In addition to the tabular overview, Fig. 5 visually illustrates the comparative global metrics among the six architectures. The illustrated bar graphs validate the superior and closely comparable performance of each model across all measures, underscoring the resilience and dependability of our federated learning methodology. This consistency indicates that federated learning, when combined with suitable data resampling methods (namely KMeans-SMOTEENN) and diverse neural network topologies, may proficiently address data imbalance, resulting in highly accurate and balanced predicted outcomes.

In conclusion, both the table and graphical analyses unequivocally endorse the efficacy and dependability of our federated neural network methodology in identifying credit card fraud across various clients, yielding robust, equitable, and interpretable predicted results.

B. *Explainable AI with LIME*

We employed Explainable AI through the LIME (Local Interpretable Model-agnostic Explanations) technique to enhance the interpretability of the Deep Neural Network (DNN) model's predictions in fraud detection. Fig. 4 demonstrates LIME visualization for a transaction classified as non-fraudulent with complete certainty (probability = 1.00) that features V11, V2, and V17 significantly bolster the non-fraud forecast (shown in blue), but features V14, V3, and V15 marginally suggest a propensity for fraud (marked in orange).

Despite certain indicators indicating possible fraud, their total impact is negligible, therefore corroborating the model's determination as non-fraudulent. This visualization improves transparency in the model's decision-making process and elucidates the significance of various attributes in certain forecasts, which is essential for stakeholder comprehension in financial contexts.

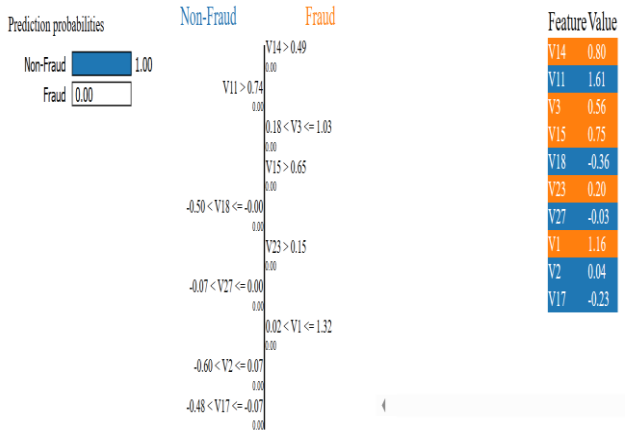

Fig. 4. Explainable AI.

C. *Performance Comparison with State-of-the-Art Methods*

To assess the efficacy and originality of our proposed approach, we performed a comparison analysis using other cutting-edge federated learning and unbalanced data management strategies documented in the literature. Table III demonstrates that our proposed model, which employs a Deep Neural Network (DNN) combined with the K-Means SMOTEENN method, exhibits exceptional performance, surpassing the majority of existing methodologies across various evaluation metrics, including Accuracy, Recall, Precision, F1-score, AUC, and AUPRC. Our method exhibited exceptional precision, recall, and F1-score, each at 99.93%, in addition to a high AUC value of 98.33% and a significantly raised AUPRC of 84.20%, outperforming comparable contemporary methodologies including those of Mustafa et al. [6], Liu et al. [13], and Saha et al. [29]. This thorough performance comparison highlights the efficacy and innovation of our federated learning methodology, especially in tackling the issues of imbalanced datasets in credit card fraud detection tasks.

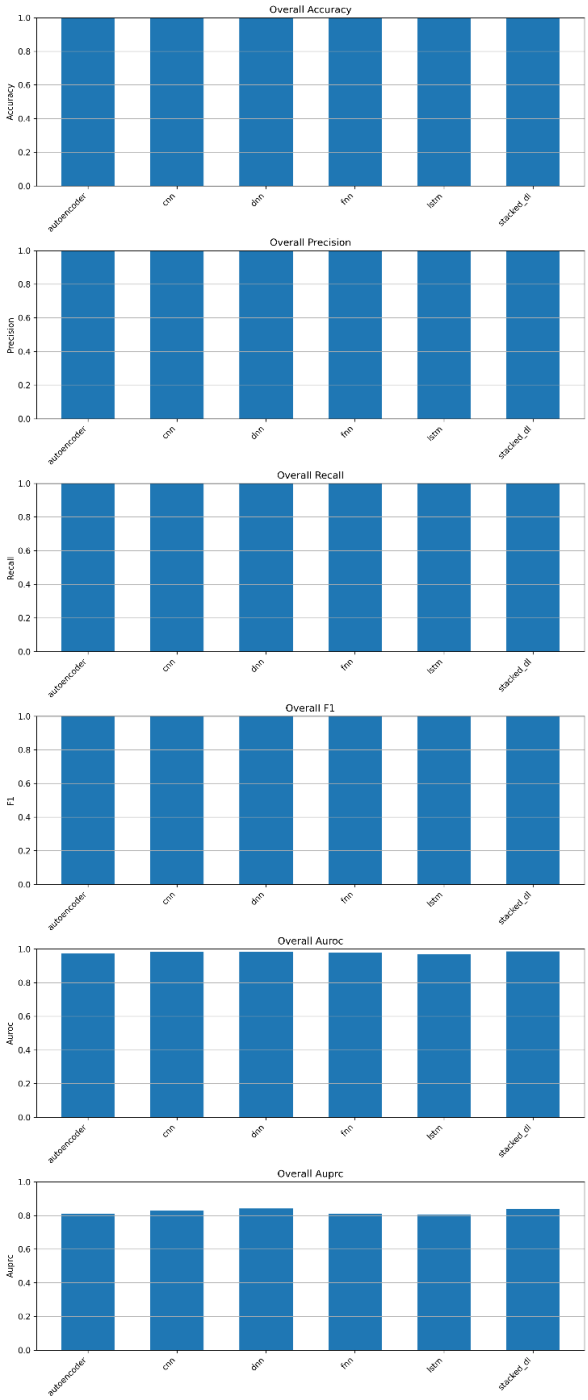

Fig. 5. Performance evaluation.

D. Discussion

Our findings illustrate the efficacy of integrating federated learning with the FedAvg algorithm, a K-Means-SMOTEENN hybrid methodology, and a Deep Neural Network (DNN) in tackling significant obstacles in fraud detection across several customers. The implementation of federated learning (FL) markedly improves data privacy by facilitating collaborative model training without the exchange of sensitive client information, consistent with prior study findings [1, 2]. Furthermore, the FedAvg technique effectively consolidates local models, yielding consistently superior prediction performance across diverse client datasets. The use of KMeans-SMOTEENN significantly enhanced the management of the pronounced class imbalance characteristic of fraud detection datasets. This hybrid approach substantially reduced the overlapping distribution between fraudulent and non-fraudulent occurrences by producing representative synthetic samples inside confined clusters. Our findings validate the results of other studies [3, 4], demonstrating that cluster-based oversampling strategies surpass conventional methods in intricate, imbalanced situations.

