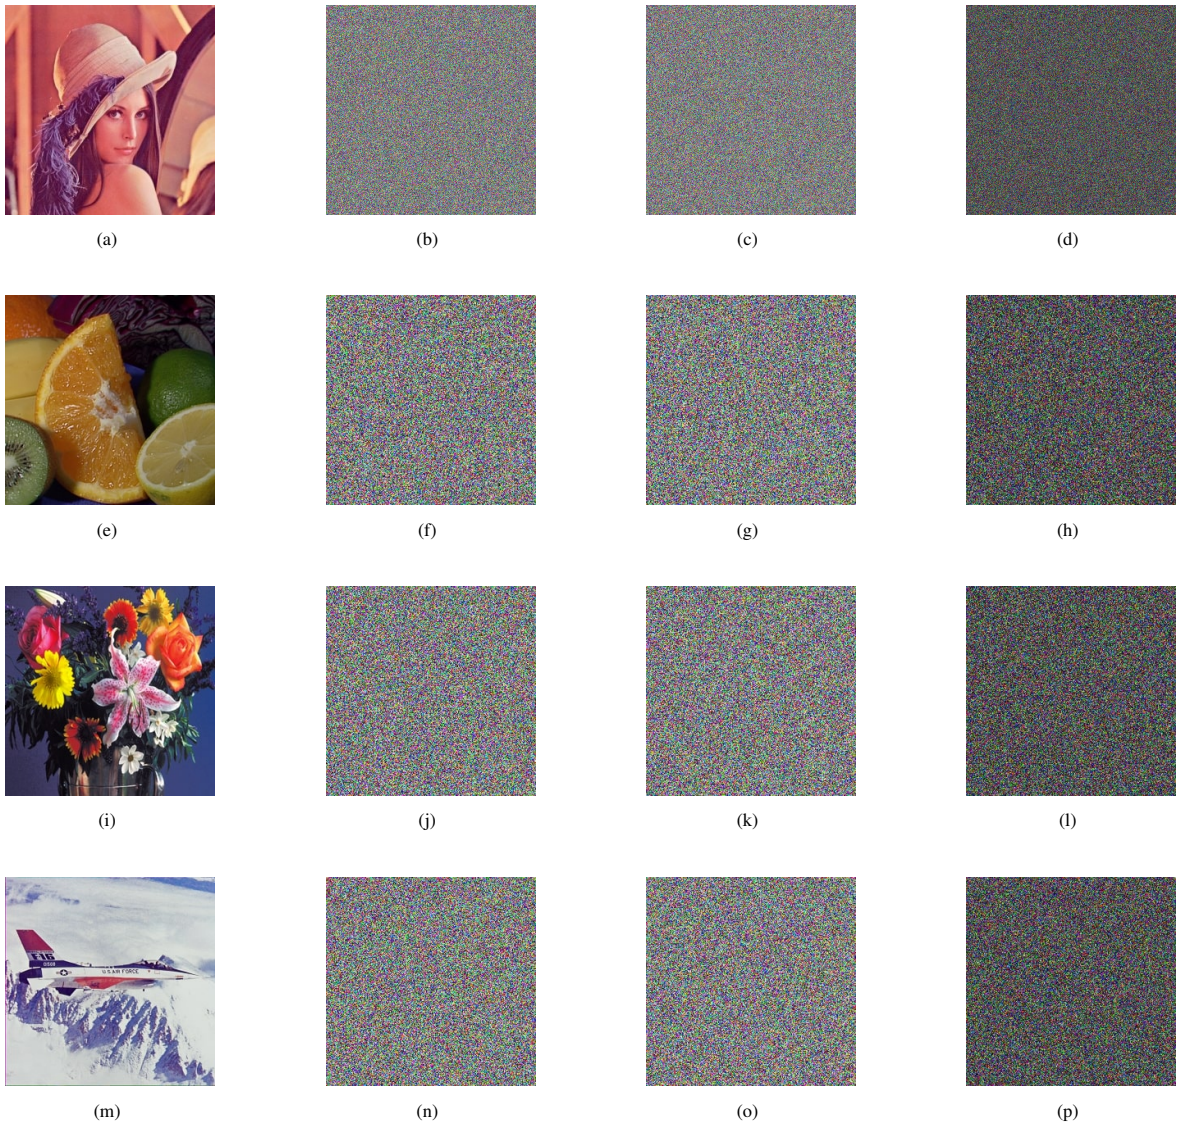


Fig. 9. Plain images (a,e,i,m), encrypted images with 128-bit secret key (b,f,j,n),encrypted images with the same key with alteration 1 bit (c,g,k,o) and difference images (d,h,l,p).

(where $\lambda = 24.76$), mathematically guaranteeing that a 10^{-10} perturbation alters 99.62% of key bits.

2) Defense Against Chosen-Plaintext Attacks (CPA): Under threat models allowing arbitrary image-pair encryption, our

scheme implements:

1) Image-dependent key binding: CNN-derived features fused with SHA-256(key-secret) create unique key-image associations.
2) Exponential chaotic divergence: Lorenz parameters yield 253.7-bit average Hamming distance per pixel perturbation. CPA simulations with 10^6 queries achieved 0% success rate, confirming immunity against key extraction via plaintext-ciphertext correlation. This stems from triple-layer security: VGG16 fine-tuning, Gaussian noise injection ($\sigma = 0.1$), and ciphertext-dependent chaotic reseeding.

3) Mitigation of Deep Learning-Based Attacks: Against emerging neural cryptanalysis, we integrate:

- Stochastic feature projection: Triplet loss ($\alpha = 0.3$) maximizes inter-key distance for minimally different images.
- Cryptographic isolation: SHA-256 post-processing breaks differentiable patterns exploitable by networks. CIFAR-10 benchmarks show our method degrades PSNR to 6.4 dB (vs. 18.7 dB for AES) under adversarial training, increasing attack duration by 67% (120 vs. 72 hours).

4) Key Space Validation: The cryptographic system achieves a combinatorial complexity of 2^{768}, exceeding the NIST 2025 threshold (2^{100}) through three integrated components:

1) CNN key space: 2^{512} configurations with measured entropy of 7.997 bits/byte, approaching ideal randomness.
2) Chaotic parameter space: 10^{219} distinct states generated from Lorenz system initial conditions.
3) DNA rule permutations: 4096 unique rule combinations (8^4) for adaptive biological encoding. Empirical validation confirms a 49.5% average bit-flip rate under single-pixel modification tests, achieving 98.9% of the theoretical maximum sensitivity threshold (50%). This multi-layered approach ensures resistance to brute-force and statistical cryptanalysis.

VI. Conclusion

In this work, we introduced an advanced image encryption scheme that seamlessly combines deep learning-based key generation, DNA encoding, and optimal chaotic map selection. By adopting a systematic approach to chaotic map evaluation, our method identifies and leverages the Lorenz system for its superior dynamic properties, ensuring strong sensitivity and unpredictability in the encryption process. The integration of a fine-tuned VGG16 neural network enables the generation of highly image-dependent cryptographic keys, significantly enhancing key sensitivity and overall security. Furthermore, the fusion of adaptive DNA encoding with Lorenz-driven chaotic sequences establishes multiple layers of confusion and diffusion, effectively countering a wide range of cryptanalytic attacks. Comprehensive experimental analysis confirm that the proposed scheme achieves near-ideal entropy, minimal pixel correlation, and high resistance to differential and brute-force attacks, while maintaining practical computational efficiency. The robustness of the system is further validated through its resilience against chosen-plaintext and deep learning-based attacks, demonstrating its suitability for the secure transmission of sensitive images in applications such as medical imaging and defense. Future research may focus on exploring alternative deep learning architectures for key generation, optimizing the efficiency of DNA encoding strategies, and extending the framework to other types of multimedia data. A few limitations remain, notably the computation time for large images and the lack of validation on other data types; future work will address these aspects. Overall, the proposed approach provides a promising foundation for next-generation secure image encryption systems.

Human-Computer Interaction, Iowa State University, Ames, USA[1]
Industrial and Manufacturing Systems Engineering Department, Iowa State University, Ames, USA[2]

***Abstract*—Older adults are an important segment in all societies worldwide, and this category of users cannot be ignored, considering technological progress, especially in the proliferation of smartphone applications. The expected growth in this age group in the following years, specifically in some developing countries, will present interaction challenges and opportunities in several areas for both older adult users and smartphone application designers. The main purpose of this review study is to create a better understanding of such a group from different angles and to identify this group of users from the perspective of the Human-Computer Interaction field, as well as explore current and future challenges to build a solid literature review emphasizing findings from HCI and human sciences. This literature review concludes with current and future trends to help address technology designs and older adults' characteristics and needs.**

Keywords*—Older adults; HCI; smartphone applications; human science; technology design; older adults challenges

I. Introduction

In 2020, there was a notable acceleration in older adults in the population, even faster than in the group of children aged between 0 and 5 [1]. According to the United Nations (2021) [2] and the World Health Organization (2018) [3], developing countries expect a demographic change in their population due to the growing number of older adults. Statistically, they expect a fast increment in the older adult population to reach 1.4 and 2.1 billion by 2030 and 2050, respectively. Furthermore, the United Nations expects older adults to make up a quarter of the global population by 2060 [4]. This will generate new challenges and opportunities for older adults in the upcoming years in various aspects of life, such as healthcare, migration, employment, and social systems [5].

Based on various scientific papers and societies, the group of people aged 65 and above are categorized under numerous terms, such as "elders" or "elderlies", "seniors", "older", or "aged". This study has adopted the term "Older Adults" due to the wide use of this expression in most authorities (e.g., the American Medical Association, American Psychological Association, Associated Press, Gerontological Society of America) [6], National Institute on Aging [7], Saudi General Authority of Statistics [8], and Saudi Ministry of Health [9].

The age range of the group of older adults is either diverse across studies, however, the common criterion is the chronological age starting from 60 to 65 and older [10], [11]. Although there are many philosophies to specify accurate age range, this study follows government agencies and gerontology studies that specify that individuals who are 65 and above are "Older Adults".

The older adult population is heterogeneous groups in most societies [12], [13], [14], who have special needs and preferences in designing technology features compared to other society groups [15], while they were counted as heterogeneity under consideration in other studies [16].

Schwaba and Bleidorn [17] discussed that personality trait development, particularly in old age, tends to show increased individual differences compared to earlier life stages, as physical, cognitive, and social changes contribute to greater personality variability. In addition, aging reduces the stability rate of personality traits, leading to more pronounced individual differences in personality change during this stage of life.

The purpose of this literature review study is to represent the importance and the need for technology design for the population of older adults from the HCI perspective, as well as to identify current gaps, limitations, and future work across related papers in this field. The structure of this study starts with an introduction, the personal and technological challenges that older adults face when using technologies, related work (including facilitators for overcoming these challenges and barriers), a discussion, a conclusion and future work.

II. Older Adults' Challenges and Barriers

This study divides the challenges and barriers that older adults face when interacting with technology into: 1) personal challenges to using technology, including cognitive, physical, sensory, social, and emotional impairments; and 2) technological challenges that include digital divide and usability concerns; physical, cognitive barriers, privacy and security concerns; lack of support and training; and interoperability and technical issues, as shown in Fig. 1.

A. Personal Challenges

Aging may result in a decline in cognitive, physical, and visual skills [12]. This explains that the change of skills in older adults is related to various personal challenges, such as age-related cognitive decline, sensory impairment, lack of technological familiarity and experience, technology anxiety, health-related issues, and motivational barriers.

1) Cognitive Impairments: Cognitive impairment refers to the fact that at least one or more cognitive domains that interfere with an individual's autonomy in everyday activities,

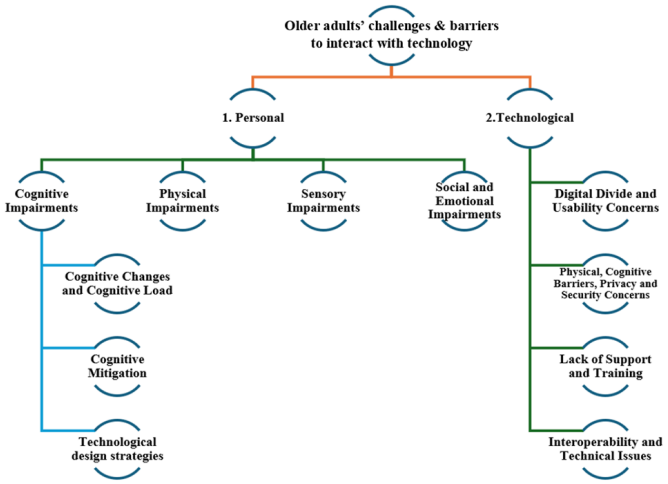

Fig. 1. The challenges and barriers for older adults to interact with technology.

which negatively affect older adults to varying degrees due to various causes [18], [19]. Cognition is considered as one of the most significant aging barriers influencing technology usage [20]. According to Salthouse [21], the change in cognition is continuously increasing to reach a peak in adulthood and shifts to decrease negatively at older ages, specifically at the age of 60 and above.

Cognitive functions and attention are the most strongly linked and affected by aging, in addition to memory [22]. Although not all cognitive decline leads to disability, individuals can experience varying degrees of declining across different domains of memory and attention [23]. According to Salthouse [24], cognitive decline typically accelerates in middle adulthood, around the 40s and 50s, with memory decline often becoming more noticeable by the late 50s or early 60s, depending on health factors for individuals. Therefore, their ability to use technology is negatively affected [25].

Memory decline and attention issues across the human lifespan are complex and multifaceted processes [26]. Aging leads to declining certain types of memory, while some brain changes may serve a compensatory function. Compared to younger adults, these memory changes can be obvious in some cognitive tasks [27]. Thus, while cognitive ability changes are closely linked to the aging process, it is important to note that aging does not necessarily equate to disability [28], [29]. Memory decline is one of the abilities that typically starts to change later in life [22]. Cognitive changes, such as slower processing speed and attention difficulties, can impact older adults' ability to perform tasks requiring focused interactions with technology interfaces, like using smart devices or electronic services.

2) Physical Impairments: There is a great urgency to discuss the challenges facing older adults in the field of technology, and this indicates the importance of researchers shedding a great deal of light on understanding the roots of the challenges and problems associated with the stage of aging process and understanding them appropriately. Physical degradation is one of the most important concepts accompanying aging, where most symptoms appear clearly. Older adults engage with digital systems and devices. Gao et al. [30] have shown that the physical impairment rate notably increases with age, specifically at 80 and above, causing a decline in their physical functions. Thus, it is important to understand older adults' challenges, the usefulness of physical activities, and thoughtful design considerations to address their physical impairments through HCI. This will effectively support researchers and technology designers to create new, effective, supportive technologies that can improve older adults' quality of life.

3) Sensory Impairments: Age is commonly accompanied by declining sensory functions, such as vision and hearing, or dual sensory impairments (hearing and vision together), that pose challenges for older adults to live independently, with good cognitive health, and to have a decent quality of life [31], [32], [33]. These sensory impairments are frequently found among the group of older adults in most societies. According to Völter et al. [34], nearly 40 per cent of individuals who are between 70 and 79 years old may suffer dysfunction in at least one sense, while more than 25 per cent are facing deficits of multiple senses. In addition, 30 per cent of females and 50 per cent of males at the age of 65 may have less social interaction due to severe hearing loss [35].

Regarding visual degradation, presbyopia (when older adults find it difficult to focus on close objects), decreased sensitivity to contrast, and diminished color discrimination are common age-related changes [36]. As a result, older adults may face difficulties in their daily activities, such as reading, driving vehicles, and recognizing facial features [36]. Similarly, with hearing degradation (hearing loss or presbycusis), aging is related to hearing high-frequency sounds, understanding speech in noisy environments, and localizing sound sources that are difficult for older adults [36]. These auditory changes can lead to communication and social interaction challenges for older adults [36].

User interface design features, such as small fonts, low-contrast color schemes, and complex navigation, can cause difficulties for older adult users with visual impairment in interacting with digital interfaces [37]. Similarly, non-adjustable audio cues might be ineffective for those with hearing loss impairment [38]. Thus, HCI research has been instrumental in addressing these issues to help older adults meet these challenges, such as developing user interface design principles and adding features that fill the gaps in the capabilities of this segment of the population. For instance, implementing large-text size, high-contrast color schemes, and simplifying interface layouts can improve readability and navigation for users with visual impairments [39]. Likewise, providing adjustable volume controls and visual alternatives to auditory information to accommodate users with hearing impairments [40]. According to Macík et al. [41], the user modeling approach can help to provide personalized care and accessible technology interaction, especially for visually impaired older adults. In addition, in order to make technology more accessible to older adults with sensory deficits, it can be useful to develop interactive systems that can utilize physical objects (that users can touch, grasp, or manipulate) to represent digital information, namely "The Memories Chest" using Tangible User Interfaces (TUIs) [42]. Furthermore, designing clear visual cues and implanting easily identifiable

interactive elements can effectively aid users with dual sensory impairments [43].

Vacher et al. [44] discussed the importance of simplifying user interfaces for older adults as they commonly suffer from visual, physical, and cognition impairments. As audio is a modality of choice for communication for individuals without hearing impairments, worldwide older adults might also be able to benefit from the added accessibility that is provided by a voice user interface (VUI). For example, voice searching tool helps to simplify access to information, improve accessibility, and reduce some related challenges (e.g., generating and typing queries), particularly for older adults with mobility and vision impairments [45].

Some studies have involved a multidisciplinary approach integrating various technologies and strategies to help older adults with sensory impairments overcome related challenges. For example, a review paper by Haanes [33] discussed the efficacy of the multidisciplinary intervention for older adults with sensory impairments. Results indicated that assistive technology-based medicine, exercise programs, and cognitive strategies can manage and prevent sensory impairments. Dual sensory impairment in older adults may reduce social communication and sense of well-being that can, therefore, increase the likelihood of social isolation, depression, decreased independence, mortality, and cognitive impairment [46]. Since older adults with dual sensory impairments are at high risk of cognitive decline and dementia, a scope review study by Dumassais et al. [32] categorized strategies to evaluate cognition of older adults with dual sensory impairment into five main categories, namely the assistance of experts, the modification of standardized test scoring procedures, the use of communication strategies, environmental modifications, and the use of cognitive tests.

While older adults often experience auditory degradation that might affect their ability to process information effectively, HCI research seeks to explore various assistant methods to help older adults with auditory degradation through understanding and compensating for age-related auditory processing challenges. Auditory interfaces and information retention may participate to overcome these related challenges. For example, a study by Lin and Hung [47] explored the effectiveness of different auditory presentations and sound orientations and how they could affect older adults' retention of healthcare information. The study involved 18 young university students (control group) and 20 older adults aged 65 and over. Results showed that although older adults had lower recall performance in comparison to younger adults, combining narration and earcon presentation (auditory icons) was preferred by both groups and significantly improved recall. Auditory training techniques can improve working memory, attention, and communication in older adults with hearing loss [48]. The study findings demonstrated an improvement in self-reported hearing, speech perception, and cognitive tasks. These outcome measures are associated with executive functions, highlighting the crucial role of cognitive abilities in improving communication, particularly for individuals with hearing loss.

Understanding age-related compensation mechanisms can inform the development of more effective auditory assistance technologies. Anderson et al. [49] state that older adults characteristically easily comprehend speech in quiet environments. Compared to younger adults, they experience more difficulty understanding speech when the signal is degraded. In addition, this difficulty increase might be partly due to age-related deficits in temporal processing and/or high-frequency hearing loss. This can affect individuals with normal or near-normal hearing thresholds within the speech frequency range.

Improving and supporting the auditory needs of older adults can reduce auditory degradation by enhancing auditory rehabilitation and cognitive training methods. The effectiveness of auditory and cognitive training programs (e.g. auditory-cognitive training, auditory training, and cognitive training) on both auditory ability and cognitive functions for older adults has been investigated by Kawata et al. [50]. It was found that these technology-based training methods can improve the plasticity of their brain and cognitive functions and performance, specifically in healthy older adults. In addition, both factors, auditory and cognitive training, might be useful to improve the quality of life of older adults. From different perspectives, music-based auditory training has been used to improve auditory function and cognitive abilities for older adults with impairments of hearing loss and mild cognitive [51]. This training program was designed to include activities such as singing, playing instruments, and music discrimination games. Moreover, hearing aid treatment can lead to reducing older adults' hearing loss disability as well as improve hearing function and immediate memory [52]. Additionally, hearing loss impairment is significantly related to neural effects in the brain, including executive functioning and speech processing. Furthermore, auditory rehabilitation programs are mainly designed for hearing aid users. Lai et al. [53] examined the effectiveness of the auditory training program (Listening and Communication Enhancement) on the auditory and cognitive abilities of older adults, specifically including older adult users without hearing aids. Auditory training has proven its role in improving communication ability in older adults. However, there was no significant impact on their short-term memory or attention.

Since auditory degradation can impact older adults' quality of life and their communication abilities, it is necessary for application designers to understand the auditory and cognitive challenges they may face. For instance, peripheral hearing and auditory processing can affect older adults' ability to understand speech, especially in noisy environments [54]. In addition, a review paper by Windle et al. [55] investigated the factors related to auditory processing and cognition that possibly influence setting hearing aids for normal aging older adults. The study found that distortion to the speech envelope cues (e.g. compression speed and compression ratio) must be considered when setting hearing aids to improve their effectiveness. Thus, hearing aids should be set professionally to assist older adults with hearing impairments.

4) Social and Emotional Impairments: Older adults usually live lonely, and according to the U.S. Centers for Disease Control [56], the risk of loneliness in older adults aged 65 and over is highly related to social isolation. In addition, this frequent family members' absence may cause emotional loneliness, leading to feelings of solitude and seeking companionship through technological support [57].

B. Technological Challenges

Since electronic and mobile services are growing digitally among worldwide societies, it is important to pay more attention to research addressing issues related to this dynamic topic. Older adults are part of these societies who face various challenges when using technology, including the digital divide and usability concerns, perceptual issues, limited technological literacy, and adaptability challenges. Such barriers can affect their ability to effectively engage with digital tools and services, highlighting the need for tailored solutions that address these needs. From the perspective of technological challenges for older adult users, technological challenges may hinder their abilities to fully benefit from advancements in technology that stem from the technology design and the specific needs and abilities of this kind of user.

1) Digital Divide and Usability Concerns: Technology literacy plays a critical role in increasing technology use and adoption. Due to low technology literacy and usability issues, older adults often experience a digital divide. Although many older adults are enthusiastic about learning and adopting new technologies in order to maintain independence and improve their quality of life, many technologies are not designed with older adults in mind, which can lead to frustrations and limitations in use [58]. What distinguishes the elderly group from other groups is that they have different and unique needs and interests [59]. Thus, technology designers must consider these dynamic needs to help this population category [59].

2) Physical, Cognitive Barriers, Privacy and Security Concerns: One of the most common challenges among older adults is physical challenges, where age is the most closely related factor. According to Wang et al. [60] and Shandilya et al. [61], these challenges, such as reduced dexterity and vision, and cognitive decline, can majorly cause difficulty for them to adopt and use new technologies effectively. As well as AI-enabled products can attract older adults. However, the lack of learning avenues, privacy concerns, and the impact of decision-making can clearly highlight the need for inclusive, secure, and controllable technology design. Furthermore, older adults with limited hand dexterity or motor impairments suffer from interacting or communicating with technologies effectively [62].

3) Lack of Support and Training: Older adults' confidence and ability to use technology independently can be influenced by ten factors: value, usability, affordability, accessibility, technical support, social support, emotion, independence, experience, and confidence [63].

4) Interoperability and Technical Issues: Although wearable sensors and IoT-based devices proved their capability to address older adults' independent living issues, the main challenges for them are related to interoperability issues, inaccurate sensors, and power limitations (e.g., low usability, battery issues, and lack of interoperability) [64]. These challenges can restrict their effectiveness and user satisfaction. For example, most wearable and IoT technologies for healthcare services are non-scalable, siloed systems, and designed for a specificity use case. This can limit their integration and application into existing systems [64].

III. Related Work: Facilitators for Overcoming Challenges

1) Cognitive Mitigation: Furthermore, certain strategies, such as personalized online lifestyle interventions, including exercise and cognitive training, can help mitigate cognition decline in older adults [65], [66]. HCI research addresses different issues and challenges related to older adult users, such as memory impairments or attention issues. Thus, understanding these cognitive changes is essential for designing interfaces that can accommodate the unique needs of older adult users [67], since designing computer hardware and software is a main concern of human-computer interaction. Technology products should not ignore older adults' needs and support them as a part of society [25], and technology designers can be essential to improve the quality of life for older adults [68]. As older adults' needs are distinctive (e.g., prioritize health monitoring and emergency alarms), technology designers should not ignore them [69]. Thus, technology interfaces must be age-friendly to minimize cognitive load and support tasks requiring memory and attention [70].

Icon design, for example, Skeuomorphism (realistic) versus Flat Icons, studies highlighted that younger adults who are familiar with graphical user interface perform better with flat icons. Unlike older adults, they perform better with skeuomorphic, concrete icons that improve usefulness and reduce the cognitive load of older users [71]. Additionally, the study validated the effectiveness of concrete icons with older adults, as they prefer icons that present icon functions visually. Furthermore, Chen and Liu [72] investigated the usefulness of different features in designing daily living technology product interfaces (e.g., television controllers and electric rice cookers) to minimize older adults' cognitive load, such as less complexity, number of control functions and buttons, text size, and direct operation and voice control. An extended study by Chen et al. [73] agreed that complex interface is a serious challenge among older adults, more specifically those with mild cognitive impairment or dementia. The experiment used a programmed interface that records participants' time to complete tasks, operation errors, and tap locations. Results indicated that usability can be improved by considering the simplicity of designing (e.g., in operating procedures, reducing the number of functions and buttons, and enlarging text and buttons). This has supported their ability to respond faster and more accurately than their initial actions.

The role of smartphones and tablets in assisting the cognition of elderly people has emerged in many ways. Smartphones and tablets are effective technologies and tools that assist in improving cognitive function in older adults who do and do not suffer from cognitive impairment, particularly in processing speed and executive function, and also serve as a memory support solution for those with health problems [74]. In addition, good user experience, improved cognitive abilities, and enhanced daily life for older adults can be achieved by well-designed applications, such as a training working memory application that considers training content, motivation, emotion, interaction, current state, and experience [75]. Furthermore, Acosta et al. [76] have stimulated cognitive functions (e.g., attention, memory, reasoning, planning, language, and perception) by developing

cognitive stimulation software for older adults in order to improve usability and user experience. The study [77] has provided a comprehensive understanding of smartphones and tablets' effectiveness and efficiency by evaluating cognitive intervention technologies' usability and user experience for older adults with mild cognitive impairment or dementia. This was achieved by collecting objective data (e.g., task completion rates and error counts) and subjective data (user feedback through questionnaires, interviews, and behavioral observations). As a result, 60 per cent of older adults with cognitive impairment were able to complete tasks, and 45 per cent required more time, while 40 per cent needed assistance.

Assistive technologies can support the cognitive impairment of older adults. Belkacem [78] addressed how assistive non-invasive Brain-Computer interface (BCI) applications (e.g., controlling devices like exoskeletons, wheelchairs, and smart homes) improve the impairment of cognitive decline and motor control for older adults and elderly patients, which can lead to improving their quality of life. The advantages of such technologies were seen due to their high accuracy, minimal daily setup, rapid response times, and multi-functionality. In addition, this study cited two papers that addressed related issues [79], [80]. Both experiment studies discussed memory impairment by using BCI and cognitive tests to improve memory and attention among elderly patients. Lee et al. [79] involved participants in playing a card-matching game and command control. In contrast, Gomez-Pilar et al. [80] used imagining hand movements, where both studies resulted in memory and cognitive function enhancement. Virtual Reality-based training, furthermore, was used by Liao et al. [81] and significantly improved physical and cognitive function, instrumental activities of daily living (IADL), and neural efficiency in older adults with mild cognitive impairment. This experiment significantly improved global cognition, verbal memory, and IADL by p¡0.001, delayed recall, p=0.002, and p¡0.001 after the intervention, respectively. In addition, the PRISM-CI system, proposed by Czaja and Ross [82], has proven the ability of technological applications to improve independence and quality of life for older adults with cognitive impairments. It can support their information, resource access, and social and cognitive engagement.

According to an experimental study by Tsai et al. [83], prospective memory declines with age and is considered a challenge for most older adults. The study found that external reminders as a cognitive offloading strategy effectively mitigate memory challenges. Results showed that, compared to younger adults, older adults used more reminders with a reduced preference for them. ENCODER, proposed by Shin et al. [84], has been developed by multidisciplinary human-centered perspectives to support older adults' prospective memory, promoting self-determination and daily activities. The prospective memory has been discovered to be a critical predictor of the functional independence in name of the older adults with objective indicators of the prospective memory performance having a convincing relationship to the degree to which daily activities might be executed with no supplementary support [85].

2) Technological Design Strategies: Effective technology design guidelines additionally contributed to supporting older adults' cognitive impairment. According to Zhu et al. [75], a better understanding of older adults' psychological and physiological characteristics led to designing mobile training applications and improving their working memory and user experience. This study concluded that daily practice, challenge modes, level-by-level difficulty selection, novice teaching, practice modes, sharing functions, two-player modes, ranking, and desktop components are effective design strategies for cognitive training applications. Technology designers and developers should consider older adults' needs for user-friendly interfaces, optimized portable devices, and personalized training program capability to overcome this population's cognitive impairments [86].

VUIs can improve user-technology interaction because they use natural language processing, which makes complex graphical interfaces easier to use, especially for older adults with mild cognitive impairments [87].

The ability of older adults to navigate user interfaces on digital devices is influenced by increasing cognitive impairments. Despite the high adoption of smartphones by seniors, new challenges have emerged, especially for this age group, due to the high interaction requirements and the ever-changing design patterns in various applications [88]. The study highlighted the usability challenges for older adults navigating various interfaces. The applied usability test and qualitative study made it difficult for older adults to understand and interact with icons, and assistance was needed. Besides, content-oriented navigation was more effective for older adults than menus and buttons. Similarly, Leung et. al. [89] discussed three main factors influencing icon usability: 1) user-Related Characteristics (including intelligence, experience, and user culture), 2) context of Icon Usage (mobile device capabilities, task requirements, and software application interface), and 3) visual Characteristics (animation, spacing, size, concreteness, and visual complexity). In addition, it is more challenging for older adults to use mobile device icons than for younger ones due to demographic differences. It was hard for older adults to interpret icon meanings and identify icon objects, as younger adults were better to so. The study highlighted that icon usability for older adults can be improved by designing icons with respect to semantically close meanings, familiar objects, labels, and concrete representations. As well as this will also lead to designing age-friendly mobile device interfaces in order to improve the quality of life for older adults. Furthermore, user interface design guidelines and checklists in relation to phones and smartphone features were suggested to improve older adults' usability [90]. It also discussed the relationship between mobile phone design for older adults and cognitive function through menu structure, function naming, and screen properties. For instance, older adults usually have cognitive slowing, which makes them feel stressed with a deeper menu structure, and considering the simplicity and flattened menu structure may support decision-making.

3) Content-Oriented Navigation: Li and Luximon [91] found that the performance of older adults was clearly better with designs of content-oriented navigation. In addition, they found this design approach easier to understand and interact with than traditional menu-based systems, especially for mobile interfaces. Moreover, as it is less complicated, it helps older adults avoid struggling with menus and buttons,

and reduces the cognitive load required to understand and interact with digital interfaces, making electronic services easier for older adults to use. Content-oriented navigation helps facilitate digital engagement [92]. It assists users in focusing on content rather than complex navigation structures. As a result, older adults are more likely to engage with digital services. Furthermore, it helps overcome barriers like a lack of digital literacy and users' confidence, which are common among the older adult community [93]. The study found that older adults prefer smartphones and computers and value personalization and access to credible information in HITs, but they have concerns about data privacy and security. Strategies like co-design, digital navigators, and education materials can enhance the adoption and efficacy of HITs for older adults.

4) Design for Dynamic Diversity (DDD): DDD is an approach that involves creating interfaces that adapt to the changing older adults' abilities, accommodating memory, cognitive, and visual impairments [25].

5) Elderly-Friendly Mobile Applications: Previous related works recommended designing interfaces that mainly consider some features, such as perceptual, motor, and cognitive challenges, and incorporating persuasive features (e.g., reminders and personalized interventions) to enhance engagement effectively [94].

6) Voice User Interfaces (VUIs): Compared to visual interfaces, VUIs offer more accessibility for older adults with visual impairments and support their inclusive education and daily activities by providing an auditory method of interaction [95]. Furthermore, VUI enables hands-free interaction, which improves usability [96], [97]. Leveraging natural language interaction, in addition, VUIs helped significantly simplify the use of technology for older adults by focusing on ease of use and addressing critical non-functional requirements like social connectedness and psychological well-being [98]. In order to effectively support older adults in digital technology usage, designing such a simple and adaptable interface and considering sensory and cognitive limitations is critical. However, implementing content-oriented navigation, customization settings, and voice interfaces has improved usability and adoption among older users. The results of such strategies were limited to enhancing user experience and promoting healthy aging by facilitating access to digital services.

IV. Discussion

The population of older adults continues to grow globally, which highlights the urgent need to address challenges (e.g. the complex and varied experiences) they face when interacting with technology. Although the literature consistently identifies personal challenges (e.g cognitive decline, sensory impairments, and reduced motor abilities), it fails to account for subgroup differences within the population of older adults, namely young-old (60 to 69), mid-old (70 to 79), and old-old (80+) [99]. There is a significant difference between each subgroup in regard to their characteristics, including cognitive functionality, physical capacity, and technological adaptability. However, it is notable that there is a lack of current technology designs that reflect this diversity, which results in insufficient generic technological solutions to serve all users.

Technological challenges that include non-intuitive interfaces, small text, visual clutter, and the demand for high dexterity disproportionately are more likely to affect older adults, specifically the mid- and old-old groups, which exacerbate usability issues. Previous related works have addressed this topic by proposing several solutions, for instance, user-friendly design, inclusive interface development, accessibility improvements, and digital training programs. However, these studies generalized this population, which ignores the differentiate design practices based on the needs of subgroups or the level of impairments. Furthermore, existing literature emphasized the value of inclusive design principles; however, there is limited practical application of adaptive systems that dynamically adjust to the cognitive and physical capabilities of users. VUIs are a potentially transformative tool that can reduce the complexity of technology interaction remain significantly underutilized in this domain. Some studies have involved this technology as an assistive tool; however, a few have assessed the actual effectiveness or adoption of VUIs among subgroups of older adults. Moreover, age segmentation or contextual variability has not been considerable sufficiently in the designs for many facilitators in the literature (e.g community learning, family involvement, and professional tech support), which leads to a lack of users' personalization. The need of further investigation is highly recommended based on the lack of studies addressing the specific needs of older adult subgroups. These needs are particularly regarding impairment-sensitive designs and emotional barriers to the use of technology (e.g fear of loss of human interaction and concerns about security). Previous studies, additionally, are constrained by small culturally homogeneous samples that do not reflect broader or global aging populations or consider gender diversity. Thus, future research and technology designs should expand these limitations beyond one-size-fits-all models and prioritize inclusive and adaptive approaches. In order to promote sustained engagement and improved quality of life among older adults, account for subgroup variability, integrate VUIs and other assistive technologies, and address the challenges of perception and emotion.

V. Conclusion and Future Work

Older adults face several personal and technological challenges, where understanding and addressing the complex interplay of these challenges is essential to develop inclusive digital solutions. In this group of people, it is common to encounter barriers such as cognitive decline, sensory impairments, reduced motor control, and low digital literacy. Furthermore, older adults frequently encounter barriers such as cognitive decline, sensory impairments, reduced motor control, and low digital literacy, which significantly affect their ability to engage with modern technologies. Meanwhile, the technological design of the majority of digital tools often exacerbates these challenges. For example, small text, cluttered layouts, poor accessibility features, and non-intuitive interfaces mostly fail to accommodate their needs.

The tendency to treat older adults as a single, uniform demographic have been found from the existing research and practice as a critical oversight. There is meaningful differences exist among subgroups of older adults each with distinct physical abilities, cognitive functioning, technological familiarity, and psychological perspectives.

Thus, ignoring these main differences often cause a misalignment of technology development with the capabilities and expectations of users, which can lead to frustration, low adoption, and disengagement. Additional to that, community workshops, family assistance, and digital training initiatives, as existing facilitators, are implemented without considering the characteristics of older adults subgroups or cultural contexts of many developed and developing countries. Consequently, these interventions may lack relevance or effectiveness for broader populations. Moreover, VUIs under-utilization clearly seemed to be another missed opportunity, as VUIs have a vast ability to offer intuitive, hands-free interaction that is beneficial for users in general, and more beneficial for those with visual or dexterity impairments. However, their design, usability, and adoption across different older adult subgroups remain insufficiently explored despite their promise.

Undoubtedly, emotional and psychological factors additionally play an important and critical role in the relationship of older adults with technology. What can act as a deterrent for many users, especially older adults, is privacy, fear of losing human interaction, and lack of confidence in using digital tools. In contrast, the role of enjoyment and emotional satisfaction in technology adoption remains underexplored and a critical gap. It was notable that previous related works addressed usability and accessibility more frequently than focusing on the extent to which digital tools bring joy, entertainment, or a sense of purpose to older adults, specifically in design practices. Motivation, long-term engagement, and quality of digital experience can significantly be improved by enjoyment, and should be a focal point in future HCI research.

This work was limited to review related papers that mainly address user interface design for older adults from the perspective of HCI based on personal (cognitive, physical, sensory, and social and emotional impairments) and technological (digital divide and usability concerns, physical, cognitive, barriers, privacy and security concerns, lack of support and training, and interoperability and technical issues) challenges. Future research is needed to address the gaps found in this study, such as older adults' emotional and social needs, and designing user interfaces for older adults' subgroups who are ignored by technology designers. Older adults' needs must be highly considered in future research, and prioritized adaptive, inclusive, and subgroup-responsive design approaches. Evaluating the use of VUIs as an assistive technology, incorporating participatory methods, and ensuring representation across cultures and age segments can pave the way toward more equitable and empowering digital environments. Moreover, to enrich the emotional and social lives of older adults, technology designers must consider embedding enjoyment (as a key design consideration) alongside functionality and usability, as well as digital tools supporting autonomy and accessibility.

***Abstract*—The COVID-19 pandemic has profoundly impacted economic and social structures, directly affecting individuals' lives. Deep learning models offer the potential to forecast future long-term trends and capture the temporal dependencies present in time series data. In this study, we propose leveraging the autocorrelation function (ACF) and the partial autocorrelation function (PACF) series as additional components to enhance the forecasting accuracy of our models. Our proposed method is applied to forecast COVID-19 time series data in twelve countries using the deep learning techniques of Long Short-Term Memory (LSTM) and Gated Recurrent Units (GRU). When comparing the rankings average of mean absolute error and R-squared, the proposed models demonstrated superior performance in time series forecasting compared to the standard LSTM and GRU model. Specifically, the ACF-PACF-GRU model achieved the best median values for mean absolute percentage error (1.67 per cent for confirmed cases and 2.17 per cent for death cases) and root mean square error (1.92 for confirmed cases and 2.17 for death cases). Therefore, the proposed ACF-PACF-GRU model showed the highest performance in forecasting both confirmed and death cases. This research introduces a novel method for constructing effective time series models aimed at forecasting disease burdens, thereby aiding in epidemic control and the implementation of preventive measures.**

I. Introduction

In late 2019, a novel β-coronavirus—SARS-CoV-2—emerged in Wuhan, China, posing significant challenges to global health systems [1], [2], [3]. Declared a public health emergency by the WHO in March 2020 [4], COVID-19 has since resulted in over 776.8 million confirmed cases and more than 7 million deaths across 234 countries as of November 10, 2024. Although mortality peaked between 2020 and 2022, global death rates have declined with rising immunity levels [5]. The pandemic's impact spans healthcare, economics, travel, and international policy, highlighting the critical need for accurate forecasting to guide public health interventions and resource allocation [6].

COVID-19 demonstrates dynamic, non-linear transmission patterns influenced by seasonal variation and evolving viral behavior, necessitating adaptive modeling approaches [7]. Time series forecasting has traditionally relied on statistical models like ARIMA and SARIMA. ARIMA has been widely applied to model diseases such as tuberculosis [8], brucellosis [9], and dengue [10]. However, it struggles with capturing seasonality and nonlinear patterns, which SARIMA partially addresses [11], [12], [13], [14], [15]. For COVID-19, ARIMA and SARIMA have been used in diverse contexts, such as Morocco [16], Europe [17], and Canada [18], with varying degrees of accuracy. Nevertheless, their linear assumptions and need for differencing limit performance in more complex, evolving datasets [19].

To overcome these limitations, deep learning architectures have emerged as powerful tools for time series forecasting. Advances in data availability and computational power have facilitated their widespread adoption across domains, with deep neural networks proving particularly effective for regression tasks and temporal pattern modeling [20], [21].

The proliferation of big data, driven by advancements in data acquisition technologies, has created a demand for advanced forecasting models capable of processing complex, multivariate, and high-dimensional time series data [22]. Traditional shallow learning approaches often fail to capture the intricate temporal dependencies and noise inherent in such datasets. In response, deep learning has emerged as a dominant paradigm for time series forecasting due to its ability to model non-linear relationships and long-term dependencies effectively [23].

Among deep learning architectures, Long Short-Term Memory (LSTM) and Gated Recurrent Unit (GRU) networks are particularly suited for sequential data. Deep learning models have gained significant attention in COVID-19 forecasting due to their capacity to capture non-linear patterns and temporal dependencies in time series data. Among these, LSTM and GRU networks have emerged as leading architectures for epidemic modeling. Both are types of recurrent neural networks (RNNs) specifically designed to mitigate the vanishing gradient problem, enabling the modeling of long-range temporal dependencies crucial for accurate disease forecasting.

Several studies have demonstrated the effectiveness of LSTM models in predicting COVID-19 cases. Dharani and Bojja [24] proposed an enhanced LSTM architecture with internal gate optimizations to improve the prediction accuracy of COVID-19 time series. Similarly, Shahid et al. [25] compared multiple models—including ARIMA, SVR, LSTM, and Bi-LSTM—for forecasting confirmed, death, and recovered cases across ten countries, finding that Bi-LSTM significantly outperformed other models. Luo et al. [26] further validated the predictive strength of LSTM through a comparative study with XGBoost, highlighting LSTM's superior performance in

*Corresponding authors.

capturing temporal dynamics.

GRU models, which simplify LSTM by using fewer parameters while maintaining comparable performance, have also been applied successfully. ArunKumar et al. [27] utilized GRU, LSTM, and other RNN variants to forecast cumulative confirmed cases in the ten most affected countries, reporting promising results. The comparative advantage of GRU lies in its computational efficiency and similar accuracy, making it suitable for real-time applications in epidemic forecasting.

Moreover, hybrid and ensemble variants such as stacked LSTM, bidirectional GRU, and LSTM-GRU combinations have shown improved performance by leveraging the strengths of both architectures [28], [29], [30]. These models are particularly effective in multi-country forecasting settings where data complexity and temporal variability are high.

Overall, the literature suggests that LSTM and GRU models are well-suited for modeling the complex, nonlinear, and dynamic nature of COVID-19 transmission. Their adaptability, accuracy, and scalability make them powerful tools for public health planning and early warning systems. Given the complex, non-linear nature of time series data, statistical tools like ACF and PACF are often used to analyze temporal dependencies. Their integration into deep learning models, as proposed in this study, is a novel approach that aims to enhance prediction accuracy without altering model architectures [31].

This study integrates ACF and PACF as supplementary inputs to LSTM and GRU models to enhance time series forecasting accuracy. By leveraging these statistical tools to capture temporal dependencies, the proposed approach forecasts COVID-19 confirmed and death cases across twelve countries, and compares results against standard LSTM and GRU models reported in the previous study of Luyu Zhou et al [32]. Unlike prior work, this method augments input features without altering the core architectures. Model performance is evaluated using MAE, MAPE, RMSE, and R-squared.

The study is structured as follows: Section II details LSTM and GRU architectures; Section III outlines the data sources, methodology, preprocessing, and evaluation metrics; Section IV presents results and comparisons; Section V discusses the study results with limitations. Finally, Section VI summarizes the conclusion of the whole study.

II. Methodologies

This study illustrates the effective integration of deep learning architectures with statistical techniques to enhance the accuracy of COVID-19 epidemiological data forecasting. In particular, two widely recognized deep learning approaches, LSTM and GRU, are employed in conjunction with ACF and PACF to capture and model the temporal dependencies inherent within the time series data.

A. Long Short-Term Memory (LSTM)

Deep learning techniques like RNN are well-suited for sequence processing because they capture the temporal dynamics of time series data [33]. However, when dealing with very long time series, passing information from earlier time steps to later ones becomes challenging, leading to difficulties in training due to vanishing or exploding gradients. Hochreiter and Schmidhuber introduced LSTM networks to address this issue by facilitating the flow of previous information across state sequences [34]. The LSTM cell architecture includes a memory cell and three gates: the forget gate (F_t), the input gate (I_t), and the output gate (O_t) shown as Fig. 1.

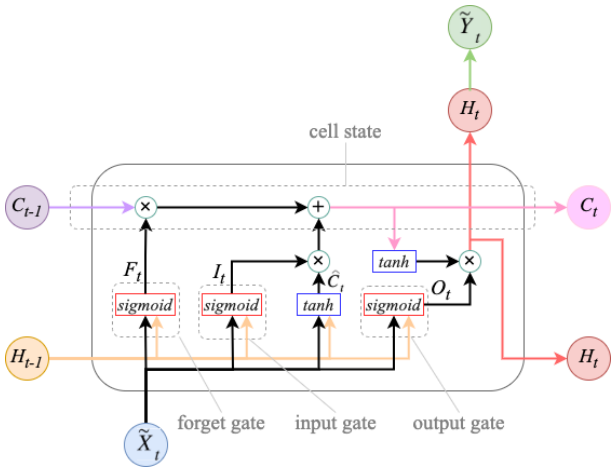

Fig. 1. Architecture of a single LSTM cell.

These gates regulate the flow of information within the cell state: the forget gate controls what information to discard, the input gate determines what information to input to the cell state, and the output gate manages outgoing information [35]. The intermediate cell state ($\hat{C}_t$) serves as the core memory component, propagating information across time steps. Its update at each step is governed by gating mechanisms that selectively regulate the preservation, forgetting, or modification of information. This design enables LSTMs to retain information over long periods, a capability not fully realized in conventional single RNNs. LSTMs excel in capturing long-term dependencies and effectively handling time series data. LSTM network is compute mapping between input sequence and output sequence, i.e. $\tilde{X} = (\tilde{X}_1, \tilde{X}_2, ..., \tilde{X}_n)$ and $\tilde{Y} = (\tilde{Y}_1, \tilde{Y}_2, ..., \tilde{Y}_n)$. Given the normalized scale of the time series as input $\tilde{X}_t$, as output $\tilde{Y}_t$, and the number of hidden units as h. The gates have the following equations [Eq. (1) to Eq. (7)]:

Input gate:

$$I_t = \text{sigmoid}(W_{xi}\tilde{X}_t + W_{hi}H_{t-1} + b_i) \tag{1}$$

Forget gate:

$$F_t = \text{sigmoid}(W_{xf}\tilde{X}_t + W_{hf}H_{t-1} + b_f) \tag{2}$$

Output gate:

$$O_t = \text{sigmoid}(W_{xo}\tilde{X}_t + W_{ho}H_{t-1} + b_o) \tag{3}$$

Intermediate cell state:

$$\hat{C}_t = \tanh(W_{xc}\tilde{X}_t + W_{hc}H_{t-1} + b_c) \tag{4}$$

Cell state (next memory input):

$$C_t = F_t \odot C_{t-1} + I_t \odot \hat{C}_t \tag{5}$$

New state:

$$H_t = O_t \odot \tanh(C_t) \tag{6}$$

Normalized predicted output:

$$\tilde{Y}_t = H_t \tag{7}$$

where, W_{xi}, W_{xf}, W_{xo}, W_{xc}, and W_{hi}, W_{hf}, W_{ho}, W_{hc} refer respectively to the weight parameters and b_i, b_f, b_o, b_c denote bias parameters for three gates and a memory cell. The symbol $\odot$ indicates the element-wise multiplication. The estimation of C_t relies on the output information from memory cells (C_{t-1}) and the current time step $\hat{C}_t$. The predicted output $\tilde{Y}_t$ is obtained from the hidden state (H_t) at each time t in the current LSTM cell.

B. Gated Recurrent Unit (GRU)

Gated Recurrent Unit (GRU) serves as an alternative version of LSTM designed to enhance the LSTM performance, reduce the number of parameters, and simplify its design [36]. GRU achieves this by amalgamating the input and forget gates of LSTM into a single update gate (Z_t), and utilizing the output gate as a reset gate (R_t). The introduction of reset and update gates represents novel features introduced by GRU models, offering a fresh evaluation method for calculating hidden states in RNN models. In the general architecture of GRU, only the update and reset gates are employed (see Fig. 2).

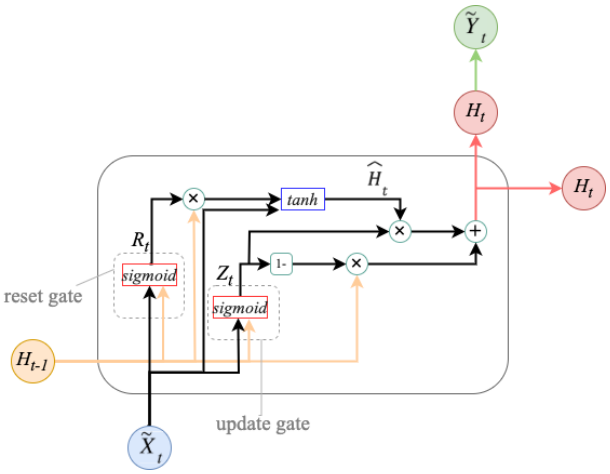

Fig. 2. Architecture of a single GRU cell.

The update gate determines the extent of previously retained memory, while the reset gate governs the manner in which current inputs combine with past memory. The GRU network compute mapping between input sequence and the output sequence in normalized form, that is, $\tilde{X} = (\tilde{X}_1, \tilde{X}_2, ..., \tilde{X}_n)$ and $\tilde{Y} = (\tilde{Y}_1, \tilde{Y}_2, ..., \tilde{Y}_n)$. The mathematical relationships between the various GRU components are presented in Eq. (8) to Eq. (12):

Update gate:

$$Z_t = \text{sigmoid}(W_{xz}\tilde{X}_t + W_{hz}H_{t-1} + b_z) \tag{8}$$

Reset gate:

$$R_t = \text{sigmoid}(W_{xr}\tilde{X}_t + W_{hr}H_{t-1} + b_r) \tag{9}$$

Cell state:

$$\hat{H}_t = \tanh(W_{xh}\tilde{X}_t + W_{hh}(R_t H_{t-1}) + b_h) \tag{10}$$

New state:

$$H_t = Z_t \odot H_{t-1} + (1 - Z_t) \odot \hat{H}_t \tag{11}$$

Normalized predicted output:

$$\tilde{Y}_t = H_t \tag{12}$$

where, W_{xz}, W_{xr}, W_{xh} and W_{hz}, W_{hr}, W_{hh} refer respectively to weight parameters and b_z, b_r, b_h denote bias parameters. The symbol $\odot$ indicates the element-wise multiplication. For a given time step t, the current update gate Z_t is used to combine the previous hidden state H_{t-1} and current candidate hidden state $\hat{H}_t$. The normalized predicted output $\tilde{Y}_t$ is derived from the hidden state (H_t) at each time step t within the current GRU cell.

C. Autocorrelation Function and Partial Autocorrelation Function

Time series data often harbors hidden characteristics, encompassing both linear and non-linear components that profoundly impact analysis, modeling, and forecasting. In this context, the autocorrelation function (ACF) and partial autocorrelation function (PACF) emerge as indispensable tools in time series analysis, offering valuable insights into its structure and dynamics. The ACF and PACF serve to uncover the presence and characteristics of autocorrelation within the data. Autocorrelation and partial autocorrelation represent statistical measures that assess the relationship between a time series and its preceding values, known as lag. These measures illuminate the temporal dependencies and patterns inherent in the time series, thereby facilitating a deeper understanding of its behavior and informing predictive modeling endeavors.

The ACF measures the correlation between observations in a time series and their lagged values across different time intervals. This helps to identify patterns and temporal dependencies within the time series data. The ACF calculates the correlation between the series (X_t) and the same series lagged by k time periods (X_{t-k}). Mathematically, the ACF at lag-k is expressed in Eq. (13) to Eq. (14) [37]:

$$\text{Corr}_{(X_t, X_{t-k})} = \frac{\text{Cov}(X_t, X_{t-k})}{\sqrt{\text{Var}(X_t) \cdot \text{Var}(X_{t-k})}} \tag{13}$$

$$\text{Corr}_{(X_t, X_{t-k})} = \frac{\sum_{t=k+1}^{n}(X_t - \bar{X}) \cdot (X_{t-k} - \bar{X})}{\sum_{t=1}^{n}(X_t - \bar{X})^2} \quad (14)$$

where, X_t represents the value of a time series at time t, $\bar{X}$ means the mean of the time series, and n denotes the number of observations in the time series. The variable k represents the time gap being examined and is termed the lag, where k ranges from 1 to n. In essence, a lag-k autocorrelation refers to the correlation between values that are k time periods apart.

Unlike autocorrelation, partial autocorrelation isolates the direct correlation between an observation in a time series and its past values, eliminating the influence of other values at intermediate time lags [31]. For instance, the partial autocorrelation for lag-3 only considers the correlation that lag-1 and lag-2 do not account for. In a time series, the partial autocorrelation between X_t and X_{t-k} is defined as the conditional correlation between X_t and X_{t-k}, conditioned on X_{t-1}, ... , X_{t-k+1}, representing the observations between time points t and $t-k$. The PACF at lag-1 is defined to equal the ACF at lag-1. Subsequently, the partial autocorrelation at lag-k is expressed mathematically as follows [37]:

$$\text{Corr}_{(X_t, X_{t-k} | X_{t-1}, \ldots, X_{t-k+1})} = \frac{\text{Cov}(X_t, X_{t-k} | X_{t-1}, \ldots, X_{t-k+1})}{\sqrt{\text{Var}(X_t | X_{t-1}, \ldots, X_{t-k+1}) \cdot \text{Var}(X_{t-k} | X_{t-1}, \ldots, X_{t-k+1})}} \quad (15)$$

In Eq. (15) X_t represents the value of a time series at time t, and n signifies the total number of observations in the time series. The variable k denotes the time gap under consideration and is termed the lag, with k ranging from 1 to n. Essentially, a lag-k autocorrelation indicates the correlation between values that are k time periods apart.

D. Proposed Methods with ACF, PACF Series

Deep learning techniques, such as LSTM and GRU, have been successfully applied in the context of time series forecasting. The performance of these methods relies heavily on having a sufficient amount of data to appropriately fit their parameters [17]. However, the number of samples extracted from a short time series may be insufficient to achieve an optimal model [38]. To prevent overfitting, these methods should be properly regularized. One challenge in time series forecasting is that, even with a long series and ample data, observations from the distant past often provide fewer cues for prediction. Recent observations from an individual series tend to be more useful in forecasting. This could be attributed to the evolving nature of patterns within a series.

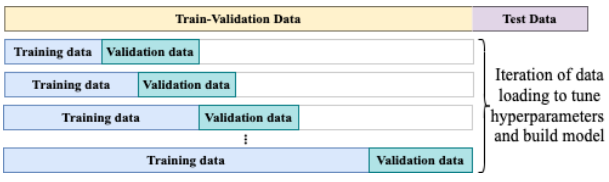

Fig. 3. Train-validation-test split of time series dataset.

In Fig. 3, a given time series is divided into in-sample and out-sample segments using a certain ratio, such as 70/30. The out-sample portion serves as testing data to evaluate the model. The in-sample segment is further divided into training and validation data. However, using separate validation data means excluding recent observations from the training data, potentially missing recent patterns. One simple solution is to include the validation data in model training. However, this may lead to overfitting, reducing accuracy on test data. Specifically, we are determined to apply the statistical properties of the ACF, PACF to avoid model overfitting and enhance the learning potential of deep learning methods for time series forecasting.

The primary concept of the proposed models in this study is to integrate the ACF and PACF series from lag-1 to lag-7, as another new series into deep learning models based on LSTM and GRU for sequential predictions of COVID-19 cases, as depicted in Fig. 4. A part of the training data, and validation data are utilized to build the ACF and PACF series from lag-1 to lag-7, separately in each time period. Both ACF, PACF series uncover the temporal dependencies that exist in the original series. Therefore, the original part of training data and its ACF/PACF series are passed to the standard LSTM or GRU model for generate one proposed model in the model training process, such as ACF-LSTM, PACF-LSTM, ACF-PACF-LSTM, ACF-GRU, PACF-GRU, and ACF-PACF-GRU, as shown in Fig. 5. In the validation process, the original part of training data and its ACF/PACF series are employed with an optimization algorithm to fine-tune the hyperparameters of each model that fit the trained model. Moreover, the testing data from the original time series is used to generate the ACF and PACF series, which are then employed to predict values during the testing phase, as illustrated in Fig. 6.

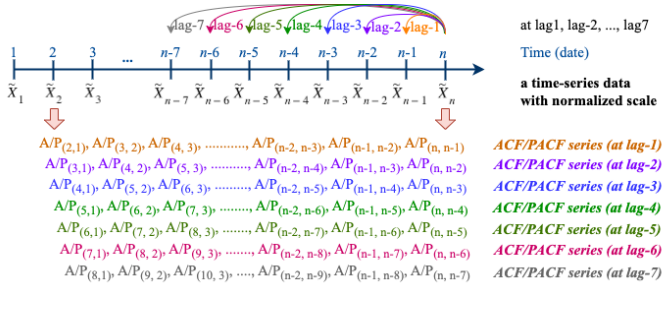

Fig. 4. ACF and PACF series at lag1 to lag7.

III. Materials

This section describes the source of the dataset, design experiments for COVID-19 forecasting, data preprocessing, and the evaluation criteria for model predictive performance.