Additionally, we utilized Explainable AI (XAI) methodologies, specifically the LIME approach, to elucidate the predictions generated by our DNN model. The LIME display emphasized the most significant features impacting individual predictions, enhancing model transparency and interpretability. The interpretability of automated judgments is essential for stakeholders, particularly in financial services, since it enhances confidence and ensures regulatory compliance, as highlighted by Ribeiro et al. [5].

Notwithstanding the attainment of encouraging outcomes, our study possesses specific limitations. The existing solution predominantly assesses federated learning in simulated client environments, which may not accurately reflect real-world operational conditions characterized by network latency, data heterogeneity, and diverse compute resources among clients. Moreover, the utilization of synthetic data, although efficient, may generate artifacts that inadequately reflect authentic fraud trends.

TABLE III. PERFORMANCE COMPARISON WITH STATE-OF-THE-ART METHODS

V. CONCLUSION

This study introduces an innovative methodology that combines federated learning using FedAvg, KMeans-SMOTEENN to tackle data imbalance, and Explainable AI with a Deep Neural Network model to improve multi-client fraud detection systems. Our proposed method exhibited strong predictive performance, enhanced data privacy protection, effectively tackled class imbalance issues, and provided clear model interpretability.

The integration of these methodologies enhanced stakeholder trust and fostered a more profound comprehension of model-driven decisions in the financial sector.

Future research has found numerous promising avenues. Investigating sophisticated federated learning methodologies, including personalized FL (e.g., FedProx, FedBABU, or adaptive FL approaches), may enhance model efficacy and adaptability to client-specific data distributions. Moreover, the integration of Differential Privacy approaches would augment data privacy, providing enhanced safeguards against potential inference assaults.

Finally, applying this methodology to extensive real-world deployments, including dynamic and streaming data, could assess and enhance the practical usability and resilience of our suggested strategy.

***Abstract*—DoS attacks have been the most popular type of attack on SDNs. The threat landscape has widened due to advanced persistent threats. Recent studies have focused on a single level of defence and conventional detection methods, which have become redundant. The study proposes and implements a novel multilevel DoS attack detection, which has a three-pronged approach to counter modern-day DoS attacks. The first level emphasizes the Zero Trust mechanism using Hash SHA-256 to validate the clients. The second level uses hybrid deep learning models to detect DoS attacks, which are trained and tested across three latest datasets, namely NSLKDD, CIC DOS 2019 and IOT2023, giving an accuracy of 95% consistently. The third level is a lightweight adaptive DoS detection, which can detect fast and low-rate DoS attacks, ensuring that the SDN is secure in a few milliseconds by ruling out any possibility of congestion. The results clearly indicate how a three-level approach can thwart most advanced persistent threats.**

I. INTRODUCTION

Traditional networks are decentralized, rigid to allow changes, and complex to configure and manage due to vendor-specific issues. SDN is a disruptive innovation as it allows remote management of large-scale deployments with ease and takes care of the rising demand for processing, storage, and networking. It has a centralized and programmable controller along with switches in the data plane. SDN takes advantage of virtualization to provide flexibility, adaptability, elasticity, scalability, robustness, security, and abstraction of the hardware [1]. Below mentioned are the vulnerabilities in SDN based on layers:

A. Control Layer (Control Plane)

As the central element of SDN, if the controller is not managed correctly, it could be a single point of vulnerability and attack. The controller establishes the direction of data flow within the data plane. When the controller is attacked and compromised, it will have a negative impact on the network.

1) Hijacked rogue controller: The attacker takes control of the original controller or changes its functionality such that they can play around with the network. Some attackers replace the actual controller with a rogue controller, which controls the entire network thereafter. [2]

2) Fake traffic and network manipulation: Intruder exhausts all the resources by introducing fake packets and simultaneously initiates other attacks on the entire network. [3, 4, 5]

3) Weak authentication, authorization and information disclosure: When the controller has weak authentication and incomplete encryption, the attacker breaches confidentiality, leading to information disclosure, making it susceptible [6].

B. Infrastructure Layer (Data Plane)

Flow Switches are non-intelligent and can be manipulated by attackers [7, 8].

1) Flow table modification: The malicious nodes alter the flow table rules by adding or deleting rules and denying updates to the table.

2) Flow table overloading/buffer saturation: Flow table rules are stored in TCAM, which is expensive, power hungry, with limited space, making it vulnerable to overloading and buffer saturation attacks. They can jam the bandwidth to cause overloading.

3) Topology spoofing/traffic diversion: Create a fake network view to redirect traffic flows to attackers and explore vulnerabilities such as eavesdropping. They can forge non-existent links between switches.

4) Side channel attack: It targets the timing information by collecting ping timings and adding delays. Also, it can inform an attacker if a flow rule exists or not.

C. Application Layer (Application Plane)

Some contemporary attackers have started to exploit the applications present in the application layer [9].

1) Malicious applications: Attacker can modify or run malicious applications to ruin the network or collect information of the network.

2) Resource exhaustion: Attacker can run resource intensive requests to controller bringing down the system.

3) Policy conflicts: Applications running on single controller give conflicting policy instructions leading to delay and confusion.

4) Privilege elevation: One application gains higher privilege access over other applications and later controls and manipulates them.

D. Interfaces

1) Northbound interface: It serves as the application layer's and the control layer's open, local, non-standard, and non-encrypted connection interface. It collects network details, state resource requirements from the upper layer and gives directions to the controller in the control plane. As there are various types of REST APIs used here, this becomes a huge point of vulnerability for attackers to tamper or eavesdrop [10].

2) Southbound interface: It serves as the control layer's and data layer's open, local, and non-encrypted connection interface. The controller uses it to create and modify rules in the Flow table. Rules can be intercepted and manipulated due to a lack of security [11]. TLS security is recommended but not mandatory, making it vulnerable to contemporary attacks [12].

3) East-West bound interface: In most architectures, there is a single controller, and there are distributed multi-controller architectures to manage the SDN. The interface between these controllers is called the East-West bound interface. These controllers synchronise and work with each other for high availability by exchanging notifications. They share updates about the network, like the state, devices, changes in the flow table, list of hosts, etc. Due to a lack of security, attackers compromise and exploit the controller [13] interface between the switches. In the data plane, switches are interconnected via links on which packets traverse till they reach the destination. Links are open, local and not encoded, making it vulnerable.

Section II discusses the various DDoS defense approaches in related work. Section III presents the proposed method. Section IV highlights the experimental setup and results. Section V presents the conclusion.

II. Related Work

DDoS defense approaches are classified into two categories based on where these defense models have been deployed. Most attacks are carried out on the Controller rather than the switch.

A. Controller-Based Solutions

Bringing down the controller helps destroy the entire SDN. The main target is the controller, and the only way to protect the entire SDN is by protecting the controller. Over the years, many solutions have been proposed by researchers to protect the controller. Four major categories are: one is entropy-based, Machine learning, Neural Networks, Statistical analysis-based.

1) Information Entropy: During normal days, the traffic flow is normal, and the entropy value is maximum. As soon as the attack starts, the traffic flow increases and entropy starts to decrease. The threshold level for entropy is set. If the traffic flow goes below this level, then it triggers the detection mechanism. In [14], the authors compute the threshold value five times, and then it triggers the detection mechanism. In [15], there is a two-step mechanism, in the first step, it checks the decrease in the threshold value, and in the second step, if the value decreases, it checks MAC addresses to differentiate between flash traffic and attack traffic. There are two modules in [16], the first one is for detection based on the threshold value, and the second module is used for mitigation by blocking unacknowledged SYN packets from the client. In [17], there are three phases, the first is normal phase of counting of packets, second is the preparatory phase, if value goes below the threshold, third is mitigate phase by dropping packets. Authors in [18] built a trust framework to identify malicious flow based on Kullback–Leibler divergence or relative entropy method. In [19], the authors use Jensen-Renyi divergence measure to estimate the variation from the threshold value for normal as well as malicious traffic. This can detect both high and low-rate attacks. Authors in [20] use three values- counter, entropy, and traffic rate. For detection as the packet flow increases the entropy decreases count gets incremented. For mitigation, it collects DPID, port and IP information to block the malicious packets.

2) Machine learning: Based on historical data or changes in traffic flow, the system learns and detects the presence of DDoS attacks. Authors [21] propose aggregating packets to create signatures which can be later used to detect attacks. In [22] authors use a sequence of feature values to predict and detect attacks. Authors in [23] classify attacks using machine learning and neural networks. In [24], an SVM classifier was used after the authors extracted key features. In [25], the authors solved the multi-class classification problem by advancing the SVM algorithms. In [26], the authors implemented and compared MLP, Decision Tree, Random Forest and SVM to conclude that Decision Tree gives the best results. Authors in [27] extracted the features from the traffic to draw the feature pattern graph. In [34], the authors used entropy on ports and applied the KNN algorithm to detect and drop malicious traffic. In [28], the authors worked on KNN to get better accuracy. In [29], the authors classify the traffic based on packet flow, size and speed. In [30], the authors figured out the attack's intensity and classified the traffic using a KNN classifier. In [31], the authors implemented the Factorization Machine algorithm to mitigate low-rate DDoS attacks. In [32], the authors developed a multi-plane security framework named VARMAN, where the switch is modified to detect anomalies and then apply ML-based classifiers to detect attacks. In [33], the authors worked on programmable switches to improve efficiency. In [34], the authors deployed a trigger mechanism on the switches which alerts the controller, who activates the ML classifier (KNN and K-means) to detect the malicious traffic. In [35], the authors implemented a low-volume defense solution with the following models (MLP, Random Forest, Decision Tree, SVM, REP Tree, J48). In [36], the authors implemented a hybrid ML algorithm (Support Vector Classifier and Random Forest) to detect malicious traffic. In [37], the authors implemented the Redis Simple Message Queue (RSMQ) mechanism with the following machine learning models (ExtraTrees, Decision Tree, KNN and Naive Bayes) to improve the accuracy of detection. In

[38], the authors classified traffic using following machine learning models (MLP, Random Forest, Logistic Regression, DT and AdaBoost).

3) Artificial neural networks: Authors in [39] implement a mechanism which traces the source of the attack as it maintains the details of the entire network and a mitigation module to delete the malicious table flow entries. Authors in [40] classify the traffic using fuzzy logic combined with L1-Extreme Learning Machines. By employing both unsupervised hashing and the discrete-time finite-state Markov chain (DTMC) model, it mitigates attacks. In [41], the controller acts selectively and focuses only on affected switches by applying the fuzzy c-means algorithm.

4) Statistical analysis: In [42], the source is verified before accepting packets. The controller acts as a proxy and verifies the source, and sends SYNACK. In [43], it maintains the state and connection list of all TCPs. This list keeps on increasing till it reaches the set limit. Once it crosses that limit, the controller blocks packets from those sources. The authors designed the RADAR framework in which the controller selects certain flows to be investigated. Authors too confirm the legitimacy of the source, and the algorithm verifies the information in the Packet-In message with this dictionary of Port, IP, and MAC addresses. The malicious traffic is taken care of by a backup controller, which temporarily saves these requests as the attack begins, then quickly sends them to the main controller. Authors compare the threshold value to the quantity of Packet-In messages with a certain header received during a specific time interval. If it crosses the predetermined value, all packets are deep scanned.

B. Switch-Based Solutions

1) TCP proxies: LineSwitch deploys proxies based on random distribution and ensures blocking malicious traffic from reaching the control plane. In another paper, both act as proxy and minimizes the timeout to improve the efficiency. Authors provide multi-layer protection by implementing filters at all entry and exit points on the switches.

2) Information entropy: Implements the algorithm on the switches instead of overloading the controller. Authors deep-scan the packets for spoofing/changes, and once it locates the attacker host, it changes the table rules to block this host. To identify an attack, it also computes entropy within a predetermined time interval. The programmable switches cannot decode the arithmetic logarithmic function, so to calculate entropy, the authors utilize the longest-prefix match (LPM) table. It determines the IP-based entropy at the source and destination. Authors detect an attack on programmable switches by computing the entropy for IP addresses. They use the longest-prefix match (LPM) table and bespoke count-sketches, respectively, to approximate frequencies and carry out computationally complex mathematical operations.