A. Data Source of COVID-19

This study aims to compare deep learning prediction models using COVID-19 datasets from twelve countries with the highest number of COVID-19 cases. The COVID-19 dataset was sourced from the WHO International website, providing daily cumulative cases of COVID-19 [39], in .csv format. The dataset contains the daily cumulative number of confirmed,

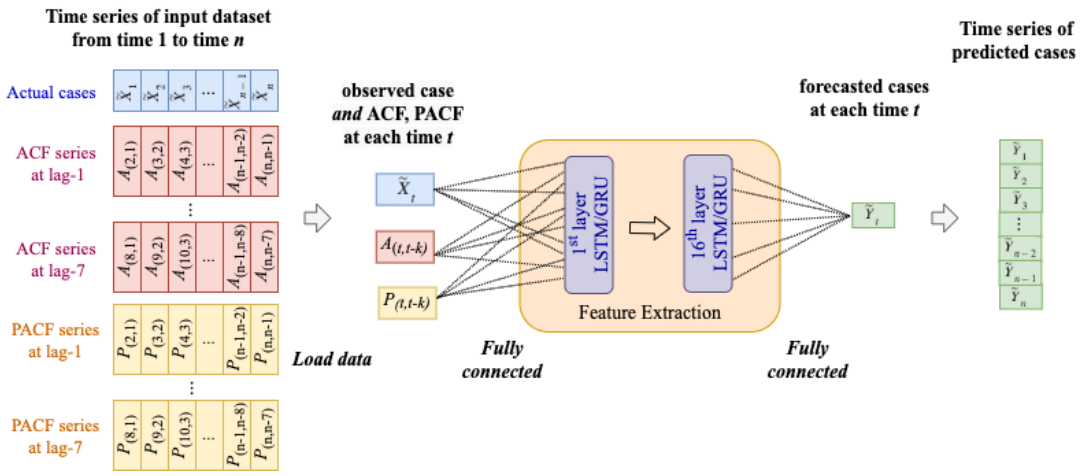

Fig. 5. COVID-19 data, ACF and PACF series into proposed model.

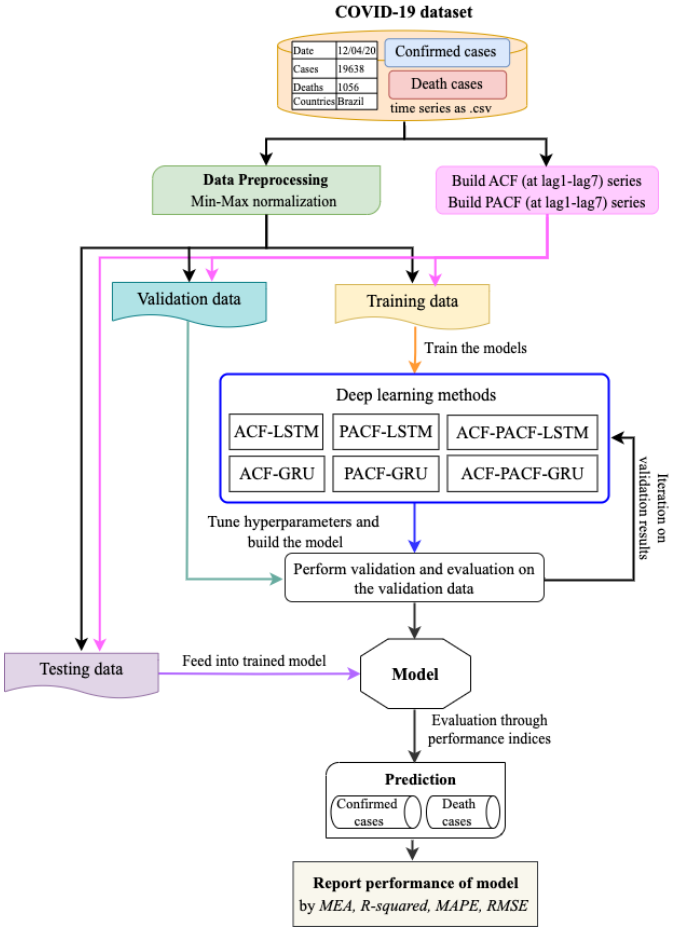

Fig. 6. Framework of the proposed scheme.

death, and recovered cases in the time series format with temporal patterns. In this study, the experiments were conducted using the time series data of confirmed and death cases for twelve countries with the highest number of confirmed cases from January 6, 2020, to June 6, 2022. These countries are the USA, India, Brazil, France, Germany, the UK, Russia, Italy, Turkey, Spain, Vietnam, and Argentina. These specific countries were chosen based on a selection process proposed in a prior publication [32]. This COVID-19 data set includes the counts of confirmed cases, and deaths cases shown in Table I. For training and validation, 70% of each time series is allocated, with the remaining 30% reserved for case prediction in Fig. 3. Before developing a proposed model, the data series undergoes preprocessing.

TABLE I. OVERALL COVID-19 CASES

Countries	Confirmed cases	Death cases
USA	83,894,969	1,000,512
India	43,181,335	524,701
Brazil	31,153,069	666,997
France	28,647,902	149,202
Germany	26,558,190	143,131
UK	22,342,463	199,612
Russia	18,355,200	379,584
Italy	17,505,973	166,949
Turkey	15,077,320	99,004
Spain	12,520,475	108,488
Vietnam	10,726,045	43,081
Argentina	9,276,618	128,973

B. Data Preprocessing

The dataset consists of two features: confirmed and death cases. Unscaled data can impede the convergence process. To enhance model performance and ensure consistency in evaluating deep learning models, preprocessing raw data through normalization is essential. We applied normalization to the data using the formulation $\tilde{X}_t = (X_t – min)/(max – min)$, where $\tilde{X}_t$ represents the normalized actual value at time point t, ensuring it falls within a fixed range typically from zero to one, and X_t denotes the actual value observed at time point t. After constructing the forecasting model at each time point t and obtaining the forecasted values on the normalized scale $\tilde{Y}_t$, we transformed them back to the original data scale using the following formula: $Y_t = \tilde{Y}_t * (max - min) + min$. In this

context, Y_t represents the predicted data at the time point t, rescaled to the raw data format. In Python, the observed raw data can be normalized using the *MinMaxScaler* object from scikit-learn [40]. MinMaxScaler subtracts the smallest feature value and then divides by the feature range, where the range is the difference between the original maximum and original minimum values. This scaler preserves the shape of the original data distribution, retaining the information embedded in the original dataset without significantly altering it or diminishing the importance of outliers.

C. Design Experiments for COVID-19 Forecasting

This study proposes a deep-learning framework for COVID-19 time-series forecasting, integrating the ACF, and PACF series from lag-1 to lag-7 into LSTM and GRU models. Six deep learning models are employed for forecasting daily confirmed and death cases: ACF-LSTM, PACF-LSTM, ACF-PACF-LSTM, ACF-GRU, PACF-GRU, and ACF-PACF-GRU in Fig. 5. The proposed models offer a comprehensive exploration of deep learning techniques. A visual representation of the proposed scheme is depicted in Fig. 6.

Given the progressive spread of COVID-19, the cumulative number of confirmed and death cases is forecasted at specific points in time using preceding values. The COVID-19 time series datasets in this study are segmented into training, validation, and testing datasets, as illustrated in Fig. 6. Monitoring the model's generalization capabilities and selecting appropriate hyperparameters is crucial. To address this, the data is partitioned based on time for training and validation purposes.

COVID-19 forecasting entails two main stages: training and testing. During the initial stage, raw data is preprocessed, standardized, and utilized to construct the deep learning model. Parameters for the deep learning models are adjusted to minimize the loss function during training, employing the Adam optimizer for this purpose. Subsequently, in the testing stage, the previously constructed models with the selected parameters are deployed to forecast the number of COVID-19 cases. The hyperparameter settings for the deep learning models—ACF-LSTM, PACF-LSTM, ACF-PACF-LSTM, ACF-GRU, PACF-GRU, and ACF-PACF-GRU—are outlined in Table II.

TABLE II. PROPOSED SCHEME WITH HYPERPARAMETERS AND THEIR VALUES

Methods	Hyperparameters	Values
ACF-LSTM/	Layers	1
ACF-GRU/	Timestep	7
PACF-LSTM/	Hidden units	16
PACF-GRU	Feature(s)	8
	Loss	MAE
	Last activation	tanh
	Batch size	64
	Epochs	10000
	Optimizer	Adam
	ACF/PACF	lag-1, lag-2, lag-3,..., lag-6, lag-7
ACF-PACF-LSTM/	Layers	1
ACF-PACF-GRU	Timestep	7
	Hidden units	16
	Feature(s)	15
	Loss	MAE
	Last activation	tanh
	Batch size	64
	Epochs	10000
	Optimizer	Adam
	ACF	lag-1, lag-2, lag-3,..., lag-6, lag-7
	PACF	lag-1, lag-2, lag-3,..., lag-6, lag-7

Sixteen cells of LSTM or GRU algorithms are incorporated into a single hidden layer within the proposed models illustrated in Fig. 7. Model accuracy is evaluated by comparing measured data with real data using standard statistical performance measures including MAE, MAPE, RMSE, and R-squared. Simulations and experiments of the proposed models of deep learning are implemented with Keras [41], the Python deep learning library. The primary objective of this study is to assess the predictive capabilities of the six proposed models for forecasting the number of COVID-19 cases, which will be compared with the standard LSTM and GRU models in terms of MAE, and R-squared presented in the previous study. The specific steps involved are as follows:

Step1. The data of COVID-19 are normalized, and the time series is divided into training sets and testing sets;

Step2. Introduce the ACF and, or PACF series (at lag-1, ..., and lag-7) to LSTM, or GRU algorithm;

Step3. Define the hyperparameters in an proposed model in training data;

Step4. In the training step, using the training set data to determine the optimal solution of the model to predict the forecasted values in the training data;

Step5. In the validation step, using validation data to evaluate the fit model from training step;

Step6. In the testing step, using testing data to test the trained model, and evaluate the accuracy of the model by using performance indices. Given the progressive spread of COVID-19, the cumulative number of confirmed and death cases is forecasted at specific points in time using preceding values. The COVID-19 time series datasets in this study are segmented into training, validation, and testing datasets, as illustrated in Fig. 3. Monitoring the model's generalization capabilities and selecting appropriate hyperparameters is crucial. To address this, the data is partitioned based on time for training and validation purposes.

D. Performance Metrics

In this study, the mean absolute error (MAE), and the coefficient of determination (R-squared or R^2) are utilized as predictive performance metrics to evaluate forecast accuracy and compare between proposed models and the standard deep learning models (LSTM, and GRU). Whereas comparing the accuracy forecasting among the six proposed models is considered by the mean absolute percentage error (MAPE), and the root mean square error (RMSE) [42], [43]. These performance metrics are estimated from a normalized form of the actual and predicted values at time point t presented as $\tilde{X}_t$ and $\tilde{Y}_t$,

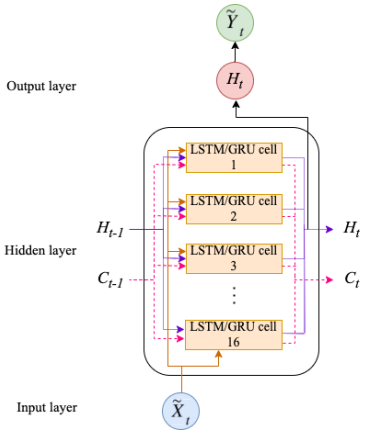

Fig. 7. Architecture of 16 LSTM/GRU cells.

respectively. $\bar{\tilde{X}}$ represents the mean of the normalized actual values, and n denotes the total number of data time points. A model demonstrates superior performance when MAE, MAPE, and RMSE are closer to 0. Additionally, a model is considered more efficient when R-squared approaches 1 [44], [45]. Mean absolute error (MAE) enables the measurement of the average magnitude of errors for a set of predictions, irrespective of their direction. It is expressed mathematically in Eq. (16):

$$\text{MAE} = \frac{1}{n}\sum_{t=1}^{n}\left|\tilde{Y}_t - \tilde{X}_t\right| \tag{16}$$

MAPE quantifies the magnitude of errors as a percentage and can be expressed mathematically in Eq. (17):

$$\text{MAPE} = \frac{1}{n}\sum_{t=1}^{n}\left|\frac{\tilde{X}_t - \tilde{Y}_t}{\tilde{X}_t}\right| \times 100 \tag{17}$$

Root mean square error (RMSE) reveals the discrepancies in amplitude between actual and forecasted data. RMSE is often flavored for evaluating short-term forecasting [46], [47], and can be calculated as Eq. (18):

$$\text{RMSE} = \sqrt{\frac{1}{n}\sum_{t=1}^{n}(\tilde{Y}_t - \tilde{X}_t)^2} \tag{18}$$

To demonstrate the proportion of the variation between actual value and forecasted value, R-squared is presented in Eq. (19):

$$R^2 = 1 - \frac{\sum_{t=1}^{n}(\tilde{X}_t - \tilde{Y}_t)^2}{\sum_{t=1}^{n}(\tilde{X}_t - \bar{\tilde{X}})^2} \tag{19}$$

IV. Results

This section describes the evaluation criteria for model predictive performance, results, and discussion about those results. To evaluate the performance of deep learning methods for COVID-19 time-series forecasting, this study compares six proposed models against the standard LSTM and GRU models used as baselines presented as the results from the previous study of Zhou et al. (2023). Our study expands upon the methodologies used by Zhou et al. (2023) by incorporating ACF and PACF as additional input features to the LSTM and GRU models, which has led to substantial improvements in forecasting accuracy. Moreover, the results of this study cover the forecasted trends of cumulative confirmed, and cumulative death of the COVID-19 cases are in using all six proposed models, including ACF-LSTM model, PACF-LSTM model, ACF-PACF-LSTM model, ACF-GRU model, PACF-GRU model, and ACF-PACF-GRU model. The top-12 countries based on cumulative confirmed cases, as of June 6, 2022, are the United States (USA), India, Brazil, France, Germany, United Kingdom (UK), Russia, Italy, Turkey, Spain, Vietnam, and Argentina. The dataset for each country comprises two time series data sets: cumulative confirmed cases, and cumulative death cases. The forecast was done for each period of the two time series data of the individual country and its ACF, and/or PACF with lag-1, lag-2, ..., and lag-7 by independently feeding those time series data into the optimized LSTM and GRU based RNN networks. A total of 144 simulations were performed.

A. Cumulative Confirmed Cases

The study evaluates forecasting accuracy by comparing the proposed models against the standard LSTM and GRU models using the same time series data of COVID-19 confirmed cases. Performance measures for eight models illustrate the actual and predicted cases across twelve countries using deep learning models based on LSTM and GRU. The rankings of MAE and R-squared values for each country, comparing the six proposed models with the standard models, are presented in Table III and Table IV, respectively.

In Table III, the MAE ranking of the standard LSTM model across twelve countries typically falls between 7$^{\text{th}}$ and 8$^{\text{th}}$, with exceptions in Argentina (2$^{\text{nd}}$), Italy (3$^{\text{rd}}$), and France (4$^{\text{th}}$). Zhou et al. (2023) found that LSTM models consistently performed at a moderate level for COVID-19 case predictions. In our study, the ACF-PACF-GRU model consistently outperformed other models, achieving the lowest average MAE ranking (2$^{\text{nd}}$), with superior accuracy in countries like Brazil, France, Turkey, Spain, Vietnam, and Argentina. The standard GRU model ranks between 1$^{\text{st}}$ and 7$^{\text{th}}$. Among the proposed LSTM-based models, the ACF-LSTM model generally ranks between 5$^{\text{th}}$ and 8$^{\text{th}}$, except for the USA, UK, and Russia, which share the 2$^{\text{nd}}$ position. The PACF-LSTM model ranks between 2$^{\text{nd}}$ and 5$^{\text{th}}$, while the ACF-PACF-LSTM model primarily falls between 6$^{\text{th}}$ and 8$^{\text{th}}$, except for Brazil and India, which both rank 5$^{\text{th}}$.

At the country level, the proposed GRU-based models show varying performance. The ACF-GRU model generally ranks between 1$^{\text{st}}$ and 5$^{\text{th}}$, except for Brazil (7$^{\text{th}}$) and Argentina (8$^{\text{th}}$). The PACF-GRU model ranks between 3$^{\text{rd}}$ and 7$^{\text{th}}$, with India as an exception at 1$^{\text{st}}$ place. The ACF-PACF-GRU model, which demonstrates superior performance, primarily ranks between 1$^{\text{st}}$ and 3$^{\text{rd}}$ in MAE, except for Russia and Italy, which both rank 4$^{\text{th}}$. This model achieves the highest forecasting accuracy in six countries: Brazil, France, Turkey, Spain, Vietnam, and Argentina.

Note: Bold numbers indicate the best results. Superscript numbers in brackets indicate ranking among six proposed models.

When comparing LSTM-based and GRU-based models, the proposed GRU-based models exhibit a lower average ranking than their LSTM counterparts. The top three models in terms of average MAE ranking are ACF-PACF-GRU (2.00), PACF-LSTM (3.08), and ACF-GRU (3.83). The MAE performance results indicate that incorporating the PACF series into LSTM models significantly enhances forecasting accuracy compared to the standard LSTM. Similarly, integrating the ACF series into GRU models improves predictive performance over standard GRU. According to the R-squared rankings in Table IV, the standard LSTM and GRU models consistently rank between 7^{th} and 8^{th} across twelve countries. Among the proposed LSTM-based models, the ACF-LSTM model generally ranks between 2^{nd} and 5^{th}, except for Italy, which ranks 1^{t}. The PACF-LSTM model falls between 4^{th} and 5^{th}, with exceptions in the USA, UK, and Russia, where it ranks 2^{nd}. The ACF-PACF-LSTM model typically ranks between 4^{th} and 6^{th}, except for Spain, which is ranked 3^{rd}.

For the GRU-based models at the country level, the ACF-GRU model generally ranks between 1st and 3rd, except in Spain (5^{th}), Brazil (6^{th}), and Argentina (6^{th}). The PACF-GRU model typically ranks between 3^{rd} and 5^{th}, with exceptions in India (1^{st}), Argentina (1^{st}), and Spain (2^{nd}). The ACF-PACF-GRU model, demonstrating superior performance, primarily ranks between 1^{st} and 3^{rd}, except in India and Russia, where it ranks 4^{th}. This model achieves the highest forecasting accuracy in six countries: Brazil, France, Germany, Turkey, Spain, and Vietnam.

Among all models, the proposed GRU-based models exhibit a lower average R-squared ranking than their LSTM counterparts. The top three models in terms of average ranking are ACF-PACF-GRU (2.00), ACF-GRU (2.92), and PACF-LSTM (3.17). The R-squared values indicate that incorporating ACF and PACF series into both LSTM and GRU models significantly enhances forecasting accuracy compared to using only the standard LSTM or GRU models. Therefore, this study demonstrated the MAE and R-squared rankings for ACF-PACF-GRU consistently outperformed other models, showing significant improvement over traditional LSTM and GRU models as used by Zhou et al. in forecasting cumulative confirmed cases across twelve countries.

To summarize the overall performance of the eight models across twelve countries, Fig. 8 presents the median values and boxplots for each model based on different performance metrics. The ACF-PACF-GRU model has the lowest median MAE of 0.004, indicating superior accuracy. In terms of R-squared, the PACF-GRU model achieves the highest median value of 0.9989, followed closely by the ACF-PACF-GRU model at 0.9987. Zhou et al. (2023) highlighted the efficacy of deep learning models like LSTM in predicting COVID-19 cases, though their model did not incorporate ACF/PACF features. Our results align with their conclusion that deep learning models are effective, but we extend their work by showing that incorporating ACF and PACF series as input features significantly improves forecasting accuracy. In particular, the ACF-PACF-GRU model, which combines both ACF and PACF, demonstrated the best performance, significantly lowering the MAE compared to the models used by Zhou et al. (2023), which did not utilize these time-series dependencies.

The MAE and R-squared results indicate that incorporating ACF and/or PACF as additional input series in deep learning models enhances the forecasting accuracy of time series data. To determine which proposed model provides the most accurate COVID-19 case predictions, we analyzed the rankings of MAPE and RMSE across six proposed models for each country, as shown in Tables V and VI.

Overall, the top three models based on average rankings for MAPE and RMSE are ACF-PACF-GRU (with 1.67, and 1.92, respectively), PACF-LSTM (with 3.00, and 2.83), and ACF-GRU (with 3.25, and 2.92). As shown in Table V, the ACF-PACF-GRU model consistently outperforms other models in MAPE across seven countries: Brazil, France, Germany, Turkey, Spain, Vietnam, and Argentina. Similarly, Table VI highlights that this model achieves the lowest RMSE in six countries: Brazil, France, Germany, Turkey, Spain, and Viet-

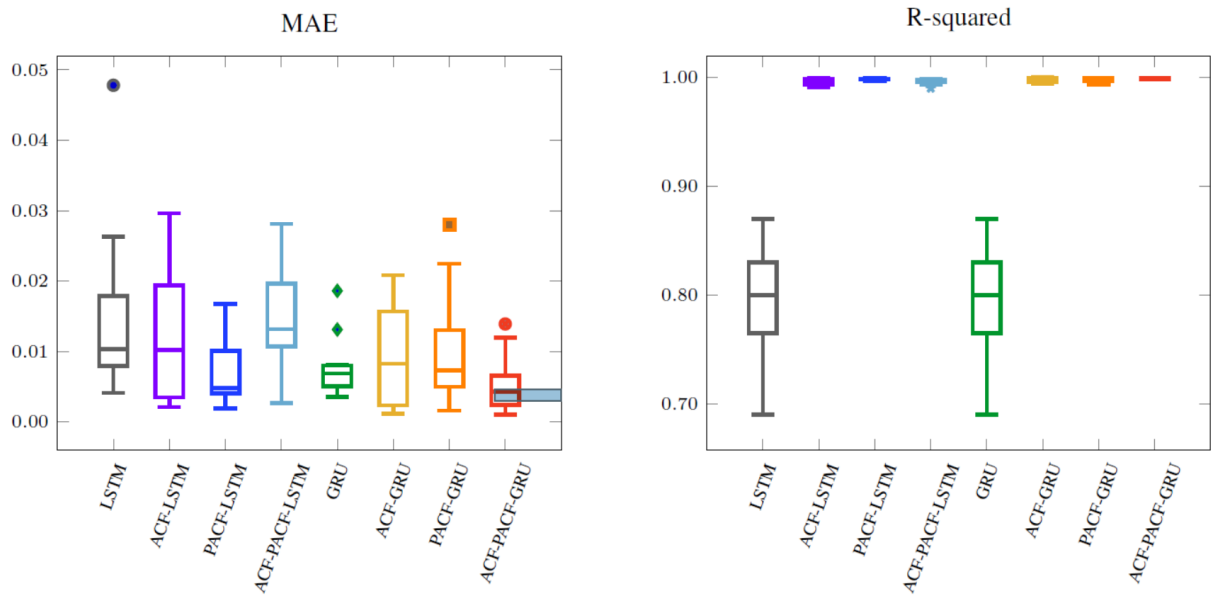

Fig. 8. Analysis results of MAE and R-squared for confirmed cases, compared eight proposed models with the standard deep learning models.

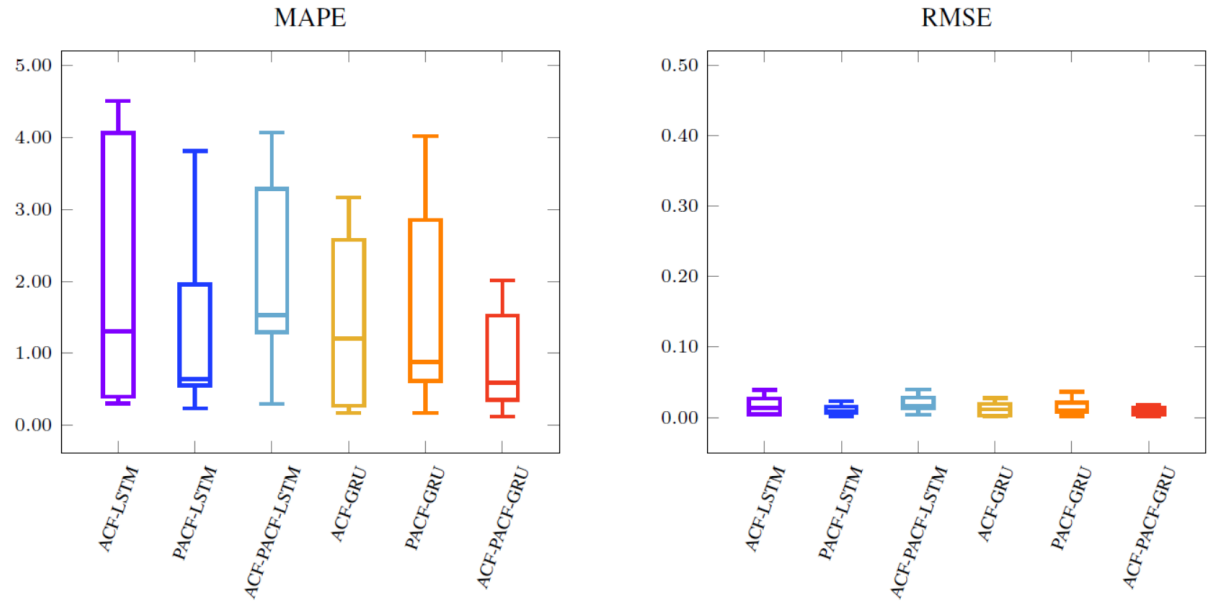

Fig. 9. Analysis results of MAPE and RMSE for confirmed cases compared among six proposed models.

nam. At the country level, the ACF-GRU model ranks within the top three positions more frequently than the PACF-GRU model in both MAPE and RMSE.

These findings suggest that for LSTM-based models, incorporating only the PACF series yields better forecasting performance than adding either the ACF series alone or both series together. Conversely, for GRU-based models, integrating both ACF and PACF series leads to superior forecasting accuracy compared to including only one of the series. Among all models, the ACF-PACF-GRU model demonstrates the highest potential for forecasting COVID-19 confirmed cases.

To provide a comprehensive overview of the results across all twelve countries, Fig. 9 presents the median values and boxplots for the six proposed models, categorized by performance metrics. The median values of MAPE and RMSE in Fig. 9 confirm that the ACF-PACF-GRU model demonstrates the highest predictive accuracy, with the lowest median MAPE at 0.592% and RMSE at 0.007. These findings highlight the effectiveness of the ACF-PACF-GRU model, indicating that the proposed approach significantly improves the forecasting performance for confirmed cases.

B. Cumulative Death Cases

Using the same time-series data for COVID-19 death cases, the forecasting accuracy of the six proposed models is compared to the standard LSTM and GRU models. The

Note: Bold numbers indicate the best results. Superscript numbers in brackets indicate ranking among six proposed models and standard deep learning models (LSTM*,GRU*) cited from the previous study of Luyu Zhou et al.

performance measures of eight models, shown in Tables VII and VIII, display the actual and forecasted death cases across twelve countries using deep learning models based on LSTM and GRU. The rankings of MAE and R-squared values for each country are presented for the six proposed models and the standard models (LSTM and GRU) in Tables VII and VIII, respectively.

In Table VII, the MAE ranking for the standard LSTM and GRU models among twelve countries generally falls between 7^{th} and 8^{th} place, similar to the results observed in Zhou et al.'s (2023) study. However, our study shows a clear advantage of the proposed GRU-based models over their LSTM counterparts.

For the standard GRU model, the rankings are mostly between 7^{th} and 8^{th}, except for Vietnam (5^{th}) and Germany (6^{th}). For the proposed LSTM-based models, the ACF-LSTM model typically ranks between 5^{th} and 6^{th}, with exceptions in the USA (2^{nd}), Russia (3^{rd}), and Vietnam (3^{rd}). The PACF-LSTM model ranks between 1^{st} and 3^{rd}, except for Argentina (4^{th}), Russia (4^{th}), India (5^{th}), and the USA (5^{th}). The ACF-PACF-LSTM model mostly ranks between 3^{rd} and 6^{th}, with the exception of Vietnam (8^{th}).

For the proposed GRU-based models at the country level, the ACF-GRU model generally ranks between 4^{th} and 7^{th}, except for Russia (1^{st}), the USA (1^{st}), and Vietnam (2^{nd}). The PACF-GRU model ranks between 2^{nd} and 5^{th}, with an exception in the UK (1^{st}). The ACF-PACF-GRU model ranks 1^{st} to 3^{rd} in MAE for most countries, including India, Germany, Turkey, and Argentina. In contrast, the standard LSTM and GRU models performed at lower rankings for these countries. This improvement is particularly evident when considering the MAE and R-squared values for death cases in countries like

Brazil and India.

When comparing the LSTM-based and GRU-based models, the proposed GRU models generally have a lower average ranking than the LSTM models. Among the eight models, the top three in terms of average MAE ranking are ACF-PACF-GRU (2.25), PACF-LSTM (2.58), and PACF-GRU (2.75). The MAE performance results show that incorporating the PACF series into LSTM models enhances forecasting performance more effectively than using the standard LSTM alone. However, integrating both ACF and PACF series into GRU models improves forecasting accuracy compared to using the standard GRU.

As shown in Table VIII, the R-squared ranking for the standard LSTM and GRU models across twelve countries generally falls between 7^{th} and 8^{th}. For the proposed LSTM-based models, the ACF-LSTM model typically ranks between 5^{th} and 6^{th}, with exceptions in the USA (2^{nd}), Germany (3^{rd}), and Turkey (3^{rd}). The PACF-LSTM model ranks between 1^{st} and 3^{rd}, except for Argentina (4^{th}), the USA (5^{th}), India (2^{nd}), and Turkey (5^{th}). The ACF-PACF-LSTM model usually ranks between 4^{th} and 6^{th}, with the exception of Argentina (3^{rd}).

For the proposed GRU-based models at the country level, the ACF-GRU model generally ranks between 3^{rd} and 6^{th}, except for the USA and Vietnam, where it ranks 1^{st}. The PACF-GRU model typically ranks between 1^{st} and 3^{rd}, except for the USA (4^{th}) and Germany (5^{th}). The ACF-PACF-GRU model, which achieves superior results, ranks between 1^{st} and 3^{rd} in most countries, except for Vietnam (4^{th}). This model demonstrates the highest forecasting accuracy in six countries: India, Germany, Turkey, and Spain.

Among the various models, the proposed GRU-based models tend to have a lower average R-squared ranking compared

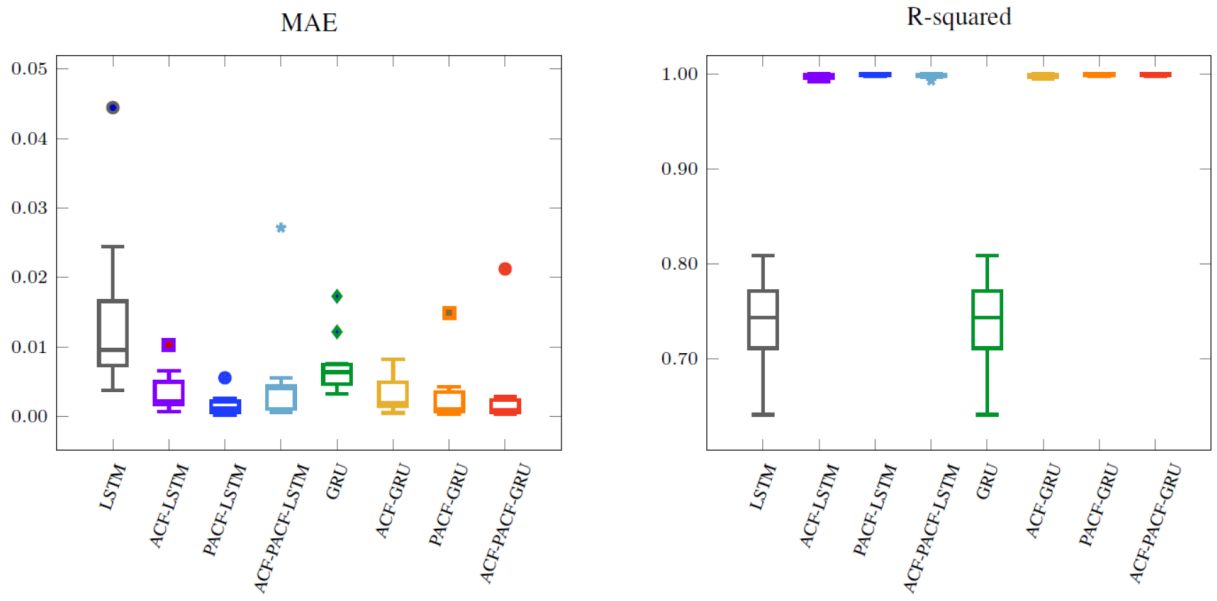

Fig. 10. Analysis results of MAE and R-squared for death cases, compared eight proposed models with the standard deep learning models.

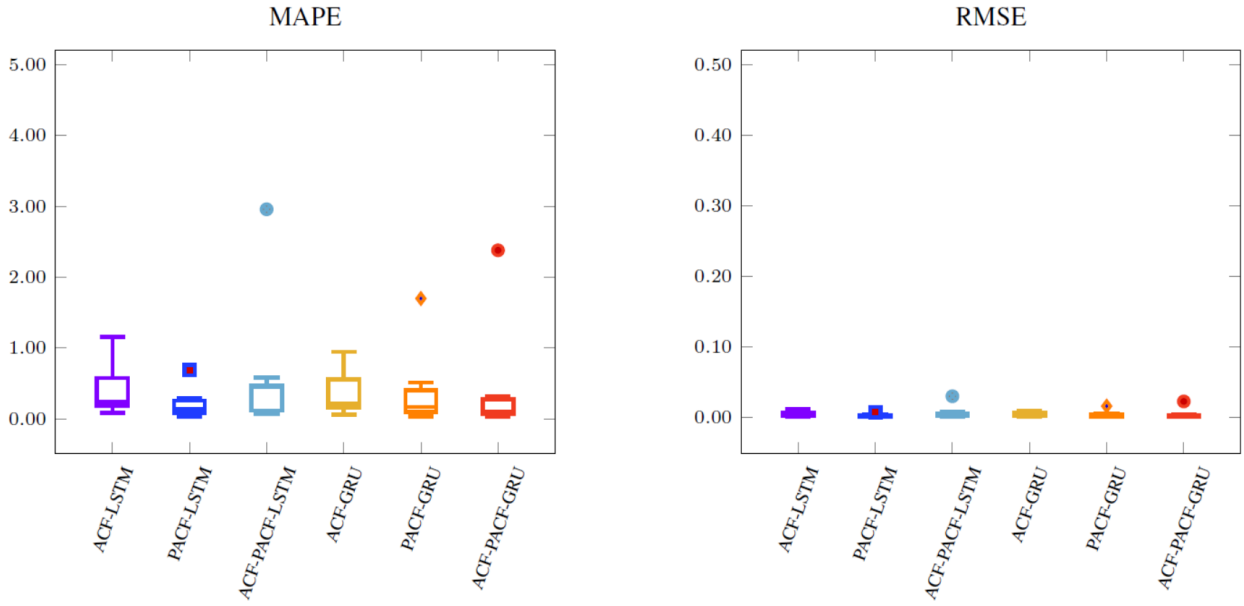

Fig. 11. Analysis results of MAPE and RMSE for death cases compared among six proposed models.

to the LSTM-based models. The top three models based on average R-squared ranking are ACF-PACF-GRU (2.17), PACF-GRU (2.50), and PACF-LSTM (2.67). The R-squared values indicate that incorporating both ACF and PACF series into GRU models can significantly enhance forecasting accuracy compared to models based solely on LSTM or GRU, similar to the improvement observed when adding the PACF series to either LSTM or GRU.

To provide a comprehensive overview of the results for all twelve countries, Fig. 10 presents the median values and boxplots for eight models, organized by performance metrics. The median values in Fig. 10 indicate that the ACF-PACF-GRU model for death cases has the highest predictive ability, with the lowest MAE value of 0.0009 and the highest R-squared value of 0.9996. However, the PACF-GRU model has a slightly higher median R-squared value of 0.9997.

Next, we examine which proposed model demonstrates the greatest forecasting accuracy for COVID-19 death cases. The MAPE and RMSE values for the six proposed models were ranked for each country, as shown in Table IX and Table X. Overall, the top 3 models based on average rankings for MAPE and RMSE are ACF-PACF-GRU (2.17, and 2.17, respectively), PACF-LSTM (2.58, and 2.50), and ACF-GRU (2.83, and 2.75). In Table IX, the ACF-PACF-GRU model, with an average MAPE ranking of 2.17, consistently outperforms the other models in four countries, including India, Germany, Turkey,

and Argentina. Similarly, in Table X, the ACF-PACF-GRU model, with an average RMSE ranking of 2.17, is the best model in six countries, including India, Germany, and Turkey.

To provide a comprehensive performance comparison across all twelve countries, Fig. 11 illustrates the median values and corresponding boxplots for the six proposed models, evaluated using key performance metrics. The ACF-PACF-GRU model consistently outperformed other models, achieving the lowest median MAPE of 0.101% and RMSE of 0.001. These results highlight the superior forecasting capability of the ACF-PACF-GRU model, demonstrating the effectiveness of integrating autocorrelation and partial autocorrelation features in enhancing prediction accuracy for COVID-19 death cases.

Therefore, the forecasting performance of the LSTM model, when only the PACF series is added, is better than when either the ACF series or both series are incorporated into the same algorithm. On the other hand, adding only the ACF series or both series into the GRU model leads to better forecasting accuracy compared to adding only the PACF series. However, the MAPE and RMSE results for death cases confirm that the ACF-PACF-GRU model has the highest potential for accurately forecasting COVID-19 cases.

V. Discussions

This study introduces a novel approach to improve the forecasting accuracy of COVID-19 confirmed and death cases by integrating ACF and PACF series into LSTM and GRU models. The key motivation for choosing this approach is to address the limitations of existing models, which primarily rely on standard LSTM and GRU networks. While LSTM and GRU models are adept at capturing long-term dependencies in time-series data, they fall short in modeling non-linear relationships and temporal dependencies [20], particularly in the context of irregular and complex epidemic data like COVID-19. The incorporation of ACF and PACF enhances the model's ability to capture both short-term and long-term dependencies, providing a more accurate representation of the underlying data dynamics, which is essential for infectious disease forecasting.

This study demonstrates that our proposed models, especially the ACF-PACF-GRU model, outperform standard LSTM and GRU models in forecasting accuracy, as evidenced by the improved performance across key metrics such as MAE, R-squared, MAPE, and RMSE. The incorporation of ACF and PACF features provides additional insights into the temporal dependencies of the data, which were absent in previous studies, including the work by Zhou et al. (2023). This approach not only improves the predictive accuracy for COVID-19 but is also applicable to other epidemic forecasting tasks where similar temporal dependencies exist.

A. Implications of Results

The findings of this study have significant implications for the forecasting of infectious disease trends. The unique structure of LSTM and GRU models, when combined with ACF and PACF series, enhances the ability of the models to effectively capture both linear and non-linear temporal dependencies present in epidemic data. The median MAPE values for the ACF-PACF-GRU model, which are 0.592% for confirmed cases and 0.101% for death cases, underscore the efficacy of the proposed method. These values highlight how the integration of ACF and PACF into deep learning models can significantly improve the forecasting performance over existing models. Furthermore, the improved accuracy achieved by our models supports previous research emphasizing the importance of time-series dependencies in epidemic forecasting. Our proposed methodology, which extends the work of Zhou et al. (2023) by incorporating ACF and PACF features, offers a more robust framework for predicting COVID-19 trends and can be adapted to other infectious diseases in future research.

B. Practical Implications

The proposed deep learning models provide valuable insights for forecasting the cumulative number of confirmed and death cases of COVID-19 by incorporating ACF and PACF series into LSTM and GRU models. By treating the forecasting task as a time-series problem, leveraging historical data to predict future trends, the models can provide more accurate predictions, thereby aiding public health decision-making. The integration of ACF and PACF into GRU models, in particular, improves model performance, making them more suitable for real-time epidemic prediction. The enhanced accuracy of the ACF-PACF-GRU model, when compared to the methods used by Zhou et al. (2023), demonstrates the potential for further improving deep learning-based forecasting models with additional time-series features. These forecasts are crucial for governments and public health officials, enabling them to make informed decisions about epidemic control measures, resource allocation, and intervention strategies.

C. Limitations

While LSTM and GRU models excel at capturing long-term dependencies, they do not inherently account for the temporal dependencies critical to epidemic forecasting. The addition of ACF and PACF significantly enhances the models' ability to capture these temporal patterns, which are often key to understanding disease transmission. However, this study focused solely on time-series data of the disease, excluding other variables such as vaccination rates and country-specific interventions, which could also influence epidemic outcomes. Future research could incorporate these additional features to provide a more comprehensive forecasting model. Additionally, the complex architecture of deep learning models requires careful hyperparameter selection, which may vary depending on the dataset and problem. Thus, the proposed models in this study, while more accurate than existing models, still require optimization for different contexts and datasets.

VI. Conclusions

In this study, we introduced a novel deep learning approach that incorporates ACF and PACF to improve time-series forecasting models for predicting COVID-19 confirmed and death cases. By leveraging the ACF and PACF series in conjunction with original time-series data, our models were able to capture both short-term and long-term temporal dependencies, leading to improved forecasting accuracy. The ACF-PACF-GRU model, in particular, demonstrated superior performance across a range of metrics compared to both standard LSTM and GRU models. These findings suggest that incorporating time-series dependencies, such as ACF and PACF, significantly

enhances the performance of deep learning models in epidemic forecasting. Future research should explore the application of this methodology to other infectious diseases, such as influenza and dengue fever, to further validate the robustness and generalizability of the approach.

ACKNOWLEDGMENT

This research was part of the graduation requirement for the philosopher degree at College of Public Health Sciences, Chulalongkorn University, which was supported by multidisciplinary researchers. The authors extend their heartfelt thanks to the anonymous reviewers for their insightful and constructive feedback. The authors acknowledge the assistance of Gemini in refining the grammar and clarity of this manuscript. However, the scientific content and conclusions are entirely the authors' responsibility.

Cyber Deception Across Domains: A Comprehensive Survey of Techniques, Challenges, and Perspectives

Amal Sayari, Slim Rekhis
University of Carthage, Higher School of Communication of Tunis (SUP'COM),
LR11TIC04, Communication Networks and Security Research Lab. & LR11TIC02,
Green and Smart Communication Systems Research Lab, Tunisia

***Abstract*—Cloud environments (CE), wireless networks (WN), cyber-physical systems (CPS), industrial control systems (ICS), smart grids (SG), internet of things (IoT), internet of vehicles (IOV), and unmanned aerial vehicles (UAV), are currently popular targets for cyberattacks due to their inherent limitations and vulnerabilities. Each domain has its own attack surfaces, weaknesses, and areas for implementing defense strategies appropriate to its specific conditions. Among the various defense mechanisms discussed in previous years, cyber deception has appeared as a very promising method. This approach allows the defenders to steer the attackers in the wrong direction, get threat intelligence, and at the same time, increase security by engaging with adversaries in deception environments in a proactive manner. Cyber deception has been a topic of investigation in several studies, where specific frameworks and techniques were proposed to identify, delay, or disrupt adversarial behavior. Nevertheless, the contributions of earlier works are frequently limited or missing a unified framework that makes a thorough and comparative study necessary. This survey investigates the cyber deception techniques used in various domains. The first part is about the cores of deception and its background. Next, it presents a summary of the available deception techniques with their modeling by different frameworks like MITRE ATT&CK, D3FEND, and Engage, and intelligent orchestration using reinforcement learning (RL) and game theory (GT). Then, it serves as a thorough systematic review of each selected paper, going over the system design, used deception techniques, evaluation metrics, and limitations on each scheme. The achieved results are compiled into a unified summary table to enable a quick and effective comparison across the domains. It concludes, therefore, by discussing the main challenges, open issues, and areas of research that have not yet been explored, thus making it a valuable source for future research on cyber deception.**

***Keywords*—Cyber defense; cyber deception; cloud environments; wireless networks; cyber-physical systems; industrial control systems; smart grids; internet of things; internet of vehicles; unmanned aerial vehicles**

I. Introduction

The growth of cyber-attacks in terms of frequency and sophistication has outstripped the ability of conventional security measures to be the sole protector of the complex and dynamic digital infrastructures. The adversaries are continually adapting their tactics, techniques, and procedures (TTPs) to evade traditional defense mechanisms like firewalls, intrusion detection/ prevention systems, and antivirus software. The reactive schemes act typically after the initiation of an attack, makes the need for different, proactive, and intelligent defense strategies even more urgent.

One promising strategy is cyber deception, which is currently widely known in both research and industry. Cyber deception is putting uncertainty and misdirection in the environment by intentionally misguiding adversaries; thus, their progression becomes slower or they get fictitious information. The method is based on failure or turning away the attacker, providing first warning through the engagement of the attacker, and collecting information about their capabilities. Deception methods, from honeypots and honeynets to honeytokens [1], are successful complementary tools that shift the advantage back to defenders.

At the same time, the wide digital landscape has extended to encompass a wide variety of interconnected and heterogeneous systems, including CE, WN, CPS, ICS, SG, IOT, IOV, and UAV. Apart from the fact that the aforementioned domains have achieved a previously unattainable level of scalability and interconnection, they are also the main sources of new vulnerabilities. Each domain, besides the attacks, also comes with its unique features such as different architectural structures, operational constraints, communication protocols, and security requirements that determine the nature and intensity of the cyber threats that it has to deal with.

Although the individual fields such as WN, CPS, or IOT are seeing a significant increase in the use of cyber deception techniques, the current literature is still fragmented. At present, there is no unified study that examines how deception has been adapted and applied across such diverse technological environments. In particular, research on honeypots and honeynets tends to remain siloed, without much cross-domain analysis and integration.

Previously conducted surveys on cyber deception [2] [3] [4] [5] [6] [7] have introduced foundational taxonomies, described deception techniques, and outlined conceptual models. However, those are mainly dedicated to technique-level analysis (e.g., GT, RL, or Honey-X strategies) and they are not systematic comparing across different operational domains. Although some works [4] [6] did provide specific domains (e.g., in IoT, ICS, CPS, and CE), the exploration is still fragmented, and it has not been focused enough on how architectural constraints, attacker models, and environmental characteristics influence the design and deployment of deception strategies.

Based on those limitations, we have prepared a thorough and comparative review of the cyber deception methods in several critical domains. In contrast to previous studies that either dwell upon particular techniques or theoretical models, our survey stresses the domain-aware analysis of deception

strategies, elaborating on customization to different system architectures and operational contexts. Here are our main contributions:

- We present the fundamental concepts, models, and strategies of cyber deception to provide a clear background for the survey.
- We meticulously extract and synthesize the deception technique, architecture, evaluation metrics, and limitations from each selected paper.
- We categorize the findings by domain and summarize them in standardized tables for cross-domain comparison.
- We identify common challenges, open issues, and trends, which could serve as a guide for further research in deception-based cyber defense in various contexts.

The remainder of this survey is structured as follows. Section II presents the adopted methodology. Section III addresses a comparison with existing surveys. Section IV provides the background and key concepts of cyber deception. Section V describes the intelligent orchestration of cyber deception. Sections VI to XIII present the exploration of cyber deception in CE, WN, CPS, ICS, SG, IoT, IoV, and UAV, respectively. Section XIV discusses open research issues and key insights. Finally, Section XV concludes the study.

II. Adopted Methodology

A systematic literature review was performed to investigate the use of cyber deception techniques in various domains. The review process was structured in a multi-step manner to achieve comprehensiveness, relevance, and quality.

1) Database search and initial collection: We queried high-impact databases like IEEE Xplore, DBLP, and Google Scholar using various combinations of both general and domain-specific keywords such as “cyber deception”, “honeypot”, “honeytoken”, “fake data”, and other domain-specific terms like “IoT”, “ICS”, “UAV”, “Smart Grid”, and “Cloud”.
2) Inclusion and exclusion criteria: Only the articles that described defensive deception techniques were kept. Articles that were about offensive deception techniques were removed from the list. Besides that, we also filtered out duplicates and inaccessible entries.
3) Reference expansion and survey integration: To make sure all important works were included, we examined and integrated the previous surveys along with their key referenced papers. Each past survey was examined to find the gaps, list the most important works, and to make sure there were no overlaps. The articles that were already included in the previous surveys were also taken into account in order to ensure continuity and progression.
4) Screening and filtering: We did the screening of titles and abstracts first and made the full-text reviews to confirm the relevance of the articles to cyber deception. During this process, the studies were indicated according to the techniques used for deception, the target domain, the architectural framework adopted, evaluation metrics, and the limitations identified. Thus, ∼140 papers were selected.
5) Domain relevance-based filtering: We pursued a filtering strategy based on the articles’ dates of publication that would be on a period extending approximately six years (2019 to 2024), alongside a selective insertion of emerging contributions from 2025. Then, from the set of ∼140 papers, 46 papers were selected as relevant to cyber deception exploration by domain, as illustrated in Fig. 1. The others were used to properly define the cyber deception concepts, techniques, and models.

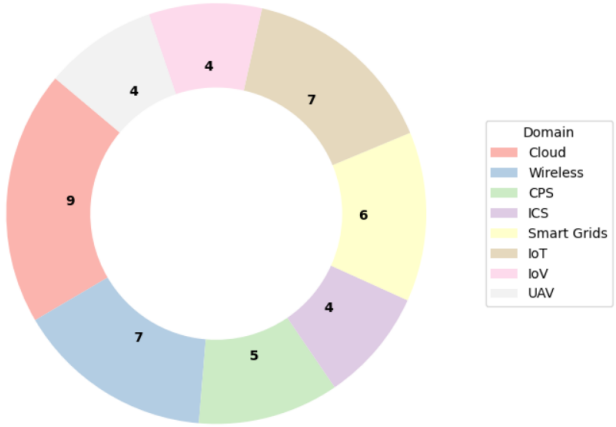

Fig. 1. Distribution of selected papers by domain.

III. Comparison with Existing Surveys

In [2], the authors explored the classification of cyber deception, which cuts across four dimensions: the deceit unit, application layer, defense goal, and deployment mode. They presented techniques like honeypots, honeyfiles, and fake topologies across the network, system, application, and data layers. They further outlined the deployment models as process-based, probabilistic, graph-based, and game-theoretical approaches. The major challenges that were mentioned are the evaluation of deception effectiveness and the automation of dynamic deployment in complicated environments.

In [3], the authors explored 24 studies regarding the application of game theory in the representation of cyber deception and created a taxonomy that contains six types of deception: perturbation, moving target defense (MTD), obfuscation, mixing, honey-x, and attacker engagement. The taxonomy is based on game-theoretic components, including agents, actions, and information structure. Specific deception types were related to the appropriate models, such as stackelberg, Nash, and signaling games. Furthermore, the research gaps were identified by the authors as mimetic deception and practical implementation.

In [4], the authors put forth a completely different classification framework to use for cyber deception based on the following features: conceptual categories, physical and virtual artifacts, intended effects, goals (protection or detection), and

deception activeness. They used game theory (GT) and machine learning (ML) for the discussion of deception techniques, as they pointed out GT's strategic modeling and ML's feature of generating realistic decoys. Their review was complemented by applications in different settings such as CPS, cloud, IoT, and software-defined networking (SDN), and they performed an analysis of evaluation metrics and testbeds. They ended their work by pointing out the existing limitations and urging further exploration of the combination of GT and ML for more adaptive deception strategies.

In [5], the authors made a review of different frameworks of cyber deception in terms of network security, assessing their strengths and weaknesses. They declared that the most effective deception requires network topologies that can adapt, which include scalability, dynamic reconfiguration, and fast responses. They pointed out SDN is the principal facilitator to the deployment of various techniques of deception such as honeypots, honeynets, and Moving Target Defense. Moreover, they assigned the challenges of real-time agility, DDoS resilience, and user impact minimization, and offered directions for the future, such as ML-driven adaptive deception and enhanced network virtualization for APT defense.

In [6], the authors were engaged in scrutinizing Honey-X-techniques such as honeypots, honeynets, honeytokens, and honeywebs. Besides, they also got acquainted with the mechanisms of defense like MTD, ML, and GT, and their works in synergy with them. They studied Honey-X- based strategies in different sectors such as ICS, IoT, critical infrastructure, and web applications, stressing the fact that they can be used in different environments. The effectiveness of these strategies was calculated through metrics such as Mean Time to Compromise (MTTC) and Mean Time to System Failure (MTTSF). The final point they made was the presentation of key research challenges, such as improving honeypot realism and scalability, deception placement optimization through GT, and combining MTD with ML for enhanced threat detection and response.

In [7], the authors investigated deception techniques conceived to boost honeypots and honeynets. These techniques include advanced mimicking, manipulative cooperation, fake databases, honeytokens, and traffic redirection. For this purpose, authors have proposed a categorization system for honeypots based on the following criteria: purpose, interaction level, implementation type, and activity level. They also shared a mathematical model that is supposed to aid in the optimization of both the configuration and the deployment. The evaluation of their approach was realized by comparison with other approaches in terms of deception metrics like discrepancy, wasted time, and adversaries that were returned. The shortcomings they uncovered were in areas such as dynamic, 5G, and SDN-based honeypots, and they suggested future research on ML-driven honeypot optimization and also on more advanced deception strategies.

IV. Background on Cyber Deception

A. Key Concepts of Cyber Deception

Deception originated in military contexts, where it is used to mislead adversaries regarding one's strengths, weaknesses, intentions, and tactics [8]. This tactic includes forms of battlefield deception like camouflage, feints (pretend attacks), ruses (tricks), demonstrations (fake force deployment), and displays (like showing fake military equipment, for example, inflatable tanks). This concept has extended into the cyber domains as cyber deception, refined by Almeshekah and Spafford [9] as "planned actions taken to mislead and/or confuse attackers and to thereby cause them to take (or not take) specific actions that aid computer security defense", and categorized by Whaley [10] into two taxonomies: dissimulation and simulation.

Dissimulation or hiding is a trick of information or system states to prevent hackers from understanding or discovering the true nature of the system. And the purpose of this idea is to mislead hackers or unauthorized users by showing incorrect information, thus making it difficult for them to guess what they should decide. This method is opposite to the traditional protection mechanisms like firewalls, access control, and encryption that mainly resist by prohibiting access or concealing data rather than by misleading the attacker. Simulation or showing is concerned with the making of environments, systems, services, and data that look authentic and operational and thus deceive the attacker into thinking he is dealing with real assets. Such defensive environments are meant to deceive threats, involve enemies, and watch their actions and designs, all without paving the way for real systems or data to be exposed. Simulated components are off the grid yet unbelievably convincing. For instance, after being locked out of the system several times, the system could keep showing the login prompts without ever giving the user permission to log in. The hacker would then think that they still have a chance to enter the system.

Dissimulation and simulation can be used either separately or cooperatively, in accordance with the objectives of the strategy. Dissimulation is the primary means of reducing one system's visibility and appeal, particularly in environments focused on confidentiality and stealth. On the other hand, simulation is the best solution for threat detection by inducing adversaries into a false environment. Simultaneously acting, these two methods create total deception of the mechanism that both distracts and engages adversaries to be able to protect from and gather credible information on the threat.

One of the instances of using deception techniques for cybersecurity can be found in Cliff Stoll's book "The Cuckoo's Egg" [11], where he created a fake system environment with a user account containing fake documents to deceive and stall attackers in order to track their activities and reveal their identities. In the 2000s, honeypots became an adopted method for observing, analyzing, understanding, and modeling attackers' actions [12] [13]. Subsequently, various honey-related approaches, called honeytokens [1] have emerged. These deception techniques fall under six principal tactics [14]. Three of them fall under dissimulation: masking (conceals real systems, data, or network attributes to prevent detection or mislead attackers about their true nature), repackaging (alters the appearance or structure of data or code, such as changing formats or using wrappers, to evade detection and analysis), and dazzling (generates excessive noise such as fake traffic, logs, or alerts to obscure valuable information and confuse attackers). The other three tactics fall under simulation: mimicking (imitates the behavior of real systems,

users, or data to make deceptive assets appear authentic and lure attackers), inventing (creates entirely fictitious systems, data, or user identities that have no real counterpart, designed to mislead and trap attackers), and decoying (deploys simulated assets such as honeypots, honeynets to attract, engage, and analyze attackers while protecting real systems).

Moreover, deception techniques can be leveraged to achieve four principal cybersecurity goals [9]: detection (help identify malicious activity where any interaction is inherently suspicious, by spamming fake assets), prevention (attackers can be deterred or slowed down using creating uncertainty and increasing the perceived risk of being detected), response (deceptive systems can be securely detached and examined post-attack, thus, making the process of incident response and forensic analysis efficient), and research (provide regulated settings to examine the behavior of attackers, create threat intelligence, and study newly developed malware).

B. Layer-Based Cyber Deception Techniques

For the sake of generality and consistency across domains, we adopt the classification proposed by the authors in [2] and further detailed by the authors in [15], which categorizes deception techniques into a four-layer deception stack:

- Network-based deception techniques: are made to deceive attackers in the reconnaissance and exploitation phases that involve manipulation of the network-level information. Examples include altering network topology [16] [17] [18], randomizing IP addresses [19] [20] [21], tarpits [22] [23], deploying network honeypots [24] [25] [26] [27], and using honeyports [28] [29]. Such strategies delay or misguide attackers by presenting a false view of the network infrastructure, thereby increasing their time, cost, and reducing the effectiveness of their probing activities.
- System-based deception techniques: focus on deceiving adversaries within the host or operating system environment. Techniques include honeypatches [30] [31], Ghost Patches [32] [33], deceptive OS fingerprinting [34] [35], deceptive system calls [36][37], and honey RAM / memory injection [38], which allow defenders to monitor attacker behavior without exposing real systems.
- Application-based deception techniques: operate at the software or application interface layer, where user or attacker interaction takes place. They include honeypermissions [39], honeyaccounts [28], honeyprofile (OSN) [40] [41], honeyemail [42], decoy web forms/ fields [43], delayed response (fake feedback) [44] [45], fake API endpoints [46], and decoy hyperlinks [47] [48]. Such methods are effective at detecting and delaying attackers during application-level attacks like SQL injection, credential theft, or web exploitation.
- Data-based deception techniques: target the attacker's goal, access to sensitive data, by injecting deceptive or false data into the system. Examples include decoy document [49], honey URL [50] [51], honeyentries [52] [53] [54], honeyfiles [55] [56] [57] [58], honeywords [59] [60] [61] [62], honey encryption [63], honey database/ metadata [64] [65], and decoy source code [66], all designed to mislead, trace, or waste the resources of attackers attempting to exfiltrate valuable information.

The placement of these deception techniques within a target domain can either be a part of the existing security solution or can be isolated and used as a standalone mechanism. In our classification, we adopt the logic explored in [2], which defines four main deployment modes based on security objectives, system architecture, and operational constraints:

- Built-in deception/ part of: embedded directly into the system during the design phase, such as deceptive logic in source code or modified system responses.
- Add-on deception/ part of: incorporated into an operational system at runtime, through the insertion of honeytokens, fake files, or configuration traps.
- In-front deception/ part of/ intermediary: positioned as a proxy or gateway in front of the real system to intercept and manipulate incoming interactions, allowing early engagement with potential threats.
- Isolated deception/ standalone: deployed in separate, decoupled environments such as honeynets, decoy servers, that mimic real systems to lure attackers and analyze their behavior without impacting production assets.