3) Artificial neural networks: Used switches as neurons in a distributed intrusion prevention system based on BPNN. Parallel operation is used by switches on the same layer. For easy computations, each swap uses minimal resources. Further, they deployed a Radial Basis Function (RBF) neural network to enhance this work's accuracy. Authors propose a simple DDoS mechanisms having machine learning based, traditional IDS on a heterogeneous system including FPGA boards, GPU, and host processors.

4) Flow statistics: The security tools such a DNS reflection defense, firewall and extensive filtering have been installed. In [14], the authors, to counteract HTTP GET flooding assaults, per-URL counting technique was created on NetFPGA-based Openflow switches. On the programmable switches, the DDoS detection logic was deployed. The switch computes a hash value using the source's MAC and IP addresses and compares it to one that was already computed.

5) Smart switches: Authors deployed smart switches which would perform source address matching. If there is a mismatch it will automatically alert and block the traffic. It helps in early detection but will lead to overloading the controller with invalid requests. In another paper the source packets are filtered, and genuine packet traffic is given specific score so as to be allowed. This method is useful to limit the attack, but if the attacker bypasses this filter, it will fail. Authors use a port-hopping defense mechanism, where the target is moved to the controller, reducing the chances of an insider attack. In this, we need to add more moving target defense mechanisms, such as address hopping, service hopping, path hopping, etc.

III. Proposed Method

The traffic flow consists of information from regular clients as well as the DoS Attacker. The proposed method shown in Fig. 1 comprises three levels to ensure robust DoS attack detection:

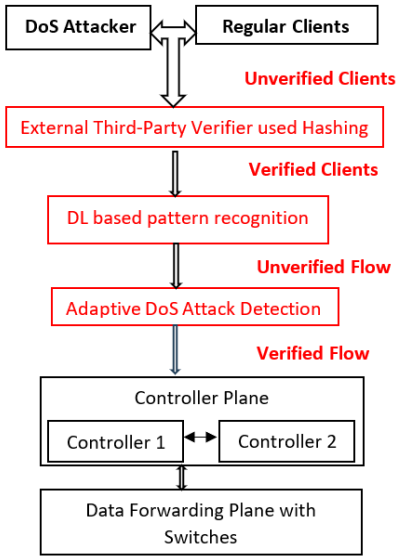

Fig. 1. Proposed method.

First Level – The first level allows only regular flow by matching the hash of the current flow with the hash of the

previously stored record. This ensures that only the verified clients go ahead to the next level.

Second Level – It consists of a deep learning-based hybrid model, namely RNN + LSTM, which has been trained and tested across three datasets to classify DoS attacks based on flow and performance-based parameters.

Third Level – Most APTs these days can mix Fast as well as Low-rate DoS Attacks to bypass the defense systems. So, we deploy the Adaptive DoS Attack detection, which will check all parameters and ensure only verified flows reach the controller.

A. Client Validation – Level 1

Fig. 2 shows an external third-party component that performs this client validation to ensure authorized users move on to the next level and reach the controller.

1) Collect - MAC Address and Source Port Number from each flow is collected by the third-party verifier.

2) Convert and Store – Third-party verifier converts the collected data into a hash value (SHA-256) and stores it in a hash table. The hash table consists of the hash value of known/regular clients.

3) Match - Repeat Step 1 and Step 2 to match the hash value of the current flow with the hash value of the flows stored in the table. If it matches, it will be classified as normal traffic and move to the next level or else block and do not allow that client to move ahead.

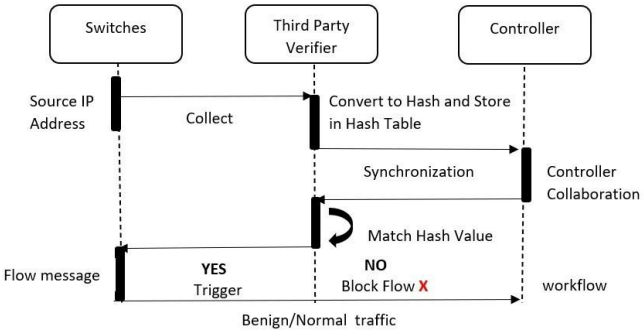

Fig. 2. Client validation.

B. Deep Learning Based DoS Detection – Level 2

The process of creating a Deep Learning based DoS attack detection system employs a methodical process beginning with the selection of three popular datasets. These datasets are NSL-KDD, CIC-DDoS 2019, and IoT-2023, which are intended to cover different types of network traffic patterns as well as possible attack types. To better illustrate these attack types, the datasets were focused on these specific attacks because they represent very prevalent attack types in real-life conditions. Certain attacks including SYN flood, UDP flood, and SQL Injection, were narrowed down for training of the model with intent of distinguishing between DoS/DDoS attacks and other attacks examples being ARP spoofing and command injection attacks. During model implementation, experimentation was carried on several deep learning architectures, namely the RNN, LSTM networks and GRU. These models were selected due to their suitability to time series data as well as their capabilities of recognizing sequential patterns in the network traffic, with LSTM networks being the superior of all in learning long-term dependencies of the data. Among the reasons for adopting such models in this work is the affordability of the economies delivered. That's the sheer speed in real-time attack detection that the models are known to allow. Some models that incorporated RNN, LSTM and GRU were also trained. Due to phased traffic across complex systems aimed at enhancing detection rates. These models were learnt in interludes in order to save time, along with hyperparameter tuning to manage factors such as learning rates, batch sizes, and number of epochs, among others, with the aim of improving model accuracy and reducing overfitting. The models achieved an assessment based on vital performance indicators, specifically accuracy, precision, recall, and the f1 score. Accuracy is the ratio of the correct predictions made to the total amount of predicted traffic given. Precision is the ratio of the correctly predicted attack traffic to the overall predicted attack traffic. Recall is the ratio of the predicted attacks captured relative to the total predicted attacks. The F1-score is the harmonic mean of precision and recall. High precision ensures accurate identification of attack traffic while minimizing false positives. A high recall reflects the system's ability to detect most attacks, reducing missed threats. Accuracy should be maximized by correctly classifying both attacks and normal traffic. The F1-score, which balances precision and recall, should approach 1, indicating a well-rounded, effective IDS. High values across all these metrics demonstrate a robust and reliable deep learning-based IDS.

Key performance metrics:

- Accuracy (AC): The number of correct forecasts relative to total traffic.

$$AC = \frac{TP+TN}{TP+TN+FP+FN} \quad (1)$$

TP: True Positive: The model correctly predicts the positive class.

TN: True Negative: The model correctly predicts the negative class.

FP: False Positive: The model incorrectly predicts the positive class.

FN: False Negative: The model incorrectly predicts the negative class.

- Precision (P): It is used to figure out how much of the attack traffic is accurately identified.

$$P = \frac{TP}{TP+FP} \quad (2)$$

- Recall (R): It measures the rate of anticipated attacks relative to overall attack traffic.

$$R = \frac{TP}{TP+FN} \quad (3)$$

- F1-score (F1): It provides a more accurate, balanced estimate of both precision and recall.

C. Adaptive DoS Attack Detection - Level 3

Earlier attackers used to flood the network or system with excessive amounts of traffic (ICMP, UDP), data or requests. Modern day attackers do not depend on only one type of DoS Attack. They use timeouts (LDoS), small queries (DNS/NTP Amplification) to bypass the DoS attack detection systems. Effective LDoS attack detection can be achieved using time-based network traffic properties.

Parameters used in the proposed mechanism are listed. Other than $Th_{Discard}$ and $TS_{Duration}$, all values are listed in Table I below:

TABLE I. LIST OF PARAMETERS

Symbol	Description
Con	No. of connections to the server in current Time slot
IA	Packet Inter-arrival time in current Time Slot
AIA	Average Packet Inter-arrival time
TO	No. of Time-outs in current Time Slot
DP	No. of discarded packets in current Time Slot
D	Time Slot Duration (in Seconds)
T	Traffic in current Time Slot
AT	Average Traffic per Time Slot
TH	Threshold number of packets discarded in a particular Time slot

$$AT = \alpha * AT + (1 - \alpha)T \quad (3)$$

$$AIA = \alpha * AIA + (1 - \alpha)IA \quad (4)$$

To analyse network traffic, there are two steps:

Step 1 - The following parameters are calculated using network traffic data from the network interface card: T, TO, DP

Step 2 - Sleeps for D before calculating the following parameters using information gathered from Step 1: IA, AIA, T. It employs the following algorithm using the previously computed parameters. Algorithm 1 details the Adaptive DoS Detection.

Algorithm 1: Adaptive DoS Detection

Step 1: Evaluate T and AT ;

If ($T \geqslant ((1+\beta) * AT)$)

Then Goto Step 2 Else Goto Step 4

Step 2: Evaluate TO with Con and DP with TH;

If ((TO >= 2*Con) and ($DP \geqslant TH$))

Then Goto step 3 Else Goto step 4

Step 3: Evaluate IA with AIA; If ($(AIA \leqslant \gamma * IA)$)

Then Assume Slow Rate DoS attack and not congestion

Else Goto step 4

Step 4: Halt processing till the end of current time slot interval

Traffic and Average traffic are compared. When the volume of traffic in the current time slot T exceeds $(1 + \beta)$ times the volume of that time slot's average traffic (AT), we proceed. We continue when there are more connections than timeouts, and more packets are refused, than the set threshold. The inter-arrival time and its average are then compared. We conclude that we are not experiencing congestion, but rather a Slow DoS assault when IA decreases. The processing is halted for that time period if any of the steps are unsuccessful.

IV. EXPERIMENTAL SETUP AND RESULTS

A. Flow Validation – Level 1

The experimental setup is shown in Fig. 3. The SDN consists of three hosts, namely Host 1 having an IP address of 192.168.0.2, Host 2 having an IP address of 192.168.0.3, and Host 3 having an IP address of 192.168.0.5. Here we use a single controller named Controller 1 with IP address 192.168.0.4. The Attacker having IP Address 192.168.0.1 is an external entity, which does fast, as well as Slow DoS-based attacks, as controlled by us.

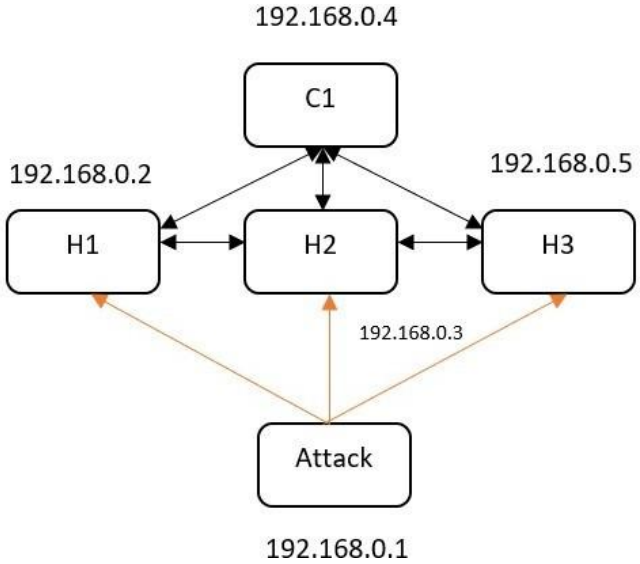

Fig. 3. Experimental setup (level 1).

We have noted their MAC addresses to verify. Data from the switches is extracted in CSV. Here we note the IP address, as well as the MAC Address, which is stored in the external storage. To store this data, remove the colon from the MAC Address and concatenate it with the Source Port Number (which is converted to a string). All the information is stored after applying SHA-256, as shown below. Each entry is stored in Table II to be matched. If the match is found, move to level 2 or wait for approval. During simulation, we found that the frequent IDs are stored and retrieved quickly from the database. New entries are not accepted and need time for approval from the controller. As soon as the entry from the attacker with source port number 6688 arrived, the hash matching failed. The attacker was blocked from moving to level 2, as expected.

TABLE II. CLIENT MATCH TABLE

B. Deep Learning based DoS Detection – Level 2

We have tested three datasets to find the best predictive model so that we can rule out flows based on the performance metrics discussed earlier [48].

The DoS attacks detection results are shown in Table III using the NSL-KDD dataset. The RNN + LSTM model records the highest accuracy of 95.14% in terms of finding DoS attacks. It is also the best in finding precision, recall and achieving F1-score. LSTM and its hybrid models also perform strongly with accuracies of more than 93%. In comparison, the accuracy rate for the SOM model is the lowest at 90.6%. This leads to the observation that, whereas models are useful in DoS detection, advanced deep learning models are on another level in DoS detection.

Table IV illustrates the performance of various machine learning models for detecting DoS attacks using the CIC-DDoS 2019 dataset. The LSTM model achieves the highest accuracy at 95.73%, followed closely by the RNN + LSTM model at 95.60%, showcasing their strong capability in identifying DoS attacks. Precision (P), recall (R), and F1 scores are consistent across all models, with values ranging between 0.85 and 0.88, indicating reliable detection performance across different approaches. However, while accuracy varies slightly, the models demonstrate comparable performance in precision, recall, and F1 score, with LSTM leading in accuracy, but all models performing similarly in overall detection quality. Thus, LSTM proves to be the most accurate, but other models like RNN + LSTM also offer strong results.