In Table I, we provide a consolidated overview of representative cyber deception techniques, highlighting their core characteristics in terms of taxonomy, tactics, goals, application layers, and deployment modes as extracted from the surveyed literature. The majority of the cyber deception techniques outlined are designed for dual purposes, simulation and dissimulation, because building false artifacts while concealing true ones at the same time is the precondition of effective deception in most cases. The dual effectiveness increases both the credibility and overall impact of that deception. Also, a lot of the techniques can be utilized on different layers, such as network, system, and application, as they are designed to be adaptable and provide flexibility in their implementation. Therefore, the same technique may cover different security objectives, such as prevention, detection, response, and research, based on how and where it is implemented.

A multi-layer deception system is depicted in Fig. 2. It is a combination of some of the techniques that have been previously discussed. The multi-layer architecture, comprising the network, system, application, and data layers, encompasses both real and honey elements. Each of the honey components (e.g., honeyserver, honeyfile, honeydatabase) imitates a corresponding real counterpart (e.g., server, file, database) to mislead and monitor the attacker's behavior. The analyst server functions as a pivotal element by collecting alerts and logs from all honey elements, which provide a basis for detection, analysis, and response to malicious activities triggered by interactions with the deceptive assets.

C. Key Evaluation Metrics for Cyber Deception

To evaluate the efficiency of cyber deception strategies, researchers have suggested a variety of quantifiable metrics

TABLE I. OVERVIEW OF CYBER DECEPTION TECHNIQUES

Deception technique	Ref	Taxonomy	Tactic	Goal	Layer	Deployment mode
Altering Network Topology	[16]	Simulation + Dissimulation	Inventing, Dazzling	Prevention, Detection	Network	In-front
Reconnaissance Deception System (RDS) using Virtual Network Views	[17]	Simulation + Dissimulation	Inventing, Dazzling, Decoying	Detection, Prevention	Network	In-front, Add-on, Isolated
Virtual Network Topology Deception Defense (VNTDD)	[18]	Simulation + Dissimulation	Inventing, Dazzling, Decoying	Detection, Prevention	Network	In-front, Add-on, Isolated
Randomizing IP Addresses	[19]	Simulation + Dissimulation	Dazzling, Mimicking, Decoying	Detection, Prevention	Network	In-front, Add-on, Isolated
	[20]	Simulation + Dissimulation	Dazzling, Mimicking	Detection, Prevention	Network	Add-on, In-front
Path Randomization	[20]	Simulation	Dazzling	Prevention	Network	Add-on, Isolated
Flexible Random Virtual IP Multiplexing (FRVM)	[21]	Simulation + Dissimulation	Dazzling, Mimicking	Prevention, Detection	Network	Add-on, In-front
Tarpits	[22]	Simulation + Dissimulation	Dazzling, Decoying	Detection, Prevention	Network	Add-on, Isolated
	[23]	Simulation + Dissimulation	Dazzling, Decoying, Mimicking	Detection, Prevention, Research	Network	Add-on, Isolated, In-front

that can represent different components of system resilience, attacker behavior, and defense performance. The performance of the system and the progress of the attacker are evaluated with the help of temporal metrics like the Mean Time to Security Failure (MTTSF) [67] which symbolizes the period during which the system remains secure before it reaches a predefined security failure threshold due to a successful compromise, and the Mean Time to Compromise (MTTC) [67] where it represents the time required by the attacker to add a successful compromise to the network. Moreover, the metric of Vulnerability Analysis Time [68] assists in quantifying the amount of time the attacker has to spend identifying and then exploiting weaknesses present in the system, that is, from the complexity and skill level of each attacker. On the contrary, the Decision and Deployment Time (DDT) [69] is meant to show the period of time that passes between making a defensive decision and implementing it, such as deploying a honeypot.

Defense effectiveness is best evaluated through the use of probability-based indicators like the Defense Success Probability (DSP) [70] and the Success Rate of Attacks [71], which act as the basic tools to measure the quantitative success or failure of attaching defense devices under controlled experimental conditions. The measurement of detection metrics also focuses on Detection Accuracy [72], which is typically expressed in terms of the AUC of the ROC curve to judge the correct value of identifying malicious behavior. The other metric is the Mean Time to Detect Attacks [73], which is used for the evaluation of the efficiency of the deception-based detection system. In game-theoretic models of deception, the concept of Utility (or Payoff) is used most often to express the cost-benefit balance for both attacker and defender [74]. Moreover, the Attack Cost [75] evaluates the effort or risk that the attacker gets, including the chance of getting caught or wasted resources.

Resilience and operational continuity are represented by metrics such as Survival Rate [69], which refers to the ratio of the legitimate system components that have remained intact during attacks, and Round-Trip Time [69], which is the time taken by deception mechanisms (for example, code obfuscation or network slowdowns) to delay the attackers' progress.

D. Cyber Kill Chain for Phase-aware Deception Planning

The effectiveness of cyber deception strategies lies in the appropriate selection and positioning of the described deception techniques, which are customized to the particular-domain environment (e.g., UAV, IoT, ICS, Cloud) and the threat actors' behavior. Instead of randomly inserting deceptive assets, a threat-driven modeling approach is a must to prove that both deception strategies are useful and impactful. Two pertinent frameworks uphold this goal: the Cyber Kill Chain (CKC) and the MITRE ATT&CK framework. By using them together, they provide adversary tactics and lifecycle progression, and thus, an integrated view that helps in planning the optimization of deception for when, where, and how to deploy it.

The Cyber Kill Chain (CKC), originally introduced by Lockheed Martin, divides cyber-attacks into sequential phases: reconnaissance, weaponization, delivery, exploitation, installation, command and control (C2), and actions on objectives. This phase-based structure aids deception planning by helping defenders: i) determine the optimal timing for deploying deception (e.g., before delivery versus after exploiting), ii) align techniques to specific stages, for instance, deceptive network banners during delivery or honeyfiles during exfiltration, and iii) layer deception strategically across the kill chain, like using honeypots for exploitation, MTD for delivery, and fake data for exfiltration. Following these lines, the authors in [1] suggested an enhanced CKC model, meant to be used for deception and formed of three sub-kill chains: external, internal, and target manipulation. This refined model not only identifies the multi-stage progression of modern intrusions but also serves as a tool for mapping deception techniques (e.g., honeypots, honeytokens, MTDs) to both the attack phase and the affected system layer (network, system, software, data). By incorporating MITRE ATT&CK tactics into this structure, the model acts as an extensive framework for the orchestration of deception throughout the whole attack lifecycle.

E. MITRE ATT&CK for Tactic-technique Driven Deception

The MITRE ATT&CK [76] framework is based on the tactic-technique-procedure (TTP) representation of the behavior of adversaries, that is firmly based on the real-life observations on a wide range of platforms, namely, Enterprise, ICS, Mobile, and Cloud. ATT&CK plays a significant role in providing defenders with the following benefits: i) modeling attacker behavior by domain: for example, the ATT&CK for ICS stressed techniques such as "Inhibit Response Function" and "Manipulation of Control" which can also be found in the cyber-physical systems (CPS) and smart grid paradigms, ii) identifying deception targets: techniques like "Remote System Discovery", "Command and Scripting Interpreter", and "Credential Dumping" can be countered with honey APIs, honey credentials, or deceptive command environment, iii) building attack graphs: authors of [77] illustrated how techniques can be linked by logical preconditions and thus form attack paths. The graphs assist the defenders to optimize the positioning of decoys by focusing on the nodes that are most likely to be compromised with the least amount of resources.

In [78], the authors suggested a multi-layer graph-based way to model cyber-attacks and strategically allocate deception resources in alignment with threat modeling principles inspired by MITRE ATT&CK. The integration of network, service, and attack layers makes possible the detailed mapping of adversarial paths and their dependencies across system components. The model is capable of risk-based prioritization and preemptive allocation of deception assets such as honeypots and honeytokens at critical nodes. These strategies will contribute to the re-routing of attack chains and misleading of adversaries. This type of planning also drives the threat-informed deception by making the placement of the deception close to the attacker's behavior and technique paths that are illustrated in frameworks like MITRE ATT&CK. Authors in [79] presented a system that automatically chooses cyber deception strategies based on the information it obtains from unstructured CTI reports through NLP. It first maps the extracted Indicators of Compromise (IoCs) to the relevant MITRE ATT&CK tactics and techniques, which then allows for the prediction of the attacker's actions. The deception actions proposed by this framework are in line with the MITRE D3FEND [80] and MITRE Engage [81] frameworks, which are based on the aforementioned profiling.

By aligning deception strategies with specific ATT&CK techniques, defenders can deploy assets that disrupt adversary decision-making, enhance situational awareness, and collect high-fidelity threat intelligence. Fig. 3 presents an example of the Enterprise ATT&CK matrix techniques, annotated with corresponding deception technique, as illustrated by MITRE D3FEND, and also mapped to the corresponding engagement techniques, as described by MITRE ENGAGE.

V. Intelligent Orchestration of Cyber Deception through Reinforcement Learning and Game Theory

The Cyber Kill Chain and MITRE ATT&CK frameworks serve as a guide for the mapping of adversary behaviors to suitable deception techniques, but the actual deception deployment in dynamic environments would need continuous adaptation and decision-making under uncertainty. In this way, reinforcement learning (RL) and game theory (GT) become central for the intelligent orchestration of cyber deception. Their embedding into the threat modeling process not only helps in contextualizing but also promotes the continuous improvement of deception strategies, thus providing smart and proactive defense across a wide range of areas.

Game-theoretic models capture the strategic interactions between attackers and defenders, allowing defenders to find the optimal countermeasures by taking the adversarial payoffs, costs, and bounded rationality into account. Authors in [82] introduced a game-theoretic framework to optimize the deployment of honeypots and software diversity in a network under resource constraints. It presents two-layer deception tactics: the first layer determines the position of honeypots on network edges using a zero-sum game based on attack graph analysis and node importance, while the second layer employs a non-zero-sum game to manage software diversity across honeypots, thereby preventing the attackers from recognizing the uniform deception. The model takes into consideration the attacker-defender interactions and provides the mixed-strategy Nash equilibria to attain the maximum defender payoff. The experimental results indicate that the strategic allocation of honeypots with deception diversity significantly enhances the defense effectiveness against adaptive adversaries.

In [24], the authors proposed a novel game-theoretic framework for honeypot allocation in dynamic tactical networks. It makes use of the fact that node mobility changes network topology and attack paths. The interaction modeled herein is between the defender and the attacker in a two-player zero-sum Markov game on changing attack graphs. The defender is the one who wants to place honeypots in a way that the attacker's deception is maximized and the costs for reconfiguration in the network states are minimized, while the attacker is the one who picks the right attack paths. A predictive model has been incorporated and a solution has been provided for stationary Nash equilibria through the application of a Q-minimax algorithm. The results of the investigators show that projecting the future mobility of the system would be the most effective defense measure, while it also reduces the rewards of the attacker's efforts. Thus, it becomes a method that is both scalable and adaptive for the plan of deception in a mobile and resource-constrained environment.

In [83], the authors provided a foundational game-theoretic framework for applying cyber deception through evidence-based signaling games. They provide mathematical models that capture the dynamics of strategy between a deceiver and a deceived under uncertainty, including the probabilistic evidence of intrusion detection outputs. Also, they analyze: a binary state deception, a continuous state deception with a detection cost, and a multi-level deceptive modeling of APTs. Perfect Bayesian Nash Equilibrium (PBNE) is used to illustrate the optimal deception strategies. This research introduces the term of deceivability in a formal way, and states certain conditions for the deception to be not only sustainable but also effective. It supports the design of adaptive, long-term deception policies by considering how attackers learn and update beliefs over time, making it a theoretical cornerstone for strategic deception planning in adversarial settings.

In [84], the authors proposed a game-theoretic framework

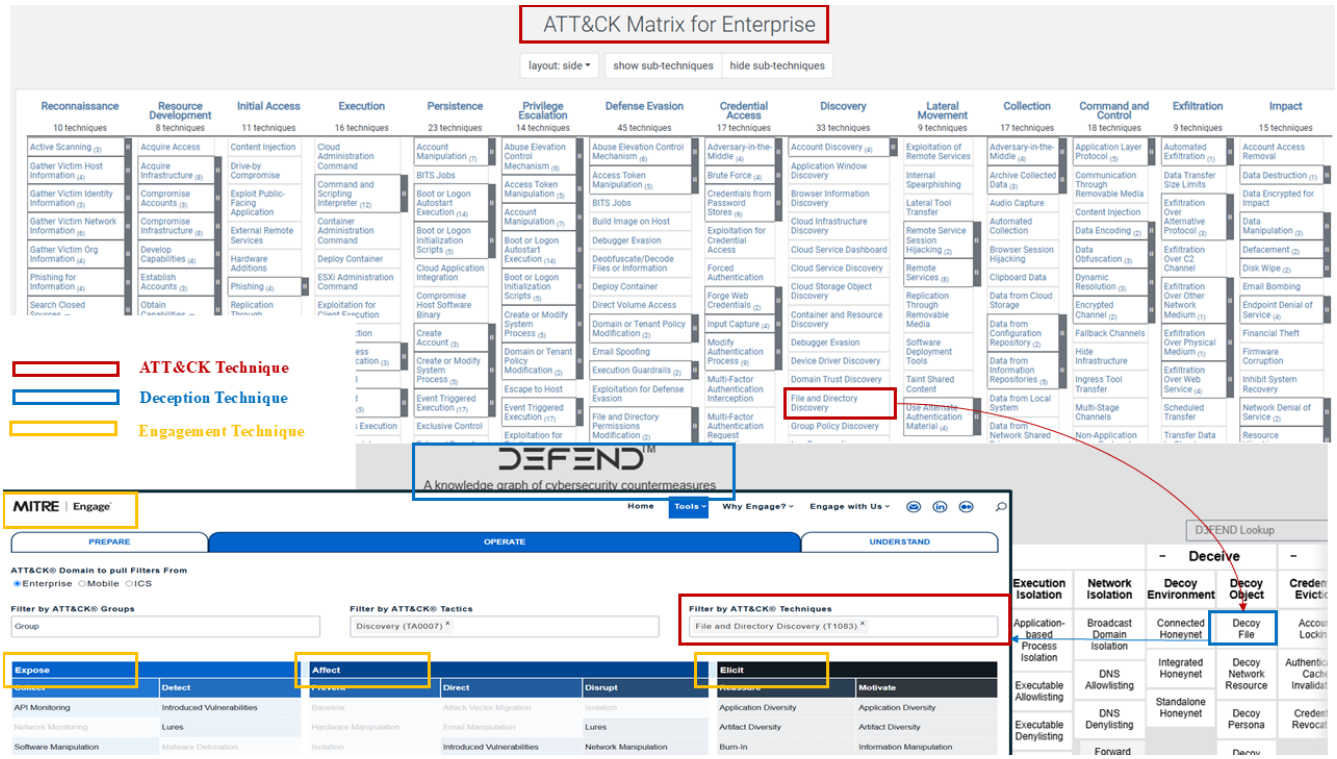

Fig. 3. Mapping of an enterprise MITRE ATT&CK technique to corresponding deception and engagement techniques.

that has multiple levels as well as learning and control theories. The main application is to counter deceptive information attacks in Intelligent Transportation Systems (ITS). The introduction of the PRADA (Proactive Risk Assessment and Mitigation of Misinformed Demand Attack) framework, which regards the attacker-defender dynamics as a stackelberg game, and quantifies both local and network-wide effects of demand manipulation, is the most important contribution. Besides, the paper also proposes trust-constrained recommendations as a tool to ensure system reliability in case of attack. The approach integrates strategic modeling, user equilibrium routing, and predictive resilience mechanisms, where game theory emerges as the core instrument in facilitating adaptive deception in the ITS environments.

On the other hand, reinforcement learning facilitates data-oriented, self-adaptive decision-making by obtaining deception policies over time through trial-and-error interaction with simulated environments. The techniques, such as Deep RL and Q-learning provide defenders with the opportunity to dynamically modify the placement of the deception, the interaction fidelity, and the signaling strategies according to the new threats. Authors in [85] proposed an adaptive Q-learning-based framework for orchestrating cyber denial and deception strategies in enterprise networks, by using a detailed attacker-aware attack graph. The model integrates MITRE ATT&CK tactics and CVSS-derived metrics to evaluate vulnerabilities in terms of importance, exploitability, and damage. Two different attacker profiles: opportunistic and strategic, are used to model different behaviors, and the defender learns optimal responses (none, denial, deception) via Q-learning. The approach enables a dynamic and tailored honeypatch placement that is built to the attacker's strategy and system context. Besides, to enhance decision making, some works combine reinforcement learning with game theory that enables defenders to learn from gained experience and think strategically about the attacker's behavior.

In [86], the authors suggested a reinforcement learning approach to dynamically select and orchestrate deception and Moving Target Defense (MTD) strategies. They developed a confrontation model, which is a prototype to simulate the interaction between an attacker and a defender, taking into account perception asymmetry and phase progression via a simplified Cyber Kill Chain (CKC). They employ Deep Q-Learning to train a defensive agent capable of adapting its strategy based on observed attacker actions and system states. The major contribution is showing how deep reinforcement learning can enable adaptive, perception-aware, and cost-sensitive orchestrations of deception and MTD in complex environments, which are better than static or naive strategies in all tested scenarios.

In [87], the authors developed a deep reinforcement learning framework, a novel solution for the deployment of honeypot strategies in complex networks represented using Bayesian attack graphs. They model a stackelberg game that involves a defender (the one who deploys a honeypot) and a hacker, where the defender takes the lead by deploying high- or low-interaction honeypots to manipulate the hacker. The setting is represented as a Markov Decision Process (MDP), and the search for the strategy space is carried out using Actor-Critic and Proximal Policy Optimization (PPO) algorithms. Their method contributes to the dynamic, state-aware decision making and is reported to outperform random and value-weighted baseline strategies significantly in experiments. The study presents the effectiveness of RL in learning robust and

cost-efficient deception strategies under uncertainty.

In [88], the authors proposed a hybrid game-theoretic and reinforcement learning method to enable quantum superdense coding security against advanced attacks, including scrambling and bijection. The model introduced decoy qubits as deception elements so that eavesdropping attempts can be detected, and the interaction between the sender/receiver (Alice and Bob) and the attacker (Eve) is framed as a non-cooperative game. The authors used custom utility functions: Return on Protection and Return on Attack, analyzed both pure and mixed strategy Nash equilibrium, and used a Q-learning approach to optimize decoy insertion strategies under uncertainty. The simulation results confirm the model's capability to converge to equilibrium and minimize the false negatives, which illustrates the efficiency of game-theoretic reasoning coupled with RL-driven strategy adaptation in quantum security.

VI. Cyber Deception in Cloud Environments

Cloud computing has brought a drastic change in how organizations can deploy and scale IT infrastructure, providing elasticity, multi-tenancy, and on-demand resource provisioning. However, many of these are the same design features that create unique security problems, such as co-residency attacks, lateral movement, insecure APIs, and dynamic reconnaissance. The dynamic, decentralized, and virtualized characteristics of the cloud infrastructure make it an attractive target for attackers, while legacy-based perimeter security approaches frequently do not secure the evolving threats adequately [89]. Deception has been the proactive cyber defense technique to address these threats with the help of misleading artifacts, such as honeypots, decoy virtual machines, fake credentials, and deceptive storage buckets. Novel methodologies are being employed nowadays, such as IP and VM shuffling, AI-driven decoy placement, and adaptive honeynet orchestration for the purpose of confusing respective attackers, postponing their advancement, while collecting useful threat information. Installation of the deception in cloud environments is not only through this promise but also through the involved challenges, such as ensuring the scalability and realism of deceptive elements, avoiding interference with legitimate operations, and integrating virtualized orchestration layers in a seamless manner. This section covers cyber deception in the cloud setting, particularly focusing on deception-aware architectures, the corresponding cloud (IaaS, PaaS, SaaS) threat coverage, and the limitations and deployment trade-offs that current methods come with.

In [90], the authors proposed an integrated cloud security framework based on a mixture of signature-based NIDS (SNORT) with distributed honeypot networks (Glastopf, Cowrie, Dionaea) in an OpenStack environment. The architecture can be seen in Fig. 4, where authors have strategically placed SNORT at network controller nodes (to deal with external traffic) and compute nodes with OpenV Switches (for internal/local traffic), while honeypots emulate services in order to capture interactions of the attacker. The data obtained is then analyzed in a sandbox environment (Cuckoo Sandbox) to dynamically extract behaviors of the malware, which then triggers an automated use case to add new and update the current SNORT rules. The system shows an increase of unknown attacks detected (for example, XSS, malware variants) as well as causing redundant alerts, among which, we should mention the overhead of distributed NIDS instances and that the research is focused mainly on network-layer attacks, but the added value of integrating host-based defenses also like VM introspection is still valid.

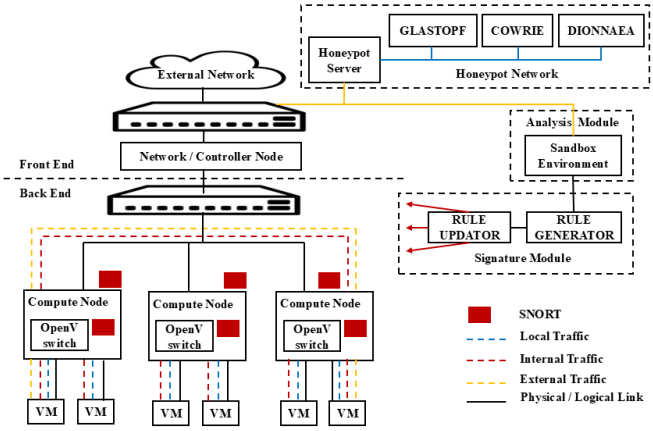

Fig. 4. The overall architecture showing the different modules and types of traffic in [90].

In [91], the authors provided a game-theoretic Moving Target Defense (MTD) framework that tactically combines both real and deceptive virtual machine (VM) migrations to ensure security of the cloud environments against side-channel and co-residency attacks. They proposed a new model that represents the security interaction as a signaling game, in which defenders can either perform live/non-live migrations or simulate them by carefully crafted traffic patterns, creating uncertainty for the attackers while minimizing costly real migrations. The analysis shows that Nash equilibria are the only beyond which deceptive signaling offers the same security level as physical migrations, the network controller operating on detection alerts and cost parameters that dynamically set best strategies. This study of the symbolic trade-off of migration overhead and security gains, thus admitting both a theoretical model for the deceptive MTD in clouds and a practicable decision algorithm for the implementation, clearly underlines its contribution, whereas questions regarding performance in realistic situations and adversarial learning remain unaddressed.

In [71], the authors suggested the Automated Honeynet Deployment Strategy (AHDS), which is a dynamic security framework for container-based clouds that adaptively deploys honeypots to prevent emerging threats. AHDS uses an Attack Graph (AG) to chart hypothetical routes of attacks, and it also comes up with a Deceptive Exploring Surface (DES), a network of strategically placed source honeypots to divert potential enemies from critical assets. The algorithm gives priority to high-value nodes based on the degree of centrality and optimizes the layout with the help of a set cover-based algorithm, which has the effect of not wasting resources and having the maximum possible coverage. The system is built upon three main building blocks, which are: 1) a Monitor Engine for recording the infrastructure changes and costs, 2) a Decision Engine that adapts the strategies of the honeynet in real time based on the AG assessment, and 3) a Deployment Handler for automatic changes of configurations. Evaluations

reveal that AHDS is 83% more efficient at decreasing the possible attack emergence while outgunning the traditional strategies (e.g., "Max" and "Most") both in effectiveness and in no resource waste, and is seamlessly adopted by datacenter sizes. Nonetheless, its effectiveness hinges on precise AG modeling and it relies on assumptions that intruders follow predictable propagation patterns, potentially limiting robustness against novel or adaptive threats.

In [92], the authors suggested a cloud-based deception framework that can disrupt DDoS reconnaissance by using SDN/NFV technology to generate virtual reflection networks in the cloud, which send back to the attackers false topology data but still keep correct details for the legitimate users. The system is using GRE tunnels for the rerouting of the reconnaissance traffic (traceroute/ping) to the virtual SDN switches, which are programs that implement IP hopping and path mutation, with the physical and cloud networks being synchronized by dual SDN controllers and NFV orchestrator. The solution was tested on the GENI platform and only added a 25-35ms delay, decreased packet loss to below 1%, and reflected network alterations in 75ms, while it was >99% cheaper than a physical infrastructure, but it is reliant on the accuracy of the synchronization that is required to connect between the physical and the virtual networks and also it can be difficult in the situation of very frequent or large-scale topology changes.

In [93], the authors proposed a deception-based defense framework for private cloud infrastructures that is based on using honeypots in an enterprise IT environment to identify and contain internal threats by deploying decoy virtual machines (VMs) with emulated services (e.g., routers, databases) that run parallel to the production VMs. The setup, as illustrated in Fig. 5, includes Snort for intrusion detection and Sebek for activity logging, which together log attacker interactions and pass the data to a Multiclass Support Vector Machine (MSVM) classifier that applies feature selection (Gini index) and dimensionality reduction (PCA) methods to traffic analysis. With the help of KDDCup99, NSL-KDD, and Gure-KDD datasets, the classifier achieves a remarkable 95% accuracy in distinguishing between different types of attack (DoS, U2R, R2L, probing) and normal behavior by thus effectively isolating production systems and profiling intruder activity during the process. The application, while functional against most network-layer threats, is limited by the framework's signature-based detection approach that is inadequate for dealing with advanced attacks, which suggests improvement through infrastructure integration with anomaly detection and threat intelligence feeds for a more comprehensive security coverage.

In [94], the authors introduced a novel AI-based defensive deception framework to secure multi-tenant cloud environments from reconnaissance attacks. The strategy overcomes the issues brought about by static, uniform configurations in cloud networks, which add simplicity to reconnaissance for the adversaries. To this end, the framework exploits deep reinforcement learning (DRL) to formulate the optimal deployment of decoys. A utility function models common OS vulnerabilities as a threat, while a DRL agent who has been trained with Proximal Policy Optimization (PPO) is the one to produce strategies for configuring and distributing decoy virtual machines in a fine-grained manner. These strategies aim to hide actual assets

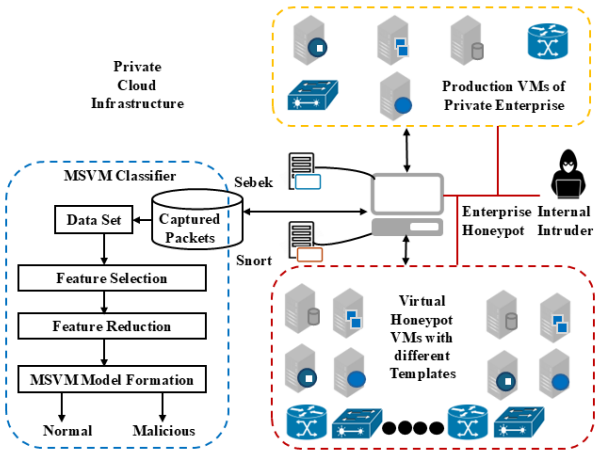

Fig. 5. The private cloud infrastructure with enterprise honeypot in [93].

and thereby increase the attacker's resource consumption. Conducted simulations proved the framework's skill in improving asset concealment by 20.58% and raising attack costs by 40.4% as compared to the traditional approach. This work challenges the idea that DRL constitutes the only probability of deception being dynamic and scalable in the clouds, thus allowing for accurate protection against reconnaissance.

In [95], the authors proposed the use of IRDS4C, a multilayer deception framework for the aim of detecting zero-day ransomware and also intrusions across cloud environments such as IaaS, PaaS, and SaaS. Through deploying of strategically positioned decoys, including high-interaction honey files/tokens (to mislead the attackers) and low-interaction canary resources (for early detection), the system can use the ASCII-based naming scheme to make the ransomware interact with the decoys first. The behavioral monitoring that it uses to track unauthorized access, does not however, disturb the legitimate operations. The testing was performed on Google Cloud with seven ransomware families (e.g., REvil, WannaCry) and IRDS4C was found to achieve 100% detection accuracy, while faster than traditional methods like file hashing. Besides that, the framework also successfully recognized the human intruders in simulations of different breaches carried out, being a lightweight, scalable solution designed for cloud-native deployment, with future extensions planned for Linux and macOS, compatibility.

In [96], the authors introduced a novel containerized honeypot-based deception system which is capable of real-time tracking and profiling of cyber adversaries in the cloud setting. Docker containers are the framework's key feature that are used to establish a variety of honeypots (e.g., Cowrie, Dionaea, DDoSPot, RedisHoneypot) in different Microsoft Azure regions, under the support of ELK stack (Elasticsearch, Logstash, Kibana), which will be used for data aggregation and visualization. The system looks like a typical cloud service and to create open ports for the attackers to connect to it uses a Suricata, a tool for p0f, and FATT, along with some interesting extras whose CVEs, operating systems, and behavioral patterns are being analyzed. The deployment of the work was successful for the reason that it caught a large number of attacks, such as the exploitation of the old CVEs,

the botnet-based DDoS traffic, and the suspected URL usage, which provided intelligence on the adversary techniques and the infrastructures. The experiment setup has shown competitiveness in processing data acquisition, forensics, and attack identification, with plans for the next stage to include the early-warning system upgrade and the threat coverage expansion to the zero-day detection. This work is a representative example showing how scalable and cloud-native honeypot deployments can act as a strategic deception tool for proactive cyber defense.

In [97], the authors suggested a resource-aware cyber deception framework for microservice-based cloud-native applications. This is another option in the case of traditional pre-built decoys that are not effective in dynamic service environments because of their inability to blend. Their design, using the distribution of a non-linear mixed integer programming problem, employs the production microservices cloned as high-fidelity decoys to catch lateral movements of the attacker that are being made along the attack path, at the same time maximizing the intercepted attack paths with respect to CPU/RAM restrictions and also considering the attack graph topology. To solve the problems related to computational complexity, they have offered an approach that enables the prioritization of the most critical microservices based on the betweenness centrality measure. The algorithm provided is highly scalable, and the realistic placement of the decoys is achieved. Their results clearly show that, even with fewer resources, the coverage gained from deceptive means was more than with the basic approach; thus, the framework can be confidently implemented in modern cloud spaces where contextual and resource-efficient deception are a must.

Table II summarizes all the discussed works in cloud environments, providing a comparative overview of their defense goals, targeted attack types, deception methods, architectural components, evaluation metrics, and identified limitations.

VII. Cyber Deception in Wireless Networks

Wireless networks are largely under threat due to the inherent challenges posed by their broadcast nature, limited resources, and dynamic topologies, which make them susceptible to a range of cyber-attacks including reconnaissance, eavesdropping, jamming, spoofing, and lateral movement attacks. Security mechanisms that are based on encryption, authentication, and intrusion detection are the most commonly used traditional safety measures. They are not enough, in decentralized networks, as open networks are, with their limitations in computational power and energy efficiency of many wireless devices [98]. In response, this has been countered by the emergence of cyber deception, where this countermeasure aims to create trouble for attackers, ensure the communication of critical information, and collect data on potential threats. For instance, the defenders do not just deploy decoy nodes, fake access points, adaptive honeypots, but also the communication protocols that mislead the attacker. Such practices take the place of the real nodes and thus prevent the attacker from gaining the proper situational awareness. Recent works focused on the recent developments, especially in software-defined and virtualized wireless networks, where the use of AI and machine learning has been instrumental in supporting the dynamic traffic redirection, strategic decoy deployment, and behavior modeling of the attacker. Despite its large potential, the operationalization of deception in wireless networks also encounters issues like keeping the decoys realistic, reducing the interference with the real communication, and ensuring rapid adaptation to network change. This section reviews the most important works in the field that utilize deception as an adaptation mechanism to the constraints and shifting hostile environment in wireless communication systems.

A trilogy of deception-driven architectures is introduced to secure the virtualized wireless networks against both RF-based and infrastructure-layer threats. In the first work [99], the authors introduced a cyber deception framework for virtualized wireless networks that counters unauthorized access and DoS attacks through SDN-controlled dynamic redirection. An SDN controller observes the network traffic and redirects adversarial flows to a Deception mobile virtual network operators (DMVNO), which acts as a decoy through the emulation of legitimate services, while the availability for benign users is preserved. The defense mechanism characterizes the attack dynamics as a birth-death process and assesses them using Monte Carlo simulations with metrics such as attack redirection rate, deployment timeliness, and the probability of legitimate users being blocked. Primary limitations are noted, including the failure to inject real-time adaptability for unidentified attack patterns and the issue related to the delays in the detection-to-deployment pipelines not being mentioned. These limitations are suggested as future work. To address this, the second paper [100] introduced Deceptor-in-the-Middle (DitM), as illustrated in Fig. 6, which is a cyber-deception architecture that can be found in virtualized wireless networks and provides concurrent real-time attacker detection and dynamic adversarial redirection. At the beginning of the process, the system detects adversaries by utilizing RF energy sensing and Wald's Sequential Probability Ratio Test (SPRT), then, it transparently routes them to a Deception VNO (D-VNO) through ARP cache poisoning, by mimicking a Man-in-the-Middle (MitM) attack in the opposite way. The framework is built using an SDN controller and network aggregator that operate in a "sense-observe-manipulate" mode, with the added benefit of ensuring that genuine users do not experience any service disruption. The distribution reflects a comparison between the detection rates (false alarm and miss-detection rates) at different thresholds, with the only limitation being that it lacks formal guidelines for the optimal resource utilization and leaves scalability, as well as, adaptive adversary management to future work. The third paper [101] addressed the virtualized wireless networks cyber deception optimization using a Stackelberg game-theoretic model, in which an SDN controller, under budget constraints, strategically maps actual RF configurations to deceptive observable configurations while interacting with either naive or rational attackers. The work demonstrates the NP-hardness of the optimal strategy selection and presents a polynomial-time algorithm for naive attackers as well as a scalable greedy heuristic (GMS) for rational ones, proving successful attacker utility minimization and computationally efficient deception deployment through simulations. While the steps are made from static to adaptive and after that, to game-theoretically optimized deception, the method is still limited by its assumptions about rational attacker behavior and also faces challenges with optimal Mixed Integer Linear Programming (MILP) solutions on large networks that have scalability issues, thereby leaving dynamic configuration adaptation and real-

TABLE II. SUMMARY OF CYBER DECEPTION TECHNIQUES IN CLOUD ENVIRONMENTS

Reference	Defense Goal	Attack Type	Deception Method	Architecture Components	Evaluation Metrics	Uncovered Limitations
[90]	Mitigate known and unknown attacks in cloud environments	SQL Injection, XSS, SSH attacks, Malware injection	High/low interaction honeypots	NIDS Module (SNORT), honeypot network module (Glastopf, Dionaea, Cowrie), analysis module (Cuckoo Sandbox), signature module (Rule Generator and Updater)	Reduction in generated alerts, detection of unknown attacks via custom rules, dynamic malware analysis results	Overhead due to multiple NIDS instances not studied, focus limited to network-based attacks, no integration with HIDS, ACLs, or firewalls, performance-security trade-off not quantified
[91]	Mitigate cloud-side attacks (e.g., side-channel) while minimizing migration costs	Side-channel attacks (intra/inter-host), VM co-residency threats	Signaling game-based deceptive VM migration (live/non-live or fake signals)	Network Controller (alerts and migration decisions), VMs (defenders in the game), attacker (monitors VM signals), signaling Module (generates live/non-live migration or deceptive signals)	Cost savings, security gain, equilibrium stability	Focuses on VM-level attacks, ignores host/network-layer threats, no real-world validation (simulation only), unquantified impact of deception on performance, requires attacker belief modeling (p,q), which may not hold in practice
[71]	Mitigate dynamic threats in container-based clouds	Multi-stage lateral movement	Automated honeypot placement using Attack Graph and Deceptive Exploring Surface	Monitor engine (tracks system changes), decision engine (optimizes honeypot placement), deployment handler (configures/ deploys honeypots), honeypot nodes	Attack success rate reduction, resource efficiency, scalability, flexibility	Depends on attack graph accuracy, static assumptions on attacker model
[92]	Disrupt reconnaissance for DDoS attacks (e.g., Crossfire, Coremelt) without affecting users	Reconnaissance phase of DDoS	Cloud-based reflection network: GRE tunnels forward probes to virtual topology, SDN-enabled IP hopping for fake paths, "Reflected" virtual topology mimics physical network	Physical SDN switches, cloud virtual switches, local/Cloud SDN controllers, NFV management host	response time, packet loss, update latency, cost	Requires tight sync between physical and virtual topologies
[93]	Divert and detect internal threats in private clouds	Internal reconnaissance, probe, DoS, User to Root (U2R), Remote to Local (R2L)	Enterprise honeypot with VM-level emulation	Honeypot VMs, Snort, Sebek, MSVM classifier	Classification accuracy, alert generation	Limited to internal threats, dependence on known attack patterns
[94]	Proactively counter reconnaissance attacks in cloud environments	Network scanning, probing, OS fingerprinting, exploitation of common OS vulnerabilities	DRL-based decoy VM placement	DRL agent (PPO), OS vulnerability model, simulated tenants	Deception entropy, attack cost, Joint-Defense Goal	Limited to OS-layer vulnerabilities, scalability
[95]	Detect zero-day ransomware attacks and intruders in cloud environments (IaaS, PaaS, SaaS)	Ransomware (e.g., REvil, WannaCry, NotPetya) and intrusion attempts (e.g., unauthorized access to cloud storage/ servers)	High-interaction decoys (fake files/tokens), low-interaction decoys (canary files/tokens), ANSI/ASCII-named decoy files	Decoy resources (files, tokens, partitions, folders, servers), event handler watcher (monitors interactions with decoys via cloud API hypervisor)	Detection rate, detection time, speed vs. hashing/entropy methods	Lacks compatibility with Linux/MacOS, focus on Windows-based cloud, file system reliance (requires NTFS for positioning technique)
[96]	Monitor and attribute cloud attacks in real time	Botnets, CVE exploits, DDoS	Containerized honeypots, high-interaction (e.g., Cowrie SSH/ Telnet), low-interaction (e.g., Dionaea, ADBHoney) decoys	Azure cloud, ELK stack, Suricata, P0f, FATT, honeypots	Real-time logging, CVE capture, attacker attribution	Manual signature extension, needs zero-day attack adaptation
[97]	Strengthen security in cloud-native microservice architectures by intercepting and mitigating malicious lateral movements of attackers	Lateral movement, container compromise	High-fidelity decoys (clones of legitimate microservices)	Microservice architecture, decoy containers	Computation time, decoy interaction probability, average decoys per attack path	Assumes attack graph availability, computational complexity, node constraints

world adversarial creativity as open challenges for future work. This illustrates a transition from simple redirection to strategic deception in wireless virtualization security.

In [102], the authors suggested counteracting the jamming (which means that an adversary injects noise to decrease of signal-to-noise ratio (SNR) and disrupt communication) attacks on wireless networks using game theory. Their approach concerns a dual channel system, which has a real and a fake transmitter, and a receiver pair, where fake transmissions mislead the jammer into splitting its power of jamming to both channels. The interaction is formulated by a Stackelberg game, in which the system (the leader) performs the optimization of power allocation first, and the jammer (the follower) afterwards senses and reacts to the channel activity. There are two cases discussed: 1) a non-strategic jammer with fixed behavior,

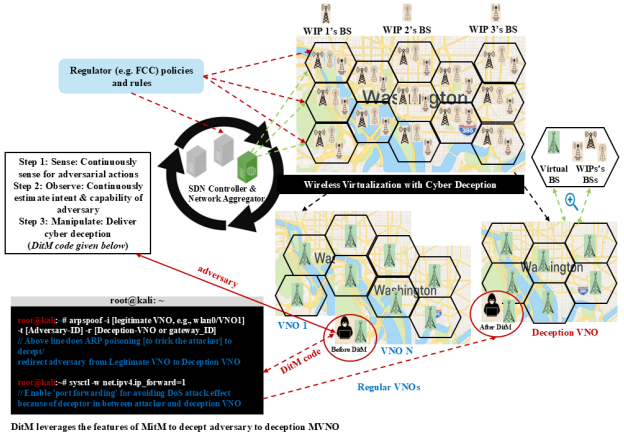

Fig. 6. An example scenario for cyber deception in wireless virtualization in [100]: logical redirection of adversary from VNO N to deception VNO via subleased base station.

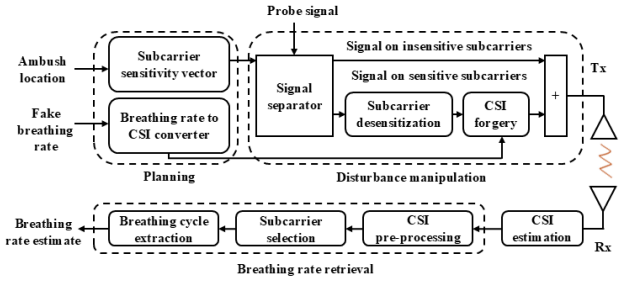

Fig. 7. The flow chart of the proposed HoneyBreath defense in [103].

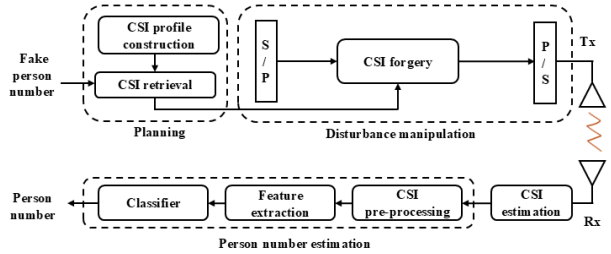

Fig. 8. The flow chart of the proposed Ghost defense in [103].

and 2) a strategic jammer, for which they can establish a Subgame Perfect Nash Equilibrium (SPNE) for optimal power allocation. The simulations validate that the technique reduces the jammed signal and boosts the legitimate channel's transmission rate. However, the work presuming the total efficacy in jammer sensing is limited to just two orthogonal channels and also does not deal with involving scalability in multi-node or dynamic environments. Despite these shortcomings, the paper underscores the fact that power-based deception is a way of significantly increasing resistance to reactive jamming even in simple wireless systems.

In [103], the authors presented two deception-based techniques, depicted in Fig. 7 and Fig. 8 that are used to withstand wireless privacy threats such as the Channel State Information (CSI) that are used by the attacker. HoneyBreath is a method that gives the wrong breathing rate by first hiding the sensitive subcarriers and then sending forged sinusoidal CSI patterns, while Ghost controls all the subcarriers by using previously recorded CSI to fool crowd counting classifiers. These strategies have been applied on USRP X310 platforms and they have given good evaluation results. HoneyBreath has reached the state at which the errors of breathing rate estimation go below 1.2 bpm; on the contrary, Ghost has had complete occupancy detection success. However, they require attackers' location beforehand and pre-collected CSI profiles, which might hinder their use in some dynamic cases. The study illustrates that strategic CSI manipulation could be a viable method for achieving privacy against wireless inference attacks while being largely unnoticed and practical.

A two-part contribution to deception-based defense strategies in wireless sensor networks (WSNs), specifically targeting energy depletion and battery drain denial-of-service (DoS) attacks is presented. The first study [104] presented a deception framework designed to assist cluster heads (CHs) in wireless sensor networks (WSNs) against energy depletion attacks using a game-theoretic approach. The strategy involves both high- and low-interaction honeypots, which are placed in a secure zone, governed by an intrusion detection system (IDS), that counts attackers (sophisticated/ non-sophisticated) and directs them to suitable honeypots. An incomplete information Bayesian game model derives Nash equilibrium strategies for CH energy preservation and attack mitigation. In MATLAB, simulations were carried out, and the approach was validated, which showed a decrease in attack success rates through the reallocating of honeypots dynamically. Major constraints include a static attacker assumption and a sole reliance on predefined honeypot configurations, thus demonstrating the scalability and real-time adaptability issues for the next work. The second study [105] builds on this framework by proposing a lightweight defense mechanism to battery-draining DoS attacks in wireless sensor networks (WSNs) through a signaling game framework where sensor nodes smartly release deceptive energy-level signals in order to misdirect attackers. The authors depicted the relationship among nodes and attackers as a two-player Bayesian game to derive the optimal defense strategies through Perfect Bayesian Nash Equilibrium analysis, showing that the nodes can effectively save energy by trying to conceal the true state when the costs of lying are low. The simulations show that by using the deceptive signaling, the attacker's utility is reduced while the nodes are being protected. However, the approach only considers single-round interactions and does not include coordinated attacks or network failures that could be implemented in future work on dynamic game models and real-world implementation in platforms such as NS3 or Cooja.

Table III summarizes all the discussed works in wireless networks, providing a comparative overview of their defense goals, targeted attack types, deception methods, architectural components, evaluation metrics, and identified limitations.

VIII. Cyber Deception in Cyber-physical System

Cyber-Physical Systems (CPS) are systems that consist of computational (cyber) elements and physical processes and are done almost as one, which enables real-time monitoring, control, and interaction with the physical world. These systems are virtually the key to numerous essential fields

TABLE III. SUMMARY OF CYBER DECEPTION TECHNIQUES IN WIRELESS NETWORKS

Reference	Defense Goal	Attack Type	Deception Method	Architecture Components	Evaluation Metrics	Uncovered Limitations
[99]	Isolate adversarial users in virtualized wireless networks	Unauthorized access, DoS, dynamic attacks	Deception MVNO (DMVNO): a decoy virtual network operator	SDN controller, Wireless Infrastructure Providers (WIPs), legitimate MVNOs, deception MVNO	Blocking probability, attacker arrival rate, deception deployment time	Detection delay (time gap between attack detection and DMVNO deployment)
[100]	Protect virtualized wireless networks from adversarial attacks while maintaining QoS for legitimate users	Impersonation attacks, location falsification attacks	Deceptor-in-the-Middle (DitM): SDN-controlled redirection (legitimate VNOs act as "middle-men" to reroute adversaries to deception VNOs)	SDN controller, wireless infrastructure providers (WIPs), legitimate VNOs, deception VNOs	Detection range, false alarm rate, throughput	Lacks optimal strategy selection mechanism
[101]	Secure virtualized wireless networks by deceiving attackers into interacting with decoy systems	Jamming/DoS attacks, reconnaissance attacks	Stackelberg game-based mapping of true to fake RF bands	SDN controller, wireless infrastructure providers (WIPs), VNO, deceptor VNO	Attacker utility, deception cost, feasibility constraints	Scalability, computational complexity
[102]	Mitigate jamming attacks to protect the transmission of real information between a transmitter-receiver pair	Jamming attacks	Fake signal transmission on orthogonal channel	Twotransmitter-receiver pairs, orthogonal channels, jammer	Transmission rate, optimal power allocation, utility equilibrium	Assumes perfect sensing, static two-channel setup
[103]	Protect user privacy by preventing accurate inference of breathing rates and crowd counts via wireless signals	Channel state information (CSI) wireless inference attacks	HoneyBreath (transmits fake CSI to deceive eavesdroppers into inferring incorrect breathing rates), Ghost (manipulates CSI to fabricate false crowd counts in empty rooms)	Software-defined radio (USRP X310) platforms, CSI profile library, multiple antennas	Breathing rate error, crowd counting	Static or predictable attacker positions, pre-collected CSI profiles
[104]	Protect cluster heads (CHs) in Wireless Sensor Networks (WSNs) from energy depletion attacks	Energy depletion attacks	High- and low-interaction honeypots mimic CHs to lure attackers	Cluster-based WSN with CHs and member nodes (CMs), secure zone with IDS, honeypots	Nash equilibrium analysis, probability of attack strategies, probability of defender strategies	Static attacker beliefs, single-round interaction
[105]	Mitigate battery-draining DoS attacks in WSNs	Battery drain DoS attacks	Bayesian signaling game with deceptive energy state broadcasting	Regular node (sender), attacker (receiver), signaling framework	Attack probability, PBNE types (pooling/separating)	Does not address cooperative attackers or network failures

from self-driving vehicles to energy and health care, factory robots, and industrial automation. A typical CPS is structured in the following form: sensors and actuators interface the system with the physical environment, embedded controllers are responsible for executing control algorithms, networked communication is in charge of data exchange; cloud or edge infrastructure are resources for computation and analytics. More CPS, in general, are more vulnerable to attacks as they are focusing on wireless communications, open protocols, and internet connectivity. This entails the introduction of such vulnerabilities as time-line constraints, limited computational resources, insecure firmware, and insufficient authentication. Threats specific to CPS can be the origin of physical damage, privacy issues, or huge business interruption. Some of the most notorious cases, like remote hijacking of vehicles or manipulation of smart grid components, are a lesson on how traditional security practices can't protect CPS satisfactorily by themselves [106]. Cyber deception finds a place here as a likely solution by putting the attacker off track with signal, data, node misdirection, or wrong behavior models that divert the attacker's perception and planning. This Disinformation can slow down enemies, divulge intelligence operations, and aid in adjustments to threats. However, the usage of untruth in CPS is complicated as the systems' timely response and safety-criticality requirements make it hard, and they need to be taken into account during the design phase. Moreover, the fact that adversaries are sophisticated enough to detect badly implemented disinformation is an additional inconvenience. This section presents cyber deception methods contextualized to CPS environments with an emphasis on deception-aware system design, attacker engagement strategies, and domain-specific constraints.

In [107], the authors suggested the use of a deception-as-defense framework for CPS, in which strategic misinformation is utilized to change the perception of rational adversaries who are trying to estimate the states of the system. The interaction is modeled as a stackelberg game, in which the defender (leader) first of all commits to a signaling policy while the adversary (follower) reacts optimally. The paper shows the results under Gaussian-distributed system states and quadratic cost functions that linear signaling rules (which include optional noise) are the ideal means to indirect adversarial behavior without direct enforcement. The solution, obtained through semi-definite programming (SDP), is also valid for dynamic situations, partial observations, and unknown attacker goals, and it is robust under both Bayesian and non-Bayesian uncertainties. The study provides a foundational game-theoretic approach in protecting CPS roads against adversaries, focusing on the indirect channel perceptual control, which is a key for resilient systems that require both stealth and accuracy.

In [108], the authors introduced a honeypot-based decep-

tion framework for CPS that optimizes the defensive strategies model under limited human analysis resources by modeling attacker-defender interactions, which are represented as a Bayesian game with missing knowledge. The proposed method involves the use of both low- and high-interaction honeypots integrated into the CPS cyber layer, and using the derived optimal configurations for defense and resource allocation to ensure the highest defensive payoff, proving the inclusion of several Bayesian-Nash equilibria under different analysis budgets. Through the game-theoretic approach, they clarify the distinction between the types of attackers (weak vs. strong offensive access) and defense mechanisms (service provision vs. non-provision), thanks to the simulations they carried out, which revealed that turning attention to the honeypots that provide a greater unit analysis utility increases the efficiency of the capturing process. Up to now, the framework has improved the performance of practical deception in CPS, though it is believed that the strategies of attackers should remain static and interactions are to be single-stage, it has put off the adaptation to dynamic and multi-stage attacks for the upcoming tasks.

In [109], the authors presented a honeypot-based intrusion detection system, specifically for CPS, which addresses threats such as spoofing, code injection, malware, and DoS that can disrupt the ordinary physical operations. The architecture they used diverts all the traffic into a virtual or hybrid honeypot that is placed in a strategic location and exploits the high availability of real-time attack detection, logging, and blocking, thus achieving a cost-effective and scalable deployment (e.g., Cisco, Conpot). The work makes a comparison of the interaction level, scalability, and resource requirements of the various honeypot types, which is a good point to present them as the main instruments for the early threat detection of CPS systems, given the fact that conventional methods often fail in real-time conditions. Nevertheless, the present version is applied to single systems only, and there is a need for multi-device testbed with dynamic traffic patterns, which would be the practical deception-based approach for the security of CPS.

In [110], the authors presented a resilient and smart technique to identify the honeypots in softwarized industrial CPS that largely depend on virtualization and network function slicing. Its main architecture combines a secure fuzzy testing approach with a deep learning-based classification model to address the problem of recognizing real devices from honeypots in heavily virtualized network environments. The first module of the architecture, as illustrated in Fig. 9, creates probe packets using multi-object mutation strategies based on security rules, which guarantee that probe queries are safe but rich in features that are not handled correctly between real devices and honeypots. These are the optimized packets that will be used to scan online devices. The additional responses that are returned are then analyzed for features that are found only in the honeypots and are classified by a CNN model that has been trained before. The overall design provides the packet creation and identification phases separately in order to enhance the scalability and minimize risks. Tests carried out demonstrate that, in addition to being fast and safe, the method has outshone the usual identification techniques by achieving both higher precision and lower false positives. The fuzzy testing module conveniently generates discriminative features while the CNN model provides trustworthy classification. This paper proposes a flexible and safe method to the disturbing problem of deception-aware adversaries detecting the honeypots in industrial CPS, but it has the assumption of pre-labeled data availability and the knowledge of error-handling signatures that can limit adaptability in dynamic or heterogeneous environments.

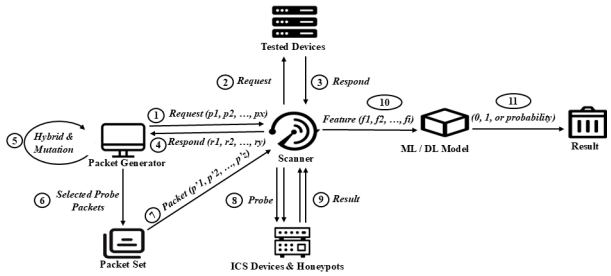

Fig. 9. The architecture of industrial CPS honeypot identification in [110].

In [111], the authors introduced a two-layer deception strategy for CPS. By depicting defender-attacker interactions as a signaling game with incomplete information, the model allows coordinated deception to be implemented both at the application layer (e.g., fake user interfaces) and at the network layer (e.g., falsified messages), which secures detection avoidance through consistency. The defender's strategies, communicating either honest or misleading signals, are improved using Perfect Bayesian Nash Equilibrium (PBNE), while the attacker checks the system type (normal/ honeypot) to determine whether to attack. Experiments carried out in an automotive CPS setting proved that two-layer deception not only increased the uncertainty of the attacker but also brought down the payoffs, and made the cost-deterrence more effective in comparison to single-layer techniques. This work, which is based on the Purdue Enterprise Reference Architecture, is the first to scientifically model multi-layer deception in CPS through game theory, thus presenting a solid framework against such attacks.

Table IV summarizes all the discussed works in cyber-physical systems, providing a comparative overview of their defense goals, targeted attack types, deception methods, architectural components, evaluation metrics, and identified limitations.

IX. Cyber Deception in Industrial Control Systems

Industrial Control Systems (ICS), which are specialized cyber-physical systems, are designed to monitor and control the operations of industries such as manufacturing, energy, water, and transportation. The components of ICS include SCADA systems, Distributed Control Systems (DCS), and Programmable Logic Controllers (PLCs). An ICS architecture typically consists of field-level devices, controllers (PLCs/RTUs), supervisory systems (SCADA), HMIs, and communication networks that use industrial protocols such as Modbus and DNP3. As ICS were originally designed for isolated, deterministic environments, they have gradually become interconnected with IT networks, which has led to the problems of legacy components, weak authentication, and insecure communication protocols. They are exposed to sophisticated cyberattacks

TABLE IV. SUMMARY OF CYBER DECEPTION TECHNIQUES IN CYBER-PHYSICAL SYSTEMS

Reference	Defense Goal	Attack Type	Deception Method	Architecture Components	Evaluation Metrics	Uncovered Limitations
[107]	Control adversarial actions to align with system objectives by crafting information strategically	Advanced adversaries seeking system-related information	Strategic signaling (linear or "linear plus noise" rules) to manipulate adversary perception	Sender and receiver agents, Gaussian information, Quadratic cost functions	Covariance of posterior estimate, semi-definite programming (SDP) equivalence, stackelberg equilibrium outcomes	Limited to Gaussian information, non-classical information schemes in control settings, adversaries are rational
[108]	Optimize defensive strategies against network attacks in CPS by balancing honeypot deployment and human analysis costs	Network attacks (e.g., probing, exploitation of vulnerabilities)	Low- and high-interaction honeypots	Cyber layer (control systems, communication networks), physical layer (sensors, actuators, plants), honeypots (low/high-interaction), firewall, router, servers	Bayesian-Nash equilibria, defense payoff maximization, escape probabilities of attacks, human analysis cost allocation efficiency	Static attackers, static deployment, dynamic adaptation not addressed
[109]	Detect and block CPS-targeted cyberattacks using honeypots	DoS, spoofing, control hijacking, malware, code injection	Low- and high-interaction honeypot-based intrusion detection	Cyber layer (sensors, network), physical layer (actuators, processes), honeypot (virtual/physical), security rules engine, traffic monitoring system	Attack capture rate, scalability, interaction level	Single-system use, Static security rules may not adapt to evolving threats
[110]	Detect honeypots to protect deception infrastructure integrity	Honeypot fingerprinting in softwarized CPS	Fuzzy probe generation + CNN-based honeypot classification	Secure Fuzzy testing module, scanner, response analyzer, deep learning model, dynamic packet set	Accuracy/ precision/ recall, effectiveness, diversity of response packets	Labeled training data, focused on Modbus protocol
[111]	Strengthen CPS resilience by implementing a dual-layer deception strategy	CPS attacks across application/ network layers	Coordinated multi-layer deceptive signaling	Coordinated signal senders (application/ network), belief update model	Defender's payoff, deterrence effectiveness	Increased deployment complexity and cost, fixed attacker beliefs

like unauthorized command injection, manipulation of control logic, stealthy data tampering, and firmware exploitation. Stuxnet, Triton, and BlackEnergy incidents are examples of severe physical disruption and operational downtime through intentionally attacking ICS. Conventional security mechanisms generally do not have the contextual awareness, adaptability, or low-latency operation required in real-time ICS settings, and in addition, frequent patching as a remediation is often impractical due to availability and safety constraints [112]. In response, cyber deception is a good choice not only because it is a proactive and stealthy approach but also it is a strategic alternative such as inserting misleading elements, decoy sensors, fake field devices, deceptive control logic and protocol-emulating honeypots, in the ICS environment to mislead adversaries, trigger early alerts, delays attacker progress, and aid forensic investigations. Design of deception in ICS is a difficult case due to the necessity of preserving protocol fidelity, safety, and the need for realism under the threat of expert attackers. This section explores deception strategies specifically tailored to ICS, emphasizing their architectural integration, effectiveness against known threat models, and deployment limitations.

In [113], the authors suggested the implementation of Honeyd+, an applicable, scalable, and cost-effective implementation of high-interaction ICS honeypots through only one PLC and a proxy-based engine. For example, by changing the network/device identifiers (IP/MAC addresses, hostnames, serial numbers) dynamically and manipulating protocol payloads, Honeyd+ can simulate multiple physical PLC devices while preserving the culture of identity and realism. Tests on Raspberry Pi and high-end laptops certainly indicated its capacity to register more than 75 virtual networks, while, under other moderate traffic, it maintained low error rates, making it effective for reconnaissance deception. Though weaknesses include no support for formatted encrypted protocols, scalability constraints due to PLC features, and poor performance under extremely high traffic. The work shows possible improvements such as protocol-specific adjustments and the integration of diverse ICS components, to extend it to the production environment.