TABLE III. NSL-KDD DATASET [45]

Score	*SOM*	*RNN*	*GRU+LSTM+RNN*	*GRU*	*GRU+LSTM*	*LSTM*	*RNN+LSTM*
AC(%)	90.6	92.45	92.95	93.07	93.20	94.34	95.14
P	0.92	0.94	0.94	0.94	0.94	0.93	0.94
R	0.89	0.91	0.92	0.92	0.92	0.91	0.92
F1	0.90	0.92	0.93	0.93	0.93	0.92	0.93

TABLE IV. CIC-DDOS 2019 DATASET [46]

Score	*SOM*	*RNN*	*GRU+LSTM+RNN*	*GRU*	*GRU+LSTM*	*RNN+LSTM*	*LSTM*
AC(%)	90.6	92.53	92.61	93.52	93.67	95.60	95.73
P	0.88	0.88	0.88	0.88	0.87	0.87	0.87
R	0.87	0.87	0.87	0.87	0.87	0.87	0.87
F1	0.86	0.86	0.86	0.85	0.86	0.86	0.86

TABLE V. CIC-IOT 2023 DATASET [47]

Score	*SOM*	*GRU*	*GRU+LSTM+RNN*	*RNN*	*GRU+LSTM*	*LSTM*	*RNN+LSTM*
AC(%)	90.8	92.40	92.81	92.92	93.07	94.23	95.79
P	0.98	1	0.98	0.99	1	0.96	1
R	0.24	0.20	0.24	0.25	0.21	0.40	0.24
F1	0.38	0.33	0.38	0.40	0.35	0.56	0.39

Table V presents the performance of different models for detecting DoS attacks using the CIC-IoT 2023 dataset. The RNN + LSTM model achieves the highest accuracy at 95.79%, followed by LSTM at 94.23%, indicating their effectiveness in identifying DoS attacks in IoT environments. Interestingly, although GRU and GRU + LSTM exhibit perfect precision (P = 1), their recall values are significantly lower, leading to lower F1-scores. This indicates that while these models are highly precise, they miss a substantial portion of true positives. On the other hand, LSTM balances precision and recall, yielding a higher F1-score of 0.56, making it one of the more reliable models in terms of both accuracy and detection performance. While the RNN + LSTM model leads in accuracy, LSTM offers a better overall balance in terms of detection metrics.

The analysis in Fig. 4 highlights the effectiveness of models in accurately detecting DoS attacks on IoT networks, with RNN+LSTM being the most effective. Models like SOM underperform, indicating that not all models are equally suitable for this specific dataset.

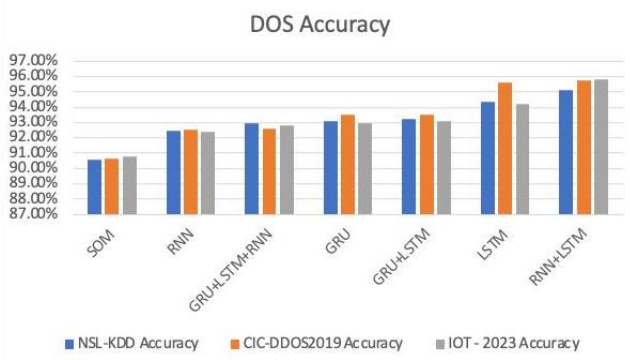

Fig. 4. Comparative Analysis of datasets based on their accuracy for DoS attack.

C. Adaptive DoS Attack Detection - Level 3

The experiment [49] is done using the Mininet Simulator, and we use a Python file to collect the flow, port, and timing statistics. Network simulation is run for 250 minutes, and 1,04,345 rows of data are collected. The simulation is run for a defined interval again, and more data can be collected. The test is divided into two phases. Initially, the simulation is started and kept ready to detect flows. Phase I – Normal simulation is done, allowing the flow of packets across all switches and controllers. Phase II – Attack is simulated, where 100 forged packets are sent. Following values of α, β, γ, and TH are taken as 0.75, 0.30, 0.70 and 1000, respectively. For Phase I: During this phase, data is gathered and data measuring the switch performance is measured, and the data is represented graph. From Fig. 5, it is clear that when there is no attack, the timeouts and discards are null. Also, the packets arrive in an orderly fashion.

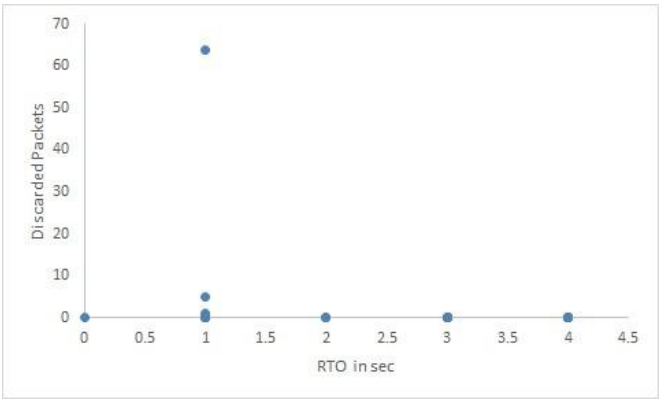

Fig. 5. Normal scenario (RTO vs discarded packets).

The typical traffic exceeds the current traffic in the time slot as soon as the attack begins, as shown in Fig. 6.

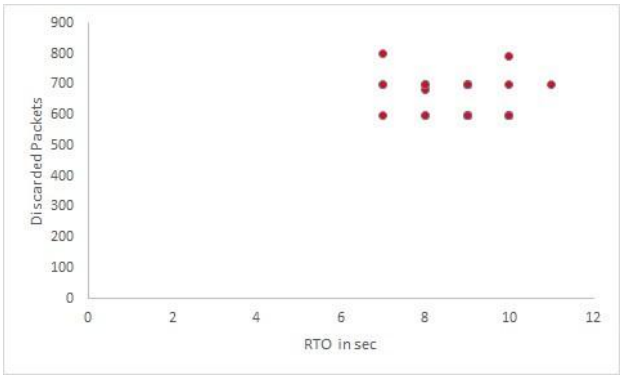

Fig. 6. Attack scenario (RTO vs discarded packets).

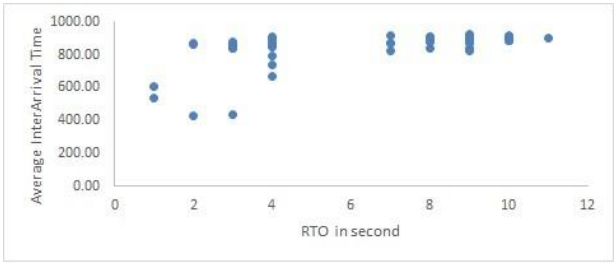

Fig. 7. Interarrival time.

Also, one can observe that the connections are 3 timeouts are 6. The number of packets discarded are way above 600. Looking at Fig. 7, the average interarrival time has gone below the packet interarrival time showing that it could be a low-rate DoS attack rather than congestion.

V. Conclusion

The results clearly indicate that the proposed method is effective against all modern DoS attacks in SDN. The level 1 zero trust approach ensures that only verified clients get access to the SDN. Level 2 based on deep learning, ensures that flows are classified and only verified flows are allowed to move forward. In case when the attacker bypasses levels 1 and 2, the level 3 adaptive DoS detection mechanism will ensure that both fast and low rates are thwarted. Researchers used blockchain for ensuring a zero-trust approach in SDN, which is time-consuming and complex. Hashing ensures that the initial check is done quickly and accurately. Researchers used various hybrid models, but the LSTM+GRU gives accurate predictions with better precision and recall. Researchers working on fast and low-rate attacks haven't worked on a simple, lightweight, combined approach relevant to real-time SDNs. This solution can be integrated with contemporary IDPS, as it is flexible and scalable.

***Abstract*—Assessing nutritional status, particularly among children and pregnant women, necessitates accurate measurement of Mid-Upper Arm Circumference (MUAC). This research introduces a novel system for MUAC estimation from digital images using the Mask R-CNN algorithm, employing a top-down panoptic segmentation strategy. The proposed model was designed to identify the upper arm region within human body images and compute MUAC values autonomously. Mask R-CNN was selected due to its capacity to perform precise segmentation of objects within visually complex scenes, especially in the mid-upper arm area. Model training was conducted using a dataset of annotated images, with subsequent evaluation confirming its ability to reliably detect and measure MUAC. The system was validated using 72 image samples, yielding a mean absolute error (MAE) of 2.31 cm when compared to manual measurements. Among these samples, 29.2% (21 individuals) exhibited a measurement discrepancy of 0 to 1 cm, 27.8% (20 individuals) showed a 1 to 2 cm difference, and 43.1% (31 individuals) demonstrated deviations exceeding 2 cm. Despite some variations in measurement accuracy, the system presents a promising tool for enhancing the automation and efficiency of nutritional assessments.**

***Keywords*—Mask R-CNN; mid-upper arm circumference; digital images; segmentation; mean absolute error**

I. Introduction

Recent advancements in artificial intelligence and image processing have significantly impacted the medical and healthcare sectors. A prominent area of application is anthropometry, where these technologies have improved the accuracy and efficiency of assessing nutritional and health status through body measurements [1]. Amongst the various anthropometric indicators, Mid-Upper Arm Circumference (MUAC) has gained recognition as a critical metric for evaluating individual health and physical condition [2] [3] [4].

MUAC is particularly valued for its effectiveness in detecting nutritional deficiencies, especially in vulnerable populations such as pregnant women [5]. As a simple, non-invasive, and rapid screening tool, MUAC is instrumental in identifying individuals at risk of Chronic Energy Deficiency (CED). CED during pregnancy poses a major public health concern, as it is linked to elevated risks of infection, anemia, hemorrhage, and adverse neonatal outcomes, including low birth weight (LBW) [6]. MUAC measurement below the widely accepted threshold of 23.5 cm is generally considered indicative of increased CED risk, necessitating further clinical evaluation and targeted nutritional support [7] [8]. Owing to its low cost, ease of use, and minimal equipment requirements, MUAC is particularly suitable for deployment in limited resource settings [9].

Traditionally, MUAC is measured by wrapping a flexible measuring tape around the midpoint of the upper arm. This process involves identifying anatomical landmarks, specifically the shoulder and the elbow—and determining the midpoint between them. The tape is then positioned horizontally and applied with sufficient tension to avoid measurement errors due to slackness or excessive compression [7]. Despite its practicality, this manual method is susceptible to variability, primarily due to inconsistencies in tape dimensions and user technique, which may compromise the reliability and accuracy of the measurements [10].

The advancement of technology, digital approaches are emerging as potentially more accurate, efficient, and scalable solutions [11][12][13][14][15]. Liu, Sowmya, and Khamis [16] showed that the photogrammetric method can produce precise MUAC measurements, with a Technical Error of Measurement (TEM) value of 3.76 mm and its reliability coefficient (R) reaching 0.99. However, this research has yet to tap the potential of the Mask R-CNN method, which has proven to be highly effective and can be generalized to various tasks, including complex analyses in medical imaging [17][18][19] and human pose estimation [20], making it highly suitable for the detailed segmentation required for accurate MUAC calculation from digital images.

Top-Down Panoptic Segmentation approach utilizing Mask R-CNN is among the pertinent innovations in developing digital image-based MUAC measurement systems. In [20], Mask R-CNN framework represents a robust methodology capable of concurrently performing object detection and generating precise segmentation masks for each detected object instance.

Panoptic segmentation as introduced in [21]. It supports comprehensive scene interpretation by unifying instance and

*Corresponding Author.

semantic segmentation in single framework. This technique assigns each pixel to either distinct objects ("things", such as the upper arm) or homogeneous background regions ("stuff"), thereby generating semantically rich image representations, a critical requirement for anthropometric analysis based on digital images.

The Top-Down approach is particularly advantageous for digital anthropometry, especially when implemented using models such as Mask R-CNN. This method operates in a hierarchical manner, beginning with the detection of regions of interest such as the upper arm through bounding boxes, followed by fine-grained segmentation within these localized areas. Mask R-CNN exemplifies this approach by coupling coarse object detection with subsequent mask refinement. Central to this process is the Region Proposal Network (RPN), which identifies candidate object regions [22] prior to the mask generation stage. This sequential pipeline enhances computational efficiency by concentrating processing resources on the most relevant portions of the image.

Integrating panoptic segmentation with a Top-Down architecture, the accuracy of MUAC measurement is substantially improved. This combination streamlines image analysis workflows, making it a promising innovation for applications in anthropometry and broader health-related fields.