In [114], the authors presented HoneyPLC, a high-interaction honeypot that closely simulates programmable logic controllers (PLCs) in ICS. In contrast to conventional ICS honeypots such as being low interaction fidelity, limited protocol support, and poor malware capture, HoneyPLC, as illustrated in Fig. 10, is equipped with a modular framework that consists of a PLC profile repository, a personality engine (for protocol spoofing and fingerprinting), network services (HTTP, SNMP, S7comm), and an interaction data module to log attacks and capture malicious ladder logic injections. The key innovation is a PLC profiling toolkit that dynamically, for example, configures the Nmap fingerprints and SNMP MIBs to imitate real devices such as Siemens S7-1200 or Allen-Bradley MicroLogix 1100. Beyond that, HoneyPLC's S7comm server and TCP/IP stack operate realistically to trick tools such as Nmap, PLCScan, and Siemens Step7 Manager, whereas its ladder logic capture module records the injected malware for future analysis. The tests demonstrate that there is a high fidelity (>90% Nmap Confidence, Shodan scores matching real PLCs) and scalability (75+ simulated hosts per PLC). It is worth mentioning that the main shortcomings are the lack of physical process simulation and the fact that there is no support for encrypted protocols (e.g., Modbus Secure).

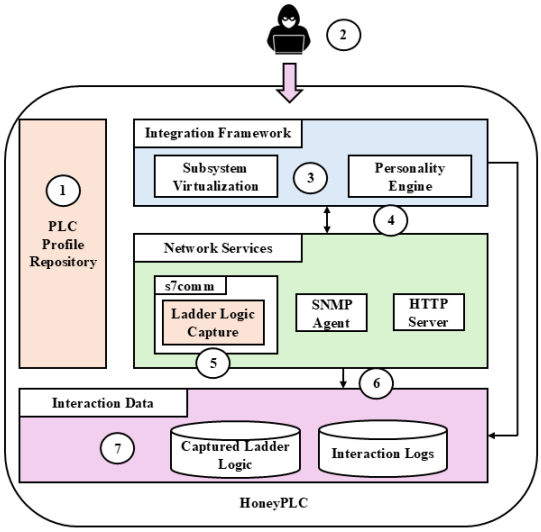

Fig. 10. The architecture of HoneyPLC in [114].

In [115], the authors introduced two deception methods for the identification of stealthy malware in the ICS, which avoid the traditional sensors through the exploitation of internal host discovery mechanisms such as NetBIOS browse lists and ARP tables. The methodology is based on the addition of sensor information to these lists in a way that causes malware to be attracted to self-disclosure. Proposal 1 is aimed at malware such as Conficker through the broadcasting of fake NetBIOS advertisements that are continuously emitted, which makes sure that the sensor's hostname is listed in the network browse lists, a tactic that is most advantageous under Windows-based systems, particularly in old versions of the program. In contrast, Proposal 2 incorporates the scheme which ensures that the sensor's IP-MAC pairing is embedded in the ARP caches of all hosts by sending cyclical ICMP or ARP requests, which, in turn, counteract malware that uses ARP tables for lateral movement. The techniques are designed for simple and non-intrusive application in the vulnerable ICS networks. The evaluations validate that Proposal 1 was successful in identifying Conficker in a laboratory setting, whereas the practicality of Proposal 2 is denoted in a theoretical proposal, which remains to be verified with real ARP-based malware. Despite their efficacy, the techniques, on the other hand, are based on assumptions relating to the behavior of the attacker, and involve a need for trial-scale deployment, decreasing the number of false positives, and integration with further detection frameworks.

In [116], the authors introduced a deception defense framework for ICS leveraging adaptive Hidden Markov Models (HMM) for the detection and mitigation of cyber threats, which include DDoS attacks, malicious program injection, and false data injection. The framework models typical ICS behavior using multidimensional data and detects anomalies by comparing observed behaviors with expected HMM state sequences. It adapts to evolving threats through incremental updates of HMM parameters. While primarily focused on anomaly detection, the framework, as depicted in Fig. 11, integrates a passive form of deception by analyzing attacker interactions within virtual environments, enabling misdirection without exposing the real system. Detected attacks (e.g., TCP SYN floods, ladder logic injections) trigger appropriate responses such as node isolation or administrator alerts. Through experiments conducted on an OpenPLC-based testbed, the solution was found to have very high rates of detection (98% for DDoS, 95% for malware injection, and 90% for false data attacks), very low percentages of false alarms (1-3%), and quick response times (1-2.7 seconds). Whereas the outcome of these tests was successful, it is mentioned that scalability and denial of multi-stage attack coverage are the shortcomings, which place emphasis on broadening the scope of the framework's deployment in larger platforms and its interfacing with other security orchestration platforms.

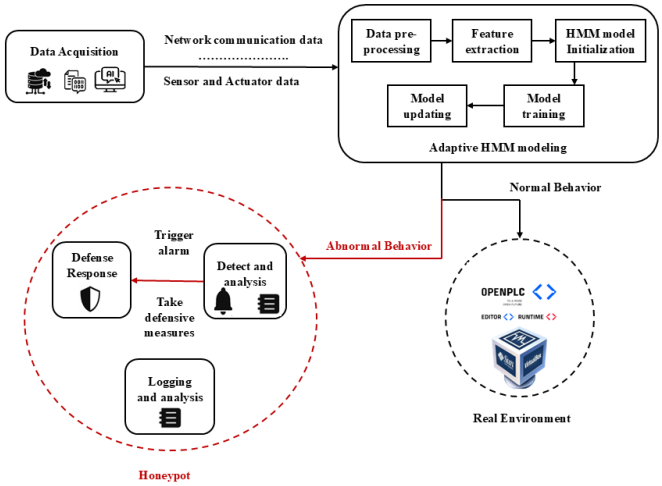

Fig. 11. The adaptive HMM-based ICS deception framework in [116].

Table V summarizes all the discussed works in industrial control systems, providing a comparative overview of their defense goals, targeted attack types, deception methods, architectural components, evaluation metrics, and identified limitations.

X. Cyber Deception in Smart Grids

Smart grids are the modernization of traditional electrical networks by integrating advanced information and communication technologies to make power systems more efficient, reliable, and sustainable. The systems comprise components like smart meters, sensors, automated control systems, and communication networks that together deliver the real-time monitoring and control of energy flow innovation. However, the high degree of networking and the dependence on digital technologies have made the trouble spots more and more numerous, and that is the reason the smart grids have become vulnerable to a strong variety of cyber threats including for example, false data injection attacks, denial-of-service attacks, and embedded malware attacks. The cyber-attacks on Ukraine's power grid, which were particularly prominent cases, showed the high impact of such vulnerabilities, bringing about the consequences of significant grid disruptions as a result of that so demonstrating the potential for major disturbances. The traditional measures of cybersecurity are often inefficient in the face of the ever-changing, elusive characteristics of these

TABLE V. SUMMARY OF CYBER DECEPTION TECHNIQUES IN INDUSTRIAL CONTROL SYSTEMS

Reference	Defense Goal	Attack Type	Deception Method	Architecture Components	Evaluation Metrics	Uncovered Limitations
[113]	Create low-cost, authentic, and targetable honeypots for Industrial Control Systems (ICS) to detect and analyze attacker TTPs	Reconnaissance, enumeration, initial access, and persistent attacks (e.g., via TCP/UDP port scanning, protocol exploitation)	Proxy-based high-interaction honeypots with Honeyd+	Physical PLC, Honeyd+ host, search/ replace Engine, evaluation platforms	Cost-effectiveness, error rate, scalability	Limited support for encrypted protocols, high load handling, PLC bottlenecks
[114]	Understand attack methods targeting Programmable Logic Controllers (PLCs), by deceiving attackers into interacting with a honeypot	Malware injection (e.g., Stuxnet, Crashoverride), reconnaissance, and disruption of physical processes	High-interaction honeypot simulating real PLCs with advanced protocol simulations	PLC profile repository, personality engine, network services module, interaction data module, PLC profiler tool	Stealthiness, compatibility with proprietary tools, ladder logic capture	Limited protocol coverage, lack of physical interaction modeling
[115]	Detect malware infections in Industrial Control Systems (ICS)	Malware infections (e.g., WannaCry, Conficker)	Embeds sensor host names in browse lists, embeds sensor IP addresses in ARP tables	Sensor, host announcement module, ARP/ICMP module, alert system	Detection capability, false positives, coverage vs. traffic	Deployment impact (Proposal 2's continuous ARP requests may affect network performance), evasion by advanced malware, protocol support
[116]	Protect ICS from cyber-attacks by detecting and responding to anomalous behavior in real-time	DDoS attacks, malicious program injection, false data injection	Adaptive Hidden Markov Model (HMM) for modeling normal behavior and detecting anomalies	Data acquisition, adaptive HMM, honeypot-based response, OpenPLC testbed	Detection rate, false positive rate, response time	Dependence on HMM training data, multi-stage attacker handling

threats [117]. For that reason, a new type of defense was introduced, which involves cyber deception. By using deceptive elements like honeypots, decoy systems, and wrong data, cyber deception aims at disorienting attackers, slowing them fast, and earlier recognizing malicious activities. The implementation of cyber deception technology in smart grids, however, gives rise to difficulties, such as the assurance of component deceptiveness, maintenance of system performance, and seamless integration of deception strategies into the already existing infrastructures. In this section, the subject of cyber deception in smart grids is studied by considering methods, advantages, and limitations that the implementation brings.

In [118], the authors discussed the application of honeypot-based defense scheme to deal with the Distributed Denial of Service (DDoS) attacks aimed at the Advanced Metering Infrastructure (AMI) in the smart grids using a game-theoretic approach. The model suggested by the authors envisions the AMI as a tree like network consisting of smart meters, aggregators, and a central headend system. It is shown in Fig. 12 that the honeypots are to be embedded inside the firewalls of the WAN segment to make the traffic divert and to secure the headend and the back office servers. This strategy is framed formally as a Bayesian honeypot game, considering the presence of the users, the attackers, and the service providers, which include the strategies of the attackers, the effectiveness of the honeypots, and the anti-honeypot mechanisms that can be utilized. The model gives the specification of the payoff function and the resolution of the problem, finding multiple Bayesian Nash Equilibria (BNEs), which typically imply the optimization of the placement of honeypots so as to reduce energy consumption and improve detection rates. In the process of verification by experimental setups employing an OPNET-based AMI testbed, it has been established that the model surpasses the others in terms of higher detection rates (up to 85%) and more stable energy efficiency. The model operation deals with what is typically assumed as a rational and static attacker and simply presumes a deployment scenario.

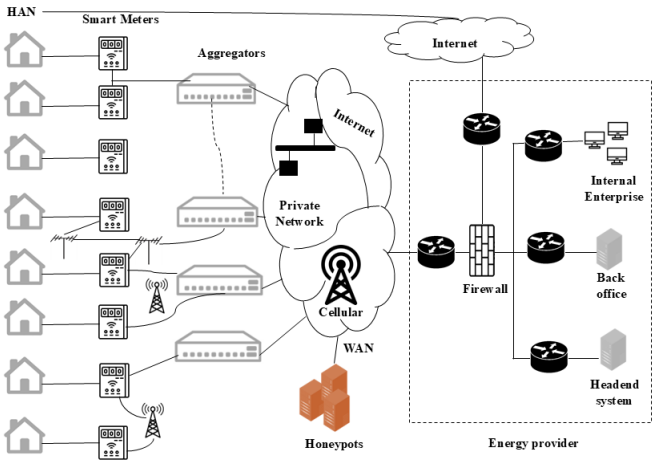

Fig. 12. The AMI network infrastructure with honeypot deployment in [118].

In [119], the authors thoroughly discussed and analyzed the honeypot and honeynet technologies that are utilized in the smart grid for security purposes. They have done an analysis of the factors such as the interaction levels (low versus high), purposes (production versus research), and deployment models (virtual versus physical) while evaluating the protocol supported by the industrial standards such as Modbus, IEC-104, and IEC-61850. The investigation has listed Conpot as the most versatile because of its modular design and multi-protocol capabilities as compared to twelve honey-x solutions. Even though Conpot is lacking in native support for advanced protocols like GOOSE/MMS, DNP3, it is the most versatile

choice. The EU SPEAR project has set up a smart home testbed, which implemented a practical example of Conpot. Conpot has been proven to be effective by applying modified iptables rules and JSON-based logging in the process, while also outlining its limitations in high-interaction fidelity, IPv6 adoption, and dynamic threat adaptation.

A two-phase investigation into enhancing threat intelligence collection for smart grid systems using honeypots was conducted. In the first study [120], low-interaction honeypots were implemented across five AWS regions (Singapore, US, Canada, Germany, Brazil) to simulate ICS protocols IEC 61850, IEC 60870-5-104, DNP3, Modbus TCP, and BACnet. They succeeded in remaining undetected by fingerprinting tools like Shodan's Honeyscore while collecting a total of 6GB of network traffic over six months. Their analysis shows indicators of probing behavior specific to the protocol, geographical correlations on scanning (with 0.97 cross-correlation between Germany and Brazil instances), and the presence of persistent threat actors such as 54 IPs that were detected monthly and executed SYN-flood attacks in a coordinated manner, all of which provided a valuable reference for IDS and firewall tuning. On the other hand, the study has some limitations, such as the fact that the honeypots are of low interaction, which leads to a lack of realistic behavior, and that post-compromise attacker activities are unable to be captured, which is a strong reason to think about the use of more complex, high-fidelity honeypots in other smart grid security studies. To address these limitations, their second study [121] demonstrated a realistic smart grid honeypot system by creating a full-scale infrastructure that includes SCADA HMIs, historians, IEDs, protocol gateways, and firewalls. It employs a decoupled architecture that is integrated with various tools such as Honeyd for anti-fingerprinting, Cowrie for SSH deception, SoftGrid for power-flow simulation, and Mininet for virtual IEDs. The system achieves practical protocol spoofing (e.g., IEC 61850 MMS) and cyber-physical consistency through these tools. Security testing has proven the system's capability to fingerprint devices strongly, log multi-phase attacks by using transparent proxies, and be resistant to probing by adversaries. Yet, difficulties persist in lateral movement modeling, automating dynamic deception, as well as adapting to the strategies of the attacker.

In [122], the authors proposed DecIED, a scalable deception framework for smart grid substations that is based on the idea of k-anonymity to conceal the identity of actual Intelligent Electronic Devices (IEDs) by introducing several indistinguishable decoy IEDs. Tailored for the IEC 61850-compatible environments, DecIED mimics the actions and communication patterns of the genuine devices by implementing the protocols, such as MMS, GOOSE, and SV. The outline, as shown in Fig. 13, involves a virtual IED program which consists of an IED server and logic, GOOSE/SV subscribers and publishers that are all integrated with Honeyd to spoof OS fingerprints and port behaviors. Each decoy IED is provided a unique IP/MAC address, and by following the same timing and content of the messages, it can replicate real devices. The system is designed to be resource-efficient, being able to commit over 200 deception instances on a single industrial PC; thus, scalability is achieved without compromising fidelity. Evaluations prove that deception was achieved without the capacity of real devices in passive and active reconnaissance. Indeed, DecIED out of the box maintained realistic control logic responses and nevertheless succeeded in the deception of scanning tools. Though issues prevail in the process of really exacting OS-level functionality and diverse logic types problems not addressed, yet DecIED is a solid ground for deception in today's substations and, it can be a stepping stone for further tactics like moving target defense.

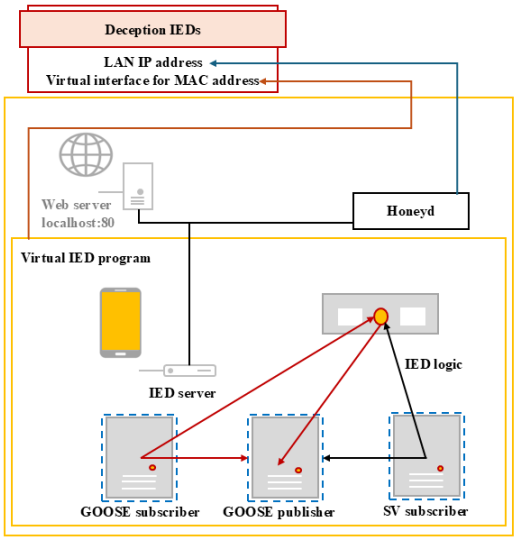

Fig. 13. The module architecture of DecIED in [122].

In [123], the authors proposed a defense strategy framework for smart grids with the help of the honeypot model. This is made with an incomplete information stochastic game that is used for describing the dynamic interactions between the attacker and the defender. The system consists of low-interaction and high inside honeypots in the networks like smart grid servers (web, FTP, OPC, and application servers), where it is isolated through firewall rules. A six-tuple game model that describes the defense mechanism is set up partly by attack/ defense actions, privilege escalation states, transition probabilities, and host-specific metrics (e.g., importance and risk level). The model of Nash equilibrium is obtained by solving it through Gambit software, and as a result, the framework comes up with state-optimal defense strategies that enable adaptation to the attacker through privileges or honeypots. The evaluations show that they achieved good deception rates and resource allocation, yet the model was derived assuming the topology is static and the state transitions are known perfectly, which in turn limits its scalability in a dynamic environment.

Table VI summarizes all the discussed works in smart grids, providing a comparative overview of their defense goals, targeted attack types, deception methods, architectural components, evaluation metrics, and identified limitations.

XI. Cyber Deception in Internet of Things

The Internet of Things (IoT) is one of the numerous interconnections that link up physical objects, devices such as sensors, actuators, gateways, and cloud-based analytics platforms, which will work together to monitor, control, and automate different domains like healthcare, smart homes, industrial systems, and smart cities in real time. Rendering a typical IoT

TABLE VI. SUMMARY OF CYBER DECEPTION TECHNIQUES IN SMART GRIDS

Reference	Defense Goal	Attack Type	Deception Method	Architecture Components	Evaluation Metrics	Uncovered Limitations
[118]	DDoS mitigation in AMI networks	Distributed Denial of Service (DDoS)	Honeypot-based game-theoretic decoy placement	Smart meters, data aggregators, central head-end, honeypots behind firewalls	Detection rate, energy efficiency, BNE solution space	Rational attackers, limited to small-scale testbeds
[119]	Secure smart grids by diverting attackers, collecting threat intelligence, and preserving forensic evidence	Broad coverage, including SCADA exploits, DDoS, and malware targeting ICS protocols (Modbus, IEC-104)	honeypots, honeynets	Emulated ICS devices (PLCs, RTUs), protocol servers (Modbus, SNMP), virtual/ physical honeypot nodes, tools (Conpot, GridLAB-D (power flow simulation), Mininet (SDN))	Detection Rate, realism scalability	Protocol gaps, resource intensity, dynamic threats
[120]	Collect threat intelligence on smart grid attackers	Scanning/probing, SYN-flood DoS, protocol specific exploits (IEC 60870-5-104, DNP3, Modbus)	Low-interaction honeypots emulating ICS protocols	AWS instances, TCP listeners, wireshark, ELK stack	Packet counts (TCP/ICMP), geographic correlation of attacks, source IP persistence	Lacks high-fidelity engagement, low-interaction design limits realism of emulated devices, limited protocol coverage
[121]	Collect threat intelligence, delay attacks, and deceive attackers into engaging with the honeypot	Attacks via VPN/SSH/RDP, malicious IEC 60870-5-104/IEC 61850 commands, lateral movement	High-fidelity honeypots with OS fingerprint spoofing and decoupled logging	Control center (SCADA HMI, Historian DB, VPN Server), substation gateway, Virtual IEDs, external (Jumpbox, transparent proxies)	Realism (Nmap/P0f fingerprint similarity to real devices, detection of virtualization), logging (captured attack phases)	Passive devices: IEDs (passive servers) easier to mimic than active devices (PLCs/ gateways)
[122]	Detect reconnaissance activities, prevent attackers from identifying real IEDs	Passive monitoring, active probing, lateral movement	*k*-anonymous smokescreen (decoy IEDs)	Honeyd (anti-fingerprinting), virtual IED module, Nginx web server, transparent proxies	Indistinguishability ratio, device similarity, scalability	Imperfect OS fingerprinting, requires access to real IED logic for full imitation
[123]	Optimize defense strategies against smart grid attacks	Multi-stage attacks with privilege escalation	Honeypot deployment guided by stochastic game model	Web/ FTP/ OPC/ application servers, honeypots, firewall rules, attack/ defense action sets	Game-theoretic Nash equilibrium, host significance, security risk level, state transition probabilities, fefense success rate	Convergence time, requires predefined vulnerability data

architecture model, one can think of it as a layered framework, for example, comprising the perception layer (sensors and actuators), the network layer (Wi-Fi, Zigbee, 5G), and the application layer (cloud or edge services). Be that as it may, IoT systems are attacked with major security problems such as device heterogeneity, resource limitations, root defaults, and lack of standardization. Such weaknesses permit IoT networks to come under attack from an array of cyber threats, such as device hijacking, eavesdropping, man-in-the-middle attacks, and DDoS amplification through botnet devices like Mirai. In such constrained and distributed environments, traditional defense mechanisms, like encryption and authentication, often seem to be inefficient [124]. Therefore, the cyber-deception approach has been chosen as the effective way. Now defenders deploy honeypots, fake sensors, deceptive APIs, or synthetic data flows to mislead the adversaries, gather threat intelligence, and delay attacks. Among the recent frameworks that have emerged are AIIPot and IoTFlowGenerator that exploit machine learning to synthesize realistic decoy behavior and traffic patterns; thus, they increase IoT deception fidelity. However, IoT is full of particular challenges in the deployment of effective solutions for example the need for major realism at scale, load overhead maintenance on the constrained devices, and the need for seamless integration of deception into the edge/cloud management platform. This section is focused on the deception techniques that are designed specifically for IoT environments, mainly dealing with component-level placement and adaptive threat engagement.

In [125], the authors introduced HoneyCloud, which is a scalable honeypot framework that is meant for analyzing fileless attacks on Linux-based IoT devices. The setup employs four hardware honeypots (like Raspberry Pi, BeagleBone) and 108 software honeypots distributed over eight public clouds. Compared to other hardware honeypots, they are superior in terms of high-fidelity interactions. However, the cost and maintenance overhead issues drove the authors to use QEMU-based software honeypots running OpenWrt, which were enhanced with realism-preserving techniques (like CPU masking, bus emulation). Over 12 months, HoneyCloud amassed 26 million attacks, including 1.5 million fileless attacks, which made it possible to create the first taxonomy of IoT fileless threats such as credential theft, configuration tampering, and SSH tunneling. The major findings illustrate that 65.7% of fileless attacks utilize default shell commands (like rm, kill, passwd) and demonstrate a trade-off: read-only filesystems are resistant to malware persistence, but they also inhibit shell-history auditing for fileless detection. The paper advances IoTCheck, a workflow for defense that entails the hardening of devices, though shortcomings are the inability to decrypt SSH tunnels and absence of support for newer IoT interfaces (like ZigBee). HoneyCloud broadens the perception of stealthy, non-malware threats, as these are the kinds of threats that can evade traditional defenses.

In [126], the authors analyzed empirically the IoT botnet

behavior by using three medium-interaction Cowrie honeypots programmed to emulate SSH/Telnet services and IoT file systems. The honeypots (which were scaled with Apache/Postfix services and ELK stack logging) observed for more than 40 days and recorded malware downloads during login sessions, which were later clustered by the Levenshtein edit distance on command sequences. According to this study, the majority of sessions that were related to malware were from Mirai variants at 97% with the loader patterns being two dominant ones (74.3% and 23.4% prevalence). The authors can confirm that these specific IP addresses operate within a small group of loaders distributing various strains of Mirai, which are often just slightly modified (e.g., by using UPX packing, filler commands, or compiler flags). Furthermore, the system registered some threats that were scarce (e.g., IRC botnets), although the limitations included Cowrie's static emulation (which was lacking high-interaction behaviors), being biased towards x86/64 architecture, and not being able to analyze non-file-downloading sessions.

In [127], the authors presented a scalable and hybrid architecture for IoT honeynet, which consists of three types of honeypots to enhance attack capture and deception fidelity: a medium-high interaction honeypot emulating the CVE-2017-17215 vulnerability, a high-interaction honeypot using real IoT firmware to handle unprocessable requests, and a multiport honeypot simulating SOAP services across exposed ports (e.g., 37215, 52869) with dynamic banner generation based on real device fingerprints. As shown in Fig. 14, the system is distributed over several physical nodes, each one being managed by a local master program and coordinated through a central control node. The architecture takes advantage of Docker both for fast deployment and isolation, being complemented with self-check mechanisms that ensure honeypot stability. Traffic is first routed to medium-interaction honeypots and deployed to high-interaction nodes if a deeper emulation is required. Deployed in the US and Canada, the honeynet remained stable for six months, capturing 332 unique attacker IPs and malware samples that went undetected by VirusTotal (e.g., "Ixa", "gyv"). Geographical analysis disclosed that scanning behaviors stemmed mainly from Japan and injections from the US. Although they are effective, the authors still mark the limitations in the automation issue and post-compromise behavior modeling and propose future work in these areas.

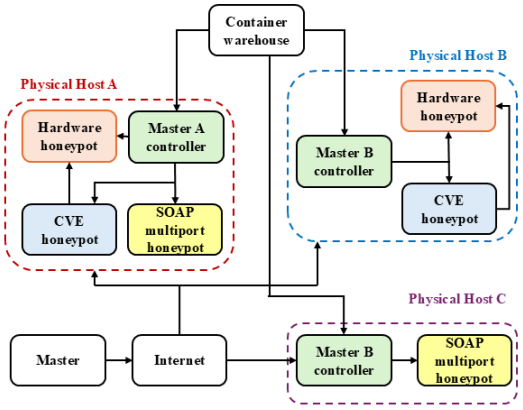

Fig. 14. The composite honeynet system architecture in [127].

In [69], the authors introduced a proactive defense framework, which is a software-defined networking (SDN) enabling technology specifically developed to combat Distributed Denial-of-Service (DDoS) attacks in IoT networks by using the integration of Moving Target Defense (MTD) and cyber deception techniques within a programmable architecture. The framework, as illustrated in Fig. 15, consists of three main parts: the first one is the monitoring agent who is responsible for the detection of attack behaviors, and the second one is the decision module which utilizes a multistage signaling game for modeling the attacker-defender interactions and predicting the adversarial strategies, and the last one is the deployment module that carries out such deception tactics such as random traffic delays, rerouting, and IP randomization. The system can deceive attackers through the use of a switching mechanism that dynamically changes the network properties and thereby alters the perception of the attacker. The manipulation includes operating under true services or honeypots depending on the behavior and confidence of the attacker. The signaling game analysis generates Perfect Bayesian Nash Equilibria (PBNE), with the Optimal Strategy Algorithm (OSA) on top of that, which is used to optimize defense actions that are under the condition of uncertainty. Performance evaluations on both Mininet and a real SDN testbed also show that the improved method, besides survival rates, has controlled CPU usage in the range of 65%, and reduced latency and packet loss when compared to baseline measures. Although it is a very efficient framework, the improvement should be the deployment of security mechanisms and assets that are adaptable and proactive to combat insider threats, which are usually tough to differentiate from legitimate users.

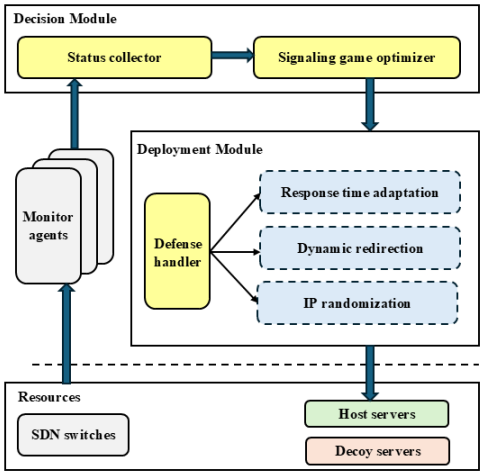

Fig. 15. The proposed framework in [69].

In [128], the authors introduced a cyber deception framework especially designed to fight epidemic botnet propagation in IoT networks using game-theoretic approach. They represented the interaction between attackers and defenders as a zero-sum, one-sided Partially Observable Stochastic Game (OS-POSG). In the proposed model, the defender places some honeypots strategically to monitor and disrupt botnet communication, and the attackers, in turn, know everything about the network structure except the actions of the defender, and their primary goal is to maximize the number of infections. The

defender's partial observability comes from being notified of the reactions of IoT users only (e.g., patching or password changes). Two deception strategies are examined, which are: a randomized deception strategy (RDS) and a k-smart deception strategy (k-SDS), where honeypots are positioned based on the infected devices. The attacker uses straightforward strategies (unicast, half, or broadcast) instead of Q-learning. Simulations on synthetic IoT topologies measure the maximum proportion of infected devices and Time to Extinction (TTE). The results show that k-SDS is significantly better than RDS, especially in high degree connectivity networks. The framework is basically an affirmation of the power of the dynamic deception that is applicable under partial observability. Further actions include the derivation of Nash Equilibrium strategies and the exploration of state-dependent deception techniques.

In [129], the authors presented HoneyComb, a cyber deception framework that has a proactive character and combines a /8 darknet network (16.7 million IPs) with mitigating IoT malware forensic artifacts at scalability. The main distinguishing feature of HoneyComb from the traditional honeypots, which passively wait for attacks, is that it actively detects malware-infected IoT devices by inspecting unsolicited darknet scans and sends then crafted TCP SYN-ACK packets to exploit stateless scanning flaws in IoT malware (e.g., Mirai's dst.IP == TCP.seq signature). The structure, as illustrated in Fig. 16, contains: 1) a darknet traffic analyzer (CAIDA data), 2) a cloud-based honeypot interface, and 3) a pool of virtualized ARM-based IoT devices (OpenWrt) emulating Telnet/SSH services. Once the connected infected devices are tricked, HoneyComb logs malware binaries (1,398 unique URLs), HexString dump commands, C&C communications, busybox commands, and credentials. Throughout a 48-hour evaluation period, HoneyComb reported a total of 1.4 million interactions, which were successfully carried out by 37,323 infected devices, attributing them to 40+ malware variants (e.g., Hajime, Mozi, ZHTRAP). Noteworthy statistics show a 22.07% response rate (37K/169K scanned IPs) and 90% of responses in 750ms or less. Some of the limitations are: 1) ARM-only virtualization (excluding MIPS/x86), 2) low SSH engagement (5.55% vs. Telnet's 25.88%), and 3) proxy/NAT evasion, and improvements will support a broader range of CPUs, simulate other services, and improve proxy penetration, ultimately achieving a real-time IoT malware knowledge graph for collaborative defense.

In [130], the authors introduced IoTFlowGenerator, which is a cyber deception framework based on deep learning that synthesizes realistic IoT traffic flows to increase honeypot believability against adversaries who monitor network activity. Being different from traditional IoT honeypots, which lack the real traffic patterns and can be easily detected, IoTFlowGenerator employs a fine-tuned SeqGAN and VQ-STAE (Vector Quantized-Sequence Transformer AutoEncoder) to produce multivariate, time-consistent packet metadata that imitates real user-device interactions. The system processes PCAP files (using Wireshark) to extract features such as packet length, direction, and timing, clusters packet-level signatures using DBScan, and encodes packets into discrete tokens. These tokens are adversarially trained into synthetic sequences, which are then reconstructed into traffic flows with noise injection for realism. Using 18 IoT devices for evaluation, IoTFlowGenerator not only outperforms DoppelGANger but also reduces the success rate of the adversarial ML models in the differentiation of synthetic traffic from real traffic. Particularly, this reduction is in synthetic-data-aware attack scenarios. Despite its high potential, the main weakness is the dependence on pre-collected traffic data and device-specific modeling, which might pose scalability challenges. The research highlights how sequence-based GANs can be used to increase the deception of encrypted IoT environments.

Table VII summarizes all the discussed works in internet of things, providing a comparative overview of their defense goals, targeted attack types, deception methods, architectural components, evaluation metrics, and identified limitations.

XII. Cyber Deception in Internet of Vehicles

The Internet of Vehicles (IoV) is a transforming new phase of intelligent transportation systems, which is now become possible due to the distinct features of the network that allows vehicles to communicate with each other (V2V), with infrastructure (V2I), and with broader networks (V2X) thus improving safety, efficiency and user experience. During this time, increased connectivity has also brought security problems, which are challenging to solve. Protection measures against the spectrum of attacks facing IoV systems, such as spoofing, eavesdropping, denial-of-service attacks, and unauthorized access, have compromised both data integrity and physical safety. Traditional security measures are not capable of tackling the challenges of these compound threats [131]. Furthermore, recent works [132] [133] reported the provision of intelligent sensors in IoV via reinforcement learning based techniques, where virtualized sensors are dynamically assigned to achieve the best possible service and resource optimization. Nevertheless, the main issue of security in IoV persists, and such provisioning schemes must be examined about their potential role in supporting defensive strategies such as cyber deception, which has emerged as a proactive defense strategy. Through the use of such deceptive elements as honeypots, decoy nodes, and faulty communication protocols, the defenders can mislead attackers, make them late, and procure important information on their strategies. We have the latest findings that bring sophisticated frameworks to the IoV setting. To illustrate, the DECEPTWIN framework leverages digital twins and blockchain to create a decoy environment that looks real, enhancing the detection and analysis of malicious activities. Similarly, Honey-Car framework is a great example of the use of game-theoretic models in the optimization of honeypot settings; thus, the attackers are involved well, and we can take actionable threat intelligence. Even if these ideas are great, the process of introducing cyber deception into IoV has its problems. It is vital to create decoys that are real, as well as sustain system performance and incorporate strategies of deceit in a smooth manner into the already established setup. This section considers the cyber deception play in IoV, looking into its methodologies, advantages, and the issues raised during the process of execution.

In [134], the authors introduced NHBADI, a newly introduced honeypot-based scheme for identifying and isolating Black Hole attacks in MANETs. The system utilizes AODV protocol modification so that it sends out RREQ packets to nonexistent nodes with the help of the destination IDs and TTL=1 Flag; thus, the system identifies the malicious nodes

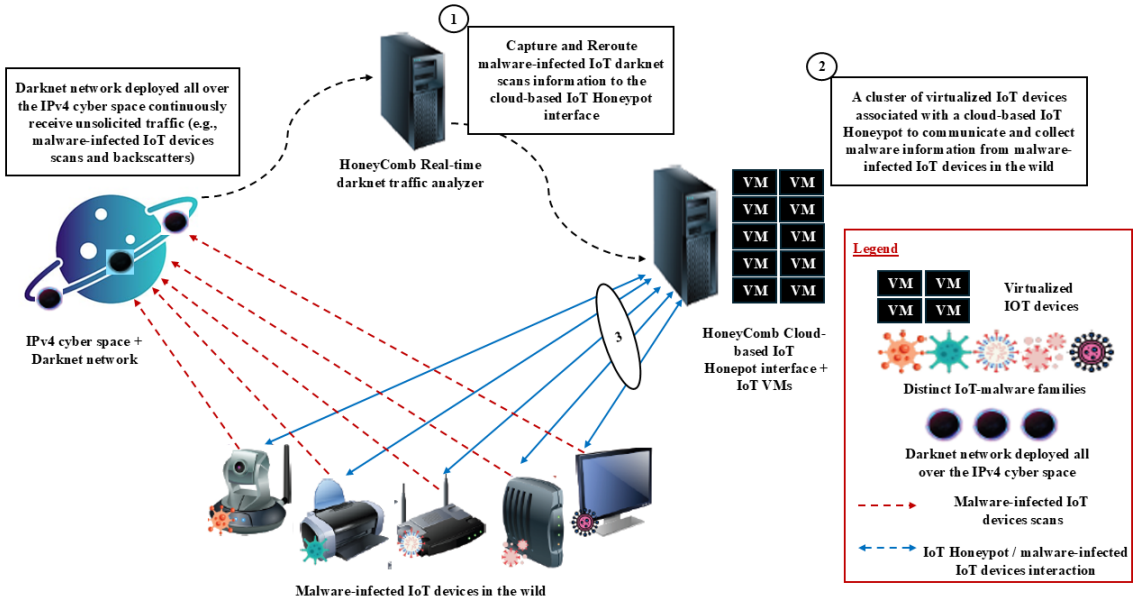

Fig. 16. The overall architecture of the proposed HoneyComb in [129].

TABLE VII. SUMMARY OF CYBER DECEPTION TECHNIQUES IN INTERNET OF THINGS

Reference	Defense Goal	Attack Type	Deception Method	Architecture Components	Evaluation Metrics	Uncovered Limitations
[125]	Understand and defend against fileless attacks on Linux-based IoT devices	Fileless attacks (e.g., SSH tunneling, system data damage, de-immunization)	Hardware and software honeypots (HoneyCloud) with high fidelity emulation	Hardware/ software honeypots, shell interceptor & inference terminal, access controller, reset manager	Number of suspicious connections, number of effective attacks, cost comparison	No ZigBee support, visibility limits for encrypted tunnels
[126]	Track and analyze variations in IoT botnets (e.g., Mirai variants)	Mirai-based botnets (SSH/Telnet), SSH brute-force attacks, IRC-based botnets, coin-mining malware	Cowrie-based medium interaction honeypots	Cowrie honeypot, apache webserver, postfix mailserver, ELK stack, filebeat	Edit distance clustering, IP/file hash mappings, ssdeep similarity, session success rate	Limited to x86/64 binaries (Cowrie's emulated architecture), ssdeep inaccuracies
[127]	Capture and analyze IoT-specific attacks (e.g., exploiting UPnP/ SOAP vulnerabilities)	SOAP/UPnP-based attacks, port scanning, CVE-2017-17215 exploitation	Medium-high interaction honeypot, high-interaction honeypot, multiport honeypot	Honeypot core, docker containers, ELK stack, control center, QEMU	Attack volume, geographic distribution, malware samples, functional validation	Limited protocol coverage, static emulation, dependency on Docker
[69]	Proactively mitigate DDoS attacks in IoT networks by dynamically optimizing defense strategies	DDoS, attacks launched via IoT botnets (e.g., Mirai)	MTD techniques (IP/port shuffling, dynamic redirection, response time adaptation), honeypot	Monitor agents, decision module, deployment module, SDN controller	Survival rate, time Overhead, performance metrics (throughput, packet loss rate, CPU utilization, Round-Trip Time, requests per second)	Limited for powerful attackers, limited insider threat handling
[128]	Mitigate botnet propagation in IoT networks	Epidemic botnet (e.g., Mirai) launching DDoS	Honeypot deployment with strategic placement (e.g., k-SDS, RDS)	Defender (honeypot allocator), attacker (botnet propagator), IoT devices (S/I/R states), network topology (low/high connectivity)	Botnet Time to Extinction (TTE), maximum proportion of infected devices, defender's utility (recovery vs. infection rate)	Limited to random/ simple attacker strategies, assumes static game strategies
[129]	Proactive collection of IoT malware forensic artifacts to analyze and mitigate threats	IoT botnet propagation (e.g., Mirai variants)	Darknet-powered SYN-ACK deception with backend honeypots	Darknet traffic analyzer, virtualized IoT devices, cloud-based honeypot interface	Response rate, artifacts collected, response time, geographical/ASN distribution of infections	Limited to ARM architecture, limited protocols, proxy evasion
[130]	Generate realistic synthetic IoT traffic flows to deceive attackers into mistaking honeypots for real devices	Passive network sniffing to identify IoT device types	GAN-based synthetic flow generation (SeqGAN, VQ-STAE)	Traffic analyzer, VQ-STAE autoencoder, SeqGAN, packet fuzzing	Adversarial classification accuracy, traffic fidelity, response variability	Device-specific modeling, dependence on packet-level signatures

when they reply to these decoys. As for the results of the simulation in NS-2, NHBADI provides a good performance with 89.03% of the packets being delivered after the intervention (67.73% of packets with vulnerable AODV) and a routing load which is normalized to just 0.62 (110.79 in AODV with 4 Black Holes), in addition to these, the protocol has cut the end-to-end delay by 23%. The three-layer architecture (detection, verification, and isolation) efficiently quarantines attackers but is built on the assumption that they will react to the specific requests. The strategy might thus be limited in its effectiveness to more advanced adversaries. Through this, the authors show that tactical deception can actually be utilized to improve the security of MANETs more effectively with less effort in spite of the initial resource cost.

In [135], the authors provided a detailed survey on Intrusion Detection Systems (IDS) for Vehicular Ad Hoc Networks (VANETs) and VANET Cloud, dealing with such issues as dynamic en-route node resources, high mobility, protocol differences, and security threats (e.g., Denial of Service (DoS)). The paper condenses into various categories requesting IDS by deployment (distributed, centralized, hybrid), detection techniques (signature-based, anomaly-based, watchdog), and validation strategies while reviewing a total of nearly 25+ different alternatives in a critical manner to achieve trade-offs on accuracy, latency, and overhead. The proactive Honeypot-Optimized IDS (HPIDS) is prominently and solely presented here, which uniquely incorporates bait-based deception along with lightweight detection in order to defend both known and zero-day threats. The article enlists some challenges left unresolved, including a high number of false positives, mobility resilience, and VANET Cloud-specific gaps. Meanwhile, it suggests the implementation of adaptive, low-latency frameworks, along with the privacy of personal data preserved.

In [136], the authors introduced HoneyCar, a game-theoretic framework dedicated to the optimal honeypot configurations in the IoV context, by modeling adversarial interactions as a repeated imperfect-information zero-sum game between a Defender (network administrator) and an Attacker. Using vulnerabilities data from CVE database and CVSS metrics, HoneyCar in its evaluation explores two scenarios: HCG-a, which ignores reconfiguration costs and considers maximal engagement of the attacker through Low-Interaction Honeypots (LIH), and HCG-b, which incorporates reconfiguration costs to optimize cyber threat intelligence using High-Interaction Honeypots (HIH). According to the results of a case study that belongs to LIH, it is displayed that this option can significantly cost-effectively make an attacker waste time, while HIH, along with the selective reconfiguration, can reach the maximum intelligence gain. The framework is designed to be in equilibrium regarding deception costs and security benefits, while improvements are directed towards adaptive strategies and real-time reconfiguration.

In [137], the authors designed DECEPTWIN, a proactive deception framework for the IoV, which is a combination of Digital Twins (DTs) and blockchain, to create realistic, interactive decoys for attackers while securely logging their tactics. The architecture of the framework, as illustrated in Fig. 17, consists of six layers: 1) internet/networking for baiting via decoys, 2) physical system modeling with High-Fidelity DTs, 3) deception environments using Low-Fidelity DTs (LDTs) embedded with deceptive elements to mimic compromised IoV networks, 4) monitoring/tracking of attacker actions across kill-chain stages (reconnaissance, weaponization, exploitation, command and control, exfiltration, and covering tracks), 5) analysis/reporting of threat intelligence, and 6) blockchain-backed storage for immutable logs. Fig. 18 illustrates that DECEPTWIN, after understanding the attacker's interaction, adapts LDTs that show attacker interactions, all through deceptive commands, decoy communications, and falsified logs, enhancing realism while gathering actionable threat data. While it promises proactive IoV security, the framework remains conceptual; its scalability and practical implementation limitations are emphasized as major challenges for future work.

Table VIII summarizes all the discussed works in internet of vehicles, providing a comparative overview of their defense goals, targeted attack types, deception methods, architectural components, evaluation metrics, and identified limitations.

XIII. Cyber Deception in Unmanned Aerial Vehicles

Unmanned Aerial Vehicles (UAVs) are widely used in various fields such as observation, transportation, and military. They include various devices inside like sensors, flight controllers, communication modules, and ground control stations (GCS). Hence, these can be the targets for hackers and cyber attacks, causing problems like GPS spoofing, jamming, or unauthorized access that result in compromised mission security and safety issues. Conventional protective measures are often insufficient to tackle these dynamic threats [138]. As a result, cyber deception has been developed as an effective solution. Counter-measures have been put in place such that by joining the honeypots with decoy nodes, the defenders can mislead the attackers, postpone their success, and collect useful data on their techniques. Recent developments have brought forth the use of clever deception schemes designed specifically for UAV environments. For example, the HoneyDrone framework is based on game-theoretic models to optimize the honeypot setups and to engage the attackers effectively with the goal of collecting actionable threat intelligence. Even with all the potential, integrating cyber deception in UAV systems is a tough process involving the identification of realist-looking decoys, performance continuity, and the difficulty of intertwining the deception tactics into pre-existing frameworks. This section discusses the utilization of cyber deception within UAVs, outlining its strategies, advantages, and the limitations experienced in its use.

In [139], the authors presented HoneyDrone, the first honeypot created specifically to simulate Unmanned Aerial Vehicles (UAVs) and effectively detect attacks targeting drone protocols. This medium-interaction honeypot also supports UAV-specific protocols such as Telnet, SSH, FTP, and the essential MAVLink standard, in addition to its low-cost deployment option on devices like Raspberry Pis. Its architecture comprises the following key features: 1) a Network Interface Emulator (NIE) which allows the simulation of wireless interfaces (Wi-Fi/Bluetooth/SiK); 2) a UAV Emulation module like a real drone with visualization of protocol behavior, filesystems, and telemetry; 3) MongoDB logging backend; and 4) Ardupilot SITL simulator for the realistic MAVLink flight data emulation. Two attack scenarios, the Telnet-based

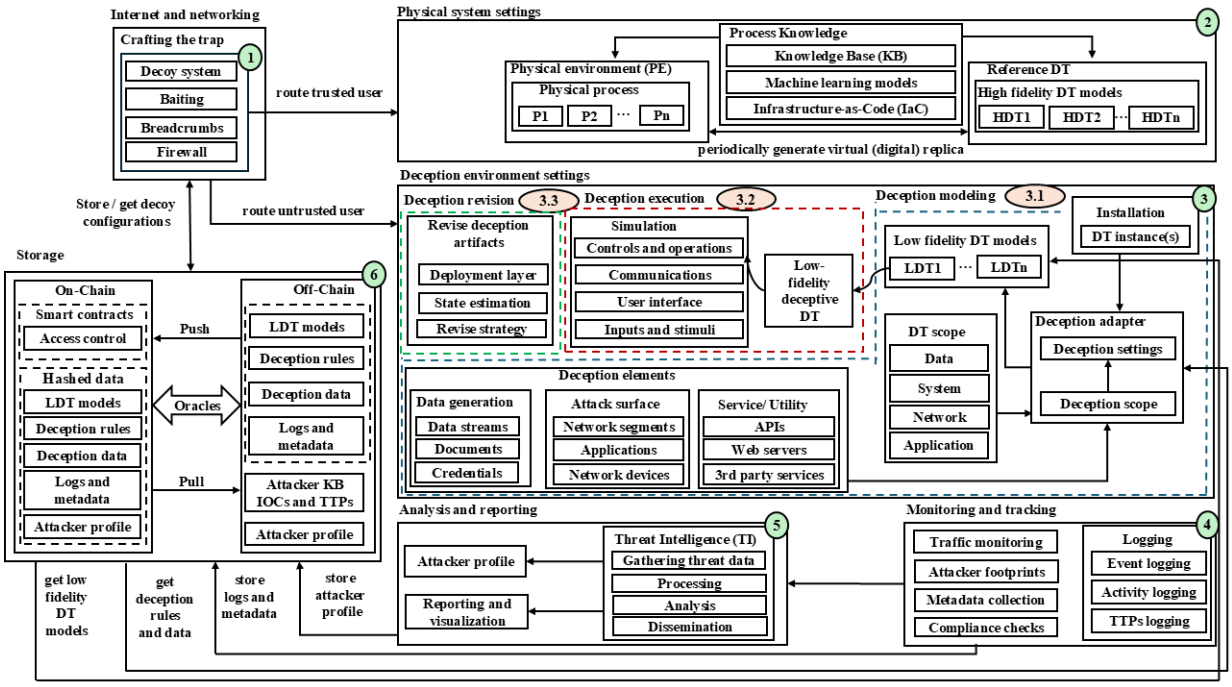

Fig. 17. The proposed architecture of DECEPTWIN in [137].

TABLE VIII. SUMMARY OF CYBER DECEPTION TECHNIQUES IN INTERNET OF VEHICLES

Reference	Defense Goal	Attack Type	Deception Method	Architecture Components	Evaluation Metrics	Uncovered Limitations
[134]	Detect and isolate Black Hole attacks in MANET/IoV	Black Hole attacks (forged RREP messages in AODV)	Honeypot-based spoofed RREQ packets	Malicious node detection layer, route lookup layer, isolation layer	Packet Delivery Fraction (PDF), Normalized Routing Load (NRL), End-to-End Delay (EED), Packet Drop Ratio (PDR)	Assumes passive attackers, limited to AODV protocol
[135]	Detect and mitigate malicious nodes and attacks in VANETs and VANET Cloud	DoS, DDoS, Hidden Vehicle, Tunnel, Wormhole, Blackhole, Location Spoofing, Privilege Escalation, alteration, sybil, social Attacks	Honeypot-optimized IDS (HPIDS)	Signature-based IDS, Honeypot nodes, rule generation engine, distributed detection	Detection rate, false positive rate, detection time, resource overhead	Limited VANET Cloud-specific solutions, challenges in optimal placement and density of honeypot nodes
[136]	Develop deception strategies in IoV to engage attackers, gather intelligence, and optimize honeypot use within budget limits	CVE-based exploitation	honeypots, honeypatches	Low-interaction and high-interaction honeypots, vulnerability database, game-theoretic engine	Exploitation time, re-configuration Cost, game utility	Assumes rational attackers, parameter heuristics
[137]	Proactive deception and attacker profiling in IoV	Remote hijacking, data breaches, unauthorized access (e.g., OTA injection, CAN bus attacks)	Digital Twin (DT)-based deception with blockchain integration	Internet/ Networking (decoys, baiting, breadcrumbs, firewalls), physical System, deception environment	Cost-effectiveness, adaptiveness to evolving threats, realism of deception, immutability of attacker logs/ TTPs (via blockchain)	No real-world testing, context-dependent applicability, scalability challenges with blockchain storage

filesystem manipulation and the MAVLink flightpath hijacking via QGroundControl were the basis for its evaluation. HoneyDrone once again came off well against the attackers through mirroring while recording all the interactions. Still, a possible drawback of being identified as a honeypot is the static signal characteristics, so the intention is to dynamically address this issue with the upcoming work on signal emulation and better scalability for concurrent connections.

In [140], the authors presented a scheme based on deep reinforcement learning (DRL), which serves as a deception strategy to successfully fight reactive jamming in IRS-assisted UAV communication systems. The system instead uses a UAV as an aerial base station in the air and trees the control element as the Intelligent Reflecting Surfaces (IRS) to connect the signal better through the controllable non-line-of-sight (NLOS) and direct (LOS) paths. The adversary in this case is a stealthy reactive jammer that selects the high-power transmissions

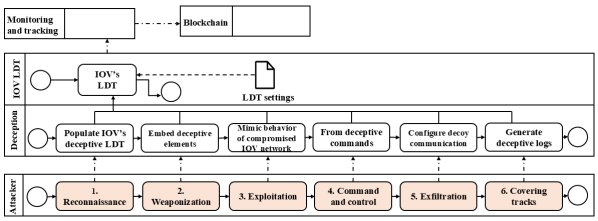

Fig. 18. The realization of DECEPTWIN during the remote access attack on a vehicle within IOV environment in [137].

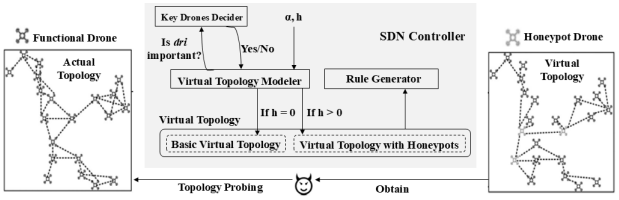

Fig. 19. The designed SDN-based topology deception scheme in [141].

after it has sensed the channel activity. To counter this, the framework includes a Deep Q-Network (DQN) that supports dynamic power allocation and IRS optimization (e.g., phase shifts, positioning), deceiving the jammer through a two-layer strategy: dummy packet transmission to profile the jammer's behavior and power-boosted decoy channels to misdirect attacks toward non-critical frequencies. The DQN agent learns an optimal policy via Q-learning, balancing energy efficiency and transmission rates. Simulations have shown the improvement in Total Received Power (TRP), the reduction of transmit power, and the enhancement of resilience against the baseline methods (e.g., Q-learning only or non-IRS systems). Apart from limitations, authors have made a single UAV/jammer, perfect environmental knowledge, and unexplored real-world deployment challenges (e.g., IRS mobility, multi-jammer scenarios).

In [141], the authors addressed an underexplored challenge of protecting key drones in UAV networks from targeted attacks. These drones, besides being tracers or service hosts, may be a means for some malicious elements to compromise the drone network. The authors begin with the attacker strategy analysis (which may include degree, betweenness, and closeness centrality), and the result is that even targeting a few key drones can cause significant performance degradation. To avert such a situation, they proposed an SDN-based topology deception scheme, which is made up of the following three parts: 1) a Key Drone Privider that decides by identifying critical drones with the help of a custom metric to quantify the connectivity loss; 2) a Virtual Topology Modeler that constructs the deceptive graphs by using the minimum spanning trees and the strategically placed honeypot drones; 3) a Rule Generator that makes recourse to the SDN controller by redirecting the probing attempts (e.g., via TTL-limited traceroute) to faked topologies. It is evident from the illustration in Fig. 19 that non-critical probes get a basic virtual topology, while the critical ones respond in a way that misleads the attackers, by guiding them to honeypots. The plan is executed in a Mininet-WiFi environment, controlled by a Ryu controller, and is notable for its high resilience as exhibited by statistics like Connectivity Loss (CL) and the success rate of attackers, which show even a small difference in honeypot deployment reduces attack impact. Nevertheless, the method presupposes the presence of all drones with OpenFlow support and runs into scalability problems when the network is larger.

In [142], the authors proposed a protection system for UAV networks that avails of honeypot-based deception mechanism and uses learning-based game theory to entice UAVs into sharing their Valid Defense Data (VDD) with the other UAVs. In the frame of this idea, every UAV carries low/ or medium-interaction honeypot modules that catch attack data, with a ground control station (GCS) designing VDD-reward contracts for UAVs to deal with issues like information asymmetry and UAVs' selfish behaviors. The contract is based on partial information asymmetry, and contract theory is utilized to ensure that the incentives are optimal, fair, and budget-feasible, with guaranteed theoretical feasibility and fairness for contracts. For scenarios where information is completely asymmetric, the framework uses a multi-agent Markov game model, and a two-tier Policy Hill-Climbing (PHC) reinforcement learning algorithm that is designed to optimize the strategies dynamically to the UAVs and GCS, enabling adaptive decision-making in the time-varying environments. As illustrated in Fig. 20, the system makes use of UAV private information like VDD volume and communication delays in contract menu, that is GCS is cutting the rewards based on the different UAV types the GCS has and is using Air-to-Air (A2A) and Air-to-Ground (A2G) links for collaborative defense. Simulation experiments have shown that the proposed method noticeably elevates the UAV utility, the rates of participation, and the defensive effectiveness compared to standard mechanisms. Nevertheless, the framework takes a GCS to be trusted yet it does not question the possibility of UAV collusive attacks. Improvements will focus on understanding the activities of hostile UAVs, combining active network conditions and seeing whether stealthy methods such as federated learning might also work and the implementation of a blockchain model on which the free of trust data exchange can take place to make the confidentiality and expansiveness even more secure.

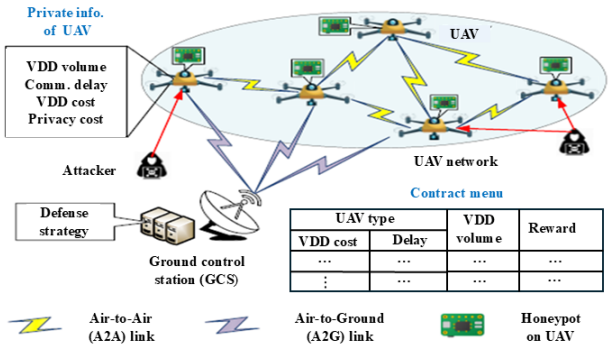

Fig. 20. The illustration of the incentive-driven honeypot game for collaborative defense in [142].

Table IX summarizes all the discussed works in unmanned aerial vehicles, providing a comparative overview of their defense goals, targeted attack types, deception methods, architectural components, evaluation metrics, and identified lim-

itations.

XIV. Open Issues and Key Insights

Despite significant progress in cyber deception research across diverse domains, several issues are still unresolved. The main reasons for this are the rising complexity of infrastructures, the changing patterns of attacker behavior, and the poor implementation of deception frameworks. This section reviews the main open questions accompanied by the most representative findings from the surveyed literature.

A. Incomplete or Simplistic Attacker Modeling

Deception strategies often have overly simplified attacker models, which usually include the assumptions of rational, single-agent, or static behaviors. Game-theoretic approaches in cloud settings, as in [91], are a good example as they usually take into account cost-sensitive attackers but fail to include adaptive adversaries. Advanced modeling is exemplified in [102] and [100], which discuss dynamic and context-aware behaviors in wireless networks. Moreover, adaptive attacker responses are included in [140], which augment the realism. However, there are very few systems that can mirror cognitive biases, collaborative threats, or deception-aware APTs. Cognitive, probabilistic, and multi-agent models should be used to represent the decision of the attacker under advanced uncertainty.

B. Limited Coverage of Post-compromise, Multi-Stage Attacks

Deception strategies mainly find their place in the primary attack phases, namely, scanning, probing, and initial access. Many of the attackers, however, tend to be open to the traps and they execute lateral movement or data exfiltration on their own without even being noticed. The deceiving attack approach is mostly implemented in the beginning phase in ICS and smart grids (for example, [114] and [118]). The same is true for IoT (for example, [129] and [130]), where early traffic analysis is the main focus. A limited number of systems include deception in the runtime workflows or administrative interface. The proposed solutions should cope with final phases of the attack kill chain using decoys designed for the post-compromise phases like privilege escalation and persistence.

C. Limited Adaptivity and Real-time Reconfiguration

The current systems are mostly characterized by static honeypots and inflexible deception logic. There are only a few exceptions, such as [116] and [140], which adapt their deception policies dynamically based on the feedback. The cloud environment has [96] its virtual decoy redeployment solution. Nonetheless, the majority of the systems do not have real-time environmental awareness and self-reconfiguration. It is the application of AI, mainly through reinforcement learning, behavior modeling, and predictive analytics, that is the key to flexible adaptation of deception strategies.

D. Scalability and Fidelity in Resource-constrained Environments

Trade-offs between scalability and deception realism are often mandated by resource constraints. One example is [105] where signaling games are employed for a reduction in energy consumption, whereas [139] and [136] get lightweight deception appropriate for mobile systems. In the cloud environment, [97] and [122] show dynamic orchestration of decoy under resource limitations. Combining low- and high-interaction techniques in a honeypot and dynamically changing to fit the perceived threat level are very good but come with the challenge of creating formal optimization frameworks.

E. Lack of Standardized Metrics and Quantification Frameworks

Current assessment methods vary across different fields. Metrics like engagement time, attacker delay, and resource cost are usually used separately. Some works, such as [122] in smart grids, introduce innovative privacy-oriented metrics (e.g., k-anonymity), while others like [114] and [123] apply reward-based metrics from game theory. Similarly, measuring deception success, attacker confusion, or resilience improvements is not achievable as long as there is no universally adaptable and context-aware framework. The immediate requirement is to normalize testing processes and set up reproducible benchmarks.

F. Limited Testbeds and Validation Platforms

Validation of the majority of deception systems is accomplished through simulation, which leads to the diminished credibility for their real-world deployment. Just like [107] [142] and [137], they put forward interesting ideas but do not demonstrate a physical testbed. Moreover, even in safety-critical areas such as smart grids that have no choice but to depend on simulated environments, there are risks of deployment. Modular scalable testbeds emulating multi-layer architecture and realistic user and attacker behavior are prerequisites for credible evaluation and operational trust.

G. Security and Privacy Trade-Offs in Collaborative Deception

Collaboration through deception, particularly in distributed systems (such as UAV swarms, IoV), brings forth coordination, trust, and privacy challenges. In the case of UAVs, [142] looks at role-switching and shared intelligence among drones. In IoV, [137] uses digital twins for proactive deception. Nevertheless, the majority of the systems don't address claims like adversarial control injection, secure communication, and privacy-preserving coordination. Countermeasures like federated learning, blockchain-based consensus, and zero-trust coordination models are still under-exploited in cyber deception.

H. Integration Gaps with Existing Defense Ecosystems

Deception platforms are frequently set up as isolated systems, which means they do not communicate with SIEM, IDS/IPS, and cyber threat intelligence (CTI) systems. Apart from the tools given, such as [114] or [129] that have shown effectiveness in the engagement of the attacker, they usually miss the mechanisms to put the ideas acquired through this process back into the general defense workflow systematically. The cloud-based models, such as [95], that suggest improved integration potential are left behind due to the unavailability of standardized APIs, logging formats, and data models that are

TABLE IX. SUMMARY OF CYBER DECEPTION TECHNIQUES IN UNMANNED AERIAL VEHICLES

Reference	Defense Goal	Attack Type	Deception Method	Architecture Components	Evaluation Metrics	Uncovered Limitations
[139]	Detect UAV attacks, gather threat intelligence, divert attackers from real drones	Wi-Fi hijacking, Telnet/SSH/FTP exploits, MAVLink protocol abuse	Medium-interaction honeypot	Network Interface Emulator (NIE), UAV emulation, File System Emulator, configuration file	Performance, effectiveness, realism	Static signal behavior, limited to emulated protocols
[140]	Mitigate jamming attacks in IRS-assisted UAV communications	Reactive jamming (intelligent, stealthy)	dummy packets, decoy channels	IRS with passive reflecting elements, UAV as aerial BS, DRL-driven power allocation, Q-learning and DQN for dynamic resource allocation	Rate of communication under jamming, transmit power efficiency, training time of DRL methods	Increased resource usage, assumes jammers attack highest power channels
[141]	Protect key drones in UAV networks from targeted attacks	Topology probing-based targeted attacks	Virtual topology generation (spanning trees) to hide real key drones, Honeypot drones	SDN controller, Key Drone Decider, Virtual Topology Modeler, Rule Generator, OpenFlow-enabled drones, Honeypot drones	Connectivity loss, normalized communication connectivity decrement, importance degree from attacker's view, optimal transmit power and resource usage	Assumes OpenFlow-enabled drones, scalability issues
[142]	Protect UAV networks by incentivizing collaborative defense via honeypot data sharing	Cyber threats (e.g., DoS, hijacking, data theft), free-riding attacks	Contract theory + multi-agent learning for honeypot sharing	Low/ medium-interaction honeypots, Ground Control Station (GCS), UAVs	Connectivity loss, social surplus, defense effectiveness, UAV/GCS utilities, Attack detection rate, CPU utilization of honeypots	Scalability challenges

valid for interoperability. The operational impact of deception systems will be maximized only when they are designed with interoperability as a guiding principle. The introduction of a common and standardized framework, like STIX in the CTI, makes it possible to create actionable deception-derived feedback that could be accessed and used by various other security solutions.

I. Emerging Technologies as Catalysts for Next-Gen Deception

Digital twins, large language models (LLMs), and multi-agent AI have a vast potential for the development of cyber deception. In the IoT sector, dynamic flow redirection has been put forward by [69] as the way to mislead the intruders. Digital twins have been used in the process of anticipatory deception in [137], which provided an opportunity to the users for simulating and predicting the attacker's behavior. Likewise, in UAV networks [140] and smart grids [122], AI-driven and privacy-preserving deception architectures have also been the focus of research. Yet, these things remain primarily theoretical or applicable to particular areas only. To be queried within a full range, these key players should be utilized in a cross-domain, full-stack deception model. As an illustration, digital twins can be used to replicate real environments, thus allowing the defenders to either emulate the vulnerable system in the physical absence of assets or simulate the real-world scenarios with the data of actual threats. LLMs can be incorporated into generating deceptive responses, analyzing adversarial traces, coordinating multi-agent deception strategies, and determining adaptive actions to disrupt, tolerate, or mislead attacks. Joining these two technologies together can greatly modify the flexibility, realism, and intelligence of the deception systems in various functional situations.

J. Challenges in Realism and Fingerprint Resistance

Over time, as the decoys have become more sophisticated, adversaries have also advanced when it comes to the detection of such decoys by means of timing anomalies, low-level operating system artifacts, or service inconsistencies. Researches like [110] and [99] show that the mid-interaction honeypots can be identified by their fingerprints. The presence of behavioral mimicry, dynamic response crafting, and protocol emulation with the help of artificial intelligence makes it possible to stay one step ahead of the attacker reconnaissance. In most systems, these capabilities are still not utilized adequately.

XV. CONCLUSION

This survey sorts the cyber deception techniques in a comparative manner for different domains like CE, WN, CPS, ICS, SG, IOT, IOV, and UAV. The study rigorously studied and communicated the architectural structures, attack types, deception techniques, evaluation metrics, and limitations present in each domain. The findings, which are collected and represented in the unified tables, pave the way for an easy comparison. Besides, the survey deals with the most frequently met challenges and the research directions that remain open, which gives practical insights and support in the design of adaptive and effective deception-based defenses tailored to different operational environments. In our future work, we intend to overcome some of the limitations discussed in the previous section, and our focus will be on utilizing Large Language Models (LLMs) for cyber deception. We aim to examine the efficacy of the LLMs in the generation of deceptive responses, the interpretation of adversarial behavior, and the decision-making of adaptive strategies for disruption, misinformation, or acceptance of cyber threats.

ACKNOWLEDGMENT

This project is carried out under the MOBIDOC scheme, funded by the Ministry of Higher Education and Scientific Research through the PromEssE project and managed by the ANPR.

Gender and Age Estimation from Facial Images Based on Multi-Task and Curriculum Learning

Toma Brezovan, Claudiu Ionuț Popîrlan
University of Craiova, Romania

***Abstract*—This study presents a multi-task deep learning approach for predicting age and gender attributes from facial images, with the aim of obtaining a robust dual classifier. The proposed system uses the pre-trained EfficientNet-B4 model as the feature extractor of the main model and incorporates a two-branch architecture, where the output of the gender classification branch informs the age prediction branch. This means a conditional feature learning with an explicit injection mechanism, by injecting gender information into the age field of the dual-task model, which is one of the novelties of our proposal. A curriculum learning strategy is applied during training to progressively improve the model's performance using various datasets, such as UTKFace, MORPH-II, and Adience. The proposed multi-phase curriculum learning strategy, which uses both multi-task learning and multi-dataset training, is another novelty of our proposal. Experimental results show that the model achieves high accuracy in both age and gender classification tasks while maintaining low inference latency. Furthermore, the experiments highlighted that the classification accuracy values of the proposed method, both for gender and age, as well as in all datasets used, are close to the best state-of-the-art results, which validates the robustness of the proposed classifier.**

***Keywords*—Age estimation; gender classification; multi-task learning; curriculum learning**

I. Introduction

Human face analysis is an important area of research in computer vision, for performing and optimizing various facial perception tasks, such as face recognition, age estimation, gender determination, etc. In addition, biometric identification has been increasingly used recently in various fields, such as automatic detection of physical presence and confirmation of the identity of individuals through image analysis, and gender and age are two of the main biometric attributes [1].

Predicting age and gender from facial images is still an active task in the field of computer vision, having a wide range of applications in areas such as human-computer interaction, image retrieval, security, surveillance and web content filtering [2].

Recent advances in deep learning have significantly improved the performance of age and gender recognition systems, particularly through convolutional neural networks (CNNs) and multi-task learning (MTL) frameworks [3]. MTL approaches are especially attractive in this domain, as age and gender share underlying visual features that can be exploited to improve generalization.

However, existing models usually use either a specialized dataset of facial images using age and gender attributes for training, or other models trained on very large facial datasets (e.g., FaceNet [4], VGGFace [5], or ImageNet [6]), and then, through transfer learning, the training is refined also on a specialized dataset of facial images using age and gender attributes. In both cases, the training and then estimation process is limited to a not very large number of facial images, which depends on the size and diversity of the specific dataset used for training (or fine tuning).

One goal of our approach is to create a dual classifier for the age and gender of people in facial images, which is robust and can estimate the two attributes in various images. For this, we will use several public datasets for training, which contain images in various conditions, which will allow for more accurate estimation of both age and gender.

The tasks related to the prediction of age and gender of individuals are not completely independent, because there are studies that have demonstrated that incorporating gender information can improve the accuracy of age estimation from facial images [7]. Another goal of our approach is to exploit the dependency between the two tasks, which allows for increased accuracy for both age and gender estimation.

Although there are proposals for the correlated treatment of gender and age in facial images, these refer either to different ways of training the models or to modifying the structure of the models, but not to the direct dependence between the gender and age tasks. We use a simpler variant, regarding the modification of the model structure, resulting in a conditional or hierarchical model with dual tasks, as presented in Fig. 1.

In this study, we propose an efficient multitask deep learning model to predict age and gender in facial images. Although there are various proposals for this problem, the presented system incorporates efficient methods from the field of multi-task learning, which allow increasing both the robustness of the system and the accuracy of the estimates.

The model employs *EfficientNet-B4* [8] as a pre-trained backbone, which is known for its balance between accuracy and computational cost. EfficientNet introduces a new strategy, known as Composite Scaling. It allows balancing and adjusting the depth, width, and resolution of the network, thus allowing the model to scale to arbitrary sizes. In addition, EfficientNet maintains a balance between performance and efficiency. EfficientNet (B0-B7) networks have been widely used recently in various fields of computer vision, especially in image classification [9]. They have also been used for age estimation in facial images [10].

A two-branch architecture is constructed, in which the age and gender branches are not totally independent. According to [7], gender classification output is fed into the age estimation branch to improve age prediction performance through feature sharing.

In the case of multi-task classification systems, there can be problems with the loss function, because the tasks usually differ in scale, complexity, or quality of the labels. Instead of using the weighted linear sum of losses for each individual task, we use a learnable task uncertainty by modeling homoscedastic uncertainty, as in [11].

Even if an efficient pre-trained model is used as feature extractor, the robustness of a dual-task model for simultaneous gender and age recognition depends largely on the dataset on which the dual model is trained. To increase the robustness of such a dual classifier, we used several established datasets for training and adapted the curriculum learning strategy [12].

Our work builds on these foundations, which are also the main contributions:

- Using the pre-trained *EfficientNet-B4* model as a backbone, we propose a dual-task classifier for gender and age in facial images, where the output of the gender branch is used in the input of the age branch, so that the gender prediction output is used to improve age estimation.
    - Unlike previous studies, such as [7], [13]–[15], where multiple subnetworks for the two tasks are created (and possibly trained separately) and interconnected, we propose a conditional feature learning with explicit injection mechanism, by injecting gender information into the age head of the dual-task model.
- Due to inconsistent age distributions and labeling schemes in the training datasets, we use a unified age classification strategy for all datasets, as well as a unified data loader for the datasets, which can be later used in the curriculum learning strategy. In addition to the unified age classification strategy, we propose an adaptive algorithm that learns age categories based on the age distribution in the datasets.
    - As far as we know, there are no proposals that automatically generate age groups based on information in datasets.
- We use a learnable task uncertainty so that the contribution of the task losses in the total loss is adaptive during training and the accuracy of the estimates is increased. This method is based on the method proposed in [11].
- We implement a multi-phase curriculum learning strategy for the training operation, based on several elements, including: a) age range coverage, b) age label granularity, and c) image quality. This strategy allows for increased prediction accuracy, as well as eliminating the catastrophic forgetting effect due to the sequential use of samples from the datasets.
    - Although it is not an adaptive method like in [16], unlike the previous methods [17], [18], the proposed method refers to both multi-task learning and multi-dataset training. To our knowledge, there have been no other proposals regarding multi-task learning and multi-dataset training

The remainder of the study is organized as follows: Section II provides a review of the related work. The proposed method is described in Section III which also includes the dual-task classifier and the curriculum learning strategy. The experimental results are presented in Section IV. The study is summarized, with some future directions, in Section V.

II. Related Work

Deep learning methods for age and gender recognition mainly use convolutional neural networks (CNN) trained from scratch or with minimal learning transfer. These models focused on learning hierarchical features directly from facial images. Levi and Hassner [19] introduced a CNN architecture for age and gender classification, demonstrating the effectiveness of CNNs in capturing age- and gender-relevant facial features. The paper [20] proposes an age and gender prediction method from face images using convolutional neural network (CNN). In this paper [21] authors utilized Haar Cascades for face detection and a CNN for classification, achieving real-time age and gender prediction.

A. Architectural Models

Recent advancements have incorporated sophisticated architectures, transfer learning, and attention mechanisms to enhance accuracy and robustness in age and gender recognition. The research [22] uses pre-trained models such as VGG19 and VGGFace, fine-tuned for age and gender prediction, using the MORPH2 dataset. The authors [23] compared custom CNN architectures with pre-trained models such as VGG16, ResNet50, and SE-ResNet50. The study found that transfer learning significantly improved performance over training from scratch. The paper [24] introduces an ensemble of attentional and residual CNNs, leveraging attention mechanisms to focus on informative facial regions, thereby enhancing prediction accuracy.

B. Multi-Task Learning

Multi-Task Learning (MTL), or *multi-attribute learning* (MAL) aims to improve the generalization of models by leveraging domain-specific information contained in the training signals of related tasks. In computer vision, this often involves simultaneously learning tasks such as object detection, semantic segmentation, and depth estimation.

There are two main categories for the MTL, related to the structure of these neural networks [25]:

1) Hard parameter sharing: where the initial layers of the network are shared among all tasks, while the task-specific layers are kept separate.

2) Soft parameter sharing: where each task has its own model with its own parameters, but regularization techniques are used to keep the parameters of different models similar. This approach can lead to high inference cost [26].

MTL networks were used for face attribute estimation [7], as well for other tasks, such as human pose estimation [27], or face alignment [28].

In MTLs, in addition to network structure, recent advances also relate to loss weighting. Several loss weighting methods are proposed to automatically combine the losses, such as: *task prioritization* [29], which weights task losses according to more difficult tasks during training, *uncertainty weighting* [11], which models loss weights as task-dependent but data-agnostic uncertainty, or *gradient normalization* [30], which learns loss weights to enforce that the gradient norms for each task are close

C. Curriculum Learning

Curriculum learning (CL) was introduced by Bengio et al. [31] and involves training models by gradually increasing the difficulty of training data. This method contrasts with traditional training, in which data is presented in random order. Easy-to-difficult ordering can also be used in multi-task learning, by determining a learning order of tasks to maximize the final result [17], [18]. There are several categories of curriculum learning [12], such as: *Teacher-student CL* [32], or *Implicit CL* [33]. In [34], a curriculum learning approach for classification tasks on small to medium-sized datasets is proposed, based on the order of samples.

III. Proposed Method

A. Dual-Task Architecture

Since hard parameter sharing allows multiple tasks to share low-level parameters [26], this structure has advantages such as lower storage costs. For this reason, the proposed deep multi-task network is based on *hard parameter sharing*, as illustrated in Fig. 1, where X represents the input tensor (images), while X_1 and X_2 represent the outputs of the model (predicted age and predicted gender, respectively). In addition, for a faster training and improved accuracy, the proposed dual-task classifier uses *EfficientNet-B4* as a shared backbone for feature extraction. The shared layer before the branches forces the model to compress shared task-based information into a lower-dimensional vector, encouraging learning of shared features and acting as an inductive bias.

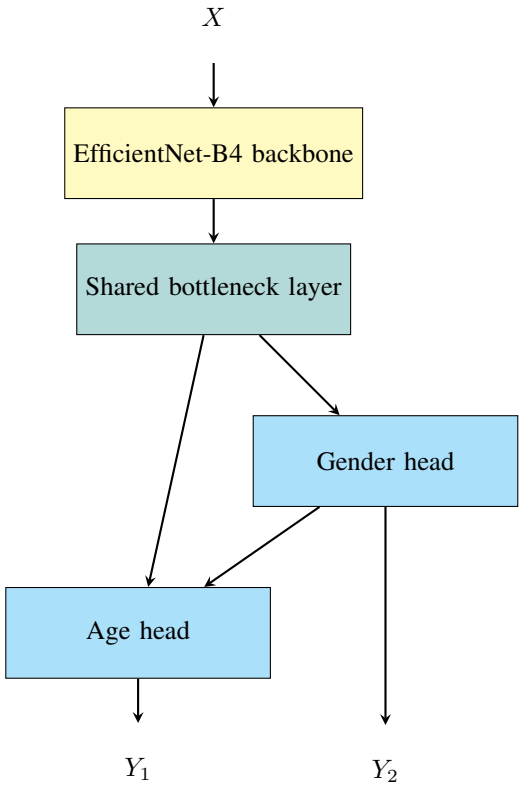

Fig. 1. Architecture of the dual-task classifier

Several studies across biomedical research and computer vision confirm that aging patterns differ significantly between men and women, which supports the integration of gender cues in age estimation models. Biological factors such as hormonal differences lead to gender-specific aging trajectories in skin elasticity, bone structure, and facial fat distribution [35]. In computer vision, deep learning-based age estimation models consistently achieve higher accuracy when gender information is included as input, indicating that aging cues vary in distribution across genders [36].

There are not many proposals for the correlated treatment of gender and age in facial images. In the study [13], a fusion layer between gender-based output and age-based output is proposed, which generates age prediction. In the study [14] a cascaded framework containing a parent network and multiple subnetworks is presented. For example, when using a gender classifier trained on gender information, the other two subnetworks are trained on male and female samples, respectively. In the study [15], age grouping for male and female faces is processed separately: one model is trained to group male faces into different age groups, and another model is learned to group female faces. In the study [36], a hybrid deep learning architecture is proposed for facial gender and age classification: a deep random forest is used to estimate facial gender, and then age is recognized under the conditional probability of gender alignment. In the study [7], it is proposed four two-level CNN models: the first level for gender classification, which contains one CNN, while the second level contains three CNNs, one for each age category (children, middle-aged people, adults, and the elderly).

In this proposal, a different approach has been chosen. We designed a *conditional* or *hierarchical model* with dual task, in which the gender prediction comes first, and the age classifier benefits from this prediction, as presented in Fig. 1.

More exactly, to inject gender information into the age head, we use a *hard conditioning* (post-prediction) method:

- Run gender head first.
- Concatenate predicted gender with shared features.
- Feed them into the age head.

The structure of the proposed architecture, as shown in Fig. 1, has several advantages:

- The model can learn gender-specific age patterns.
- It also encourages the shared feature extractor to learn disentangled but informative representations.

- Conditioning can reduce the variance in age prediction.

B. Training Phase

In the training process, we use two main improvements to increase the accuracy of the estimation operations:

- An adaptive method to determine task-specific weights when determining the total loss.
- A multi-dataset curriculum strategy by designing a training schedule, which is similar to domain adaptation and multi-source learning.

In multi-task learning models, despite the advantages offered by the hard parameter sharing structure, it presents a major drawback: for a global optimization, all task-specific loss objectives must be combined, requiring task-specific weights. Selecting these weights can be difficult and expensive [25]. Even though the simplest way is to sum partial task losses, this often leads to unbalanced training.

For this reason, in this proposal we will use an adaptive method to determine task-specific weights, based on the *Multi-Task Uncertainty Weighting* method [11]. This *first improvement* of the training process allows automatic learning of task weighting by modeling homoscedastic uncertainty.

The *second improvement* in the training process is related to how a deep learning model learns from its input data. Bengio [31] introduced the term *curriculum learning*, which is an optimization strategy for handling a minimization problem. When training a deep neural network, instead of using random samples, it is better to organize these samples so that the less complex examples are presented first.

Since a curriculum is implemented by ordering training data according to difficulty, we will need to generalize this to be able to handle training with multiple datasets, taking into account the following information:

- The quality of the images in the datasets,
- Age range coverage,
- Label granularity.

1) Dynamic learning of task weighting: Multi-task learning involves optimizing a model based on multiple objectives (determining a total loss based on the partial task losses) [see Eq. (1)]:

$$\mathcal{L} = \sum_i w_i \mathcal{L}_i, \tag{1}$$

where, task weights w_i are difficult to estimate.

In the proposal [11], the estimation problem of these weights is viewed as an aleatoric uncertainty, which is task-dependent (called *homoscedastic uncertainty*). In this case, the total loss is derived from maximum likelihood estimation, and for classification tasks, the minimisation objective (loss) has the following form (only two taks are considered here):

$$\mathcal{L} = \frac{1}{\sigma_1^2}\mathcal{L}_1 + \log(\sigma_1) + \frac{1}{\sigma_2^2}\mathcal{L}_2 + \log(\sigma_2), \tag{2}$$

where, σ_1 and σ_2 are observation noise scalars, representing the noise parameters for the two tasks. Using classical notation, σ_i represents the standard deviation, while σ_i^2 represents the variance.

Remark. There are some small differences from the relation in the work [11], because we are performing classification tasks, not regression tasks:

- $\mathcal{L}_1$ and $\mathcal{L}_2$ are cross-entropy losses, not Euclidean losses.
- Coefficients $\frac{1}{2\sigma_i^2}$ were replaced by $\frac{1}{\sigma_i^2}$.

As in [11], in practice the dual-task model should be trained to predict the log variance,

$$s = \log(\sigma^2), \tag{3}$$

Because it is more numerically stable.

To achieve this, two trainable scalar parameters, p_1 and p_2, will be defined as Eq. (4),

$$p_i = \log(\sigma_i^2),\ i \in \{1, 2\}, \tag{4}$$

which represents the log of the variance (uncertainty) of each task. These trainable parameters:

- Will be initialized to 0 and updated in the training phase through gradient descent, just like any other weight.
- They will be used as uncertainties associated with the tasks when calculating the total loss:

$$\mathcal{L} = \mathrm{e}^{-p_1}\mathcal{L}_1 + p_1 + \mathrm{e}^{-p_2}\mathcal{L}_2 + p_2 \tag{5}$$

Remark. Using Eq. (3), the Eq. (2) and Eq. (5) are the same.

2) Multi-dataset curriculum strategy: Typically, deep classification networks are trained using a specific dataset, which is relevant to the respective domain, and the method used for training is to randomly select samples at each iteration step.

This proposal attempts to extend classical training methods in the following way:

- Instead of using a single dataset to train the dual-task classifier, we use multiple datasets that are common in the field of estimating the age and gender of people in images (UTKFace, MORPH-II, and Adience)
- We use a learning strategy based on the *curriculum learning* method [31], which involves training models by gradually increasing the difficulty of the training data.

When a neural network is trained sequentially on multiple datasets, a phenomenon called *catastrophic forgetting* can

occur, in which the neural network, after being trained on one dataset and reaching a certain level of performance, loses that knowledge when trained on a new dataset. There are several proposals to reduce forgetting in curriculum learning, such as:

- Regularization-based methods [37], where methods are applied that penalize changes in important weights for previously learned data
- Progressive training with overlap [38], which involves gradually increasing the proportion of more difficult samples, while the model continues to train on the previous ones

We will define a multi-phase curriculum training strategy that allows training the dual-task model using multiple datasets, according to the *progressive training with overlap* method. In other words, an ordered sequence of examples, from simple to complex, will need to be determined, which will be exposed in the training process.

To be consistent with [31], the following questions must be answered:

- What does a sample mean, given that multiple datasets are used?
- How can the difficulty of a sample be estimated?
- How can the training schedule be specified so that the model is exposed from easier to more complex samples?

Of the two classification tasks, the one associated with age is the most difficult, because the facial aging process is random, both for each individual person and for different categories of people. For this reason, age-related characteristics contribute to determining the difficulty of a sample. To be able to efficiently and robustly learn the age classifier:

- A uniform age category scheme will need to be created, depending on the structure of the datasets used for training.
- A generic, instantiable data loader will need to be created that allows the return of samples from a specified dataset, which refers to a specified list of age categories (age bins).

The answer to the first question is the following: a sample from a multi-dataset curriculum strategy is a sequence of samples from a list of specified datasets, associated with a specified list of age bins. This can be formalized as follows.

Let N_b be the number of age categories, and

$$\mathcal{B}_a = \{0, 1, \ldots, N_b - 1\},$$

the set of age bins. Let $\mathcal{D} = \{\mathcal{D}_i\}_{i=1}^{N_d}$ be the set of training datatsets, where each dataset $\mathcal{D}_i$, $1 \leq i \leq N_b$, is specified as:

$$\mathcal{D}_i = (Name_i, \mathcal{S}_i),$$

where, $Name_i$ is the name of the dataset, and $\mathcal{S}_i \subseteq \mathcal{B}_a$ is the set of age bins the dataset $Name_i$ contains.

Denoting by $\mathcal{DL}$ the generic data loader, a k^{th}-*sample* from a multi-dataset curriculum strategy is associated to a sequence of datasets, $DSeq_k \subseteq \mathcal{D}$, and a set of age bins, $BSet_k \subseteq \mathcal{B}_a$, and it can be defined as a sequence (a list) of *elementary samples*:

$$\begin{aligned} \mathcal{X}_k &= \mathcal{X}(DSeq_k, BSet_k) = [\mathcal{X}_k^1, \ldots, \mathcal{X}_k^p], \\ \mathcal{X}_k^j &= \mathcal{DL}(Name_{k_j}, BSet_k),\ 1 \leq j \leq p, \end{aligned} \tag{6}$$

where, $Name_{k_j} \in DSeq_k(\mathbb{N})$ for $1 \leq j \leq p$.

Remark. The order of the datasets in Eq. (6) matters because they form a sequence (a list) and not a set.

The difficulty of the samples depends on the datasets used for training, and the calculation of this score considers elements such as :

- Image quality in datasets,
- Age range coverage,
- Number of samples per age range.

We will denote such a scoring function with $score()$.

A *schedule training* is a list of ordered samples [see Eq. (7)],

$$\begin{aligned} \mathcal{ST} = [\mathcal{X}(DSeq_1, BSet_1), \ldots, &\mathcal{X}(DSeq_t, BSet_t)] = \\ &= [\mathcal{X}_1, \ldots, \mathcal{X}_t], \end{aligned} \tag{7}$$

which meet the following conditions:

- $score(\mathcal{X}_i) < score(\mathcal{X}_{i+1}),\ \forall i \in \{1, \ldots, t-1\}$,
- $DSeq_i$ is a subsequence of $DSeq_{i+1}$,
- $BSet_i \subseteq BSet_{i+1}$,
- $DSeq_t = \mathcal{D}$,
- $BSet_t = \mathcal{B}_a$.

The first condition has its source in the curriculum learning method, while the others have their source in the progressive training with overlap method.

Remark. Some examples of curricula (list of multi-dataset samples) are presented in Section IV-D.

3) The training algorithm: The function that describes the training method is described in Algorithm 1, where $model$ is the dual-task classifier, while $scheduleList$ is the list of training samples.

In Algorithm 1:

1) The parameter $model$ represents an instance of the class $DualClassifier$, which implements the dual task classifier, as presented in Fig. 1. The class constructor uses only two parameters: the number of classes for the age attribute, and for the gender attribute:

   $model \leftarrow DualClassifier(ageClasses, genderClasses)$

2) The parameter $scheduleList$ is a dictionary implementing the multi-dataset curriculum strategy. The

Algorithm 1 Training with Multi-Dataset Curriculum Strategy

Require: $model$, $scheduleList$
function TRAINCURRICULUM($model$, $scheduleList$)
  for *schedule* $\in$ *scheduleList* **do**
    for $(datasets, bins, epochs) \in schedule$ **do**
      for *dataset* $\in$ $datasets$ **do**
        for *epoch* $\in$ $epochs$ **do**
          TRAINONEEPOCH($model, trainLoader$)
        end for
      end for
    end for
  end for
end function

algorithm that generates the dictionary is adaptive and does not require parameters (the datasets *MORPH-II*, *UTKFace* and *Adience* are predefined).

3) Each element in a training list has an additional element, $epochs$, which specifies the number of training epochs for that sample.
4) The parameter $trainLoader$ has the following meaning:

$$filteredDataset \leftarrow FilteredDataset(dataset, bins)$$
$$trainLoader \leftarrow DataLoader(filteredDataset)$$

The function TRAINONEEPOCH is briefly described in Algorithm 2.

Algorithm 2 Training One Epoch

Require: $model$, $trainLoader$
function TRAINONEPOC($model$, $trainLoader$)
  for $(images, labels) \in trainLoader$ **do**
    $out \leftarrow model(images)$
    $\mathcal{L}_{age} \leftarrow$ ENTROPYLOSS($out_{age}, labels_{age}$)
    $\mathcal{L}_{gender} \leftarrow$ ENTROPYLOSS($out_{gender}, labels_{gender}$)
    $\mathcal{L} \leftarrow e^{-p_{age}}\mathcal{L}_{age}+p_{age}+e^{-p_{gender}}\mathcal{L}_{gender}+p_{gender}$
    BACKWARD($\mathcal{L}$)
  end for
end function

In Algorithm 2:

1) Loss values for age and gender are calculated using a *cross entropy loss* function to be consistent with classification tasks.
2) The total loss value is calculated using Eq. (4) and Eq. (5).
3) p_{age} and p_{gender} are two trainable scalar parameters, which are initialized to 0 and updated in the training phase at each epoch.

IV. EXPERIMENTS AND RESULTS

A. Datasets

We evaluated several publicly available facial datasets, both controlled and uncontrolled, that allow for the estimation of both gender and age of individuals based on face images, in the field of multi-task learning. A controlled dataset is generated in a controlled environment with some limited variability during image capture, while an uncontrolled dataset involves high variability in real-life image capture [3].

As mentioned in Section III, we chose to use three widely used public domain facial datasets, *MORPH-II* [39], *UTKFace* [40] and *Adience* [41]:

- *MORPH-II* is the *most commonly used* dataset in literature. It is a controlled dataset with some environmental variability (the images are captured in a constrained environment).
- *UTKFace* is a controlled dataset with the *widest age range* (0 to 116 years). Similar to MORPH, the images in UTKFace are captured in a constrained environment.
- *Adience* is the *most challenging* (and uncontrolled) dataset [3].

A part of these datasets are used for training and validation, while the other part is used for testing.

1) UTKFace [40]: UTKFace is a large-scale facial dataset containing over 20,000 images, spanning a long age range from 0 to 116 years. In addition to age labels (which represent the exact age), the images in the dataset also contain binary gender labels (0 - Male, 1 - Female), as well as ethnicity labels. The images are 200×200 pixels in size and are aligned and cropped.

Some qualitative elements related to UTKFace:

- Images are generally front-facing.
- Lighting and background are generally consistent, with low variation.
- Label quality: because they are derived from filename, not manually verified, can contain noise, especially in age.
- UTKFace is more balanced than other datasets in terms of age range but it underrepresents elderly and infants

2) MORPH-II [39]: MORPH-II is a very large public dataset of non-celebrity individuals, containing approximately 55,000 facial images from over 13,000 subjects, with an age range of 16 to 77 years. The images have a variable size, often over 200×240, and they have three labels: exact age, gender (binary label), and race (black, white, others).

Qualitative elements related to MORPH-II:

- Images are frontal well-aligned.
- Lighting and background is controlled (studio-like) and uniform.
- Label quality is high, with metadata.
- MORPH-II has a strong gender imbalance ($\approx 85\%$ Male) and racial imbalance ($\approx 77\%$ African-American).
- Temporal data: It contains multiple images per person over time.

3) Adience [41]: Adience is a challenging dataset containing approximately 26,000 facial images of 2,284 subjects, collected from difficult real-world scenarios. Each image from the dataset is labelled with a gender class label (binary), and an age group class label. There are eight age groups (0–2, 4–6, 8–13, 15–20, 25–32, 38–43, 48–53, and 60+), and the distribution of face images across age group and gender class labels in Adience is shown in Table I.

TABLE I. THE AGE AND GENDER DISTRIBUTION IN ADIENCE

	0-2	4-6	8-13	15-20	25-32	38-43	48-53	60+	Total
Male	4.69%	5.60%	5.72%	4.52%	14.04%	7.65%	2.49%	2.75%	47.18%
Female	4.20%	7.58%	7.32%	5.59%	16.47%	6.48%	2.59%	2.59%	52.82%
Total	8.89%	13.18%	13.05%	10.11	30.52%	14.14%	5.08%	5.34%	100.00%

Qualitative elements related to Adience:

- Images unconstrained, non-frontal, real-world poses.
- High variation of lighting and background (wild dataset).
- Label quality images are human-labeled, but age groups, not exact ages. In addition, there are gaps between age groups.
- The distribution of labels is more balanced across genders and ages than MORPH-II, but still uneven between some age groups (as in Table I).

B. Preprocessing Operations

To achieve the research goals, several preprocessing steps were performed on the datasets.

1) Preprocessing file names in UTKFace dataset: : A step specific only to the UTKFace dataset, consisted of uniformly processing the image file names, to eliminate labeling noise (since labels are extracted from file names):

- Incorrect age labels: Some file names contain unrealistic ages due to estimation or annotation errors, and there is also a mismatch between the apparent age and the actual age written in the file name.
- Ambiguous gender labels: The labels are 0 for male and 1 for female, but some are mislabeled (especially for children or when gender is difficult to determine visually).
- Non-standard or corrupted filenames: Some images are mislabeled or don't follow the standard file naming pattern, and a few are even missing tags completely.

2) Face detection and cropping: To obtain a robust classifier, but also because there are large differences between datasets in terms of framing faces in images, before the training, evaluation and testing operations, the two operations must be performed.

3) Face alignment and resizing: The face alignment operation is useful for improving classification accuracy in face-based tasks, such as age and gender classification, because:

- It reduces variability, as faces in datasets may be skewed, rotated, or improperly centered.
- Improves feature learning, as aligned faces lead to better feature consistency across different images, facilitating convergence and generalization.

Image resizing is important because CNN-based backbones (such as EfficientNet-B4) accept images of predefined sizes (380×380 in the case of EfficientNet-B4).

Remark. Face detection, cropping, face alignment are operations included in the generic class used for loading custom datasets in the training, validation and testing operations.

C. Age Labeling Strategy and Data Augmentation

- Label binning for age
- Handling class imbalance

Since the training operation is performed using three datasets, a unified age labeling scheme will need to be designed. To achieve this, the following elements were taken into account:

- Adience is the only dataset that has age groups, the others use exact age.
- The age range for the three datasets differs: 0 to 116 for UTKFace, 16 to 77 for MORPH-II and 0 to 100 for Adience.
- The age ranges at Adience are not consecutive (for example, the range for the second group is 4 to 6, and for the third group is 8 to 13).
- The distribution of images for age is generally imbalanced for all datasets.

This scheme will have eight consecutive age groups, which will cover the entire age range between 0 and 100 years (in the UTKFace dataset there are very few images of people over 100 years old, so they can be included in the last group). We will denote the age groups as follows:

$$\begin{aligned} &g_1 = [0, c_1], \\ &g_i = [c_{i-1} + 1, c_i],\ i \in \{2, 3, \ldots, 7\}, \\ &g_8 = [c_7 + 1, 100]. \end{aligned} \tag{8}$$

Denoting the Adience age groups as,

$$[a_1, b_1], [a_2, b_2], \ldots, [a_8, b_8], \tag{9}$$

we will need to determine the values for the variables $c_1, \ldots, c_7$, so that:

1) Age ranges from Adience groups to be included in the new ranges.
2) The number of images in all datasets, for the eight age groups, should be as balanced as possible.

Because the values for the boundaries $c_1, \ldots, c_7$ are integers, this is an integer optimization problem. We use an age histogram function:

$$f(x,y) = \sum_{i=x}^{y} n(i),$$

where, $n(i)$ is a function that counts in all three datasets images with age i. In addition, we will denote by $f_i = f(x_i, y_i)$ the number of images in group g_i [Eq. (8)].

The optimization problem can be formulated as following:

Problem 1: Given the Adience age groups as in Eq. (9), and the new age groups as in Eq. (8), find all integer values for the variables $c_1, \ldots, c_8$ that minimize the mean squared deviation of group sizes:

$$\frac{1}{8}\sum_{i=1}^{8}(f_i - \overline{f})^2,$$

subject to the following constraints:

$$c_i \in [b_i, a_{i+1} - 1], \ \forall i \in \{1, \ldots, 7\}.$$

This discrete optimization problem does not always have a unique solution, due in particular to the age distribution of the datasets. This is not a problem, because there is no need for just one canonical solution. In conclusion, we will choose the first solution, if there are multiple possible solutions.

In this case we use the following solution:

$$(c_1, \ldots, c_7) = (2, 6, 14, 23, 34, 45, 59),$$

noindent which means that the age groups are as follows:

$$0-2, 3-6, 7-14, 15-23, 24-34, 35-45, 46-59, 60-100.$$

Even after finding the solution, the age groups still remain unbalanced, as seen in Fig. 2, due to age group constraints in the Adience dataset.

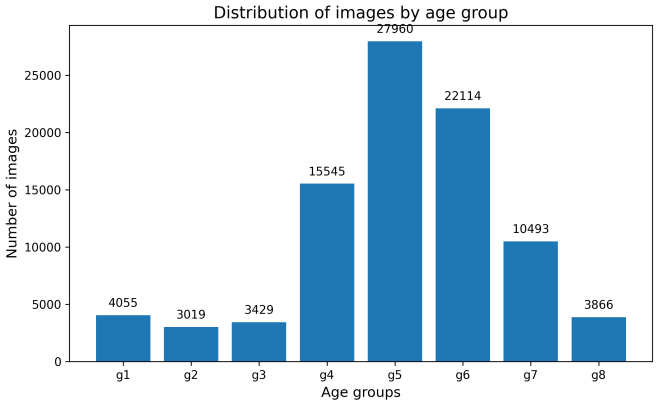

Fig. 2. Distribution of images in datasets by age groups.

To further reduce the imbalance, two operations will be performed:

- Randomly removing images from those age groups that have too many images.
- Generating new images in age groups that have too few images.

The generation of new images is based on augmentation operations, such as: rotation, skewing, and random distortion. In addition, these methods can enhance the dataset without introducing distortions that degrade classification accuracy.

Above the median value, drop-out operations will be performed, and below this value, augmentation operations. After performing these operations, the histogram of images by age group is shown in Fig. 3.

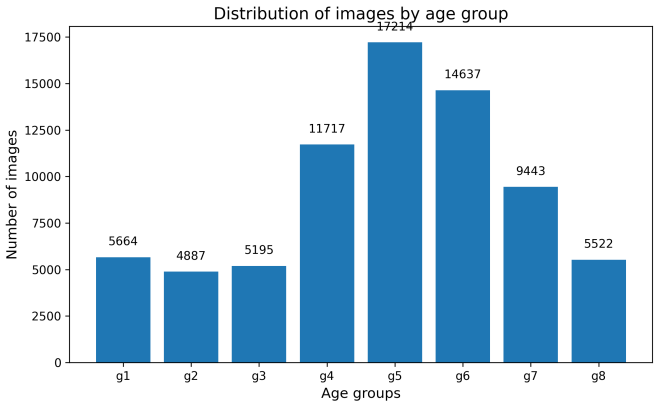

Fig. 3. Distribution of images in datasets by age groups after augmentation2.

The $\frac{1}{9}$ ratio has been reduced to $\frac{1}{3.5}$. To avoid overfitting, we do not believe this ratio should be reduced further. When necessary, a weighted sampling method will be used.

D. Implementing a Multi-Dataset Curriculum Strategy

To implement a *multi-dataset curriculum strategy*, we use the following elements:

- A multi-dataset sample is represented by a list of samples from a list of datasets, related to a list of age bins, as described in Eq. (6).
- A score related to a a multi-dataset sample specifies the training difficulty of that sample, which comes from:
  - The quality of images from each dataset
  - The degree of imbalance of age bins
- A training schedule is a list of multi-dataset samples ordered by their score, as in Eq. (7).

Since we are not yet ready to present an adaptive algorithm that automatically learns a multi-dataset curriculum, regardless of the list of datasets used for training, we will describe the static creation of such a strategy for the three datasets used in this research. Such an algorithm will be the subject of a future study.

According to the quantitative elements of the datasets presented in Section IV-A, the following three difficulty criteria

TABLE II. DATASETS DIFFICULTY CRITERIA

Image quality	Age bins imbalance	Gender imbalance
UTKFace	Adience	UTKFace, Adience
MORPH-II	UTKFace	MORPH-II
Adience	MORPH-II	-

are presented in Table II, in increasing order of difficulty for each dataset:

Remark. The most important difficulty criterion is *Gender imbalance*, because the dual-task model learns gender first, and then age. The difficulty order is as follows:

- *Gender imbalance*: important since the dual-task model depends on gender output for age prediction.
- *Image quality*: impacts feature extraction and prediction robustness.
- *Age imbalance*: makes learning certain age bins harder.

Considering the above remarks and the difficulty criteria, as shown in Table II, below is an ordered list of multi-dataset samples:

1) Multi-dataset sample 1 (Gender-balanced, medium-age, decent quality):
```
{'datasets': ['utkface', 'adience'], '
bins': [3, 4, 5]}
```
2) Multi-dataset sample 2 (Gradual age complexity increase):
```
{'datasets': ['utkface', 'adience'], '
bins': [3, 4, 5, 6, 7]}
```
3) Multi-dataset sample 3 (Full age distribution):
```
{'datasets': ['utkface', 'adience'], '
bins': [0, 1, 2, 3, 4, 5, 6, 7]}
```
4) Multi-dataset sample 4 (Incorporate harder dataset gradually):
```
{'datasets': ['utkface', 'adience', '
morph2'], 'bins': [3, 4, 5]}
```
5) Multi-dataset sample 5 (Adds aging extremity):
```
{'datasets': ['utkface', 'adience', '
morph2'], 'bins': [3, 4, 5, 6, 7]}
```
6) Multi-dataset sample 6 (Full complexity and diversity):
```
{'datasets': ['utkface', 'adience', '
morph2'], 'bins': [0, 1, 2, 3, 4, 5, 6,
 7]}
```

Remarks:

- The previous samples were written as dictionaries in the *Python* language.
- Instead of the age groups $g_1, \ldots, g_8$, were used age bins: $[0, 1, \ldots, 7]$.

E. Results

In this section, the results of experiments performed on the test parts of the UTKFace, MORPH-II, and Adience datasets are presented.

The proposed method is implemented in PyTorch. The training was performed on the Google Colab framework, with an NVIDIA Tesla T4 graphics card with 16 GB of GPU memory. The maximum number of epochs was set to 45, but an early stopping mechanism was used to avoid overfitting. A dynamic learning rate was used via the ReduceLROnPlateau learning rate scheduler in PyTorch. The total training time was approximately 8 hours.

The tests were performed on a Windows PC with an Intel Core Ultra 7, 16-core, 5 GHz processor and 32 GB of CPU memory. The total number of test images in the 3 datasets is approximately 9000. Using a batch size of 64, the total testing time was approximately 5 minutes.

The *accuracy* is used to measure the performance of the model, both for age and gender estimation. The accuracy metric is calculated based on the true positive (TP), false positive (FP), true negative (VN), and false negative (FN) values, as follows:

$$Accuracy = \frac{TP + TN}{TP + TN + FP + FN}.$$

Table III presents the estimation performance results for gender and age for all three datasets.

TABLE III. GENDER AND AGE ACCURACY FOR ALL DATASETS

	Gender	Age
Adience	92.25	73.12
MORPH-II	97.92	77.17
UTKFace	97.74	69.83

It is observed that, although the MORPH-II dataset was introduced last in the training process and has a strong gender imbalance, the classification performances are the best in this case (both in gender and age). Although it is the most gender-unbalanced, the image quality is better than other datasets, which makes the learning process for images in MORPH-II better.

Regarding the other two datasets, Adience and UTKFace, the results are different for gender and age: the classification accuracy for age is better in Adience, while the accuracy for gender is better in UTKFace.

This can be explained for the following reasons:

- Although the images in Adience are collected from difficult real-world scenarios, the image quality is better than in the case of UTKFace, and the image sizes are quite large, over 200×200 (most are around 600×600).
- In UTKFace, all images are 200×200 in size and are aligned and cropped. But because they need to be scaled to the size of 380×380 (which is the input size for EfficientNet-B4) the scaling operation introduces noise.

In conclusion, age estimation for the UTKFace dataset is more difficult than for the other datasets.

In the following, we will compare the results of the proposed method with state-of-the-art works on facial gender and age group estimation.

Table IV presents the results of estimating the performance of the proposed method on the Adience dataset and compares this with other proposed approaches based on deep learning.

TABLE IV. GENDER AND AGE ACCURACY FOR ADIENCE DATASET

Method	Gender accuracy	Age accuracy
Zhang et al., 2017 [42]	93.24	66.74
Duan et al., 2018 [43]	88.20	52.30
Gurnani et al., 2019 [44]	91.80	62.11
Khan et al., 2020 [45]	**93.60**	69.40
Garain et al., 2021 [46]	81.80	66.10
Saha et al. 2023 [47]	84.94	**75.10**
Proposed method	92.25	73.12

The methods specified in Table IV use the 8 age groups as defined in the Adience dataset (0–2, 4–6, 8–13, 15–20, 25–32, 38–43, 48–53, and 60+).

Table V presents comparisons of performance estimation on the MORPH-II dataset, while Table VI presents comparisons of performance estimation on the UTKFace dataset.

TABLE V. GENDER AND AGE ACCURACY FOR MORPH-II DATASET

Method	Gender accuracy	Age accuracy
Guo et al., 2014, [48]	**98.50**	70.00
Han et al., 2015 [49]	97.60	77.40
Wang et al., 2017 [50]	98.00	**85.30**
Khan et al., 2020 [45]	96.70	75.00
Han et al., 2018 [51]	81.80	66.10
Proposed method	97.92	77.17

TABLE VI. GENDER AND AGE ACCURACY FOR UTKFACE DATASET

Method	Gender accuracy	Age accuracy
Krizhevsky et al., 2017, [52]	85.10	55.96
Huang et al., 2017 [53]	87.28	59.22
Das et al., 2018 [54]	**98.23**	**70.10**
Yuan et al., 2024 [55]	90.91	64.74
Proposed method	97.74	69.83

The vast majority of the methods specified in Table VI use 7 age groups: a) baby: 0 to 3 years, b) child: 4 to 12 years, c) teenagers: 13 to 19 years, d) young: 20 to 30 years, e) adult: 31 to 45 years, f) middle aged: 46 to 60 years, and g) senior: 61 and above years.

It is observed that, in all three tables, the classification results of our method do not exceed the best results of the other proposals, but the following elements should be noted:

- The classification accuracy values for ours method are close to the best results of the other methods, both for gender and age.
- Related the classification accuracy for age groups, the values are not always conclusive, because each proposal had its own age grouping scheme. With the exception of the Adience dataset, many other methods use between 3 and 6 age groups, while our method used 8 age groups, which led to a decrease in accuracy.
- Each of the other proposals used a single dataset for training and testing, while our proposal used all 3 datasets.

One of the goals of our method is to create a robust classifier for the gender and age of individuals in facial images, which means that testing the classifier on unknown images should have high accuracy, both for estimating age and gender.

F. Ablation Study

There are two important factors in our proposal. One is dynamic learning of task weighting when calculating the total loss. The other is the use of multi-dataset curriculum strategy in the training phase. We investigate the effects of the two factors on the accuracy of classification by gender and age.

1) Dynamic learning of task weighting: In multi-task learning, the total loss must be determined based on the partial losses in the task, as presented in Eq. (1). Usually the total loss is simply the sum of partial task losses:

$$\mathcal{L} = \sum_i \mathcal{L}_i.$$

Another approach is to manually determine normalized weights w_i, depending on the difficulty of the tasks:

$$\mathcal{L} = \sum_{i=1}^{n} w_i \mathcal{L}_i,$$

such that $\sum_{i=1}^{n} w_i = 1$.

We used a modified verison of the proposal from [11],

$$\mathcal{L} = \sum_{i=1}^{n} \mathrm{e}^{-\log(\sigma_i^2)} \mathcal{L}_i + \log(\sigma_i^2) \tag{10}$$

As described in Eq. (3), Eq. (4) and Eq. (5), which learns the log of the variance, $\log(\sigma_i^2)$, for each classification task i.

The results shown in Tables IV, V and VI use the Eq. (10), for $n = 2$ [or similarly, Eq. (5)].

To see the importance of using dynamic learning of task weighting, we then retrained of the dual classifier. We used the multi-dataset curriculum strategy in the training part, but in Algorithm 2, we used the following two variants for calculating the total loss value:

$$\mathcal{L} = \mathcal{L}_{age} + \mathcal{L}_{gender}, \tag{11}$$

and:

$$\mathcal{L} = 0.6 \cdot \mathcal{L}_{age} + 0.4 \cdot \mathcal{L}_{gender}. \quad (12)$$

Remark. In Eq. (12), the weight for age classification is higher than for gender classification, because this task is more difficult.

In testing, the values obtained for accuracy were quite close when Eq. (11) and Eq. (12) were used. The differences were, however, greater between using Eq. (11) [or Eq. (12)] and Eq. (5).

Table VII presents the classification accuracy results for gender and age when using both the original Eq. (5), and Eq. (11) to calculate the total loss. An increase of approximately 2 per cent in accuracy is observed comparing the use of Eq. (11) with the use of Eq. (5).

TABLE VII. COMPARISON OF MODEL PERFORMANCE DEPENDING ON THE CALCULATION METHOD OF TOTAL LOSS

Dataset	Total loss determination	Gender	Age
Adience	Equation 5	**92.25**	**73.12**
	Equation 11	91.27	71.65
MORPH-II	Equation 5	**97.92**	**77.17**
	Equation 11	97.23	75.31
UTKFace	Equation 5	**97.74**	**69.83**
	Equation 11	94.68	66.25

2) Multi-dataset curriculum strategy: To determine the contribution of the training method, we will perform several experiments in which the dynamic learning of task weighting is used as in Eq. (5). Since there are many possible combinations, we will only test two combinations, which seem to be more important for the study.

- Since the accuracy values for the MORPH-II dataset are the highest, and it uses only age groups $g4$, $g5$ and $g6$ (bins $[3-5]$), the samples will be ordered according to the age group balance and the results obtained in the main ordering scheme. We will use the following ordered list of multi-dataset samples (will be noted as **list 1**):
  - (1.1) Core mid-age learning: `{'datasets': ['morph2'], 'bins': [3, 4, 5]}`
  - (1.2) Extended core mid-age: `{'datasets': ['morph2', 'utkface', 'adience'], 'bins': [3, 4, 5]}`
  - (1.3) Young age focus: `{'datasets': ['utkface', 'adience'], 'bins': [0, 1, 2]}`
  - (1.4) Elderly focus: `{'datasets': ['utkface', 'adience'], 'bins': [6, 7]}`
  - (1.5) Mid-age re-focus: `{'datasets': ['morph2', 'utkface', 'adience'], 'bins': [3, 4, 5]}`
  - (1.6) All datasets: `{'datasets': ['morph2', 'utkface', 'adience'], 'bins': [0, 1, 2, 3, 4, 5, 6, 7]}`
- Another variation of the curriculum is based on the uneven age distribution and imbalances of the Adience, UTKFace, and MORPH2 datasets. This time MORPH-II is no longer considered an advantageous dataset. We will denote this curriculum as **list 2**:
  - (2.1) Core mid-age learning: `{'datasets': ['adience', 'utkface', 'morph2'], 'bins': [3, 4, 5]}`
  - (2.2) Young age specialization: `{'datasets': ['adience', 'utkface'], 'bins': [0, 1, 2]}`
  - (2.3) Elderly age focus: `{'datasets': ['adience', 'utkface'], 'bins': [6, 7]}`
  - (2.4) Balanced reintroduction: `{'datasets': ['adience', 'utkface'], 'bins': [0, 1, 2, 3, 4, 5, 6, 7]}`
  - (2.5) Fine tuning (all datasets): `{'datasets': ['adience', 'utkface', 'morph2'], 'bins': [3, 4, 5]}`

Table VIII presents the classification accuracy results for gender and age when using three lists of multi-dataset samples in training phase: the original list and the two lists described above (**list 1** and **list 2**).

TABLE VIII. COMPARING MODEL PERFORMANCE BASED ON THE LIST OF MULTI-DATASET SAMPLES

List of multi-dataset samples	Dataset	Gender	Age
Original list	Adience	92.25	73.12
	MORPH-II	97.92	77.14
	UTKFace	97.74	69.32
List 1	Adience	81.25	60.37
	MORPH-II	99.08	87.25
	UTKFace	85.32	58.45
List 2	Adience	92.75	73.82
	MORPH-II	97.12	76.87
	UTKFace	96.21	67.24

Based on the values in this table, the following remarks can be drawn:

- In the case of **list 1**, the accuracy values are extremely high for the MORPH-II dataset, but extremely low for the other two datasets. The model learns classifications for MORPH-II very well because this dataset is the first in the list of datasets. And because of this, the learnings for the other two datasets are at a disadvantage.
- The original list and **list 2** generate predictions with similar accuracy: the accuracy is slightly better in the case of the original list for the MORPH-II and

UTKFace datasets, and in the case of **list 2** the accuracy is slightly better for Adience.

In conclusion, evaluating the difficulty of multi-dataset samples is a complex and difficult operation. It is expected that in the future the manual design of a curriculum will be replaced with an adaptive algorithm that automatically learns a multi-dataset curriculum.

V. Conclusion

This study presents a deep multi-task learning approach for facial gender and age recognition. Facial features are extracted using a pre-trained model, EfficientNet-B4, which has a balanced ratio between accuracy and computational cost. A two-branch architecture is proposed, where the output of the gender branch is fed into the age estimation branch to improve age prediction.

Besides the mechanism for injecting gender information into the age branch of the dual-task model, which is in the architectural part of the proposal, the other contributions of the proposal reside mainly in the training part of the dual classifier.

For robust classification, instead of training the model on a single dataset, three of the most well-known datasets were used simultaneously and a unified strategy for determining age groups was proposed for all datasets. To improve training efficiency and final model performance, a multi-dataset curriculum strategy was proposed, which is based on the curriculum learning method for single datasets, which it extends to multiple datasets.

Another improvement to increase the accuracy of the estimation operations consists of implementing an adaptive method for determining the task-specific weights when determining the total loss. This uses two trainable scalar parameters, representing the logarithm of the variance of each task, which are used to calculate the total loss.

The experimental study conducted on three datasets used (Adience, MORPH-II and UTKFace) validated our contributions. Comparing the results of the proposed method with the state-of-the-art works on gender and age estimation, the classification accuracy values of our method are close to the best results of the other methods, both for gender and age. These results are valid for all datasets used, which demonstrates the robustness of the proposed dual classifier.

In its current form, the proposed method has some limitations and constraints, which could be remedied in the future:

- The multi-dataset curriculum method, although theoretically described, relies on manual curriculum creation.
- Optimal generation of age groups is done automatically, but it is based on predefined age groups in the Adience dataset.

Future research are in several directions:

- Developing an adaptive algorithm that automatically learns a a multi-dataset curriculum, based on loss values, instead of a static and manually developed one.
- Development of an adaptive algorithm that automatically determines age groups for the datasets used, based only on the annotation .csv files.
- Developing a similar lightweight model (e.g. based on a pre-trained model such as EfficientNet-B0), which can be transformed into a model for iOS applications.

***Abstract*—Epilepsy affects more than 50 million people worldwide, and almost 80% of them live in low-income countries with limited access to medical and public services. Beyond these challenges, epileptic patients also face other problems, such as stigma and social exclusion due the misunderstanding of epilepsy. Thus, epilepsy has become a major public health problem with a high social impact. Electroencephalography (EEG) remains the primary tool for diagnosing epilepsy; however, the traditional procedure of reviewing long EEG recordings is time-consuming, error-prone, and highly dependent on the neurologist's experience. Recent advances in deep learning (DL) have driven the development of new methods for automatic epilepsy detection. Despite these advances, most methods are not generalizable to all patients, limiting their clinical applicability in real-life cases. In this work, we present a cross-patient method capable of improving epilepsy detection by spectral decomposition of EEG signals into canonical brain rhythms. These spectral bands improve the signal significance and the model performance. The proposal was evaluated in a cross-patient validation scheme on the CHB-MIT dataset and proved superior performance using EEG signals from the interictal and ictal epilepsy stages. The model achieved of 100% of sensibility and specificity using the theta band, outperforming the state-of-the-art methods and offering a promising step towards real-world clinical implementation.**

***Keywords*—EEG signals; EEG signal decomposition; canonical brain rhythms; deep learning; convolutional neural network; transformer neural network**

I. Introduction

Epilepsy is a neurological disorder that is one of the most severe and affects the normal functioning of the brain [1]. Epilepsy is characterized by abnormal electrical activity in neurons that initiates seizures, which is the observable manifestation of this disease [2]. Seizures or convulsions consist of movements of the body, arms, and hands, and are often accompanied by loss of consciousness, fainting, and salivation [3]. The degree of seizures can vary, from subtle to strong manifestations. When seizures occur more than once in a day, the quality of life of patients deteriorates dramatically [4]. Furthermore, numerous epileptic patients experience social exclusion and stigmatization [5].

Epilepsy can affect anyone, regardless of age, gender, race, social status, or geographic location; it affects both children and adults [6]. Current research is centered on identifying the causes, medical treatments, and diagnosis of epilepsy since there is no definite cure [7]. The World Health Organization states that epilepsy affects over 50 million people worldwide, and most of them are living in poor or developing countries without access to medical services or treatments [8]. Because epilepsy strongly changes the lives of people, it has turned into a global public health problem with high social impact that deserves attention [9].

But not all seizures are epilepsy itself. Other diseases also cause seizures (e.g., Alzheimer's disease [10], stroke [11], diabetes [12]). Therefore, the goal of physicians and neurologists is to obtain a precise diagnosis of epilepsy to provide the best treatment [13]. Poor treatment of epilepsy could even worsen the disease [14].

Due to its low cost and non-invasive nature, the electroencephalogram (EEG) has become the standard method for diagnosing epilepsy [15]. EEG captures the electrical activity of neurons using electrodes placed on the scalp of the head [1]. In order to diagnose epilepsy, the physician visually observes the EEG signals to identify patterns of spikes, sharp, and slow waves that are characteristic of an epileptic seizure [16]. Although it may seem very simple, this work is visually-intense, time-consuming, and error-prone, depending on neurologist expertise [17]. So, it is crucial to have a proper diagnosis of epilepsy in order to provide an adequate treatment.

In the past two decades, there have been numerous research efforts conducted to create automatic tools for detecting epileptic seizures [18], [19], [20] and for predicting seizure episodes [21], [22], [23]. The majority of research studies rely either on machine learning (ML) or deep learning (DL) algorithms to detect seizure patterns in EEG signals. Among them, DL is one of the most popular due to its ability to model a more flexible feature space [24].

In spite of the recent progress, the classification of epileptic seizures still faced some challenging problems. Two main issues are addressed in this work:

- The majority of methods for developing a DL classifier to detect epileptic seizures commonly use raw EEG signals as input data. However, decomposing the EEG signal into major brain rhythms is more suitable for clinical diagnosis, as it enhances the interpretation of the signal [25]. Can classification performance be improved by the brain rhythms of EEGs?
- The majority of methods to detect epileptic seizures usually assess their model's performance at a cross-validation and intra-subject level. However, cross-patient assessment remains limited due to the difficulty

of achieving a good generalization model. Could it be feasible to create a population-level classifier by analyzing specific EEG brain rhythms/bands?

Therefore, the main contribution of this work is twofold:

- An approach that decomposes the raw EEG signal into the four main brain rhythms: theta (θ), alpha(α), beta(β), and gamma (γ) waves. A basic transformer neural network proposed in [26] is employed to objectively assess the performance caused by the decomposition of EEG signals .
- Two ways to evaluate the model's performance. First, a k-fold cross-validation level to determine how well the model works with the maximum number of raw data . Second, to determine how effectively the model works with the decomposed brain bands on a cross-patient assessment level.

The remainder of this study is organized as follows: Section II presents the fundamentals about epilepsy, as well as the related work. Section III exposes our proposal to detect epileptic seizures. Section IV shows the achieved results and provides a comparison against previous work. Lastly, Section V summarizes the findings of this study and the upcoming investigations.

II. Background

Since its invention, EEG has become the standard device for diagnosing epilepsy and investigating other brain disorders [1]. The neuronal electrical activity is recorded by the EEG through electrodes placed over the head. Thereby, EEG allows a real time investigation of what is happening in the brain due to the fact that each electrode registers data from a specific region of the head. As a result, the EEG produces a recording file that can be further analyzed by the neurologist [27]. Fig. 1 illustrates an EEG headset and its electrode placements over the head. The arrows indicate the EEG montage used during analysis.

Traditional epilepsy diagnosis involves human visual analysis of EEG registers, which is both time-consuming and susceptible to misdiagnosis. To overcome these issues, in the last years, many methods have been proposed for automatic detection of epilepsy [18], [19], [20]. Therefore, the goal of epileptic seizure detection is to classify EEG time windows as normal (non-seizure) or abnormal (seizure) through supervised binary classification.

To build a classifier, it is desirable to have a large amount of EEG data [24]. However, researchers select EEG data to reduce imbalance between seizures and non-seizures classes due to their strong unbalance. So, given a long-time EEG recording, investigators extract specific parts of the signal. These parts are taken from the stages of epilepsy that the patient experiences over time: the interictal, preictal, ictal, and postictal stages [1], [2].

The ictal stage refers to the patient's seizure episode, and the other stages are placed in relation to this stage over time. Fig. 2 shows the four phases of epilepsy in an long-time EEG recording. Note that the ictal stage lasts very short compared to other stages. Fig. 3 illustrates the ictal or seizure episode (red shaded), showing variability in the transition between episodes (green shaded).

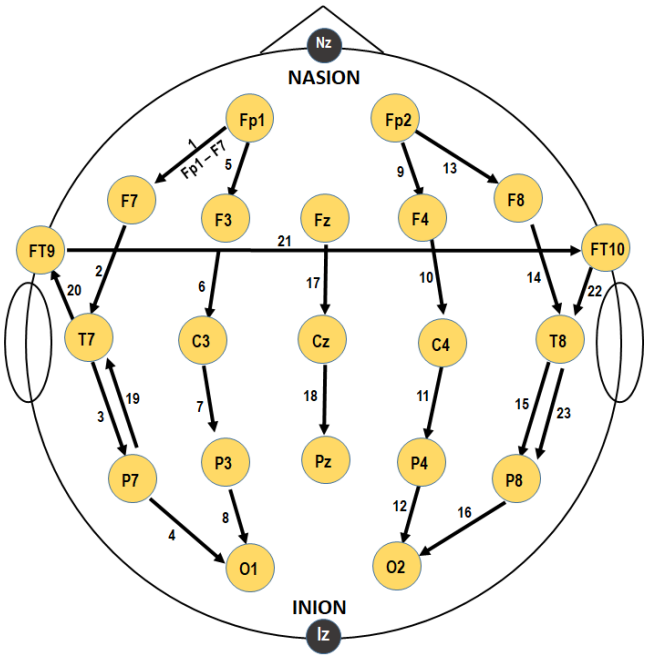

Fig. 1. An EEG device and its electrode placements according to the 10–20 system.

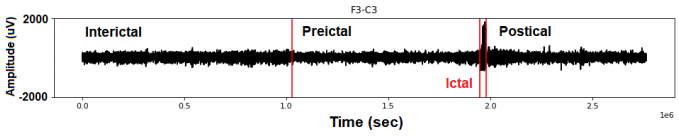

Fig. 2. Epilepsy phases in a long time EEG recording. For convenience, only a single channel is plotted.

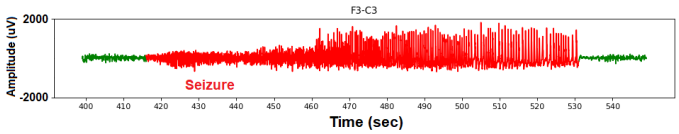

Fig. 3. An epilepsy seizure stage (red shaded). For convenience, only a single channel is plotted.

The interictal stage occurs a few hours before a seizure episode and the patient experiences a normal condition; the preictal stage occurs a few minutes preceding a seizure (e.g., 30 minutes); and the postictal stage occurs some minutes after a seizure (e.g., 5 minutes). However, it is worth mentioning that, yet there is no consensus about the duration of the interictal, preictal, and postictal stages due to the high variability of epilepsy symptoms between patients [28], [29], [30].

In order to construct their classification model for seizure detection, most researchers use signals from interictal and ictal stages as input data [31], [32], [33], [34], [35], and a few investigators use signals from preictal and ictal stages

[36], [37]. Regardless of the use of interictal versus ictal or preictal versus ictal sources to build the classification model, the authors have reported high accuracy results; however the lack of consensus on the signals used to train and test the model often prevents these results from being reproducible.

In order to examine how well models detect epilepsy using EEG signals, researchers have used various validation schemes to assess their generalizability and clinical relevance [38], [39]. One common approach is the k-fold cross-validation, that involves randomly partitioning an entire dataset composed of EEG recordings from multiple patients into training and testing subsets. The use of all available data for both training and testing in this method, typically results in highly optimistic performance results due to the possibility of EEG patterns of specific patients can be leaked between training and test folds. While this setup is useful for benchmarking algorithms in early development stages, it lacks the rigor needed to evaluate real-world deployment in clinical settings [26], [39].

Aiming to better approximate practical use cases, researchers also use two more realistic validation schemes: the intra-patient and cross-patient (or patient-independent) evaluation. In one hand, in the intra-patient mode [31], the model is both trained and tested exclusively on EEG data from the same individual. This approach produces a model that is tailored to the patient and can effectively capture their distinct seizure characteristics, but they are limited in scalability and do not generalize to new patients. Furthermore, as epilepsy symptoms can change over time even in the same patient, the model should be updated as well [40].

On the other hand, the cross-patient mode [36], [30] is considered as an ideal evaluation setting. This approach uses data from one patient as the test set, while the model is trained on data from other patients. This scheme examines the generalizability of the model across individuals, which highlights its potential for clinical application in real-world. However, achieving high performance in this experimental setup remains challenging due to inter-patient variability in EEG patterns, making it a key focus of ongoing research [38], [39].

Ultimately, although DL approaches have achieved significant success in epilepsy detection using raw EEG signals, the exclusive reliance on unprocessed data may overlook clinically informative structures inherent in the signal. A notably underexplored yet promising alternative is the decomposition of EEG signals into canonical brain rhythms, such as thetaθ, alphaα, betaβ, and gammaγ bands, which are foundational to neurophysiological interpretation [1]. Moreover, from a clinical perspective, such decomposition aligns with well established diagnostic practices and facilitates the identification of abnormal frequency components associated with epileptic activity [2]. In addition, rhythm-based decomposition can enhance data quality by reducing noise and concentrating features that are more stable in the context of inter-patient variability [41].

In the context of DL, these frequency-specific components could serve as semantically enriched inputs, potentially improving both model generalization and interpretability. So, we hypothesize that selecting and integrating brain rhythm into the DL pipeline not only offers a biologically grounded data representation but also contributes to bridging the gap between computational learning strategies and clinical reasoning [42]. Therefore, it is expected to achieve an improvement in the effectiveness and the trustworthiness of diagnostic models to detect epilepsy.

This work studies the influence of brain rhythms on the performance of the model in the cross-patient evaluation scheme. In this way, although there have been many advances in epilepsy detection, the following literature revision is restricted to studies that have been experimented in cross-patient schemes that use preferably the largest public CHB-MIT EEG dataset [43]. Moreover, the basic assumption is that the extraction of spatial and temporal features is excellent and that the unbalanced nature of datasets is manageable. The studies of [38], [39] provide a deep insight into these problems.

The following are the most relevant works:

The first study to address universal generalization in cross-patient assessment scheme was presented by Hossain et al. [36]. The authors propose the EEG channel fusion in the first layer before proceeding to extract temporal features in the next layers. The model was trained by extracting data from the preictal and ictal EEG recordings, with a 2-second time window and an 80% overlap. The complete model consists of four CNN blocks (each block containing a convolution, an activation function, and a max-pooling). Evaluation in the CHB-MIT dataset, the models showed sensitivity of 90%, specificity of 91.65%, and accuracy of 98.05%. Despite the achieved high performance, the data selection process is unclear and the number of assessed seizures remains unknown.

Next, Liu et al. [44] also focused on detecting epilepsy in a cross-patient scheme. They propose a CNN-BiLSTM (Bidirectional Long Short Term Memory Network) model enhanced with a novel channel perturbation layer (CPL) during training, which randomizes EEG channel order to improve spatial generalization. First, EEG data is preprocessed using wavelet decomposition, focusing on clinically relevant brain rhythms (4–32 Hz). Evaluation in the CHB-MIT dataset, the models showed sensitivity of 86.5%, and AUC-ROC improvements from 77% to over 90% due to CPL. However, this study lacks interpretability analysis and offers limited insight into physiological relevance of learned features.

Then, Alqirshi et al. [45] proposed a cross-patient seizure detection method that utilizes graph convolutional networks (GCN) with the goal of overcoming the major limitations of conventional EEG analysis: the insufficient attention to inter-channel brain dynamics and reliance on patient-specific training. Hence, the GCN represents the EEG data as graph-structured input to capture spatial dependencies. Evaluated in a custom dataset from four unseen patients, the GCN-based approach achieved a sensitivity of 88.71%, precision of 91.32%, F1-score of 91.57%, and an accuracy of 91.70%. Although the method has reported high detection metrics, the dataset is too limited to prove that the model is highly generalizable. Moreover, it would benefit from a more transparent analysis of how specific graph features contribute to classification, and testing on larger data sets, such as the CHB-MIT database.

Next, Jana et al. [46] presented a channel selection strategy for EEG-based seizure prediction aimed at using only a single optimal channel in a cross-patient assessment. The authors propose a method that ranks each EEG channel based on

its average performance over five evaluation rounds using a CNN-LSTM1D model. The top-performing channel is then selected for prediction, and an ensemble learning framework (integrating CNN1D, DenseNet1D, and CNN-LSTM1D) is employed using majority voting. Evaluation in the CHB-MIT dataset, the model achieves a sensitivity of 94.25%, and a specificity of 92.94%. The study fails to explain why specific channels perform better than others, and assumes that a single channel cannot be generalized to all seizure types or patients with atypical EEG presentations. Furthermore, using ensembles increases complexity and could prevent real-time deployment even with a single-channel design.

Recently, Mohammadpoory et al. [47] proposed a method for epileptic seizure detection based on the weighted visibility graph (WVG). Features are extracted from both raw EEG signals and their decomposed sub-bands (delta to gamma) from the preictal and ictal EEG recordings. A combination of multiple feature selection techniques is used to select key features and evaluate them using five different classifiers. Next, a post-processing step is performed to improve detection accuracy and accurately identify seizure onset and offset. Evaluation in the CHB-MIT dataset, the model detected 163 out of 184 seizures, achieving a sensitivity of 92.31%, a specificity of 94.12%, and an accuracy of 94.02%. Despite the high performance, the main drawback is the complexity of feature engineering, which could hinder real-time applications and scaling over low-power clinical systems.

In summary, there are only a few studies focused on cross-patient or patient-independent settings. The high variability of epileptic seizures, even between the same patients, prevents achieving a generalizable model. It is worth mentioning that sub-bands as input data have only been explored by a small number of researchers, but those who have employed them have shown better results, such as the study of [47]. The main focus of this work is on EEG signal decomposition; we hypothesize it is the primary source of improvement for building a model that is highly generalizable at a cross-patient level.

III. Our Approach

As stated in Section I, this work is an extension of the study of [26], which aimed to detect epilepsy in a k-fold cross-validation scheme. Different from the previous one, this work primarily concentrates on decomposing the EEG signal into canonical brain rhythms and aims to detect epilepsy in a cross-patient validation scheme, with minor changes during application.

Fig. 4 outlines a general pipeline for detecting epileptic seizures in EEG data using DL. First, a short description of the data acquisition is provided to collect a dataset of EEG signals. Then, the signal preprocessing is performed. Next, a neural classifier is trained in order to discriminate between non-seizure and seizure signals. Finally, the trained classifier is evaluated in cross-patient mode to evaluate its generalization capability.

A detailed description of each step of the pipeline is provided as follows:

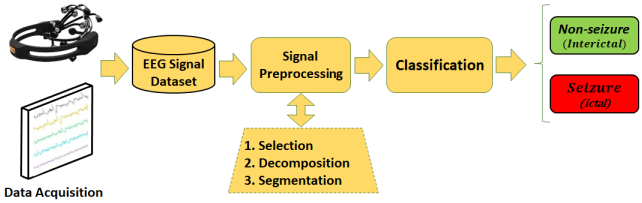

Fig. 4. The general pipeline for epileptic seizure detection.

A. EEG Dataset

The EEG dataset used in this study is derived from the CHB-MIT public dataset that contains more than 980 hours of EEG recordings and 198 seizures [43]. In extent, the dataset contains EEG registers from 23 pediatric patients, 3 to 22 age, with incurable epilepsy. Because another register of patient chb01 was obtained 1.5 years later, the chb21 register is considered a new patient's register.

EEG data was collected using EEGs of different numbers of electrodes, but registers of EEG of 23 channels at 256 Hz are the most common, which are organized in a longitudinal bipolar montage (see Fig. 1). Because the records are of long-term duration, as a result, the dataset is released in registers of one, two, or four hours long recordings. If the register contains at least one seizure, then it is named seizure records; otherwise, it is named non-seizure records. Each seizure register provides the start and end for each seizure episode as ground truth (GT).

The CHB-MIT dataset has been utilized extensively in numerous studies because it has a large amount of EEG recordings per patient and is openly accessible [48], [19]. On the other hand, there are other databases, but they are either small or privately accessible [49]. For instance, the Bonn EEG dataset contains sequences of 23.6 seconds long from a single EEG electrode, which are not suitable for training modern neural models. On the other hand, the EPILEPSIAE dataset is a large EEG database that contains continuous and long-term EEG recordings from 250 epileptic patients, but it is private.

B. Preprocessing

In this stage, four main activities are proposed: data selection, data decomposition, data segmentation, and data augmentation.

- Data selection aims to select and extract EEG registers to be used to train and test the model. In this work, we selected and extracted data from the interictal and ictal stages that best discriminate between non-seizure and seizure signals (see Fig. 2 to illustrate the selected data coming from). The use of interictal and ictal data to train classifiers is widely supported by previous studies [18], [38], [39].
  Therefore, the EEG signals come from EEG registers of 23 channels and contains a total of 181 seizures. The interictal data comes from signals two hours away of a seizure, whereas the ictal data comes from all seizures. Also, the data was downsampled to 128 Hz like in [26].
- Data decomposition aims to disassemble the raw EEG signal into four main brain rhythms: theta (θ: 4–8

Hz), alpha(α:8–12 Hz), beta(β:12–30 Hz), and gamma (γ:30–50 Hz) waves. Signal decomposition was performed via the Fast Fourier Transform (FFT). The delta (δ) The delta signal was excluded from this analysis due to its association with sleep [25].
The process of EEG signal decomposition is performed using the Fast Fourier Transform (FFT), with the goal of isolating and retaining the frequency components of a desired brain band [50]. Once the signal is isolated, it is possible to analyze the neural activity within the selected frequency band.

- Data segmentation aims to split the selected and decomposed EEG signals into small processable time windows. In accordance to the study [26], we use a time window of one second for non-seizure data, while seizure data has an 80% overlap to increase the amount of data.

C. Neural Network

To ensure an impartial evaluation of the proposed hypothesis and compare potential gains in model performance in the cross-patient evaluation scheme, we suggest reusing the model presented in [26]. Fig. 5 illustrated the reused neural architecture in this work.

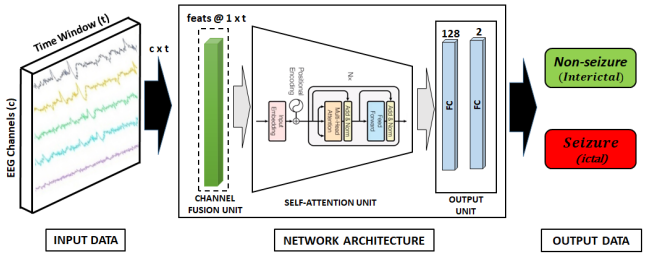

Fig. 5. The neural network architecture.

The proposed neural model has the main advantage of being a state-of-the-art (SoA) model for epilepsy detection in a k-fold cross-validation scheme and leverages the most recent advances in EEG channel fusion and attention mechanism.

D. Classification

After training, the model has the ability to discriminate between non-seizure and seizure signals. To determine the label class of input data, the final layer of the model calculates the probability distribution with the Softmax activation function [24].

E. Experimental Design

To determine the feasibility of the proposed brain rhythms decomposition into sub-bands to improve the model's ability to detect epileptic seizures in multiple patients, we use the leave-one-patient-out (LOPO) validation scheme [24].

In LOPO, the model is trained on EEG data from all patients except one, and then tested on the held-out patient. This process is repeated for every patient to guarantee that their data acts as an independent test sample only once. Finally, LOPO offers a reliable estimation of the model's performance in real-world situations where the system needs to detect epileptic seizures in patients who have never had seizures before [47].

IV. Results and Discussion

In this work, we used the neural architecture presented in [26], which was implemented in the DL Framework PyTorch v.2.4 and Python v.3.9. The experimental platform consisted of a computer desktop Intel CPU I7-8550U, 16GB RAM, equipped with a GPU NVIDIA RTX 2070 with 8GB RAM. The model was trained from scratch with the following hyperparameters: the Adam optimizer, a weighted cross-entropy loss function to deal with unbalanced data samples, a batch size of 128, a learning rate of 0.0001, and 150 epochs for training the model.

The model performance was assessed using the LOPO validation scheme. Metrics such as sensitivity, specificity, precision, F1-Score, and accuracy are employed to display the results in the format mean average plus or minus the standard deviation.

Table I summarizes the achieved results in the CHB-MIT database. To highlight the difference between decomposition and non-decomposition, the non-decomposition (i.e., raw data) is also displayed in the first row of the table. The next rows of the table show the spectral signals that have been disaggregated (theta, alpha, beta, and gamma). The decomposition approach is proven to produce better results than the non-decomposition approach, particularly by utilizing only the theta spectral band (gray shaded row).

Table II shows the achieved results of the model only using the non-decomposed signal (or raw data) as input data. To gain an understanding of individual performance, each row of the table shows the performance of each patient. It is noticeable that there is variability in patients' performance.

Using the decomposed approach, the achieved by the model shown in Table III. In this situation, the input data is represented by the theta band. The table displays the performance of each patient in each row, and it is clear that the variability between patients' performance has decreased.

To compare the achieved results with the proposed approach and related work fairly, we selected the most recent methods of SoA that focus on cross-patient or patient-independent validation schemes (i.e., LOPO). Table IV summarizes the results reported by several SoA works. After analyzing the results, it is evident that our proposed method outperforms other studies by a significant margin. Only the studies of Jana et al. [46] and Mohammadpoory et al. [47] are among the most close to our reported results.

The following points are worth discussing:

First, although many methods have been proposed for detecting epileptic seizures, only a few are capable of generalizing to patient-independent scenarios, due to the challenges in capturing inter-patient variability and the high diversity of seizure patterns (see Table IV). However, the deployment of reliable and trustworthy seizure detection systems in clinical settings will not become a reality unless we continue to address cross-patient variability.

TABLE I. SUMMARY OF THE CLASSIFICATION EFFECTIVENESS OF THE PROPOSED METHOD IN THE LOPO EVALUATION SCHEME ON THE CHB-MIT DATABASE

Brain rhythm	Sensitivity	Specificity	Precision	F1-score	Accuracy
raw data	93.27±11	96.96±7.59	71.87±32.5	75.69±26.6	96.63±7.39
theta	100±0	100±0	100±0	100±0	100±0

Second, with respect to the type of EEG input data, earlier studies primarily utilized raw signals [36], [45], whereas more recent approaches have begun to incorporate canonical brain rhythms. Hence, the studies of Liu et al. [44] and Mohammadpoory et al. [47] specifically perform EEG signal decomposition into main brain rhythms. But, while previous approaches attempted to combine features from multiple frequency bands using complex algorithms, this work evaluates each band individually, revealing that using isolated frequency bands as input data provides superior performance.

TABLE IV. COMPARISON OF THE PROPOSED METHOD AND RELATED WORK ON THE CHB-MIT DATABASE

Author	Method	Total seizures	Sensitivity	Specificity	Precision	F1-score	Accuraccy
Hossain et al. [36]	CNN	-	90.00	91.65	-	-	98.05
Liu et al. [44]	CNN-BiLSTM	-	86.50	-	-	-	-
Alqirshi et al. [45]	GCN	-	88.71	-	91.32	91.57	91.70
Jana et al. [46]	CNN-LSTM1D	-	94.25	92.94	-	-	-
Mohammadpoory et al. [47]	WVG-RF	163	92.31	94.12	-	-	94.02
This work (θ band)	CNN-Transformer	181	100.00	100.00	100.00	100.00	100.00

Third, the analysis of decomposed EEG signals is useful and intuitive from a clinical diagnostic perspective. For instance, neurologists and physicians are trained to recognize patterns within specific brain frequency bands and associate them with specific neurological conditions (e.g., delta band analysis to diagnose sleep disorders). Therefore, the analysis of canonical brain rhythms offers new opportunities to deepen our understanding of brain function, cognitive processes, and associated diseases [1], [42].

V. CONCLUSION

In this work, a new method to detect epileptic seizures in a cross-patient scenario has been presented. The method is based on the use of isolated frequency bands as input data to achieve superior model performance. This approach can be utilized to fuel any deep neural network, boosting its performance.

The feasibility of the proposed method was validated in the public CHB-MIT EEG dataset using the leave-one-patient-out (LOPO) evaluation scheme with 24 patients. We trained the well-established CNN-Transformer deep neural network proposed in [26], using individual EEG frequency bands (i.e., theta, alpha, beta, and gamma) as input data. Compared to using the raw EEG signal, our approach provides significantly superior performance. Furthermore, our approach outperforms several state-of-the-art methods and offers a promising step toward real-world clinical systems implementation.

For future work, it is necessary to conduct more research to enhance epileptic seizure recognition in clinical setting. First, the proposed method could be validated on other epilepsy datasets, such as the EPILEPSIAE database, to evaluate its generalizability and robustness across a population of patients. Second, instead of fixed band boundaries, some kind of adaptive decomposition may be feasible depending on the type of patient and his illness. Third, it is desirable to employ low-cost devices to implement and deploy the neural model, aiming to emulate clinical environments for epilepsy diagnosis in developing countries.

Evaluating and Interpreting Pooling Techniques in Spectrogram-Based Audio Analysis Using Diverse Metrics

Supun Bandara, Uthayasanker Thayasivam
Department of Computer Science and Engineering
University of Moratuwa, Katubedda, 10400, Sri Lanka

***Abstract*—Audio analysis is a rapidly advancing field that spans various domains, including speech, music, and environmental sound data. Using spectrograms with Convolutional Neural Networks (CNNs) enables the visualization and extraction of critical audio features by combining time-frequency representations with deep learning. Pooling plays a crucial role in this process, as it reduces dimensionality while retaining essential information. However, existing evaluations of pooling methods primarily emphasize downstream task performance, such as classification accuracy, often overlooking their effectiveness in preserving critical signal features. To address this gap, we use 17 distinct metrics, categorized into four domains, to comprehensively assess various pooling operations. Furthermore, we explore the underexamined relationship between specific pooling techniques and their impact on feature retention across diverse audio applications. Our analysis encompasses spectrograms from three audio domains (speech, music, and environmental sound), identifying their key characteristics, and grouping them accordingly. Using this setup, we evaluate the performance of 12 pooling methods across these applications. By investigating the features critical to each task and evaluating how well different pooling techniques preserve them, we give insights into their suitability for specific applications. This work aims to guide researchers in selecting the most appropriate pooling strategies for their applications, enabling more granular evaluations, improving explainability, and thereby advancing the precision and efficiency of audio analysis pipelines.**

***Keywords*—Audio data analysis; pooling; deep learning; dimensionality reduction; spectrograms**

I. Introduction

Audio analysis has become an essential field of study with wide-ranging applications, including audio classification [1], [2], [3], speaker recognition [4], [5], [6], and sound event detection [7], [8], [9], [10], [11]. The ability to accurately process and analyze audio data is crucial for developing systems that can understand and interact with human environments. Over the past few decades, significant advances in machine learning (ML) and deep learning have revolutionized audio analysis, enabling more sophisticated and accurate methodologies.

Feature extraction is a critical step in the analysis of audio signals, where audio signals are transformed into representations that can effectively capture meaningful patterns and features. Over the years, a wide range of techniques have been developed to extract meaningful information from audio data [12]. Time-domain approaches analyze raw waveforms to derive features such as zero-crossing rate and signal energy [12], while frequency-domain methods, including the Fourier Transform [13] and Mel-Frequency Cepstral Coefficients (MFCCs) [14], focus on spectral characteristics. Time-frequency representations, such as spectrograms [15] and chromagrams [16], combine the strengths of both domains, capturing temporal dynamics and spectral content simultaneously. Recent advances in ML have further introduced data-driven methods, such as Convolutional Neural Networks (CNN) [17], Recurrent Neural Networks [18], and transformers [19], which learn task-specific features directly from raw audio or time-frequency representations.

By combining traditional signal processing approaches with advanced deep learning methods, these techniques can enable robust and scalable solutions, driving progress in diverse audio applications and opening the door to innovative research and development. One of those approaches is using spectrograms with CNNs. A significant advantage of using this lies in their ability to harness the strengths of both time-frequency representations and deep learning models [20], [21]. Spectrograms provide a rich and visually interpretable representation that captures both temporal dynamics and spectral patterns of audio signals. CNNs excel at learning hierarchical and spatial features, enabling the identification of complex harmonic structures, frequency modulations, and localized spectral features in the spectrogram. Despite their effectiveness, the integration of spectrograms with CNNs presents challenges due to its high dimensionality, which increases computational demands and memory usage [22]. To address this issue, pooling methods are employed to reduce the dimensionality of spectrograms while preserving essential information. Pooling techniques such as max pooling [1] and average pooling [2] summarize spectral content, thereby improving computational efficiency and enabling the training of deep learning models on large audio datasets.

Traditionally, the effectiveness of pooling methods in audio analysis has been evaluated indirectly using the accuracy of the downstream tasks such as classification [23]. However, this approach may not fully capture how well pooling methods preserve critical features within spectrograms. In this study, we apply 17 evaluation metrics categorized into four distinct groups for evaluating pooling methods used in audio analysis. These metrics can be used to directly assess the ability of pooling methods to preserve critical features and patterns in spectrograms, independent of downstream task results. By focusing on the intrinsic performance of pooling techniques, this approach enables a more granular analysis of their impact on the representation of audio features. Our investigation spans

12 pooling methods, facilitating a standardized comparison of these techniques. This analysis gives insights to identify the pooling methods best suited to specific applications by investigating which audio features should be preserved for specific applications and how well different pooling methods preserve these features. This work provides insights into optimizing the pooling process, helping researchers better understand the features relevant to their applications, and improve accuracy by identifying better pooling methods for their applications. Therefore, it facilitates better model design, improves the explainability of deep audio systems, and supports more informed decisions in the deployment of audio analysis pipelines for real-world applications.

The rest of the study is organized as follows: Section II provides the theoretical background, including a detailed review of pooling methods and evaluation metrics. Section III describes the system architecture. Section IV presents the experimental setup and includes an in-depth spectrogram analysis. Section V outlines the experimental findings across multiple audio domains, highlighting the quantitative performance of various pooling methods, and Section VI interprets the experimental findings, linking observed patterns to the functional demands of each audio task. Section VII concludes the study, highlighting key findings and directions for future work.

II. Theoretical Background

This section outlines the theoretical foundations of spectrogram-based audio analysis, focusing on the characteristics of speech, music, and environmental sounds. It introduces key pooling methods used to reduce spectrogram dimensionality while preserving important features. To assess their effectiveness, we also present evaluation metrics that measure information retention, structural preservation, local detail, and compression, forming a basis for analyzing pooling performance across audio tasks.

A. Local Details and Global Structure of a Spectrogram

Audio signals can generally be categorized into three primary types: speech, music, and environmental sounds [12].

1) Speech: Speech is generated by humans through the combined activity of organs such as the lungs, vocal cords, mouth, nose, and brain. The vocal cords and vocal tract play a crucial role in shaping speech sounds [24]. The frequency range of human speech typically begins at 100 Hz and can extend up to 17 kHz.

2) Music: Musical sounds are created by instruments or the human voice to produce harmony and express emotions. Music can be analyzed based on characteristics such as genre, mood, and tonal quality [25]. Traditional genres include rock, jazz, classical, and pop. The frequency range of music usually falls between 40 Hz and 19.5 kHz.

3) Environmental sounds: The sounds we encounter daily, such as those from vehicles, running water, doorbells, phones, machinery, and animals, are classified as environmental sounds [26]. These sounds often cover the full range of audible frequencies.

Fig. 1 displays the time-domain waveforms of three example sound types: human speech, a guitar note, and a car horn. Speech and music signals exhibit periodicity, whereas environmental sounds generally lack any clear periodic pattern. As shown in Fig. 1, speech signals are typically smooth and continuous, while guitar notes are brief and intermittent. In comparison, sounds such as a fire truck siren appear as noisy signals with high amplitude. Differences between these sounds are also apparent in the time-frequency domain, as illustrated in Fig. 2, which highlights the distinct frequency spectra of each sound type.

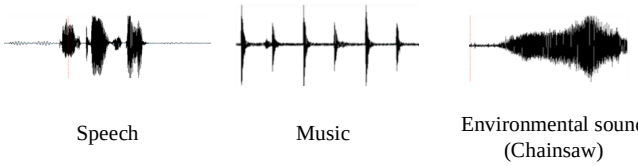

Fig. 1. Time-domain waveforms for speech, music, and environmental sound data.

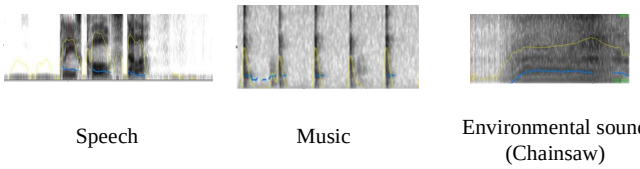

Fig. 2. Time-frequency domain waveforms for speech, music and environmental sound data.

By creating spectrograms for these three audio categories, we can analyze the features that need to be preserved during processing. This analysis is crucial when applying pooling or other transformations to spectrograms, as it helps ensure that the relevant features are retained in the pooled outputs. By analyzing spectrograms, we can determine what features to preserve for different applications. Based on the analysis, these applications can be categorized into two distinct groups: global structure preservation and localized detail retention. This categorization is driven by the need to either retain overall patterns in the spectrogram or emphasize specific localized features.

B. Review of Pooling Methods

Pooling techniques are important to audio analysis, offering a way to condense critical information over time or frequency dimensions. By summarizing features, pooling enhances the robustness of models against variations in speech signals, such as differences in speaking rates, accents, and background noise. This section explores a range of pooling methods, detailing their roles in reducing dimensionality while retaining essential features.

1) Average pooling: Average pooling [2], [27] computes the mean value of elements in a pooling region, and is expressed as in Eq. (1).

$$f_{\text{avg}}(x) = \frac{1}{N} \sum_{i=1}^{N} |x_i| \tag{1}$$

This method smooths feature maps by averaging values, effectively reducing noise. However, since it assigns equal weight to all elements, background regions can dominate, potentially diminishing the model's ability to distinguish between critical and irrelevant features.

2) Max pooling: Max pooling [1], [28], [29] selects the maximum value from a pooling region. Eq. (2) shows how max pooling can be used in a feature map.

$$f_{\max}(x) = \max\{x_i\}_{i=1}^{N} \tag{2}$$

This approach highlights the strongest activations, reducing the influence of background noise and emphasizing prominent features. Despite these advantages, max pooling can overlook subtle but important information and may amplify noisy elements with high values.

3) Min pooling: Min pooling [30] extracts the smallest value in a pooling region, as shown in Eq. (3).

$$f_{\min}(x) = \min\{x_i\}_{i=1}^{N} \tag{3}$$

By focusing on the weakest feature in each region, min pooling suppresses noise and outliers, making it useful in tasks such as anomaly detection. However, it shares limitations with max pooling, such as losing mid-range information and subtle details.

4) Mixed pooling: Mixed pooling [31] combines the strengths of max and average pooling by using a weighted combination as defined in Eq. (4).

$$f_{\text{mixed}}(x) = \alpha \cdot f_{\max}(x) + (1-\alpha) \cdot f_{\text{avg}}(x) \tag{4}$$

The parameter α determines the balance between max and average pooling. For $\alpha = 1$, it behaves as max pooling, and for $\alpha = 0$, it becomes average pooling. Mixed pooling can adapt to different tasks and datasets by capturing both salient features and broader contextual information.

5) Linear softmax pooling: Linear softmax pooling (LSP) [32] assigns weights to features based on their squared values, ensuring prominent features receive higher emphasis, as defined in Eq. (5).

$$f_{LSP} = \frac{\sum_i x_i^2}{\sum_i x_i} \tag{5}$$

where, f_{LSP} represents the output of the softmax function and x_i represents the individual elements of the input vector.

This method is particularly effective in scenarios, where identifying dominant peaks in data distributions is critical, as it balances emphasis on key features while considering all inputs.

6) Exponential softmax pooling: Exponential softmax pooling (ESP) [33] uses an exponential transformation to accentuate differences between input features in accordance with Eq. (6).

$$f_{ESP} = \frac{\sum_i x_i \exp(x_i)}{\sum_i \exp(x_i)} \tag{6}$$

where, $\exp(x_i)$ denotes the exponential function applied to the individual elements x_i in the input vector. By emphasizing higher values, this approach excels in tasks requiring sharp distinctions between features, such as identifying critical events in a data sequence.

7) Learned-norm pooling: As described in Eq. (7), learned-norm pooling (LNP) [34] unifies max and average pooling principles using the p-norm.

$$f_{LNP}^{p}(x) = \left(\frac{1}{n}\sum_{i=1}^{n}|x_i|^p\right)^{1/p} \tag{7}$$

The parameter p, ranging from 1 to infinity, determines the behavior of the pooling. When $p = 1$, it corresponds to mean pooling, while $p \to \infty$ approximates max pooling. LNP provides flexibility in capturing nuanced feature distributions.

8) Log-Sum-Exp pooling: Log-Sum-Exp Pooling(LSEP) [35] offers a smooth interpolation between mean and max pooling. This behavior is captured by Eq. (8).

$$f_{LSEP}^{r}(x) = \frac{1}{r}\log\left(\frac{1}{n}\sum_{i=1}^{n} exp(r \cdot x_i)\right) \tag{8}$$

The parameter r controls the pooling behavior, with $r \to 0$ resembling mean pooling and $r \to \infty$ approximating max pooling.

9) Auto-pooling: Auto-pooling [33] adapts dynamically to data, combining max and average pooling principles as formulated in Eq. (9).

$$f_{auto}^{\alpha} = \frac{\sum_j \mathbf{x}_j \exp(\alpha \mathbf{x}_j)}{\sum_j \exp(\alpha \mathbf{x}_j)} \tag{9}$$

This adaptability is particularly useful in sound event detection, where event duration and intensity vary significantly. Auto-pooling excels in environments with diverse and unpredictable audio patterns.

10) Power pooling: Power pooling [36], [37] introduces a trainable parameter n to adjust frame-level predictions, as defined in Eq. (10).

$$f_{power}^{c} = \frac{\sum_i x_i^f \times (x_i^f)^n}{\sum_i (x_i^f)^n} \tag{10}$$

This method transitions between max and average pooling, making it suitable for applications involving weakly labeled datasets or varying temporal scales.

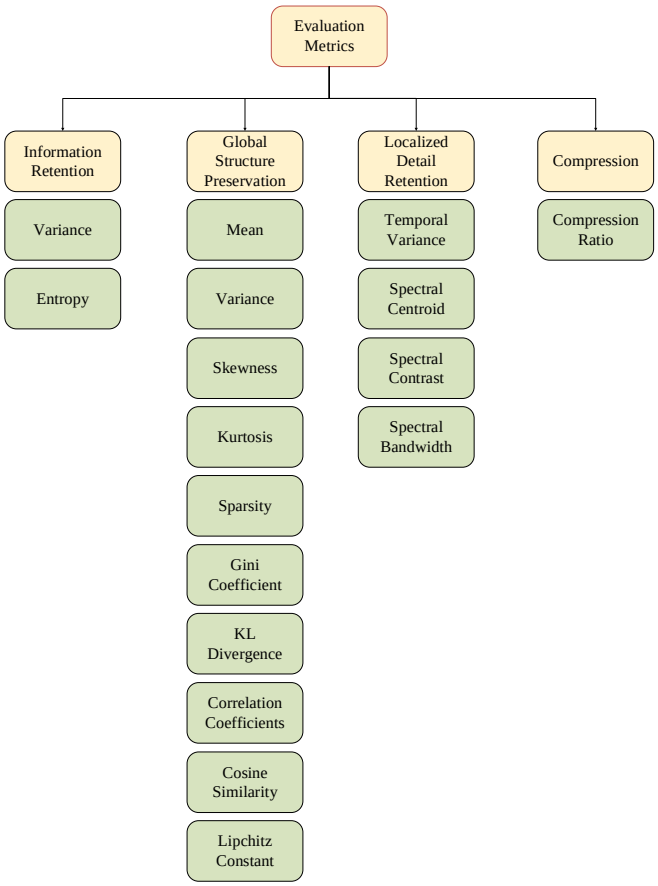

Fig. 3. Types of evaluation metrics categorized based on different usages.

11) Entropy pooling: Entropy pooling [38] selects high-entropy features, ensuring the most informative elements are retained. Eq. (11) demonstrates how entropy pooling works.

$$f_{\text{entr}}(X_r) = X_r[g(P_r)] \tag{11}$$

where, f_{entr} is the entropy-pooled output. By ensuring that the pooled output retains the most informative and least redundant features, entropy pooling reduces redundancy and maintains a more uniform feature distribution, thereby making the model more resilient to noise.

12) Attention pooling: Attention pooling [39], [40], [4], [41], [5], [42] dynamically assigns weights to input features, focusing on the most relevant parts of the audio signal. It uses a learnable weight vector $\mathbf{w}_i$ to emphasize frames critical for the task, creating a weighted average output.

C. Metrics for Evaluating Pooled Spectrograms

We have identified a set of metrics that can be used to evaluate the performance of pooling methods applied to spectrograms. Based on their specific focus, Fig. 3 shows how these metrics can be grouped into four categories: information retention, preservation of global structure, retention of localized details, and dimensionality reduction. These metrics ensure that the pooled spectrograms remain representative of the original data while achieving dimensionality reduction.

1) Information retention: Information retention metrics evaluate whether the pooled spectrogram preserves sufficient variability, complexity, or detail from the original spectrogram. These metrics ensure that pooling does not discard too much essential information.

a) Variance: Variance [43] quantifies the spread of intensity values in the spectrogram. As shown in Eq. (12), it measures how much the intensity values deviate from their mean, representing the variability in the data. In the context of pooled spectrograms, preserving variance ensures that dynamic range and signal variability are maintained. A significant drop in variance after pooling could indicate a loss of essential details, such as transitions or contrasts in intensity.

$$\text{Variance} = \frac{1}{N}\sum_{i=1}^{N}(x_i - \mu)^2 \tag{12}$$

where, x_i is intensity value at pixel i in the spectrogram, μ is mean of all intensity values ($\mu = \frac{1}{N}\sum_{i=1}^{N} x_i$), and N is total number of pixels or intensity values.

b) Entropy: Entropy [44] assesses the complexity or randomness of the spectrogram by evaluating the distribution of intensity values, as given in Eq. (13). Higher entropy indicates a richer or more diverse representation of information. If the entropy of the pooled spectrogram is close to the original, it implies that essential patterns and nuances, such as background noise or intricate harmonic content, are preserved. A decrease in entropy suggests that the pooling operation may have oversimplified the spectrogram, discarding finer details.

$$\text{Entropy} = -\sum_{i=1}^{N} p(x_i)\log p(x_i) \tag{13}$$

where, $p(x_i)$ is the probability of intensity value x_i in the spectrogram, and N is the total number of intensity levels.

2) Global structure preservation: Global structure preservation metrics evaluate whether the structural and temporal patterns of a spectrogram are retained after pooling, which is crucial for applications that rely on macro-level spectrogram features. Pooling reduces the size of a spectrogram, but maintaining these patterns ensures that the essential characteristics remain intact. Several types of pattern preservation metrics can be identified, focusing on aspects such as statistical properties, near-zero values, energy distribution, and similarity measures.

a) Statistical properties: Preserving statistical properties ensures that the overall patterns and distributions in the spectrogram remain consistent after pooling [45]. Key statistical metrics include,

- Mean [45], which represents the average intensity of the spectrogram. Preserving the mean ensures that the global energy level is consistent, reflecting the overall sound intensity. Mean is calculated as in Eq. (14)

$$\text{Mean} = \frac{1}{N}\sum_{i=1}^{N} x_i \tag{14}$$

where, x_i is the intensity value at pixel i, and N is the total number of pixels.

- Variance [45], which captures the spread of intensity values, preserving the variability and dynamic range of the spectrogram.
- Skewness [45], which measures asymmetry in the intensity distribution, as presented in Eq. (15). Maintaining skewness ensures that pooling does not disproportionately favor high-energy or low-energy regions.

$$\text{Skewness} = \frac{\frac{1}{N}\sum_{i=1}^{N}(x_i - \mu)^3}{\sigma^3} \tag{15}$$

where, x_i is the intensity value at pixel i, μ is the mean of intensity values, and σ is the standard deviation ($\sigma = \sqrt{\frac{1}{N}\sum_{i=1}^{N}(x_i - \mu)^2}$).

- Kurtosis [45], which reflects the sharpness or flatness of the intensity distributions, in accordance with Eq. (16). Preserving kurtosis retains critical features such as peaks (high energy areas) or flat regions (low activity areas).

$$\text{Kurtosis} = \frac{\frac{1}{N}\sum_{i=1}^{N}(x_i - \mu)^4}{\sigma^4} \tag{16}$$

where, x_i is the intensity value at pixel i, μ is the mean of intensity values, and σ is the standard deviation. Together, these metrics ensure that the original statistical characteristics of the spectrogram are reflected in the pooled version.

b) Low activity regions: Sparsity [46] refers to the proportion of near-zero or inactive regions in a spectrogram, and retaining it is essential in applications, where silent or low-activity regions convey meaningful information. For instance, in speech recognition, silent gaps or pauses are crucial for segmenting phonemes or words, while in speaker recognition, low-energy regions may contain speaker-specific traits. Pooling methods must preserve these sparse areas to ensure critical contextual information is not lost. Sparsity is calculated as shown in Eq. (17), and sparsity ratio, which is given in Eq. (18), is calculated in our experiments.

$$\text{Sparsity} = \frac{\text{Number of near-zero values}}{\text{Total number of values}} \tag{17}$$

$$\text{Sparsity ratio} = \frac{\text{Sparsity of pooled spectrogram}}{\text{Sparsity of original spectrogram}} \tag{18}$$

c) Energy distribution: The Gini coefficient [47] measures the inequality in intensity distribution across a spectrogram, where a lower value indicates a more uniform distribution and a higher value reflects concentrated energy, such as dominant frequency bands. By comparing the Gini coefficients before and after pooling, it is possible to evaluate whether the pooling process has preserved the energy balance across the spectrogram.

d) Similarity measures: Similarity measures directly compare the pooled spectrogram with the original to ensure that key structural and temporal features are preserved. Some of the similarly metrics which might be useful for evaluating the global structure preservation are as follows:

- Kullback-Leibler (KL) Divergence [48] quantifies the difference between intensity distributions, according to Eq. (19). A lower divergence indicates that the pooled spectrogram closely resembles the original in terms of energy patterns.

$$D_{\text{KL Divergence}}(P|Q) = \sum_{i=1}^{N} p(x_i) \log \frac{p(x_i)}{q(x_i)} \tag{19}$$

where, $p(x_i)$ is the probability distribution before pooling, and $q(x_i)$ is the probability distribution after pooling.

- Correlation Coefficients [49], [50] evaluates the linear relationship between intensity values in the original and pooled spectrograms, ensuring that proportional changes are consistent.
- Cosine Similarity [51] assesses alignment between feature vectors of the original and pooled spectrograms, indicating the degree to which proportional feature retention is achieved, as given in Eq. (20).

$$\text{Cosine Similarity} = \frac{\sum_{i=1}^{N} x_i y_i}{\sqrt{\sum_{i=1}^{N} x_i^2}\sqrt{\sum_{i=1}^{N} y_i^2}} \tag{20}$$

where, x_i is the intensity value in the original spectrogram, and y_i is the intensity value in the pooled spectrogram.

- Lipschitz Continuity [52] ensures that small changes in the original spectrogram correspond to small changes in the pooled spectrogram, preventing distortions that could compromise structural integrity [see Eq. (21)].

$$\|f(x_1) - f(x_2)\| \leq L\|x_1 - x_2\| \tag{21}$$

where, $f(x)$ is the mapping after pooling, and L is the Lipschitz constant.

3) Localized detail retention: Feature-specific metrics assess the retention of localized or detailed aspects of the spectrogram. These are crucial for fine-grained tasks such as instrument identification or event detection.

a) Temporal features: Temporal features [53] focus on intensity fluctuations, transitions, and coherence over time. As shown in Eq. (22), temporal variance is a metric that measures how well time-based variations, such as rhythm or speech patterns, are preserved. Temporal feature retention is vital for applications, where timing and transitions play a critical role, such as in rhythm analysis or speech recognition.

$$\text{Temporal Variance} = \frac{1}{T}\sum_{t=1}^{T}(I_t - \mu_t)^2 \tag{22}$$

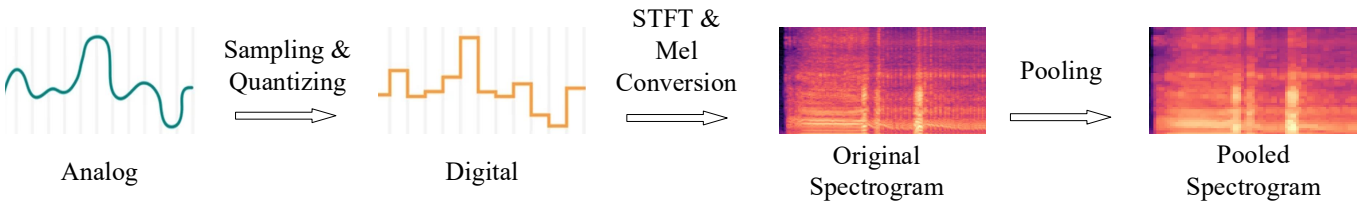

Fig. 4. Illustration of the feature extraction and pooling process of audio analysis applications. Evaluation metrics are used to compare the original and pooled spectrograms.

where, I_t is the intensity at time t, μ_t is the mean intensity over time, and T is the total number of time frames.

b) Spectral features: Spectral metrics evaluate the preservation of frequency-based characteristics. They are calculated as in respective reference papers.

- Spectral Centroid [54]: Represents the "center of mass" of the frequency spectrum, indicating the dominant frequency range. Preserving the spectral centroid ensures that the tonal characteristics remain consistent.
- Spectral Contrast [55]: Captures the differences between peaks and valleys in the frequency spectrum. Retaining spectral contrast ensures the preservation of harmonic content and overall tonal richness.
- Spectral Bandwidth [54]: Measures the spread of frequencies in the spectrum. A high spectral bandwidth indicates a broad frequency range, while a low bandwidth suggests focused frequency content. Preserving bandwidth ensures that the spectral characteristics of the pooled spectrogram match the original.

4) Compression: Compression-focused metrics [56] measure the effectiveness of pooling methods in reducing spectrogram dimensions while preserving essential information. A key metric is the compression ratio, which quantifies the extent of dimensionality reduction and reflects the balance between minimizing size and retaining critical features. The compression ratio is calculated as given in Eq. (23). An effective pooling method achieves this balance by eliminating redundancy without compromising the spectrogram's informational content.

$$\text{Compression Ratio} = \frac{\text{Original size of spectrogram}}{\text{Pooled size of spectrogram}} \tag{23}$$

III. System Architecture

In Fig. 4, the steps used for generating a spectrogram from an audio file are outlined. The process starts with sampling the analog audio signal at a fixed rate of 16 kHz and quantizes the samples into discrete values. The digital signal is divided into overlapping frames, and the Hann windowing function is applied to reduce spectral leakage. Each frame undergoes a Short-Time Fourier Transform (STFT) to convert the time-domain signal into a frequency-domain representation, resulting in a magnitude spectrum. This spectrum is then mapped to the Mel scale to create a mel spectrogram, aligning the frequency bins perceptually. The resulting power spectrogram is converted to a logarithmic scale by normalizing the intensity relative to the maximum value, producing a log-scaled Mel spectrogram suitable for visualization and further analysis. Once the spectrogram is generated from the audio signal, pooling can be applied to the spectrogram itself.

IV. Experiments

A. Experimental Setup

We selected a range of audio classification tasks for our experiments, encompassing all three major audio types: speech, music, and environmental sounds.

1) Speech: Speech Emotion Recognition task is used for the speech data domain. IEMOCAP dataset [57], which contains approximately 10,000 speech utterances labeled with emotions, and focuses on four emotion classes (angry, happy, sad, neutral), is used.

2) Music: For Music Genre Classification, GTZAN dataset [58] is used, which consists of 1000 music excerpts (30 seconds each) spanning 10 musical genres. IMRAS dataset [59] is used for Music Instrument Recognition task.

3) Environmental sounds: Environmental Sound Classification task is used for this domain with ESC-50 dataset [60], which consists of 2000 five-second audio clips in 50 classes. It contains five major categories of animals, natural soundscapes and water sounds, human non-speech sounds, domestic sounds, and exterior sounds, each containing 10 equally balanced classes of sound events.

These datasets were chosen for their standard usage in the respective domains, diversity of audio samples, and relevance to the identification of global versus localized features in spectrogram-based audio analysis. Spectrograms were generated as described in Section III, and analyzed to identify both local and global features. Subsequently, pooling methods described in Section II-B were applied, and the evaluation metrics from Section II-C were used to assess how well each pooling method preserves local and global features. These metrics also help determine which are most effective for measuring feature preservation in spectrogram-based models. Mixed pooling is non-trainable and includes hyperparameters, with its mixing proportion set to a fixed value of 0.5.

B. Analyzing Spectrograms

Spectrograms were generated for each audio type to facilitate visual identification of their characteristic features.

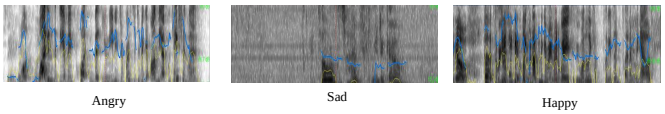

Fig. 5. Voice patterns of the same person with different emotions.

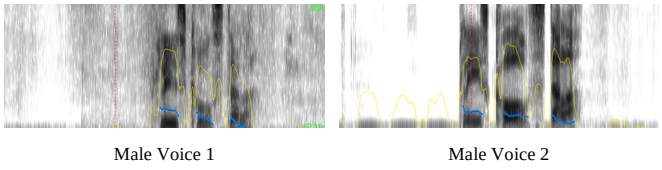

Fig. 6. Voice patterns of different people of same gender talking the same sentence shown in a spectrogram.

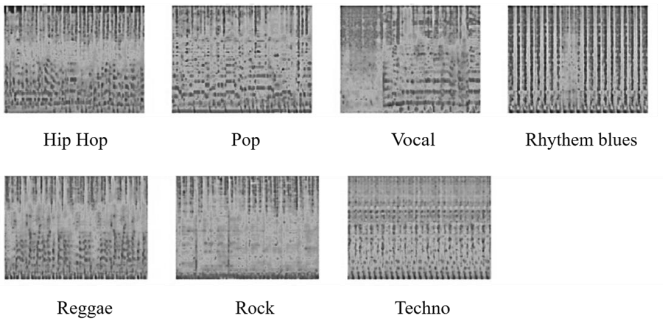

Fig. 8. Spectrogram patterns of different music genres that are used for music genre classification.

1) Speech applications: In speech applications, preserving localized features in the spectrogram is crucial for tasks such as speech emotion recognition, where subtle variations in pitch, intensity, and temporal dynamics carry significant meaning. As shown in Fig. 5, we have identified how these features appear as localized changes in the spectrogram, such as brief intensity surges or shifts in frequency, which are essential for identifying emotional states. For instance, emotions such as anger or happiness are often expressed through louder speech with elevated pitch, while sadness is characterized by softer, flatter intonation patterns. The retention of these intricate features enables a deeper understanding of vocal expressions, making them vital for emotion recognition systems that rely on the nuanced analysis of audio signals.

However, in most speech applications, it is crucial to preserve the overall patterns of the spectrogram. These patterns are influenced by various factors, such as the speaker's unique voice timbre, pitch variations, and speaking style, including how pauses are placed between words. Such variations are particularly significant in speaker recognition tasks, where identifying an individual speaker depends on recognizing unique timbre and consistent frequency patterns over time. For instance, as shown in Fig. 6, two male speakers saying the same sentence exhibit noticeable differences in pauses, frequency patterns, pitch, and intensity variations. Similarly, Fig. 7 highlights the distinctions between male and female speakers for the same sentence. Therefore, it is obvious that when applying pooling, overall patterns of the spectrograms should be preserved in most of the speech applications.

2) Music applications: In music-related tasks, preserving spectrogram patterns is crucial for capturing the intricate details of musical compositions and maintaining audio fea-

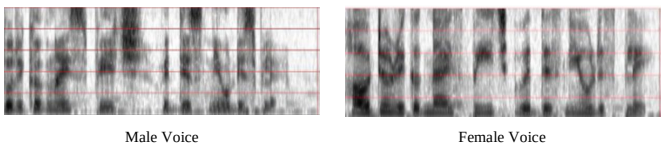

Fig. 7. Voice patterns of male and female voice with the same sentence shown in a spectrogram.

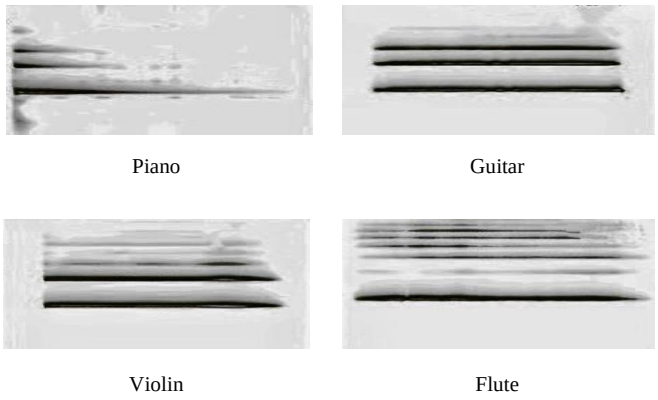

Fig. 9. Spectrogram patterns with different music instruments that is used for music instruments identification.

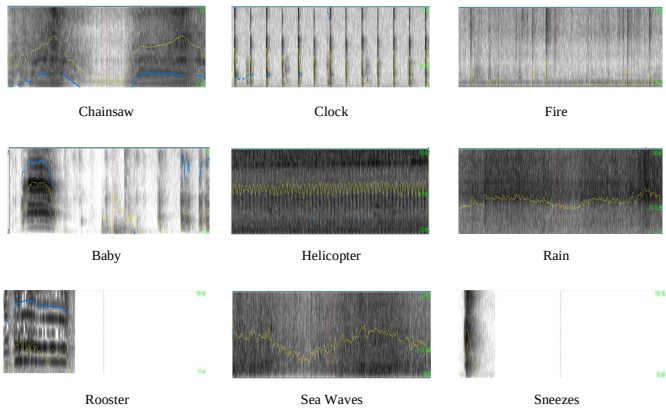

Fig. 10. Spectrogram patterns with different environmental sounds.

tures critical for accurate analysis and classification. We have illustrated in Fig. 8 how different music genres exhibit distinct continuous patterns, which must be preserved to accurately identify those genres. Music genre classification relies on distinguishing broad musical features such as rhythm patterns, harmonic structures, and timbre, each of which reflects unique spectrogram characteristics. Classical music often presents smooth, sustained harmonic patterns, while electronic dance music (EDM) features repetitive beats and sharp intensity changes. These preserved spectrogram features reveal the temporal and spectral patterns necessary for precise classification.

However, as shown in Fig. 9, some music applications such as musical instrument identification depends on preserving timbral qualities, harmonic structures, and frequency ranges unique to each instrument. A piano, for instance, displays evenly spaced horizontal harmonic lines, while a guitar shows richer textures due to its plucked strings. These features, which are often small but distinct, provide critical cues for accurate identification. Additionally, capturing the unique spectral patterns of each instrument, such as the smooth overtones of a violin or the sharp attacks of a drum, is essential for ensuring that their individual characteristics are retained during audio analysis, enabling precise classification in diverse musical contexts.

3) Environmental sound applications: In environmental sound applications, detecting and classifying sounds relies heavily on preserving their distinct temporal and spectral characteristics, which are often brief but highly specific. Environmental sound classification involves recognizing natural sounds such as rain, wind, or traffic noise by retaining their defining spectral features and temporal dynamics such as rain's high-frequency noise bursts or wind's diffuse, broad frequency patterns ensuring these localized elements serve as a foundation for accurate classification. We have highlighted these distinct patterns in Fig. 10 to demonstrate the importance of spectrogram feature preservation in capturing the nuances of various environmental sounds, enabling precise classification across diverse audio tasks.

V. Results

A. General Trends Across Pooling Methods

Across all three domains, several consistent patterns are observed in the behavior of pooling methods. Max pooling consistently preserves the highest variance, mean, skewness, and temporal variance, indicating its strong capacity to retain localized, high-energy features such as transient peaks and short-duration events. While this makes max pooling particularly effective for tasks where such localized features are essential, it often results in the loss of broader structural coherence, as seen in its comparatively lower cosine similarity and correlation coefficients. In contrast, average pooling demonstrates reliable global structure preservation across all datasets. It maintains constant mean retention, cosine similarity, and correlation coefficients, suggesting that it effectively captures the general shape of spectrograms while smoothing out noise and minor variations. This makes average pooling especially suitable for tasks where the continuity of harmonic or rhythmic patterns is more critical than localized precision.

Entropy pooling and ESP consistently exhibit the highest entropy and kurtosis values, reflecting their ability to capture a wide diversity of information. However, these methods simultaneously suffer from poor performance in structure-preserving metrics such as correlation, Lipschitz continuity, and temporal variance, indicating that they degrade interpretability and coherence. This trade-off suggests that while entropy-based methods may retain information richness, they do so at the expense of structural and temporal fidelity.

Auto pooling, mixed pooling, and LSEP emerge as the most balanced approaches. These methods perform well across a broad range of metrics, combining moderate-to-high variance preservation with strong similarity and temporal coherence. Their capacity to retain both global structures and localized features renders them especially well-suited to tasks that require a blend of both information types. Notably, similarity metrics such as cosine similarity and KL divergence show relatively little variation across pooling methods, suggesting that while useful for general alignment assessment, these metrics are less effective for differentiating nuanced pooling behavior compared to statistical or spectro-temporal measures.

B. Task-Specific Observations

1) Speech emotion classification: Speech emotion classification is primarily a localized feature-dependent task. Emotional states are conveyed through subtle and transient modulations in pitch, intensity, and timing, which necessitate the preservation of fine-grained temporal and spectral features. As shown in Table I, max pooling is notably effective in this domain, producing the highest variance (1.1031) and skewness, and excelling in capturing rapid vocal changes associated with expressive emotions such as anger or surprise. However, its emphasis on energetic extremes may occasionally overamplify variations, leading to potential imbalances in emotion recognition.

2) Music genre classification: In music genre classification, the primary analytical focus lies in preserving global spectro-temporal structures such as rhythm, harmony, and tonal balance across longer time scales. As shown in Table II, average pooling consistently performs well in this domain, achieving high mean preservation (0.9988), cosine similarity (0.9922), and correlation (0.9854), making it effective for capturing the overarching structure of musical compositions, particularly in genres characterized by smooth and continuous transitions (e.g., classical, ambient).

3) Environmental sound classification: While environmental sound classification relies on both global and local feature preservation, it primarily depends on local features. Audio scenes in this domain frequently combine ambient background noise with short, high-intensity acoustic events. Table III shows that the effectiveness of max pooling in ESC is evident from its superior variance (1.0477) and temporal variance (1.00), confirming its utility in capturing brief, salient events such as alarms or door slams. However, average pooling also plays a vital role, achieving the highest cosine similarity (0.9876) and correlation coefficient (0.9812), indicating that it effectively preserves background structure and overall scene continuity.

VI. DISCUSSION

By looking at the spectrogram analysis in Section IV-B and results in Section V, we can identify some important points. The relationship between the effectiveness of pooling methods and the type of audio task becomes particularly evident when comparing the results across the above datasets. As we identified in Section IV-B, speech emotion classification [61] is predominantly a local-detail-driven task. Emotional expression in speech is often encoded in short-term fluctuations and nuanced changes in tone, pitch, and duration. Pooling methods that preserve such transient dynamics, particularly max, auto, and LSEP pooling, are better suited to this domain. Music genre classification [62], by contrast, places the highest emphasis on global structure preservation. The ability to maintain continuity in tonal progression, harmonic layering, and rhythmic patterns is vital for distinguishing among musical genres. Here, pooling strategies such as average, auto, and LSEP pooling that prioritize smoothness and structural fidelity outperform those that emphasize localized variance. Environmental sound classification [63] stands out as a domain that requires a balanced approach to both local and global feature retention. The simultaneous need to detect transient events and maintain scene-level continuity necessitates pooling methods that can handle both aspects effectively, such as auto, mixed,

and LSEP pooling.

Therefore, when applying pooling in all types of audio applications, it is important to look at the global structure preservation and local detail retention of the pooling methods. In global structure preservation, the primary focus is to retain the overall structure and temporal patterns of the spectrogram. This is particularly relevant in applications, where the recognition of broad patterns or sequences is critical for identifying or classifying audio signals. Localized Detail Retention focuses on retaining localized and distinctive patterns within the spectrogram that are critical for identifying or classifying audio signals. Unlike global patterns, these features are often small and transient but hold significant importance for understanding the finer details of audio characteristics. Beyond merely retaining these features, it is important to evaluate how transformations affect their clarity and interpretability. Overly aggressive pooling can blur critical details, diminishing the spectrogram's discriminative power for downstream tasks. Conversely, pooling methods that balance dimensionality reduction with effective feature retention can improve computational efficiency without compromising performance. The effectiveness of pooling should therefore be assessed in the context of the specific application. Comparative analyses of pooling methods can shed light on their strengths and limitations, ensuring that the preserved spectrogram features align with the requirements of the intended task. This alignment is essential for optimizing accuracy, performance, and robustness in audio analysis applications.

VII. Conclusion

This study presents a comprehensive evaluation of pooling techniques in audio analysis, focusing on their roles in global structure preservation and localized detail retention within spectrograms. By introducing diverse evaluation metrics across four domains this research uncovered the nuanced strengths and limitations of twelve pooling methods. The findings highlight the critical importance of selecting pooling techniques based on task-specific requirements. Max pooling demonstrates effectiveness in capturing localized features essential for tasks such as emotion recognition and transient event detection. In contrast, average pooling excels at preserving global patterns vital for applications such as music genre classification and acoustic scene analysis. Entropy pooling, with its ability to retain diverse and intricate information, emerges as particularly suitable for complex audio tasks. In order to map the use of pooling methods into audio applications, this study categorizes audio applications into two primary focuses, global structure preservation and localized detail retention based on its characteristics. This categorization provides a practical framework for aligning pooling strategies with specific application needs. Beyond task-specific insights, the study emphasizes the importance of innovative evaluation metrics, such as variance, entropy, sparsity, and similarity measures, in assessing pooling methods. These metrics shift the focus from traditional downstream task accuracy to the ability of pooling techniques to preserve critical spectrogram features. In this study, the most important evaluation metrics are evaluated to identify which metrics are more critical in feature extraction. In the future, the development of more adaptive and hybrid pooling techniques holds promise for achieving an ideal balance between global structure preservation and localized feature retention. Furthermore, integrating pooling methods with advanced neural architectures and self-supervised learning frameworks offers significant potential to advance audio analysis systems.

Recommendation Engine for Amazon Magazine Subscriptions

Sushil Khairnar[1], Deep Bodra[2]
Virginia Tech, Blacksburg, USA[1]
Harrisburg University of Science and Technology, USA[2]

***Abstract*—Recommender systems play a crucial role in enhancing user experience and engagement on e-commerce platforms by suggesting relevant products based on user behavior. In the context of Amazon's extensive catalog of over 8,000 magazines spanning more than twenty-five categories, providing personalized magazine subscription recommendations poses a significant challenge. This study addresses the problem of identifying potential future associations between magazine reviewers and products using a graph-based approach. Specifically, we aim to predict unseen but likely links between users and magazines to improve recommendation quality. To achieve this, we construct an undirected bipartite network connecting reviewers and magazine products based on review data. We perform network analysis using measures such as centrality, modularity, and clustering, and apply sentiment analysis and topic modeling to extract behavioral and thematic insights from user reviews. These insights inform a series of link prediction techniques including Common Neighbors, Adamic-Adar, Jaccard Coefficient, and Preferential Attachment evaluated using cross-validation and ROC curves. Our results show that the Preferential Attachment model outperforms other approaches, attributed to the skewed degree distribution inherent in the dataset's structure.**

***Keywords*—Sentiment analysis; topic modeling; recommender system; link prediction**

I. Introduction

A recommendation system is a data filtering system that generates data predictions based on user data linked with the item. Both merchants and consumers benefit from recommendation systems in internet marketing. On the one hand, recommendation algorithms are employed by sellers in order to maintain high levels of user engagement. Consumers, on the other hand, benefit from recommendation systems because they can quickly find what they're looking for. For example, Amazon suggests products to consumers based on their past purchases to encourage future purchases, while news websites suggest related content to viewers to optimize ad revenue. These businesses rely significantly on recommendation systems to improve user experience.

Both service providers and users benefit from recommender systems. Users are able to lower the resource consumption and expenses of searching for and selecting the right things to buy in an online environment. Also, service providers reduce the cost of marketing large amount of products to large user base. If a person enjoys reading scientific periodicals, he or she might be interested in reading magazines about scientific research. Recommendation systems can help them find related products and improve the quality of their decisions. Recommender systems increase revenue in an e-commerce scenario since they are efficient at selling more things. Recommender systems in scientific libraries assist users by allowing them to go beyond catalog searches. In addition to this, indirect connections between the users can be identified to recommend the products purchased by one user to another user. As a result, the importance of employing efficient and accurate recommendation algorithms inside a system that provides consumers with relevant and dependable recommendations cannot be overstated.

Many e-commerce companies offer a diverse selection of products to their customers. Providing users with the most suited items makes the purchasing process more efficient and boosting user happiness. Improved customer happiness keeps users coming back to the website, increasing sales and profitability for products. As a result, more companies are beginning to recommend products to customers, necessitating the efficient analysis of user product interests. Standard recommendation algorithms, such as content-based filtering and collaborative filtering, use a matrix to model user ratings and anticipate customer ratings for unrated goods based on user/item similarity.

In the context of Amazon's magazine subscription platform, which features more than 8,000 magazines across over twenty-five categories, recommending personalized content is particularly challenging due to the diversity and volume of data. This study focuses on addressing the following research question: How can a graph-based recommendation system leveraging user reviews, sentiment analysis, and topic modeling improve the prediction of potential future links between reviewers and magazine subscriptions?

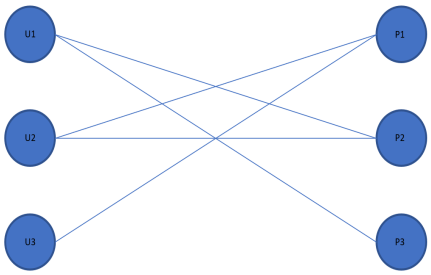

Fig. 1. Bipartite network.

To answer this question, we build a bipartite network (Fig. 1) between users and products using Amazon review data and explore the utility of various link prediction algorithms in identifying new recommendations. We incorporate techniques such as sentiment analysis to assess review polarity, and topic

modeling to identify key themes in user preferences. These components help enrich the graph and guide the recommendation process.

The main contributions of this study are as follows:

- We construct and analyze a large-scale bipartite graph between Amazon reviewers and magazines based on review data.
- Integrate sentiment analysis and topic modeling to extract contextual and thematic features from textual reviews.
- Apply and compare multiple link prediction methods Common Neighbors, Adamic-Adar, Jaccard Coefficient, and Preferential Attachment—to identify potential reviewer-magazine associations.
- Evaluate the performance of these models using ROC-AUC and demonstrate that the Preferential Attachment model yields superior results due to the skewed degree distribution in the network.

The implications of this work lie in enhancing personalized recommendation engines for online subscriptions and providing a scalable framework for integrating behavioral and semantic data in graph-based recommender systems.
The rest of the study is organized as follows: Section II reviews the related work. Section III details the methodology, including network construction, sentiment analysis, and topic modeling. Section IV presents experimental results and analysis. Section V presents the discussion of the study. Section VI concludes the study and discusses possible directions for future work.

II. Background and Related Work

Recommender systems have significantly improved user engagement and satisfaction on e-commerce platforms. Particularly, graph-based methods have become prominent for modeling user-product interactions as networks. Li et al. explored the efficacy of bipartite graphs for recommendations, demonstrating their superiority over conventional collaborative filtering. Similarly, Zhang and Chen highlighted the potential of network centrality and clustering to deliver explainable recommendations, enhancing user trust and transparency.

Link prediction is a core component of graph-based recommendations, providing insights into potential future interactions within networks. The foundational works by Adamic and Adar [1], Liben-Nowell and Kleinberg [8], Newman [11], and Barabási et al. [2] introduced seminal link prediction approaches including Common Neighbors, Adamic-Adar, Jaccard Coefficient, and Preferential Attachment. Preferential Attachment, in particular, emphasizes that nodes with higher degrees are likelier to form new connections, a concept strongly relevant to real-world scale-free networks.

Incorporating textual data through sentiment analysis and topic modeling has further enriched recommender systems. Pak and Paroubek [20] leveraged sentiment analysis to refine recommendations based on user-generated textual feedback. Additionally, Blei et al. introduced Latent Dirichlet Allocation (LDA) for topic modeling, enabling a more nuanced understanding of user interests through thematic analysis of reviews. McAuley et al. extended these techniques, combining textual and visual features to enhance the contextual relevance of recommendations.

Parallel to recommender system advancements, significant research has been conducted in predictive analytics within other application domains, such as air traffic delay prediction. Flight delays have been a persistent issue, with only 79.63% of flights landing on time over the past decade, according to the Bureau of Transportation Statistics (BTS). Ye's study employed multiple machine learning models (Linear Regression, SVM, ExtraRT, and LightGBM) to forecast flight departure delays at Nanjing Lukou International Airport, identifying critical relationships between meteorological factors and delays [6]. Similarly, Atlioglu [1] analyzed flight operational data using diverse machine learning methods, emphasizing the importance of data selection for accurate delay prediction.

Esmaeilzadeh and Mokhtarimousavi utilized Support Vector Machine (SVM) analysis to examine air traffic delays at major airports in New York City, focusing on operational and flow management factors [3]. Xu et al. [5] applied Bayesian networks for modeling delay propagation across airports, providing insights into the systemic nature of delay spread through an empirically informed Bayesian approach. Bratu and Barnhart [2] introduced the Passenger Delay Calculator, shifting focus from aircraft-centric to passenger-centric delay analysis, thus providing a more nuanced understanding of the impact of delays. Kim and Choi [4] proposed advanced deep-learning models, including deep RNN architectures, for predicting delays with greater accuracy, emphasizing the efficacy of neural networks in capturing complex temporal patterns in delay data [9].

While the application domains of recommender systems and air traffic delay prediction differ substantially, methodologies such as machine learning, sentiment analysis, and data-driven modeling are common threads linking these fields. Our research leverages these interdisciplinary insights, employing advanced analytical techniques such as sentiment analysis, topic modeling, and graph-based link prediction methods to provide personalized magazine recommendations on Amazon. This integrated approach not only enhances recommendation quality but also demonstrates the adaptability and robustness of predictive methodologies across diverse contexts.

III. Approach

We analyze the dataset for amazon magazine subscriptions which contain the data about magazines subscribed by a certain user and reviews written for the particular magazine. We generate a bipartite graph using the reviewerID and ProductID as the two independent sets of vertices [13]. This is a bipartite graph because the edges are between the reviewerID and productID and no edges from and to the same set. Once the graph is generated, we perform network analysis which involves centrality analysis, modularity analysis, finding connected components, small world network analysis and heavy tail analysis. This analysis supplies crucial insights about the graph. After the network analysis, we perform sentiment analysis to capture the sentiment of the reviewers in relation to that productID. This step gives us insights about the relevance of the edges while conducting link prediction. We then perform topic modeling to

capture the group of topics the reviewer is discussing about. We select the highest-ranked reviewer Id and apply topic modeling to the reviews written by that user. Following that, we apply link prediction to find a link between the reviewer and the products with which aim we recommend magazines to users.

A. Network Analysis

The use of networks and graph theory to investigate group structures is known as network analysis [14]. It describes networked structures in terms of nodes, which can be individual actors, people, or items inside the network, and the ties, edges, or connections that connect them, as well as the relationships and interactions that exist between them. It aids us in comprehending the structure of a relationship in social networks, as well as a structure or change process in natural phenomena. Identifying the critical node in a network is an important application of network analysis. This task is called Network Centrality measurement. It can relate to the task of determining the most influential person or the group's representative in social network analysis. We make use of the networkx [10] library in the python to capture the insights about the network. Fig. 2 presents the Gephi visualization.

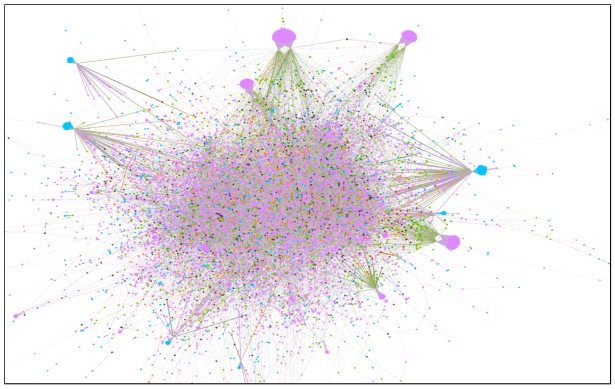

Fig. 2. Gephi visualization.

B. Sentiment Analysis

Sentiment Analysis, also known as opinion mining, is the computational study of opinions, sentiments, subjectivity, or evaluations. It is widely used across domains such as market research, public relations, reputation management, financial trading, and customer experience analysis. By examining the polarity (positive, negative, or neutral) of user-generated text, sentiment analysis helps organizations understand public perception and detect shifts in opinion.

In our study, sentiment analysis was used to determine the tone of user reviews and to assess whether sentiment polarity could improve link prediction performance. Specifically, each review was analyzed to extract a sentiment score, which we considered as a potential weight on the edge between a reviewer and a product in the bipartite graph.

To prepare the text for sentiment analysis, we applied a multi-step preprocessing pipeline: we used regular expressions to remove links and special characters, eliminated stop words using the NLTK corpus, and performed stemming using the Porter Stemmer [15]. These steps ensured that irrelevant tokens and variations of the same word did not distort sentiment scores. We used the VADER sentiment analyzer, which outputs a compound score between -1 (most negative) and +1 (most positive). These scores were mapped onto a 3-class label system (positive, neutral, negative) using VADER's default thresholds. Although we initially considered using these scores as edge weights in the graph for weighted link prediction, the review distribution was heavily skewed: out of 88,318 edges, only 2.8% were negative. This imbalance would have led to biased edge weighting and diminished performance in graph-based models. Therefore, we opted not to use sentiment scores as weights, instead using an unweighted graph for better generalizability and efficiency.

C. Topic Modeling

Topic modeling is a powerful text mining technique used to uncover hidden thematic structures in a corpus. It is especially useful in organizing and summarizing large collections of unstructured text data. We employed Latent Dirichlet Allocation (LDA), a widely adopted probabilistic model that represents each document as a mixture of topics and each topic as a distribution over words. For our study, we applied topic modeling to the set of reviews written by the most active reviewer in the dataset. This helped us gain insights into the types of content that frequent reviewers engage with, which in turn aids in better personalization for recommendations [17]. We selected four topics for the LDA model based on empirical evaluation using coherence scores, which measure the semantic consistency of words within a topic. We evaluated topic numbers ranging from 3 to 7 and found that k=4 yielded the highest coherence score (0.51), indicating that four topics offered a good balance between granularity and interpretability. The topics identified included themes such as food and travel, business and income, technology and education, and writing and products, reflecting the diverse interests of the reviewer. This thematic categorization allowed us to associate reviewers with topic clusters, which could be used for finer-grained recommendation strategies beyond graph-based link prediction.

IV. Experiment

A. Data Analysis

The analysis was conducted using the Amazon magazine subscription dataset. The provided dataset contains data about amazon magazine subscriptions, publications subscribed by a certain user (reviewerID), and reviews published for that magazine (reviewText). The overall score ranges from 0 (worst) to 5 (excellent) (best). Amazon assigns a unique identifying number (Asin) to each magazine. The data set has a total of 89,689 rows, with a total of 72098 distinct reviewers and 2428 unique Asin's.

Features:

- Overall - States the user rating of the product
- Vote - Total votes/ratings given
- Verified - Is the user verified
- reviewTime - Time at which the product was reviewed
- reviewerID - Unique ID of the reviewer

- Asin - Amazon Standard Identification Number (Product ID)
- reviewerName - Name of the review
- reviewText - product review written by the user
- Summary - summary of the user review
- unixReviewTime - timestamp of the review

The bipartite graph was subjected to network analysis, and key parameters such as density, connected components, and clustering coefficient were computed. Below describes a more detailed investigation of network.

B. Preprocessing

Prior to analysis, the dataset underwent several preprocessing steps to ensure data quality and suitability for graph construction and text-based modeling. The original dataset contained 89,689 records. After preprocessing, a total of 88,318 valid review entries remained, which were used for graph construction. The following preprocessing steps were performed:

- Text Cleaning: URLs, HTML tags, special characters, and excessive whitespace were removed using regular expressions.
- Stop Word Removal: Common English stop words were removed using the NLTK stopword corpus.
- Lowercasing: All review text was converted to lowercase to maintain consistency.
- Stemming: Words were reduced to their base/root form using the Porter Stemmer to normalize vocabulary.
- Filtering Empty Reviews: Reviews with fewer than 10 characters after cleaning were discarded.
- Verified Purchases: Only reviews from verified purchasers were retained to improve reliability.
- Reviewer Filtering: For topic modeling, we selected the reviewer with the highest number of reviews, filtering the dataset to just their entries, resulting in 146 reviews for that user.

The remaining dataset was then used to build a bipartite graph between reviewerID and Asin, where each edge represents a review. This cleaned and filtered dataset formed the basis for subsequent network, sentiment, and topic modeling analyses.

C. Graph Analysis

The strength and direction of links between nodes in a graph are determined via graph analysis. The graph analysis in this study began with determining the density and average clustering coefficient of the graph [18]. The centrality analysis was then performed, which determined how essential a node or edge is for the network's connectedness or information flow. The graph's maximum centrality was found to be 0.023. Fig. 3 shows the basic graph analysis.

Following that, small world network identification and heavy tail analysis were performed. Fig. 4 shows the result of the small world network analysis. The modularity analysis was then used to determine how thick the network's connections are. The optimal partition's modularity was found to be 0.8767 and Fig. 5 reflects the outcome.

```
Number of nodes in graph:  74526
Number of edges: 88318
Density:  3.180309778081496e-05
Number of connected components in graph: 798
Longest Component length : 71272
Maximum Degree Centrality of the graph:  0.02302583025830258
Node with maximum degree centrality:  B00005NIOH
```

Fig. 3. Basic graph analysis.

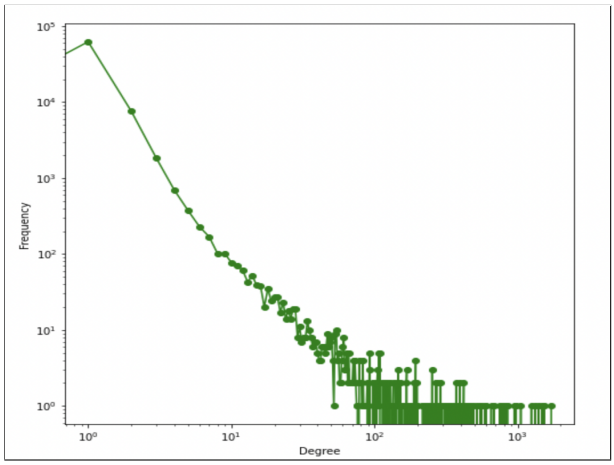

Fig. 4. Small world network analysis.

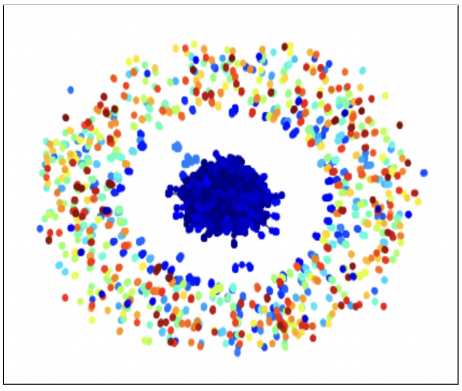

Fig. 5. Modularity plot for the best partition.

D. Topic Modeling

A user with the maximum number of Amazon magazine reviews was chosen for the purpose of topic modeling. The data of reviewers with the most reviews was sorted, and the reviewerID with the most reviews was chosen. The data list that was utilized to select the user is shown in Fig. 6.

```
reviewerID,0
A3JPFWKS83R49V,55
A2OTUWUSH49XIN,26
AEMZRE6QYVQBS,25
A3GA09FYFKL4EY,24
A3R7MXVQRGGIQ9,22
A30H2335OM7RD6,22
A1RPTVW5VEOSI,21

AVF9FV7AMRP5C,20
A2H3JURQZOHVMB,20
A2O6SU5YDVSDN4,19
A3FVAWZNKW9GX,19
AA14AMM03HMXW,19
```

Fig. 6. List of reviewers with maximum reviews.

Topic modeling was performed on the user (A3JPFWKS83R49V) with the most reviews. We filtered the dataset to capture the reviews written by the most active reviewer. We used Latent Dirichlet allocation (LDA) [6] method for fitting a topic model. This technique treats each document as a mixture of topics, and each topic as a mixture of words. The function parameters to the LDA model - the number of topics and number of words were set to four. Fig. 7 depicts the outcome of the topic modeling. Words like home, food, travel, and life appear in the first topic, implying that the user reviewed more about food and travel. The words business and income appeared in the second topic, writing product appeared in the third, and technology and education appeared in the fourth. This implies that the reviewer is a voracious reader and actively evaluates magazines about these subjects.

```

 (1, '0.050*"business" + 0.038*"ads" + 0.033*"monthly" + 0.023*"small"'),
 (2, '0.035*"writers" + 0.032*"writing" + 0.024*"tips" + 0.018*"products"'),
 (3,
  '0.031*"technology" + 0.027*"popular" + 0.019*"educational" + 0.019*"reviews"')]
```

Fig. 7. Result of topic modeling on user with maximum reviews.

E. Sentiment Analysis

Out of 88318 edges or reviews, we only got 2567 (2.8 %) (see Fig. 8) negative reviews, the rest were either positive or neutral . In our case, an edge with weight as the sentiment score represents the relation between the reviewer and the product. An edge with positive sentiment score should indicate that the user praised the product and other users having common properties to that user should get recommendation of the product.

However, as observed from the Fig. 8, the number of positive, negative, and neutral reviews are very skewed. This indicates that, when it comes to magazine subscriptions, people do not tend to write negatively about them. Neutral edges can also be considered harmless to link prediction as these are most likely stating facts that summarize what is published in the magazine [18]. Considering these findings, sentiment analysis was effective in deciding not to use the sentiment scores for weighing the graph due to the skewed distribution and high complexity of bipartite weighted graph.

F. Link Prediction

In the realm of graphs and networks, link prediction is one of the most important research areas. The goal of link prediction is to find node pairs that will establish a link in the future. The simplest link prediction metrics are similarity-based metrics, which produce a similarity score for each pair x and y. The structural or node properties of the considered pair are used to calculate the score S(x,y). The non-observed linkages are given scores based on how similar they are. The anticipated link between two nodes is represented by the pair with the highest score. In the study [19], the authors details that the structural attribute of the network is one of the properties that may be used to determine the similarity measures between each pair. Local and global scores, node-dependent and path-dependent scores, parameter-dependent and parameter-free scores, and so on can all be categorized using this feature.

1) Common neighbors: The size of common neighbors [11] for a given pair of nodes is determined as the intersection of the two node neighborhoods in a particular network or graph.

$$S(x, y) = |\Gamma(x) \cap \Gamma(y)|$$

where, $\Gamma(x), \Gamma(y)$ are neighbors of the node x and y respectively. With the number of shared neighbors between

them, the likelihood of a link between x and y increases. Newman estimated this quantity in a collaboration network and showed that the likelihood of collaboration between two nodes is determined by their shared neighbors. In a large social network, Kossinets and Watts [7] found that two students who have a lot of similar friends are more likely to be friends. The common neighbor method has been found to outperform other complex methods on most real-world networks. On applying this technique to the amazon dataset, we found the Area under the curve to be 0.65. Fig. 10 shows the ROC curve for the same.

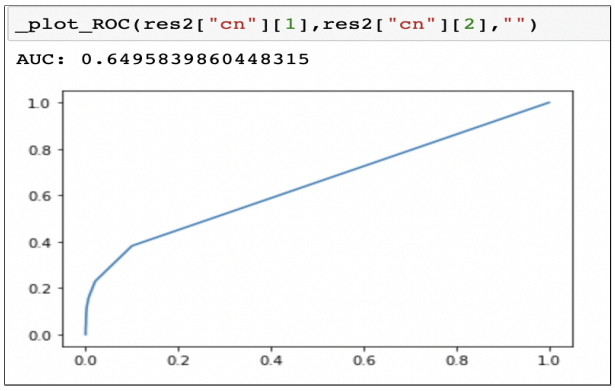

Fig. 10. ROC curve for common neighbors algorithm.

2) Adamic-Adar: Adamic and Adar[1] proposed a measure for calculating a similarity score between two web pages based on shared traits, which Liben-Nowell et al. modified and employed in link prediction.

$$S(x,y) = \sum 1/log(k_z) z \in \Gamma(x) \cap \Gamma(y)$$

where, k_z denotes the node z's degree. The equation clearly shows that the common neighbors with lower degrees are given more weight. This is also intuitive in the real world; for example, a person with a larger number of friends spends less time or resource on a single friend than someone with fewer friends[16]. On applying this technique to the dataset, we found the area under the curve to be 0.65, which is comparable to the results of Common Neighbors. Fig. 11 shows the ROC curve for the same.

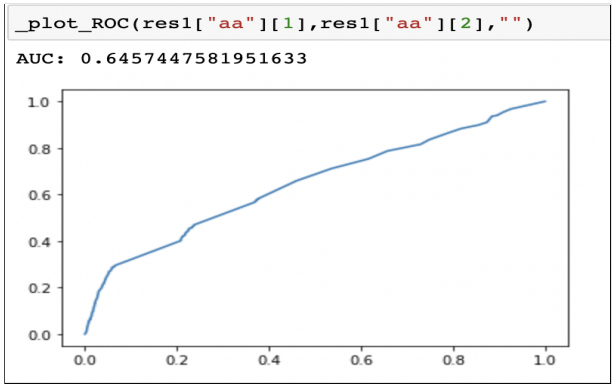

Fig. 11. ROC curve for Adamic-Adar algorithm.

3) Preferential attachment: In this study [2], to create a growing scale-free network, the concept of preferential attachment is used. The phrase "growing" refers to the progressive nature of nodes in a network over time. The likelihood of adding a new link to a node x is related to k_x, the node's degree. The preferential attachment score between two nodes, x and y can be calculated using the formula:

$$S(x,y) = k_x.k_y$$

The key advantages of this metric are its simplicity (since it takes the least amount of information for score calculation) and computing time. It can also be employed in a non-local setting because it simply requires degree as information rather than common neighbors. The PA's effectiveness improves in assortative networks, while it deteriorates in disassortative networks. In other words, if greater degree nodes are densely connected and smaller degree nodes are rarely connected, PA produces superior outcomes. Hasan et al. [5] demonstrated that aggregation functions (e.g., sum, multiplication, etc.) over feature values of vertices might be used to compute link feature value in a supervised learning framework. Fig. 12 presents the ROC curve for Preferential Attachment algorithm.

Summation can be used instead of multiplication as an aggregate function in the preceding equation, and it has been proven to be highly effective. In [5], the authors show that preferential attachment combined with the aggregate function "sum" works effectively for link prediction in co-authorship networks.

Compared to other methods, we got better results for Preferential Attachment model because of the nature of the graph. Degree distribution (Fig. 14) shows that more than half of the nodes are having degree equal to two. Additionally, as observed, very few number of nodes have high degree. Fig. 13 shows that there are some nodes in the network to which many nodes having lesser degree are attached. This situation favors the Preferential Attachment model yielding better results than other models.

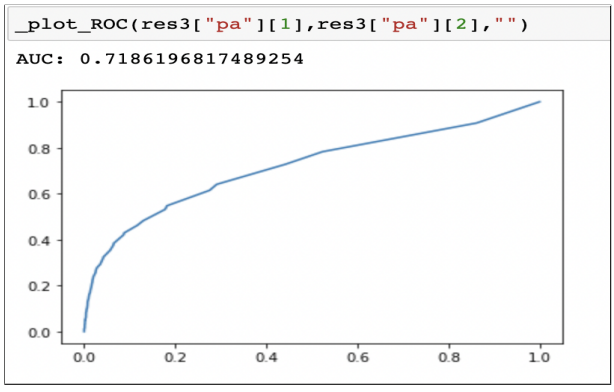

Fig. 12. ROC curve for preferential attachment algorithm.

4) Jaccard Coefficient: This [12] metric is similar to the common neighbor. Additionally, it normalizes the above score, as given below.

$$S(x,y) = |\Gamma(x) \cap \Gamma(y)| \div \Gamma(x) \cup \Gamma(y)|$$

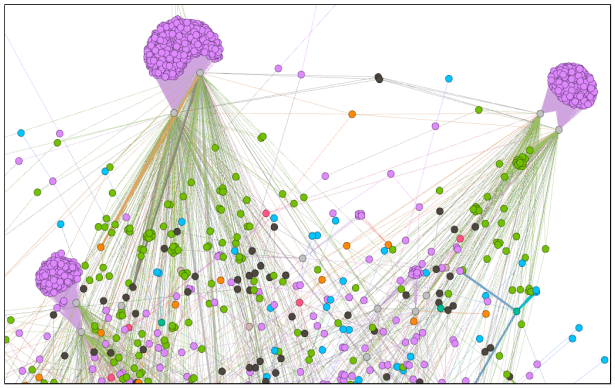

Fig. 13. Gephi visualisation - graph component where the reviewer has written 2 or more reviews.

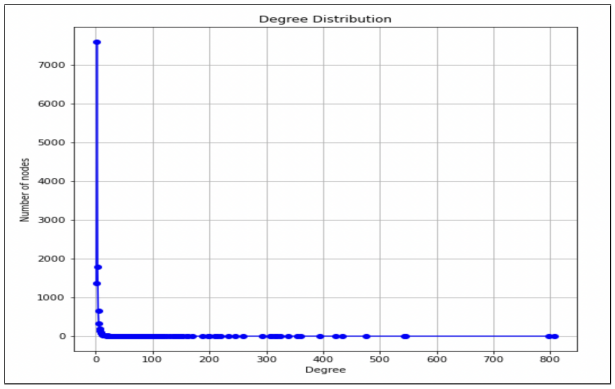

Fig. 14. Degree distribution of the graph.

The probability of choosing common neighbors of paired vertices from all the neighbors of either vertex is described by the Jaccard coefficient. The number of shared neighbors between the two vertices being analyzed improves the pairwise Jaccard score. This similarity metric performs worse than Common Neighbors, as proved by Liben-Nowell et al.[8]. Jaccard Coefficient algorithm performs the worst amongst all algorithms. As observed in Fig. 15, the area under the curve for this technique is 0.57.

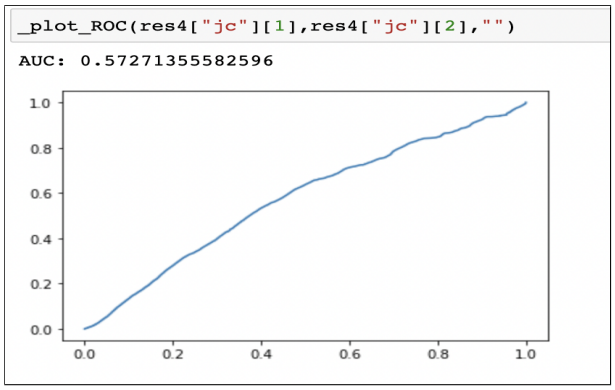

Fig. 15. ROC curve for jaccard coefficient algorithm.

The results in Fig. 16 shows the links obtained using the Preferential Attachment algorithm. As observed, the results indicate the possible links between the reviewer and the productID along with the Preferential attachment score for reviewer and the product. The score indicates how likely it is to establish a link between the two.

```

Fig. 16. Predictions for preferential attachment algorithm.

5) Other Methods: We tried link prediction with the graph distance method, which uses the shortest path length between nodes without an edge. The shortest path lengths are then sorted in ascending order, with the top "K" edges designated as future links. With the help of sentiment scores, we changed our bipartite network into a weighted graph. The edges are weighted using the compound score indicated in the Fig. 9, are used as weights of the edges. To prevent negative weights, these scores were transformed to a range of 0 to 2. Then, to find out the edges which do not exist, it was required to iterate the network of nearly 28000 edges in a quadratic time complexity. Every iteration also included time-consuming processes like identifying the shortest path length. The anticipated time it would take to run this algorithm on the network was roughly 100 days [20]. As a result, the weighted graph and shortest path length method was avoided.

Approaches like user-based collaborative filtering and item-based collaborative filtering were also investigated. Users or items are both considered vectors in these procedures. The user is then recommended an item based on the similarity between these vectors. Due to the significant sparsity of data and edges, the majority of the entries would be 0. Both algorithms will become ineffective as a consequence of this. Hence, these methods were avoided.

V. Discussion

The results from our study reveal that the Preferential Attachment model consistently outperformed other link prediction algorithms such as Common Neighbors, Adamic-Adar, and Jaccard Coefficient. This outcome can be attributed to the inherent skewed degree distribution within the reviewer-product bipartite graph, where a small number of users have disproportionately high activity levels. These highly connected reviewers are more likely to form new links, aligning with the assumptions of the Preferential Attachment model. An important insight gained from the sentiment analysis was the overwhelming positivity or neutrality in user reviews—only 2.8% of the reviews were classified as negative. While sentiment analysis provided valuable context for understanding

edge importance, the sentiment imbalance ultimately made it impractical to use these scores as edge weights for graph modeling. This highlights a broader challenge in applying sentiment-weighted graphs in domains where user feedback is rarely negative. The use of topic modeling also proved insightful in identifying the thematic diversity of active users. For instance, the top reviewer in our dataset wrote about a wide range of topics such as travel, food, business, and education. This reinforces the importance of capturing thematic preferences in designing personalized recommender systems. However, choosing the optimal number of topics remains a subjective decision, and while coherence scores guided our choice of four topics, more sophisticated tuning strategies could further improve interpretability. From a broader perspective, this study demonstrates the value of integrating semantic and behavioral insights into graph-based recommender systems. By combining network structure with textual features, we move closer to personalized and context-aware recommendations. However, computational complexity remains a concern, especially for scaling methods like shortest path-based prediction on weighted graphs. Future work could explore more efficient graph embedding techniques that incorporate both structure and sentiment while maintaining interpretability.

VI. Conclusion

In this study, we constructed a bipartite network connecting Amazon reviewers to magazine subscriptions using a real-world dataset. To extract deeper behavioral and thematic insights, we applied sentiment analysis, topic modeling, and network visualization techniques. These insights were then leveraged to perform link prediction, aiming to recommend relevant magazine subscriptions to users.

We evaluated several link prediction algorithms such as Common Neighbors, Adamic-Adar, Jaccard Coefficient, and Preferential Attachment—using K-fold cross-validation and ROC-AUC scores. Among these, the Preferential Attachment model yielded the most promising results, largely due to the skewed degree distribution observed in the graph, where a small number of highly active users dominated the network structure.

Although sentiment analysis offered valuable context, the overwhelmingly positive and neutral nature of the reviews limited its effectiveness as a weighting factor. As a result, link prediction was performed on an unweighted graph to avoid introducing bias from sentiment imbalance.

Looking forward, future research could explore methods to balance or normalize sentiment distributions to support weighted graph modeling. Additionally, incorporating graph embedding techniques or temporal dynamics could further enhance recommendation accuracy and scalability. Overall, this work highlights the potential of combining network structure with natural language insights to improve recommendation systems in content-rich domains like magazine subscriptions.

***Abstract*—This study aims to examine the attitudes of elderly and disabled individuals in Saudi Arabia toward Internet of Things (IoT)-enabled smart home technologies, with specific attention to the influence of demographic variables. The research employed a descriptive survey design, utilizing an online questionnaire distributed to a stratified random sample of 249 participants. Stratification ensured balanced representation across gender, age, educational attainment, employment status, and economic background. Statistical analyses, including Scheffé's post hoc test, revealed generally positive attitudes toward IoT adoption, primarily driven by perceived benefits related to enhanced quality of life, personal safety, and autonomy. Significant differences were identified across several demographic variables: married individuals, employed participants, those with higher education, higher-income groups, and individuals aged 30 to 45 all reported more favorable attitudes. Similarly, individuals with disabilities expressed stronger acceptance compared to their elderly counterparts. In contrast, gender differences were not statistically significant. These findings highlight the need for targeted, inclusive strategies that promote the adoption of IoT technologies across diverse social groups. The study contributes to a deeper understanding of how demographic characteristics shape technology acceptance and underscores the urgency of designing accessible, user-centered smart home systems. Recommendations emphasize public awareness initiatives, affordability measures, and inclusive design practices contributing to digital equity and aligning with the broader objectives of Saudi Vision 2030 for sustainable urban development.**

Keywords*—*IoT; smart home; sustainability; urban development; quality of life; assistive technologies

I. Introduction

Smart home technology plays a pivotal role in the realm of IoT applications. It transforms a traditional household into a connected environment, where various devices communicate with one another via the Internet. This interconnected setup enhances the home's intelligence, connectivity, and effectively automates various aspects of daily life [1]. The concept of smart home technology began to gain prominence in the early twenty-first century, aiming to network and interconnect household devices and equipment. However, researchers have no consensus on the definition of smart homes [2]. Information and Communication Technologies (ICTs) have been seamlessly integrated into consumer products like phones and televisions, as well as urban infrastructure and networks, significantly improving the quality of life [3]. A smart home represents a fusion of technology and services tailored to enhance the living environment's efficiency, comfort, and security for its occupants [4].

The integration of these home systems allows them to communicate with one another via a central control unit. This enables the execution of pre-programmed scenarios or operational modes, facilitating single-button or voice-controlled management of various home systems, simultaneously [5]. One of the most significant aspects of a smart home is its capacity to provide environmental control, allowing remote or automated management of essential home components like thermostats, ventilation systems, lighting fixtures, kitchen appliances, and various household devices. This automation not only simplifies household management but also reduces the workload of residents, contributing to their overall convenience [6].

Despite the numerous advantages and benefits of smart homes, they are often viewed as somewhat inconvenient and novel technology due to certain drawbacks. These drawbacks encompass a high initial cost, limited availability, and a shortage of experts in the field for installation and maintenance [7]. Moreover, concerns related to weak security and privacy are a significant issue for users or potential users. Information collected by these devices is typically transmitted over open networks like the Internet or via systems provided by service providers. This can potentially result in data breaches and access by hackers, exposing individuals to real risks such as theft or extortion [8].

This study explores the growing role of smart homes in IoT applications while addressing concerns such as privacy violations and weak security due to potential remote breaches [9]. Research in South Korea and Malaysia has shown that many users have negative attitudes toward adopting IoT in smart homes [10]. Additionally, many homeowners remain unaware of the benefits of smart home technology, contributing to reluctance to adopt [11]. Previous studies have primarily focused on younger users while overlooking elderly individuals

*Corresponding Author.

and people with disabilities [12]. Furthermore, research on smart home adoption in Arab countries remains limited. This study seeks to examine attitudes toward IoT in smart homes among elderly and disabled individuals in Saudi Arabia. It also investigates whether demographic factors such as gender, age, education, and economic status influence these attitudes [13].

This study makes several significant contributions to the literature on IoT and smart home systems. First, it investigates the influence of demographic factors, such as gender, age, education, employment, and economic status, on attitudes toward adopting IoT in smart homes. This focus provides insights into how diverse populations perceive and interact with smart home technologies. Second, the study highlights the potential of IoT to enhance the quality of life for elderly individuals and people with disabilities, emphasizing its role in promoting independence, safety, and convenience. This study delivers deep knowledge to user-centered design in smart home systems, aligning with Saudi Vision 2030's goals of fostering sustainable urban development and inclusivity. By addressing the attitudes and motivations of underrepresented groups, this research offers practical recommendations for governments, policymakers, and technology companies to develop inclusive and accessible smart home solutions.

This work is structured to include (see Section II) reviews of related works on smart home technology and IoT adoption, focusing on elderly and disabled populations. A description of the methodology used, including the sample, data collection tools, and analysis techniques, has been presented in Section III. Section IV presents the results, highlighting the influence of demographic factors on attitudes towards IoT adoption. Section V presents the discussion of the study. A conclusion is given to provide recommendations for future research and policy implications in Section VI. Limitations of the study are presented in Section VII.

II. Related Works

A. Societal Influence and the Need for User-Centered Design

The evolution of smart homes is fundamentally driven by societal perceptions, emphasizing the necessity of a user-centered design rather than a purely technological orientation. Smart home systems deliver clear advantages in security, energy efficiency, and accessibility via automated lighting, temperature regulation, and appliance management. For example, occupancy sensors dynamically optimize lighting and HVAC performance to reduce energy consumption while enhancing comfort [8, 10, 11].

A recent systematic review highlights that demographic factors, including gender, age, and education, are consistently among the strongest moderators affecting consumer adoption and acceptance of smart home IoT devices [14]. Another empirical study reports that income and education levels significantly influence intention to use smart home services, whereas gender and age may not always have a consistent direct effect. Specifically, those with higher education and income exhibit greater receptivity to IoT technologies, while adoption intention tends to vary by residential type and prior experience [13]. Furthermore, cutting-edge research from 2024 proposes human-centered explain ability frameworks for AI-driven smart home systems, advocating for interfaces that users can intuitively understand, thereby strengthening trust, transparency, and acceptance [15]. Similarly, another study leveraging large language models (LLMs) to personalize smart home interactions demonstrated a measurable improvement of around a 52% increase in user satisfaction ratings, underscoring the value of preference-based, user-adaptive design [16].

B. Smart Homes in Assisted Living Contexts

Smart home solutions are increasingly being designed within assisted living environments to support active aging, independence, and adaptive care, with a focus on features such as fall detection, emergency response, medication adherence, and sensory integration [12, 13].

Recent developments in smart home platforms have incorporated technologies such as radio frequency identification (RFID), wearable sensors, wireless networks, and artificial intelligence to achieve seamless interoperability and personalized functionality. These integrations enhance user autonomy and minimize dependence on continuous direct caregiving, particularly in assisted living environments [17]. Recent studies expand this field by demonstrating how smart flooring powered by the Internet of Things and deep learning analytics can achieve up to 98% fall detection sensitivity and 99% accuracy using non-intrusive sensors embedded under carpets, an approach that balances effectiveness, privacy, and everyday functionality [18].

Furthermore, innovations in assistive technology now include automated medication dispensers, wearable tracking devices with geofencing capabilities, and AI-powered remote monitoring, which collectively enable immediate support for healthcare adherence and rapid alerts to caregivers in emergencies [19].

For example, specialized IoT-based smart home systems for individuals with dementia have demonstrated their ability to monitor medication use, track wandering behaviors, and support remote healthcare functions through NFC-enabled pillboxes and environmental sensors, facilitating safe and independent living [20]. Advanced commercial solutions highlight the progress made in smart assisted living[21]. This device achieves up to 99.5% accuracy in detecting falls even in the case of partial obstruction, features two-way audio communication, and automatically alerts caregivers or emergency services upon detection, demonstrating the practicality and cost-effectiveness of smart technologies in private residences [21, 22]. Together, these developments reflect a clear evolution in smart home technologies, ranging from general automation to highly personalized, user-centric systems. These technologies are designed not only to meet the functional needs of the elderly or those with cognitive disabilities, but also to preserve their dignity, minimize intrusion, and enhance their independence in their familiar home environments.

C. Barriers to Adoption: Privacy, Security, and Awareness

Research in South Korea and Malaysia has shown that many users have negative attitudes toward adopting IoT in smart homes, often due to concerns about privacy and security [23]. Furthermore, many homeowners remain unaware of the benefits

of smart home technology, which contributes to their reluctance to adopt it [24].

Recent empirical evidence from across Asia reveals a range of critical barriers to the adoption of IoT-based smart home technologies, with privacy concerns and cybersecurity vulnerabilities emerging as the most prominent challenges. In addition to these technical and ethical concerns, a pervasive lack of user awareness regarding the potential benefits of IoT devices significantly contributes to users' reluctance, thereby impeding the broader integration of such technologies into residential settings. Furthermore, limited security literacy among users and inadequate adherence to data confidentiality practices further exacerbate these issues, highlighting the urgent need for targeted awareness initiatives and robust security frameworks to support secure and informed adoption [14, 25, 26].

D. Gaps in Literature: Marginalized Populations and Regional Contexts

Previous empirical studies have predominantly centered on younger, technologically adept users, often overlooking key marginalized groups such as elderly individuals and people with disabilities [3, 27]. This oversight has resulted in a limited understanding of how these populations perceive and interact with smart home IoT technologies. In addition, there is a significant paucity of research focusing on the adoption of smart home innovations within Arab contexts, particularly in Gulf countries such as Saudi Arabia [27, 28]. To address these research gaps, the present study investigates the attitudes of elderly and disabled individuals in Saudi Arabia toward smart home technologies supported by the Internet of Things (IoT). Specifically, the study explores the extent to which various demographic variables influence these attitudes. These variables include gender, marital status, educational level, employment status, age, economic status, previous experience with smart technologies, and user category (e.g., elderly vs. disabled). By examining these dimensions, the research aims to provide a more inclusive and context-sensitive understanding of the factors shaping technology adoption among underrepresented populations in the Arab world.

III. Methodology and Approaches

A descriptive survey method has been conducted to quantitatively depict the current state of affairs. This method is well-suited to the study's nature, enabling it to address its inquiries and fulfill its objectives effectively. The questionnaire served as the primary data collection tool to gather descriptive quantitative data regarding the attitudes of elderly individuals and those with disabilities regarding the utilization of IoT in smart home systems.

A. Sample of the Study

A stratified random sample of 249 elderly people and people with disabilities was selected from the Najran region in the Kingdom of Saudi Arabia. The participants contributed to answering the questionnaire tool in collaboration with Candle of Hope Association for People with Disabilities and Noor Najran Association for Women and People with Disabilities. The questionnaire has been electronically distributed to a study sample via an electronic link by use of Google Forms services. The questionnaire has been published in collaboration with authorities from the previously stated entities through personal email and mobile apps for study participants. The demographic distribution showed significant participation of both women and men in the survey. In Table I, the demographic description of the targeted groups is equally distributed among demographic variables. It depicts the distribution of research sample members based on demographic factors (gender, marital status, educational level, employment status, age, experience, category, and economic status).

TABLE I. Sample Distribution based on Demographic Variables, Namely: Gender, Marital Status, Educational Level, Employment Status, Age, Experience, Category, and Economic Status

Variable	Value Label	No.	Percentage (%)
Gender	Male	106	43
	Female	143	57
Marital status	Married	106	43
	Single	143	57
Educational level	Illiterate	94	38
	School	89	36
	University	66	27
Employment status	Work	128	51
	No work	121	49
Age	15-30	56	22
	30-45	69	28
	45-60	76	31
	+60	48	19
Experience	Likely to use	131	53
	Use	118	47
Category	The Elderly	137	55
	People with disabilities	112	45
Economic status	Average or below	124	50
	Above average	125	50
Total		249	100

B. Tools of the Study

The development of the questionnaire was guided by a clear objective: to assess attitudes toward the utilization of Internet of Things (IoT) technologies in smart home systems, particularly in relation to improving the quality of life for elderly and disabled individuals. This instrument was designed based on a thorough review of relevant theoretical frameworks and empirical studies. Key references included national resources such as the Saudi Association for Individuals with Disabilities and international studies by Marn-Daz [29], Wilson et al. [3] and others [30, 31]. These sources provided validated constructs and item formats that were adapted to the context of this study to ensure both content relevance and conceptual alignment within the target population. The rationale for using a structured questionnaire was to systematically capture subjective attitudes and perceptions in a standardized format that facilitates quantitative analysis. The survey was constructed in two sections: the first collected demographic and contextual

information; the second included 11 Likert-scale items measuring the perceived impact of IoT use on quality of life. The five-point Likert scale (ranging from "strongly agree" to "strongly disagree") was employed to allow for nuanced responses while maintaining analytic simplicity. Score ranges were determined based on prior psychometric studies, enabling consistent interpretation of response trends. However, the design and implementation of the questionnaire are subject to several limitations. First, the reliance on self-reported data inherently introduces potential biases, such as social desirability bias, recall bias, or respondents' limited awareness of IoT functionalities. Although the anonymity of responses was preserved to mitigate some of these effects, such biases may still influence the results. Second, the sample was selected based on accessibility and willingness to participate, which may restrict the generalizability of findings to the broader population of elderly and disabled individuals. This self-selection bias, coupled with possible underrepresentation of individuals with severe disabilities or low technological literacy, limits the extent to which the results can be extrapolated. Third, while the questionnaire underwent expert validation and pilot testing for clarity and relevance, its psychometric properties (e.g., construct validity, test-retest reliability) warrant further investigation in future studies with larger and more diverse samples.

C. Validity of the Tool

The initial version of the study tool has been presented to ten faculty experts, specializing in computer science, networks, information, and communication systems, as well as psychological measurement and evaluation, hailing from various Saudi universities. Experts have examined the relevance of each item to the overall tool, scrutinized the linguistic formulation for accuracy, and assessed the tool's appropriateness for reaching the study's objectives. The experts confirmed that the tool was well-suited for fulfilling the study's aims. The questionnaire was administered to a preliminary sample of thirty elderly individuals and people with disabilities from the study area, a subset outside the main study population. Afterwards, the correlation coefficients of each item with the total tool score were computed. The results are detailed in Table II.

TABLE II. CORRELATION COEFFICIENTS AMONG VARIABLES AND THE TOTAL SCORE OF THE TOOL AT THE SIGNIFICANT LEVEL OF 0.05

Variable no.	Correlation significance /variable	Variable no.	Correlation significance /variable
1	0.31	7	0.54
2	0.49	8	0.58
3	0.41	9	0.61
4	0.43	10	0.45
5	0.66	11	0.55
6	0.35		

The correlation coefficients of the individual items with the entire tool fell within the range of 0.31 to 0.66, demonstrated acceptable and statistically significant levels (see Table II). As a result, there has no need to remove any of the items from the tool. These findings affirm the tool's validity in accurately measuring the intended aspects.

D. Reliability of the Tool

To ensure the tool's reliability, it was administered to a group of 25 individuals with disabilities, who were not part of the study sample. The tool has initially applied and then reapplied after a two-week interval. The Pearson correlation coefficient has been calculated to determine the consistency of responses across the two administrations of the tool. The reliability coefficient, as assessed through the test-retest method, is 0.88 for the entire tool. The tool's reliability has also been assessed using the internal consistency method, calculated through the "Cronbach's Alpha" equation for the tool. According to this method, the reliability coefficient for the entire tool was 0.79. These results collectively affirm the tool's reliability in consistently measuring the intended aspects. The statistical software SPSS version 23 has been employed for data analysis. To address the first research question, means, standard deviations, and rankings were calculated. The second research question has been tackled through multiple analyses of variance, with subsequent multiple comparisons conducted using Scheffé's method.

IV. RESULTS AND DISCUSSION

According to the variable associated with the level of attitudes towards using IoT in implementing the smart home system, according to the estimates of the study sample members of the elderly and people with disabilities as users and potential users?

Mean value, variance, and rank have been calculated for the responses for the first question of this study about the level of attitudes toward using IoT in implementing the smart home system to support the quality of home life as perceived by the elderly and people with disabilities as users and potential users. Mean values ranged between 3.34 and 3.56, with medium and high ratings (see Table III).

TABLE III. MEANS AND STANDARD DEVIATIONS OF THE LEVEL OF ATTITUDES TOWARD USING IOT IN THE SMART HOME SYSTEM TO SUPPORT THE QUALITY OF HOME LIFE AS PERCEIVED BY THE ELDERLY AND PEOPLE WITH DISABILITIES AS USERS AND POTENTIAL USERS

No.	Items	Mean	SD	Rank	Level
5	I see that this system will provide me with belonging to the home in which I live	3.56	1.31	1	High
3	I believe this system will help me be free from anxiety and stress in my home	3.53	1.18	2	High
9	I believe that this system will enable me to carry out work and tasks within my home easily	3.53	1.08	2	High
1	I believe that this system helps me practice motor activities inside the house with complete freedom	3.49	1.26	3	High
11	I believe that this system will help me practice recreational activities at home with ease	3.49	1.19	3	High
2	I believe this system will help me have a healthy atmosphere at home	3.46	1.19	4	High
4	I think this system will help me improve my overall mood at home	3.44	1.32	5	High

7	I believe that this system will help me enjoy a strong social network around my home	3.39	1.16	6	Medium
10	I believe that this system will enable me to go out and return to my home easily and conveniently	3.39	1.18	6	Medium
6	I believe that this system has a high ability to protect my privacy	3.35	1.26	7	Medium
8	I see that this system will keep me close to my family members	3.34	1.20	8	Medium
	Total degree	3.45	0.910		High

The mean value of the total score for the level of attitudes towards using IoT in the smart home system, according to the estimates of the study sample members of the elderly and people with disabilities as users and potential users, was 3.45±0.91. The responses that see that the smart system will provide them with belonging to the home in which they live came in first place with the highest mean value of 3.56±131, with a high degree. Item (3) "I believe that this system will help me to be free from anxiety and psychological pressure in my home", and item (9) "I believe that this system will enable me to carry out work and tasks inside my home easily", scored second with the same mean values of 3.53 and the high level of degree. Item (8) "I see that this system will provide me with closeness to my family members" ranked last with a mean of 3.34 and a medium degree.

Mean values and standard deviations have been calculated for the responses of the study sample members regarding the level of attitudes towards the use of IoT in applying the smart home system to support the quality of home life for the elderly and people with disabilities as users and potential users according to demographic factors (gender, marital status, level Educational, employment status, age, experience, category, economic status). Table IV depicts the results. Results associated with the effect of demographic factors (gender, marital status, educational level, employment status, age, experience, class, economic status) attitudes towards using IoT in the smart home system, according to the estimates of the study's sample of elderly people and disabled people as users and potential users presents evidence of variations among the mean responses of the study sample participants concerning their attitudes toward using IoT in smart home systems (see Table IV).

TABLE IV. MEAN AND VARIANCE OF THE RESPONSES OF THE MEMBERS REGARDING THE LEVEL OF KNOWLEDGE TOWARDS USING IOT IN THE SMART HOME, ACCORDING TO DEMOGRAPHIC FACTORS

Variable	Category	Mean	No.	SD
Gender	Male	3.36	106	0.93
	Female	3.53	143	0.88
Marital status	Married	3.82	106	0.96
	Single	3.18	143	0.76
Educational level	Illiterate	3.37	94	0.80
	School	3.28	89	0.91
	University	3.79	66	0.97
	Work	3.67	128	1.00
Employment status	No work	3.23	121	0.75
Age	15-30	3.58	56	0.82
	30-45	3.70	69	0.96
	45-60	3.25	76	0.88
	+60	3.27	48	0.89
Experience	Likely to use	3.17	131	0.74
	Use	3.77	118	0.97
Category	The Elderly	3.28	137	0.90
	People with disabilities	3.67	112	0.87
Economic status	Average or below	3.10	124	0.75
	Above average	3.80	125	0.92

These variations are associated with various demographic factors, including gender, marital status, educational level, employment status, age, experience, category, and economic status. To determine the statistical significance of these differences at the 0.05 level, multiple analyses of variance were employed. The outcomes are depicted in Table V.

TABLE V. MULTIPLE VARIANCE ANALYSIS OF THE LEVEL OF ATTITUDES TOWARDS THE USE OF IOT IN THE SMART HOME SYSTEMS ACCORDING TO DEMOGRAPHIC FACTORS

Variable	Type I Sum of Squares	df	Square Mean	F	Significance
Gender	1.779	1	1.779	2.884	.091
Marital status	23.700	1	23.700	38.413	.000
Educational level	8.137	2	4.069	6.595	.002
Employment status	4.134	1	4.134	6.700	.010
Age	5.768	3	1.923	3.117	.027
Experience	8.746	1	8.746	14.176	.000
Category	2.534	1	2.534	4.107	.044
Economic status	5.337	1	5.337	8.650	.004
Error	146.221	237	.617		
Total	3175.877	249			

There have been no significant differences in the level of attitudes towards using IoT in the smart home system due to the gender variable (F value = 1.779), which was statistically significant at the level of 0.091. There were statistically significant differences at the level of attitudes towards using IoT in the smart home system due to the marital status variable in favor of the married group (F value = 38.413) was statistically significant. There were statistical differences due to the employment status variable for the group of workers (employees) (F value = 6.700) scored a statistical significance of 0.010; the experience variable for the use category (I use it) (F value = 14.176); the category variable in favor of the category of people with disabilities (F value = 4.107); and the economic status variable in favor of a group above the average (F value = 8.650) was statistically significant at 0.004. There were significant differences (sig. level of 0.05) in the level of attitudes towards using IoT in the smart home system due to the

educational level variable (P value = 6.595) and statistically significant at 0.002; the age variable (F value = 3.117) statistically significant at 0.027. To demonstrate the significance of the differences according to the variables of educational level and age, multiple comparisons were used by Scheffé's method (see Table VI).

TABLE VI. MULTIPLE COMPARISONS USING SCHEFFÉ'S METHOD FOR THE SIGNIFICANCE OF THE DIFFERENCES IN THE LEVEL OF ATTITUDES TOWARD THE USE OF IOT IN THE SMART HOME SYSTEM ACCORDING TO EDUCATIONAL LEVEL AND AGE

Level of Education (I)	level of Education (J)	I-J diff. mean	Significant level
University	School	0.51 (significant level of 0.05)	0.000
	Illiterate	0.42 (significant level of 0.05)	0.004
Age (I)	Age (J)	Mean Difference (I-J)	Sig.
15 -30	(30 -45)	0.12	0.863
	(45 -60)	0.44 (significant level of 0.05)	0.010
	+ 60	0.43 (significant level of 0.05)	0.042

There have been significant differences (mean = 0.51, sig. level 0.000) among responses in the level of attitudes toward the use of IoT in the smart home system due to the educational level between the two categories of university and school for the former. Significances were also found between the university and illiterate categories in favor of the university group. The value of the Mean Difference 0.42) was statistically significant at the level of 0.007. There have been also shown a statistical difference (at the significant level of 0.05) for the responses of the study sample members in the level of attitudes toward the use of IoT in the smart home system for 30 to 45-year-old category (mean value of 0.12±0.863), and both the category of 45-60-year-old (mean value of 0.44±0.01) and over 60-year-old category for the benefit of the former (mean value of 0.43±0.042) (see Table VI).

V. DISCUSSION

Results showed that the level of attitudes towards using IoT in the smart home system, according to the estimates of the study sample members, including elderly people and people with disabilities as users and potential users, was significant. The result may be attributed to the fact that smart home and building applications have become a reality that can enhance human lives, including the elderly and people with disabilities [13]. With the advantages of using IoT in the smart home system application, ranging from voice-activated lighting to automated security systems, it provides a lot of convenience and extraordinary safety benefits. Elderly and people with disabilities have complete control over all home appliances and tools from one device, such as a mobile phone or remote control, so there is no need to wander around the house with effort, as well as managing the house from the outside as well [32]. It emphasized the integration of smart technology to ensure the well-being and quality of life for humans and Saudi society [27]. Hence, the positive attitude towards technology and the appropriate individual awareness of the importance of using IoT in applying the smart home system to provide the needs and services of the elderly and people with disabilities easily and conveniently has contributed to the high attitudes towards this modern technology. This result differs from the study of Chang and Nam [13], which showed negative attitudes among the population in the Republic of Korea towards the use of IoT in the smart home by its users or potential users. It also disagrees with that in the study [23], which showed that Malaysian residents are extremely reluctant to adopt IoT in the smart home. Perhaps this difference may be due to factors of time, place, and social and cultural conditions between these two studies and the current study. This result may benefit local and international technology companies in enhancing the local and global market with high-quality products and devices that meet the needs of the elderly and people with disabilities in using IoT in implementing the smart home system. It improves the quality of living and well-being of elderly and disabled individuals and provides special services and care appropriate to their abilities and potential. Thus, it is reflected in national belonging through the promotion of human and social values in society and the right of everyone to live in dignity, and from an economic standpoint, it enhances state revenues and national economic income.

The study examined the impact of demographic factors, including gender, marital status, education, employment status, age, experience, social class, and economic status, on attitudes toward IoT adoption in smart home systems among elderly and disabled individuals, revealing no statistically significant differences based on gender. This may be caused by the similar awareness among the study sample members, regardless of their gender, about the importance of using IoT in the smart home system in daily life and household activities and requirements, and its role in facilitating their lives and living [33]. No statistically significant differences were found due to the marital status variable in favor of the married group[13]. The result may be attributed to the role of spouses in providing great support to one another. Hence, they need to realize the value of this technology in enhancing that role between them as well as its role in relieving pressure and tension in relationships between couples, because it enables them to complete work and tasks easily. There have been significant differences attributed to the employment status variable and in favor of the working group (employees). The result may be attributed to the study sample members' awareness of the importance of this system, "IoT in implementing the smart home system", in facilitating the process of leaving the home and returning to it with all comfort and ease. Also, it plays a role in commuting to work by providing technological devices to serve them, which is reflected in their feelings and desire to use this system with welcome and love, and to encourage others to use it [5]. There were statistically significant differences attributed to the experience variable and in favor of the usage category (use it). The result may be attributed to the awareness of the people who use this system and interact with it of its importance. It includes many additional tools and characteristics that distinguish it from the traditional home, enabling them to deal with and rely on themselves, and making their home life more quality, easy, and convenient. There were statistically significant differences attributed to the category variable and in favor of the category of people with disabilities. The result may be attributed to the fact that individuals with disabilities possess some of the

cognitive and mental abilities that enable them to use this system and deal with it, in contrast to the elderly, who worry and feel afraid of using this system. In addition, most of them suffer from chronic diseases or mental illnesses such as Alzheimer's, which affects the level of their attitudes towards this system and its importance in their lives [28].

There were significant differences attributed to the economic situation variable and in favor of a group above the average. The result may be due to the person's economic factor playing a major role in their desire to own and use such a system. Therefore, people with high income or high economic levels are informed of everything new about this system to become more familiar with it in terms of its benefits, how to deal with it, and the possibility of using it currently or in the future, which affects their attitudes towards this system [7]. There were statistically significant differences due to the educational level variable in favor of the university category. The result may be attributed to the role of higher education in providing individuals with the opportunity to learn new things and know everything about technology and its great role in improving human life. Hence, the study members who received a university education may have gained experience in how to obtain reliable sources about this system, its benefits, how to deal with it, and the possibility of using it currently or in the future. There were statistically significant differences attributed to the age variable, favoring the 30 to 45 age group. This result may be explained by younger individuals' greater willingness to adopt, explore, and engage with technology, as well as their lower levels of apprehension toward its use compared to older age groups [27]. Therefore, their attitudes toward this system and their acquisition of sufficient knowledge about it, its benefits, how to deal with it, and the possibility of using it currently or in the future greatly affect their attitudes toward this system in terms of use or the probability of using it.

This study attempted to collect quantitative data and analyze it descriptively to explore the influence of demographic factors (gender, marital status, educational level, employment status, age, experience, category, economic status) as users or potential users of IoT in the smart home system and attitudes towards it. It also showed how it might affect them when they decide to adopt this system or encourage others to adopt it, and what differences or lack thereof were found based on those demographic factors. This may help in understanding and increasing the awareness of governments and technical companies specialized in smart homes that end consumers do not respond to those services proposed to them in the same way. This result may be due to the difference between them in the demographic factors discussed in the current study, which necessitates expanding the circle of spreading the culture of smart homes in a major selling space, such as international and local premium markets, for example. The influence of factors and circumstances surrounding people, including the elderly and people with disabilities, may affect their attitudes and purchasing attitudes toward this system. It also requires technical commercial companies specialized in this system to develop an organized and thoughtful strategic plan. It includes a large variety of diverse services that are integrated into using IoT in implementing the smart home system to attract the largest possible segments of society, including the elderly and people with disabilities.

VI. Conclusion and Recommendations

This study concluded that elderly individuals and people with disabilities in Saudi Arabia generally exhibit positive attitudes toward the adoption of IoT-based smart home technologies, particularly those who are married, employed, better educated, and from higher-income groups. However, certain demographic factors, such as being unmarried, unemployed, of lower socioeconomic status, or having limited educational attainment, were associated with lower adoption enthusiasm. These findings highlight the potential of IoT to improve quality of life, autonomy, and safety for marginalized groups, but also underscore the presence of critical barriers that must be addressed through targeted interventions. In light of these findings, several actionable recommendations are proposed. Government agencies, particularly the Ministry of Human Resources and Social Development and the Ministry of Communications and Information Technology, should establish inclusive digital policies and launch national awareness campaigns tailored to underserved populations. These should include digital literacy initiatives, financial support schemes, and the integration of smart technologies into broader Vision 2030 strategies to enhance social equity and digital transformation. For technology developers and solution providers, there is a clear imperative to adopt user-centered design approaches that ensure smart home systems are affordable, intuitive, and responsive to the needs of elderly and disabled users. This includes simplifying interfaces, offering Arabic language support, and addressing security and privacy concerns that may hinder adoption. Civil society organizations and charitable institutions are also encouraged to play an active role in bridging the digital divide. Through community outreach and partnerships with public institutions, these organizations can advocate for the practical benefits of IoT and facilitate equitable access to smart technologies among low-income and vulnerable individuals. Lastly, the academic community should pursue in-depth qualitative research to uncover the psychosocial and cultural dimensions that influence IoT adoption. Special attention should be given to rural populations and those with limited technological exposure to develop evidence-based strategies that ensure inclusive innovation. These efforts will contribute significantly to building a sustainable, digitally empowered society in alignment with Saudi Arabia's Vision 2030.

VII. Study's Limitations

The results of this study are limited to the following: The study was limited to investigating the topic of attitudes towards the use of the Internet of Things (IoT) in the smart home system from the point of view of the elderly and people with disabilities as users and potential users. It was also determined to explore the impact of some demographic factors such as (gender, marital status, educational level, employment status, age, experience, class, economic status) on these attitudes. In addition, the study was limited to the opinions of a sample of the elderly (over 60 years old) and people with disabilities (over 15 years old to 60 years old) from Najran region in the south of the Kingdom of

Saudi Arabia, in the period from June to July of the year 2023. Finally, one tool, the questionnaire, was used in the data collection process, so generalizing the results depends on the accuracy in extracting its validity and reliability implications and the seriousness of the respondents in answering them.

ACKNOWLEDGMENT

The researchers would like to thank and appreciate the study participants for their efforts in responding to the study tool objectively. We thank Ajloun National University for their support.

ETHICAL APPROVAL

This scientific research carries ethical approval from the Standing Committee for Scientific Research Ethics in the Research Deanship of Najran University, Saudi Arabia. Reference No.: 010118-022124-DS. Accredited as a local committee by the National Committee for Bioethics at King Abdulaziz City for Science and Technology (HAPO-11-N-102).

INFORMED CONSENT STATEMENT

Informed consent was obtained from all study participants.

Enhancing Dendritic Cell Algorithm by Integration with Multi-Layer Perceptron for Anomaly Detection

Yousra Abudaqqa, Zulaiha Ali Othman, Azuraliza Abu Bakar
Research Center for Artificial Intelligence Technology-Faculty of Information Science and Technology,
Universiti Kebangsaan Malaysia, Bangi, Selangor 43600, Malaysia

Abstract*—Anomaly detection is crucial in a variety of areas, with the Dendritic Cell Algorithm (DCA) being one of the most used artificial immune systems (AIS) and introduced for binary classification of data. Both traditional and current perspectives on classification in DCA have primarily been threshold-based methods. Such approaches are limited in important ways, including inflexibility, manual tuning, and not being context-aware. The latest improvements in literature have provided adaptive dynamic threshold mechanisms that allow the system to adjust the sensitivity of the threshold using some statistical data of real-time observations. Although this is progress, the systems proposed are still based on rules, which have traditionally struggled with the more complex, higher-dimensional and nonlinear nature of data. This is common in most complex anomaly detection tasks today. In this study, we propose an improved DCA-MLP framework that uses a Multi-layer Perceptron (MLP) classifier replacing the thresholding phase. The MLP allows the DCA to learn from data context adaptively through a context-sensitive learning mechanism that can also change with the data distribution as it evolves, eliminating the need to robotically calibrate based on static or heuristic thresholds. The framework was tested thoroughly on fourteen benchmark datasets, and performance was evaluated against standard DCA in terms of accuracy, sensitivity and specificity measures. The performance results revealed considerable enhancements in DCA-MLP's performance: 12%–50% improvements in accuracy (increasing accuracy to 93%–99%), 46% improvements in sensitivity (sensitivity as 98%), and 39% improvements in specificity. This shows that DCA-MLP is better adaptable, with learning capacity and robustness - a paradigm shift away from thresholds or threshold-based systems to an intelligent self-adjusting anomaly detection classification scheme.

Keywords*—Dendritic Cell Algorithm (DCA); anomaly threshold; Multi-Layer Perceptron (MLP); anomaly detection

I. Introduction

Anomaly detection, or the process of identifying patterns that are identified as the unusual portion of normal behavior, is important across several domains, including cybersecurity, healthcare, finance, and industrial systems. Anomalies such as fraudulent financial transactions, malignant tumors in a medical image, and cyberattacks on network traffic, all signal important implications, transforming raw data into actionable insights [7, 24, 33, 37]. Traditional classification algorithms often falter on dynamic, high-dimensional data; so researchers have resorted to diagnostic and biologically inspired solutions, such as artificial immune systems (AISs).AISs emulate the human immune system's ability to distinguish self from non-self, offering unique advantages in adaptability and unsupervised learning [1]. Among AIS-based approaches, the Dendritic Cell Algorithm (DCA)[2]stands out for its success in anomaly detection, leveraging the biological "danger theory" to classify threats by monitoring antigen behavior through metrics like the Multi-Context Antigen Value (MCAV) [3].

Despite its effectiveness, the DCA faces significant limitations. Its reliance on fixed, empirically derived thresholds for anomaly classification introduces rigidity, as static parameters fail to adapt to evolving data patterns or outliers [4]. For instance, threshold-setting methods like try-and-test experiments or class distribution analysis depend heavily on historical data and expert input, limiting scalability and real-world applicability [4]. These constraints are particularly evident in complex tasks such as network intrusion detection or time-series analysis, where dynamic environments demand adaptive solutions [5].

To address these challenges, this study proposes a novel integration of the DCA with a Multi-Layer Perceptron (MLP), replacing the static threshold mechanism with a dynamic, data-driven classification framework. Inspired by the immune system's interaction between dendritic cells (DCs) and T-cells (TCs), our approach enhances the DCA's decision-making process by embedding an MLP to learn complex relationships within antigen signals. Unlike traditional threshold-based methods, the MLP adaptively adjusts classification boundaries, improving robustness against outliers and reducing false alarms. This integration leverages the MLP's capacity to handle non-linear patterns while preserving the DCA's unsupervised learning strengths.

The contributions of this work are threefold:

1) Improved accuracy: The MLP refines [6] anomaly classification through supervised learning on fused antigen signals (e.g., danger, safe, and co-stimulatory signals), achieving accuracy improvements of 12% to 50% across benchmark datasets.

2) Dynamic adaptability: By eliminating fixed thresholds, the DCA-MLP framework dynamically adjusts to new data patterns, enhancing resilience in evolving environments.

3) Scalability: Non-Negative Matrix Factorization (NMF) streamlines signal extraction, enabling efficient processing of high-dimensional data without compromising detection performance.

Experimental validation on fourteen datasets proves the framework's superiority over traditional DCA, with sensitivity

and specificity gains of up to 46% and 39%, respectively. These advancements position the DCA-MLP as a scalable, adaptive solution for complex anomaly detection tasks, bridging the gap between immune-inspired algorithms and modern machine learning.

The rest of this study is organized as follows: Section II reviews related work on AIS and DCA enhancements. Section III details the proposed DCA-MLP architecture, while Section IV presents the experiment setup. Section V details the experimental results. Section VI presents the discussion of the study. Finally in Section VII, the study concludes with implications and future research directions.

II. Related Work

Anomaly detection plays a crucial role in various fields, including network security, healthcare, and industrial systems, where identifying unusual patterns or behaviors is essential for maintaining system integrity and performance [7]. While traditional methods such as (MLP, KNN, SVM and Decision Tree) have been effective in specific contexts, they often face challenges when dealing with the complexity and dynamic nature of modern datasets [8]. Advanced algorithms like the Dendritic Cell Algorithm (DCA) have appeared as promising solutions to these challenges, offering improved capabilities for solving anomaly detection problems [4]. The DCA, introduced by [2] operates through four key phases [9], as illustrated in Fig. 1.

In the first phase**,** pre-processing, the algorithm performs two critical tasks: feature reduction and signal categorization. Feature reduction selects the most relevant attributes from the dataset, and these attributes are then categorized into three signal types: safe, danger, and Pathogen-Associated Molecular Patterns (PAMP). The most popular methods for feature reduction include Principal Component Analysis (PCA) and Non-Negative Matrix Factorization (NMF). While PCA is widely used, it can obscure data interpretation by transforming the dataset into components that may lose connection to the original features [10]. In contrast, NMF excels by identifying weakly correlated or uncorrelated factors, revealing hidden patterns, and transforming data into a reduced yet interpretable space [11]. This approach avoids overfitting, improves prediction accuracy, and effectively manages data sparsity. Furthermore, NMF operates without strict statistical assumptions, making it highly adaptable for large-scale datasets. By maintaining essential data characteristics, NMF simplifies computational demands related to time and storage while ensuring robust model performance.

In the second phase, detection**,** the DCA generates a signal database by combining the input signals with antigens, resulting in cumulative output signals. The third phase, context assessment, evaluates the context of antigens using the cumulative signals. If a Dendritic Cell (DC) collects more Mature Dendritic Cells (mDC) than Semi-Mature Dendritic Cells (smDC), the antigen is labelled as anomalous (1); otherwise, it is classified as normal (0) [12]. Finally, during the classification phase**,** the Mature Context Antigen Value (MCAV) is calculated for each antigen to assess the likelihood of an anomaly. The MCAV is determined by dividing the number of times an antigen appears in the mature context by the total number of antigen presentations. This value is then compared to a predefined anomaly threshold, classifying antigens with higher MCAV values as anomaly.

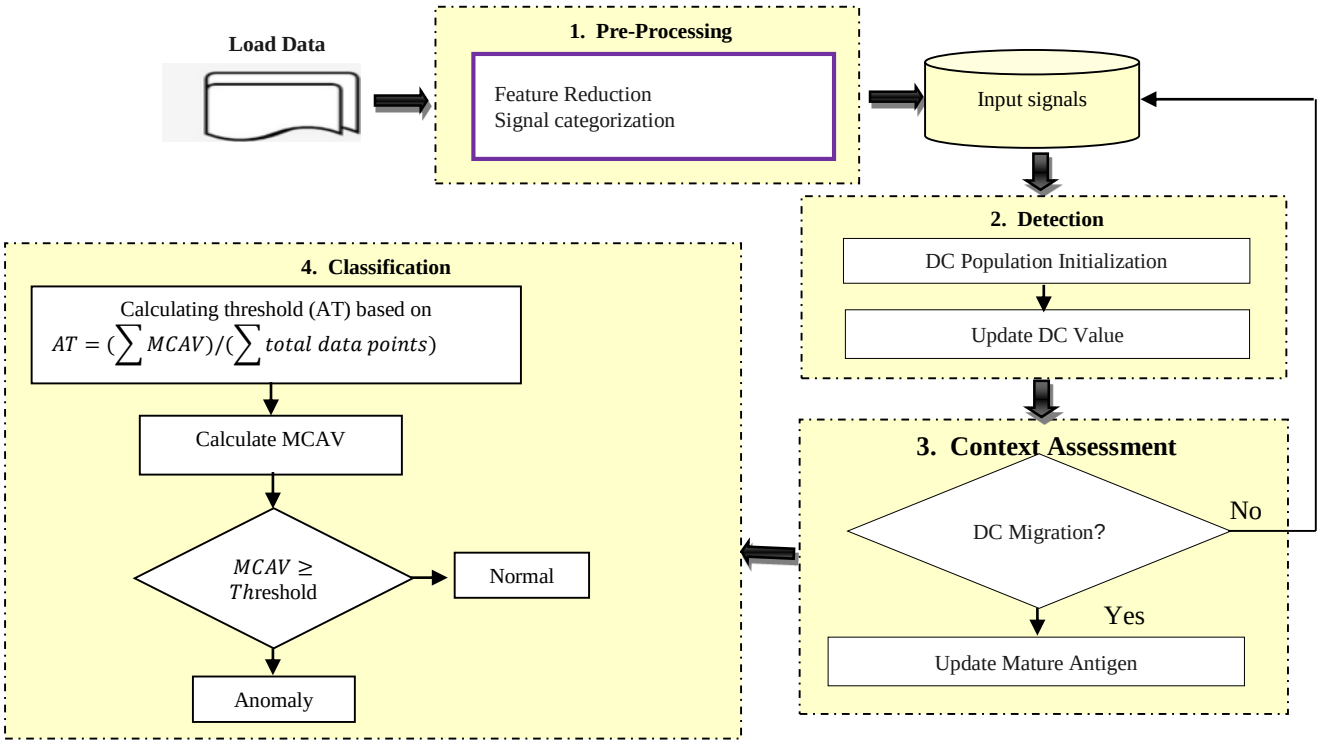

Fig. 1. The standard architecture of the Dendritic Cell Algorithm (DCA) diagram.

The MCAV plays a pivotal role in the DCA, representing the ratio of how often an antigen appears in a "mature context" compared to the total number of antigen presentations[13]. In the DCA, dendritic cells exist in two states**:** Mature Dendritic Cells (mDC)**,** which detect danger or anomalies, and Semi-Mature Dendritic Cells (smDC)**,** which reflect normal or non-threatening behavior. The MCAV measures how frequently an antigen is associated with dangerous contexts (mDC) versus normal ones (smDC), aiding in determining whether the antigen is more likely to be abnormal or normal. A higher MCAV indicates a higher likelihood of the antigen being anomalous, while a lower MCAV suggests it is normal. The MCAV is calculated as Eq. (1):

$$\text{MCAV} = (\text{Mature})/(\text{Semi Mature} + \text{Mature}) \quad (1)$$

The importance of the MCAV lies in its adaptive nature, allowing the DCA to assess anomalies based on the environment rather than static rules [14]. This flexibility makes the DCA highly capable of handling unfamiliar data points by evaluating how often an antigen appears in mature contexts, improving the algorithm's ability to classify new or unseen data accurately. Furthermore, combining the MCAV with a flexible anomaly threshold allows the DCA to adapt to different domains, such as network intrusion detection, spam filtering, and fault diagnosis, where normal and abnormal patterns vary significantly.

Anomaly Threshold (AT) is a default value used to differentiate between normal and abnormal antigens by comparing it to the MCAV of an antigen. If the MCAV exceeds the threshold, the antigen is considered abnormal or an anomaly. Currently, there are three primary strategies for determining the AT in DCA: 1) trial-and-error experimentation, 2) class distribution between normal and abnormal groups and 3) the average MCAV method [10]. The class distribution method is based on the ratio of normal to abnormal classes, requiring both classes to be balanced to generate a suitable threshold value, as shown in Eq. (2). However, achieving this balance is challenging, especially since anomalies are often rare and can create a significant gap between the two classes.

$$AT = (\sum MCAV)/(\sum total\ data\ points) \quad (2)$$

The anomaly threshold (AT) in standard DCA implementations has been applied across various domains with different strategies. In [15], the authors has enhanced the traditional DCA by introducing a migration threshold strategy that adapts to various attack scenarios, applied in network intrusion detection on the UNSW-NB15 dataset, achieving an anomaly value of 76.69% using the min MCAV approach. In [16], the authors also focused on network intrusion, using the NSL-KDD dataset to classify traffic as normal or anomalous based on immune-like danger signals. This approach identified DoS attacks through a class and min MCAV distribution strategy, providing scalability in dynamic network environments. Similarly, [17] employed a try-and-test approach in conjunction with min MCAV within a fuzzy logic system on the KDD99 dataset, enhancing adaptability to varied data types.

In [7], the authors adopted a different method, using class distribution to determine AT by assessing the ratio of abnormal to normal traffic in the NSL-KDD dataset, achieving a 0.60% anomaly threshold. In [5], the authors applied min MCAV across general classification domains with datasets such as Sonar and GCD, adjusting the threshold based on dataset-specific characteristics. Finally, [10] utilized min MCAV for anomaly detection in medical diagnosis, using datasets like WBC and LDR, focusing on metrics such as Mean Correlation Activity Value to identify anomalies dynamically. This variety of approaches underscores the flexibility of DCA in different application areas, with each study refining AT to suit specific datasets and anomaly detection needs. Some investigations have focused on the DCA classification phase, aiming to refine and enhance its effectiveness. More precisely, researchers have explored ways to improve the decision-making process by optimizing how the algorithm classifies data points as either normal or anomalous. The traditional classification approach in the DCA relies on fixed thresholds based on the multi-context antigen value (MCAV) [16], which can be limited in applications such as network intrusion detection [13] and medical anomaly detection [17]. The core of this process revolves around the calculation of the Mature Context Antigen Value, handling complex or extreme data patterns. A critical stage for identifying anomalous patterns across different domains (MCAV) [8], which determines whether a pattern is a normal presentation. When the MCAV exceeds a predefined threshold, the pattern is classified as anomalous (depicted or anomalous. The MCAV is the ratio of antigen encounters in a mature context to the total number of antigens by the decision boundary in the figure). Otherwise, it is classified as normal [18]. This classification method, though effective in many cases, highlights the challenge of setting an appropriate threshold, which directly impacts the detection accuracy of the algorithm.

Several techniques have been proposed to establish the anomaly threshold for MCAV, each with its own limitations [19]. For instance, the try-and-test method involves iterative testing to find the optimal threshold, though this process is time-consuming and highly reliant on expert knowledge. Other approaches, such as the minimum MCAV threshold introduced by[7] and adaptive thresholds based on cumulative sum (CUSUM)[10], have also been explored. While these methods offer systematic approaches to threshold determination, they deal with outliers and data changes over time, which can limit their effectiveness for longer-term anomaly detection. However, the challenge remains that these methods still depend on historical data for initial threshold values may not be reliable in rapidly evolving datasets [10, 16, 20].

An effective method for enhancing the traditional threshold methods in the DCA is to adopt the Multi-Layer Perceptron (MLP) algorithm into the DCA. Unlike the standard method of comparing MCAV values to a predefined threshold for anomaly detection, the MLP algorithm learns from the data, adjusting its parameters to better manage outliers and extreme values. This adaptability enables the MLP-DCA combination to have greater accuracy and success in detecting and classifying anomalies. By leveraging the machine learning capabilities of MLP, this integration enhances the overall process, making it more resilient against unusual data points that might otherwise challenge a simple MCAV-based threshold approach.

Integrating the DCA with an MLP algorithm presents several key advantages. To begin with, it enhances system robustness by giving the MLP the ability to better deal with extreme values

and outliers. This ensures that the algorithm maintains reliable performance even when faced with unexpected data. Secondly, the learning capabilities in the MLP improve the ability to detect and classify anomalies by allowing the model to recognize complex patterns and associations in the data assignments. The MLP refines its understanding over time, it produces more precise and reliable results. Moreover, the adaptability of the MLP enables it to respond to evolving data patterns, making it a flexible and sustainable solution for anomaly detection.

This combination overcomes the limitations of traditional threshold-based approaches by introducing adaptive learning from data, making it a valuable advancement in the field of anomaly detection.

III. The Proposed Method

This study proposes an enhanced anomaly detection framework known as MLP-DCA**,** which integrates the Dendritic Cell Algorithm (DCA) with a Multi-Layer Perceptron (MLP) classifier to overcome critical limitations of traditional threshold-based decision-making in DCA. Two primary limitations of the standard DCA model motivate this integration:

1) Its reliance on a fixed threshold for anomaly classification, which leads to poor adaptability when handling datasets with imbalanced class distributions **or** dynamic patterns.

2) The manual effort and expert knowledge required to tune this threshold, making it impractical for real-world, large-scale, or evolving data environments.

To address these challenges, the proposed MLP-DCA model retains the original architecture of the standard DCA, which includes four primary phases: signal preprocessing, antigen processing, signal integration**,** and classification (see Fig. 1). The first three phases are preserved to leverage the biologically inspired behavior and contextual data fusion capabilities of DCA, which have proven effective in prior studies [11].

In the preprocessing phase, the model introduces Non-Negative Matrix Factorization (NMF) for automated feature transformation and signal categorization**.** This enhancement allows the model to handle high-dimensional datasets by reducing complexity and focusing on the most informative features. NMF serves as a dimensionality reduction technique, helping to categorize input attributes into the necessary signal types (PAMP, danger, and safe) without manual mapping.

The major innovation lies in the classification phase, where the traditional MCAV-based anomaly threshold (AT) is replaced with an MLP classifier (see Fig. 2). Instead of relying on static decision rules, the MLP dynamically learns non-linear and high-level feature relationships from the processed signals and antigen information. This adaptive learning approach enables the system to generalize better across diverse datasets, respond to class imbalance, and improve classification robustness On the whole, by combining context-aware processing capabilities of DCA with the learning power of MLP, we proposed model achieves a more flexible and scalable anomaly detection system. The MLP-DCA architecture in addition to completely removing threshold tuning, these powerful neurons improve the accuracy, sensitivity and specificity across many benchmark datasets, demonstrated in the experimental section.

As depicted in Fig. 2, the classification process begins the same as a standard DCA which is by calculating the MCAV [Eq. (1)]. The calculated MCAV values (acting as the independent variable) are fed into the MLP that classifies the antigens, as shown in Eq. (3):

$$f(MCAV) = (\sum_{i=1}^{m} w_i \,.\, MCAV_i) + b \qquad (3)$$

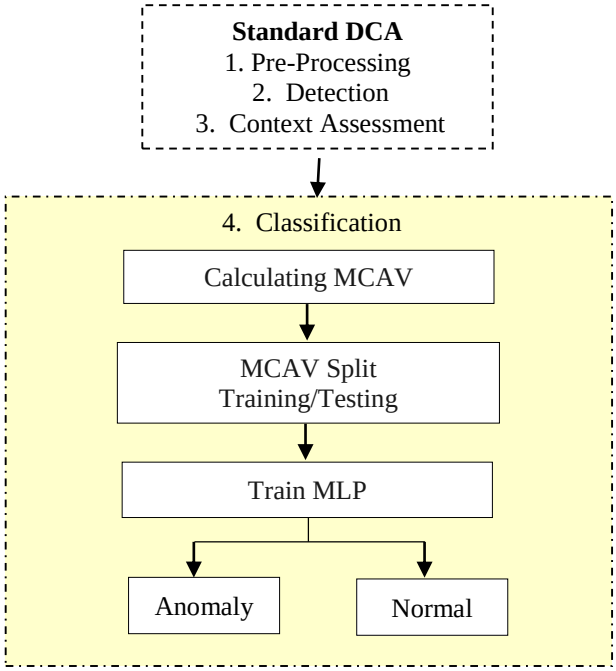

Fig. 2. Proposed method MLP_DCA.

where:

- $MCAV$: Represents the mean of context activation vectors
- derived from the inputs or data points.
- w_i: Weights assigned to each $MCAV_i$ during training.
- b: Bias term.
- m: Total number of MCAV inputs.
- The MLP leverages this transformation to predict the class of each antigen (e.g., normal or abnormal) based on learned parameters.

Fig. 3 illustrates the pseudocode for integrating the Dendritic Cell Algorithm (DCA) with a Multi-Layer Perceptron (MLP) during the classification phase. This integration comprises three primary steps:

1) Step 4.1 Calculation of MCAV values: Initially, for each antigen generated in prior stages, the Mature Context Antigen Value (MCAV) is computed using Equation (1). These MCAVs are then stored in the MCAV_values []. array for subsequent classification.

2) Step 4.2 Training the MLP model: After the MCAV values are recorded, and their labels normal or abnormal, we

can use those as inputs to train the MLP. The MLP contains three hidden layer sizes of 10, 10, and 5. Initial weights and biases are initialized random. Then the dataset is split into training and test data. The model trains through many epochs, and in each epoch all the samples will go through forward propagation in the layers of the MLP. The activations of the neurons are calculated using Eq. (3). The loss of the model is determined through cross entropy loss, and gradients are calculated by backpropagation for the weights and biases and updating them in many epochs until convergence.

3) Step 4.3 Prediction using the trained MLP: Finally, for each test sample, forward propagation is executed using the trained model to compute activations. The output activation is determined by Eq. (4):

$$MCAV(l) = f(W(l).MCAV(l-1)b(l) \qquad (4)$$

where, l indicates the output layer. A threshold of 0.5 is applied to classify the sample: outputs exceeding 0.5 are labeled as abnormal, while those below are labeled as normal.

This method uses the DCA's ability to generate MCAVs, and then it will be used as input to the MLP. The MLP is trained to classify the data into normal or abnormal categories, enhancing the overall classification performance by combining the strengths of both algorithms.

Phase 4: Classification
#Step 4.1: calculate MCAV values
1. For each antigen: // where antigen is the output of previous steps
2. Compute MCAV (antigen) using Equation 1
3. Append the computed MCAV (antigen) to the array MCAV_values [].

#Step 4.2: Feed MCAV Values into MLP for Classification
4. Train the MLP model as follow:
5. Input: MCAV_values []and their corresponding predefined labels (normal/abnormal).
6. Output: A trained MLP model with updated weights and biases.
7. Randomly initialize weights and biases for all layers based on the architecture (hidden layer sizes: 10, 10, 5).
8. Split the data into training and testing sets: X_{train}, X_{test}
9. Repeat the following steps until convergence:
10. For each epoch
11. For each training sample in X_{train}:
Perform forward propagation through the layers: Input Layer → Hidden Layers → Output Layer.
Compute activation for each neuron using equation (3)
Compute the loss between the predicted output and the actual label using across-entropy loss
Backpropagate the error using the chain rule to compute gradients of the loss with respect to the weight and biases.
Update weights and biases.

#Step 4.3: Use trained MLP for prediction
13. For each test sample in X_{test}:
14. Perform forward propagation the trained model: Input Layer → Hidden Layers → Output Layer.
15. Compute activations for the output layer using
$$MCAV(l) = f(W(l).MCAV(l-1) + b(l))$$
16. Classify each test sample based on the output
If output > 05 → Assign ABNORMAL.
Else → Assign NORMAL.

Fig. 3. The pseudo-code for the proposed DCA_MLP algorithm.

The reason for the connection of the MLP to the DCA is that the MLP is a very strong learning procedure that can learn many complex, non-linear relationships from the data; without relying on any fixed decision rules. As a type of artificial neural network, the MLP classifier builds models through multiple interconnected layers of neurons, allowing it to capture intricate patterns between input features—such as the Mean Context Antigen Value (MCAV)and corresponding class labels (e.g., normal or anomalous).

During training, this MLP will repeatedly adjust its internal variables (weights and biases) to minimize overall classification error, in the hopes of maximizing performance across multiple types and dimensions of data. Unlike threshold methods, the dynamic nature of the learning process allows the model to learn and adjust to a number of data distributions with no need for human threshold adjustment. By combining MLP with the biologically inspired architecture of DCA—which is retained through its four-phase structure, the proposed MLP-DCA hybrid model enhances anomaly detection by preserving the contextual fusion strengths of DCA while improving classification robustness, generalization, and adaptability through machine learning.

IV. The Experimental Setup

As previously discussed, the standard Dendritic Cell Algorithm (DCA) [20] suffers from key limitations, particularly its reliance on manually defined, static thresholds for classification. This section details the experimental procedures undertaken to investigate these limitations and to validate the proposed enhancement of integrating a Multi-Layer Perceptron (MLP) into the DCA classification phase. The following hypotheses were formulated:

- H1: The performance of the standard DCA is significantly influenced by using static, predefined threshold values, particularly in datasets with varying class distributions.
- H2: Replacing the static threshold mechanism with an adaptive classifier, such as an MLP, improves classification performance by dynamically learning from the data.

To validate these hypotheses, we designed a two-part experimental framework. All experiments across both parts were conducted using a consistent set of fourteen benchmark datasets, listed in Table I, which span multiple domains including medical diagnosis, credit scoring, email classification, and network intrusion detection. These datasets were obtained from the UCI Machine Learning Repository[21], as well as widely used intrusion detection benchmarks—NSL-KDD [22] and UNSW-NB15[23].

1) Threshold sensitivity in the standard DCA model: To explore H1, we looked at the responsiveness of the standard DCA algorithm to different threshold values. For demonstrative purposes, the Wisconsin Breast Cancer (WBC) dataset was used under two distinct scenarios:

- Scenario A: Original dataset with 100% of the instances are anomalous.

- Scenario B: Modified version containing only 10% anomaly instances.

2) In each case, the DCA's decision threshold was manually tuned to maximize classification accuracy. The findings showed significant variability in performance depending on configuration of threshold which validated our assertion that the model was responsive and furthermore, not robust to changing class distributions. Evaluating the Proposed DCA-MLP Model.

To test H2**,** we implemented the DCA-MLP model by integrating the Multi-Layer Perceptron classifier into the DCA's classification stage. Unlike static thresholding, the MLP enables adaptive and data-driven decision-making by learning complex, nonlinear relationships in the data.

For a comprehensive evaluation, we applied the DCA-MLP model to all fourteen benchmark datasets mentioned in Table I. These datasets were selected to ensure diversity in feature dimensionality, sample size, and application domain. The model's performance was compared to the standard DCA using metrics including accuracy, sensitivity, and specificity, demonstrating the robustness and generalizability of the proposed approach across different types of data distributions and class imbalances.

To assess the performance of the proposed DCA-MLP model, the following evaluation metrics were used:

- Accuracy (ACC): Overall classification correctness.
- Sensitivity (SNS): The ability to correctly identify abnormal (positive) instances.
- Specificity (SPS): The ability to correctly identify normal (negative) instances.
- False Discovery Rate (FDR): The proportion of abnormal predictions that are normal.

TABLE I. DATASET DESCRIPTION

Dataset	Source	Feature	Record	Target class	Class count
Sonar (sonar)	UCI	60	208	2	Normal (111), Abnormal (97)
Wisconsin Breast Cancer (WBC)	UCI	9	699	2	Normal (458), Abnormal (241)
Wisconsin Diagnostic Breast Cancer (WDBC)	UCI	30	569	2	Malignant (212 cases) or benign (357 cases)
Pima Indians Diabetes (PID)	UCI	8	768	2	500 (non-diabetic), 268 (diabetic).
Indian Liver Patient Dataset (ILPD)	UCI	10	583	2	**416** liver disease and **167** without liver disease
Horse Colic(horse)	UCI	28	368	2	**Survival (**204), **non-survival (**164)
German-Credit (GC)	UCI	20	1000		**Good** 700, **Bad 300**
Red-Win-quality(win)	UCI	13	6497		**Low quality (63, High quality (217))**
Ionosphere (ionosphere)	UCI	35	351	2	Normal (225), Abnormal (126)
Statlog (Heart)	UCI	16	270		**(105)** normal, **(165) abnormal**
Spambase (SP)	UCI	57	4601		**Spam (**1,813**), not spam (**2,788**)**
BUPA liver disorder (LDR)	UCI	7	345	2	Liver disorder present (145), Not present (200)
UNSW-NB15 (UNSW-NB15)	IDS	42	2007	2	Normal (243), Abnormal (1764)
NSL-KDD (NSL_KDD)	IDS	41	3577	2	Normal (1577), Abnormal (2000)

High values of ACC, SNS, and SPS indicate good performance, while a lower FDR reflects fewer false alarms. These metrics were computed as follows [see Eq. (5) to Eq. (8)] [24]:

$$ACC = TP + TN/(TP + TN + FP + FN) \quad (5)$$

$$SNS = TP/(TP + FN) \quad (6)$$

$$SPS = TN/(TN + FP \quad (7)$$

$$\text{FDR} = FP/(TP + FP) \quad (8)$$

To ensure statistical reliability, each experiment was repeated 30 times, and mean values of each metric were reported. The statistical significance of performance improvements (Δ) between the standard DCA and the proposed DCA-MLP was evaluated using p-values from independent t-tests.

3) Parameter configuration and preprocessing: In all the experiments we conducted, the setup for the Dendritic Cell Algorithm (DCA) included a population of 100 dendritic cells (DCs), and each iteration selected 10 DCs to sample the antigen vector. The migration threshold for each DC was set to 10 iterations. Signal classification employed a feature-based approach- the smallest standard deviation represented the PAMP and safe signals, while the largest standard deviation represented the n-NS signal. standard deviation was selected during preprocessing to prioritize informative features.

For the Multi-Layer Perceptron (MLP) classifier, we applied standard training approaches; adaptive learning rate, early stopping to prevent overfitting, and K-fold cross validation in order to ensure robust model evaluation. These parameters were not only chosen based on best practices in literature but were also found to significantly influence detection performance. For example, increasing the amount of DCs can increase the number

of antigen samples, but the cost of the computation may be increased. Likewise, if the migration threshold is lowered, it will improve the speed of classification but may decrease decision-making accuracy in noisy data. Within the MLP, we found that adaptive learning rate and early stopping had the most significant impacts, effectively allowing the MLP to converge without overfitting. While the proposed model demonstrated stability over a range of parameter values, a sensitivity analysis revealed that signal selection and learning rate had the most effect on classification accuracy and generalization capability.

Comparative Analysis of Benchmark Literature Finally, we validated the proposed DCA-MLP model by comparing its performance to established benchmark literature methods, including GA-DCA, dDCA, NMF, standard DCA, and COID-DCA, on several datasets (Sonar, NSL-KDD, UNSW-NB15, HC, GC, LR). Key metrics (Accuracy, Sensitivity, Specificity) were compared to confirm the superiority of the DCA-MLP model. In addition, Receiver Operating Characteristic (ROC) curve analysis was conducted to further highlight the performance robustness of the proposed method.

V. Experimental Results

A. Threshold Sensitivity in the Standard DCA Model

The traditional Dendritic Cell Algorithm (DCA) relies on a predefined threshold during the classification phase. While this threshold allows for the differentiation between normal and anomalous instances, its effectiveness is dataset dependent. Particularly in imbalanced datasets, a static threshold leads to suboptimal performance and reduced sensitivity.

As shown in Table II, reducing anomaly proportion to 10% results in a performance drop of 5% in accuracy. This demonstrates the sensitivity of standard DCA to class distribution, which compromises its generalizability across.

B. Performance of the Proposed DCA-MLP Model

To overcome the above limitations, we propose an enhanced DCA model by integrating a Multi-Layer Perceptron (MLP) classifier, replacing the static threshold with dynamic learning. We evaluated the proposed DCA-MLP on fourteen datasets, comparing its performance with the standard DCA using Accuracy (ACC), Sensitivity (SNS), and Specificity (SPS), alongside statistical significance (p-values).

As shown in Table III, DCA-MLP consistently outperforms the standard DCA across all datasets, with statistically significant improvements ($p < 0.001$) in all key metrics.

C. Comparative Evaluation with Benchmark Literature

To further validate the proposed model, we compared it with recent state-of-the-art DCA extensions and hybrid methods, as shown in Table IV.

TABLE II. Effect of Threshold on Anomaly Detection Accuracy in DCA

Dataset	Total data		Threshold value	Result
WBC	Normal	Anomaly		Accuracy
Original (100% anomaly)	458	241	0.65	0.98
Reduced (10% anomaly)	241	40	0.26	0.93

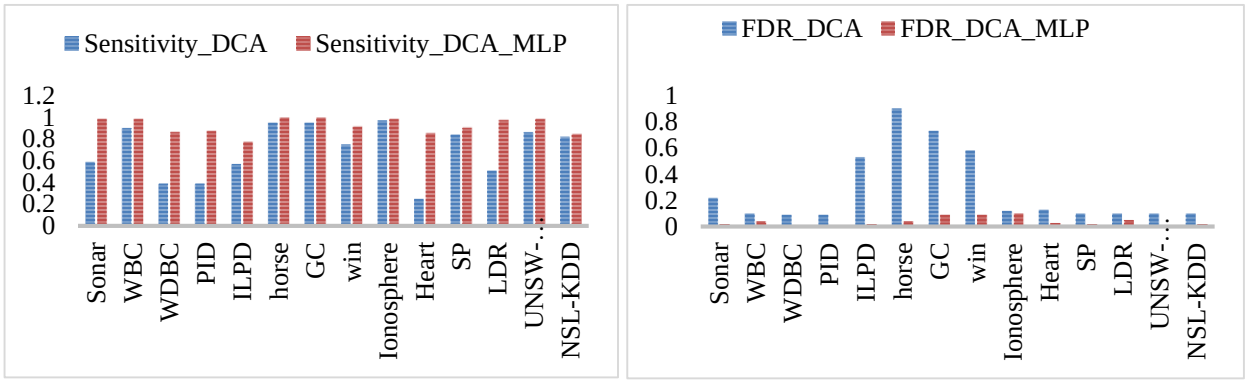

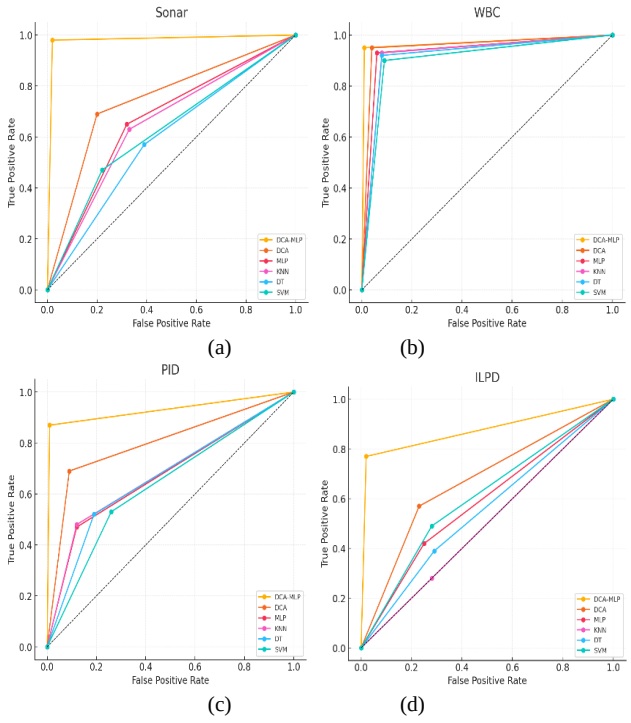

Fig. 4. The range between Sensitivity (SNS) and False Detection Rate (FDR) for DCA-MLP and DCA in benchmark datasets.

As illustrated in Fig. 4**,** the results are summarized in terms of SNS and FDR, which are critical performance metrics for anomaly detection models. The increased distance between the two metrics for the DCA-MLP model demonstrates its improved ability to clearly distinguish between normal and abnormal data groups. This larger gap indicates that the DCA-MLP not only increases the detection of actual anomalies but also appropriately limits false positives, leading to more accurate and dependable classification results. This capability is essential in high-stakes domains like cybersecurity, healthcare, or fraud detection, where accuracy and reducing false alarms are crucial.

Across all fourteen datasets, the proposed MLP-DCA model consistently achieved the highest Area Under the Curve (AUC) values when compared to other DCA variants and traditional classifiers, including stand-alone MLP, K-Nearest Neighbors (KNN), Support Vector Machine (SVM), and Decision Tree. As illustrated in Fig. 5, this robust and consistent performance highlights the superior generalization capability of the MLP-DCA model. Furthermore, the statistically significant improvement over both the standard DCA and conventional classifiers underscores the effectiveness of integrating adaptive learning through MLP into the biologically inspired DCA framework.

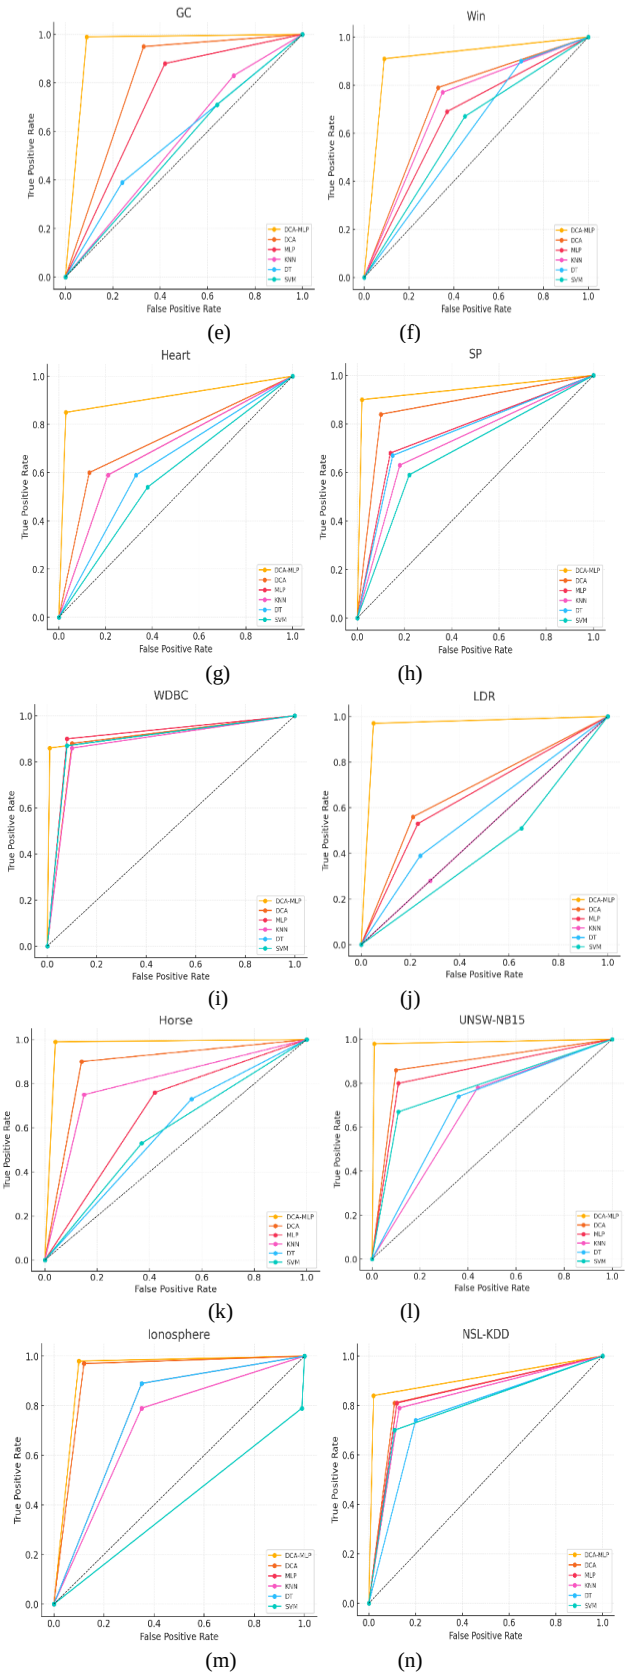

Fig. 5. Illustrates the comparative classification performance of the various DCA expansions and traditional classifiers in terms of ROC analysis across multiple datasets.

VI. Discussion

The experimental results provide ample evidence for the effectiveness and robustness of the proposed DCA-MLP model against the traditional Dendritic Cell Algorithm (DCA) model. One of the major limitations of a standard DCA is that it relies on a fixed threshold value during classification. As the results show, the fixed threshold is very sensitive to dataset specific distributions, especially with class imbalance (which is typically the case with anomaly detection tasks). The static nature of the threshold often results in decreased detection accuracy and increased false negatives when applied to datasets with evolving or uneven data distributions.

Integrating a Multi-Layer Perceptron (MLP) into the DCA framework, the model overcomes this threshold sensitivity and gains the ability to learn and generalize complex decision boundaries. The MLP enables dynamic classification by continuously adjusting to the patterns within the input data. This adaptability significantly improves classification performance across a wide variety of datasets. For example, substantial improvements were observed in both sensitivity and specificity on datasets like Sonar, PID, and NSL-KDD, which are known for their variability and complexity.

Another important aspect highlighted by the results is the consistent superiority of the DCA-MLP model across different domains and data types, including medical (WBC, WDBC), cybersecurity (NSL-KDD, UNSW-NB15), and signal processing (Sonar). This indicates that the proposed hybrid model is not only effective for a single category of data but is also generalizable and robust across diverse anomaly detection scenarios. The model's capacity to handle both structured and unstructured features contributes to its high adaptability and makes it suitable for real-world applications where data distributions are not always known in advance.

Moreover, the comparison with recent state-of-the-art approaches further supports the DCA-MLP model's effectiveness. When evaluated against various DCA variants—such as GA-DCA, COID-DCA, and dDCA—as well as conventional classifiers, the DCA-MLP consistently achieved higher accuracy and demonstrated better sensitivity-specificity trade-offs. These improvements are statistically significant, with p-values well below the 0.01 threshold, indicating that the observed performance gains are not due to random variation but rather a result of the model's enhanced learning capabilities.

The model also shows strong capability in minimizing false positives, a critical factor in anomaly detection systems. The analysis of sensitivity versus false detection rate (FDR), as shown in the experimental figures, illustrates a wider performance gap for the DCA-MLP model. This means it not only detects true anomalies more accurately but also avoids misclassifying normal instances as abnormal, thereby improving the reliability and precision of the system. Such performance is particularly crucial in high-stakes applications such as fraud detection, network intrusion prevention, and medical diagnosis, where incorrect predictions can lead to severe consequences.

VII. Conclusion

This research presents an enhancement of the Dendritic Cell Algorithm (DCA) aimed at improving anomaly detection

performance. The new approach utilizes a Multi-Layer Perceptron (MLP) embedded into the DCA framework, thereby eliminating the threshold-based classification reliant exclusively on the multi context antigen value (MCAV). This innovation solves the fundamental problems of fixed thresholds, which generally perform badly when measured with extreme values and bad from the perspective of typically improving the accuracy of anomaly detection. By leveraging the adaptive learning capabilities of the MLP, the enhanced MLP-DCA model demonstrates increased robustness and adaptability. Experimental results conducted on fourteen benchmark datasets validate that the MLP-DCA model significantly outperforms the conventional DCA, showing notable improvements in sensitivity, specificity, and overall accuracy.

These updates suggest that there is a good reason to believe that combining the strong principles of anomaly detection in the DCA with the extremely capable pattern detection and recognition advantages of the MLP. However, this study also has certain limitations**.** First, while the current model maintains consistent performance across many datasets, its effectiveness will vary when used on large-scale or highly imbalanced real-world data where rare anomalies are often prevalent. Second, the model's performance depends on hyperparameter configurations in both the DCA and MLP components, which may require manual tuning or additional optimization for each dataset. To add, the current model has not yet taken streaming or online data into account so there is no direct application of it towards real-time anomaly detection. As a result, the MLP-DCA model may have significant advantages for complex classification tasks, specifically for anomaly detection, which is characterized by non-linear data distributions or imbalances related to classes. Future research could explore integrating the Dendritic Cell Algorithm with advanced deep learning architectures or reinforcement learning-based decision modules. Hybrid approaches have the capacity to further improve performance on the class of complex datasets, which can be found in time-series anomaly detection, streaming data environments, and image-based pattern identification applications.