Despite recent progress in digital anthropometry, existing image-based MUAC methods still leave three practical gaps. First, most pipelines do not employ a top-down instance/panoptic segmentation strategy (e.g., Mask R-CNN with RPN/RoIAlign/FPN) to robustly isolate the upper-arm region under real-world variation in pose, clothing, and background, limiting measurement reliability. Second, pixel-to-centimeter scaling is commonly tied to specialized hardware or fixed capture setups, offering no simple, low-cost calibration standardizable across sites in resource-constrained settings. Third, there is limited end-to-end validation against manual MUAC using interpretable metrics that jointly assess region localization (e.g., IoU) and circumference agreement (e.g., MAE in cm) on real subjects. In response, we: i) develop a top-down panoptic-segmentation pipeline based on Mask R-CNN to detect and segment the upper arm from complementary front and side views, ii) formalize an ellipse-based MUAC estimation that fuses both views, and iii) introduce a lightweight, field-feasible pixel-to-centimeter scaling procedure using a ubiquitous wall power outlet as reference. We then evaluate detection/segmentation and MUAC agreement against manual measurements on 72 individuals.

Accordingly, this study develops a top-down panoptic-segmentation pipeline based on Mask R-CNN (with RPN, RoIAlign, and FPN) to detect and segment the upper-arm region from two complementary views (front and side), and formalizes MUAC estimation using an ellipse-based circumference approximation that combines the front- and side-view measurements. To realize field feasibility, the pipeline includes a lightweight pixel-to-centimeter scaling procedure that uses a standardized wall power-plug as a ubiquitous reference object. The system is implemented in Detectron2 [28] and evaluated using Intersection over Union (IoU) [25] for detection/segmentation and mean absolute error (MAE, cm) for MUAC agreement with manual measurements, alongside distributional error analysis and training-configuration comparisons.

The significance of this work is twofold. Practically, it reduces dependence on operator skill and measurement hardware by shifting MUAC assessment to a camera-based, low-cost workflow that can be standardized across sites and is well-suited to limited-resource environments. Technically, it demonstrates how top-down panoptic segmentation can strengthen digital anthropometry by delivering reliable region isolation prior to metric estimation, laying the groundwork for near-real-time and mobile implementations that can support large-scale nutritional screening and follow-up [21].

To guide the reader, the remainder of this study is organized as follows: Section II presents the related works. Section III (Materials and Methods) details the dataset and annotation protocol, image-capture standards, reference-object scaling, the MUAC estimation formulation for front/side views (ellipse-based), the MAE metric, and the Mask R-CNN–based top-down panoptic segmentation pipeline. Section IV (Implementation and Results) first describes the dataset preparation and training environment, then details the system architecture. It also presents a comparative evaluation across training iterations and model variants (loss and accuracy), and reports the test results—detection IoU; MUAC–vs–manual agreement summarized by MAE (in cm) with its error distribution; and qualitative top-down panoptic-segmentation visualizations. Section V (Discussion) analyzes the findings, limitations, and avenues for improvement. Section VI (Conclusion) summarizes the contributions and key findings. Finally, acknowledgments are provided.

II. Related Work

Prior digital anthropometry solutions span: i) manual tape measurement, ii) monocular photogrammetry and regression, iii) 3-D imaging systems, and iv) learning-based detection/segmentation pipelines.

1) Manual tape. MUAC is commonly measured by wrapping a dedicated MUAC tape around the upper arm; however, design differences (e.g., material thickness and scale placement) introduce systematic measurement discrepancies, and there is no single global tape specification—prompting calls for common design standards and standardized reporting [10].

2) Single-camera photogrammetry/regression. Liu et al. showed that MUAC (and height) can be estimated from images using linear regression under controlled capture with high reliability (TEM$\approx$3.76 mm, R$\approx$0.99). These systems typically rely on strict imaging geometry and explicit calibration/landmarking, and do not perform instance-level region isolation of the upper arm [16].

3) 3-D imaging. Automated 3-D anthropometry has demonstrated precise body measurement extraction, including in low-resource settings, but requires dedicated hardware and controlled environments that can increase deployment cost and operational complexity [11], [29], [14].

4) Learning-based segmentation. Mask R-CNN and related top-down components (RPN, RoIAlign, FPN) [20], [24] deliver strong instance segmentation across diverse medical-imaging tasks, including organ and lesion analysis [17]–[19]. To our knowledge, integrating this paradigm into an end-to-end MUAC pipeline—with explicit centimeter scaling and paired-view fusion—remains underexplored.

Our study advances category (iv) by: 1) using a top-down Mask R-CNN pipeline to robustly isolate the upper-arm region from both front and side views, 2) fusing the views via an ellipse-based circumference formulation, and 3) introducing a lightweight, field-feasible pixel-to-centimeter calibration using a ubiquitous wall power outlet as the reference object. We evaluate both localization (IoU) and agreement with manual MUAC (MAE), on 72 subjects, thereby reporting interpretable, end-to-end accuracy rather than proxy metrics alone. Compared to (ii), our approach avoids hand-crafted landmarking and yields explainable, mask-level measurements; compared to (iii), it requires only commodity cameras and a common reference object, improving deployability in resource-constrained settings [16], [11], [29].

Across categories, open challenges remain: a) robust segmentation under clothing–background similarity and sub-optimal pose; b) calibration methods that are reference-free or self-calibrating; c) generalization beyond standardized capture; and d) near-real-time, mobile deployment. These gaps motivate methods that combine reliable instance-level isolation with simple, field-feasible calibration and interpretable circumference estimation.

III. Materials and Methods

This section establishes the methodological foundation of the proposed MUAC-from-image system. We first outline the Mask R-CNN–based top-down panoptic segmentation pipeline—covering the backbone-FPN architecture, RPN/ROIAlign heads, and instance masks—then formalize MUAC estimation from front/side views via an ellipse-based circumference formulation. We also define the MAE metric and detail the dataset acquisition and image standards, COCO-formatted annotations (person, hand, upper arm) prepared in Roboflow, and the pixel-to-centimeter scaling derived from a wall power-plug reference.

A. Mask R-CNN

In the realm of instance segmentation, Mask R-CNN introduces a substantial enhancement, enhancing the Faster R-CNN framework by integrating both object detection and detailed pixel-wise delineation of individual objects [20]. Its primary innovation lies in the addition of a separate, parallel pathway dedicated to producing binary segmentation masks for each proposed region, known as a Region of Interest (RoI). This structure allows the model to simultaneously perform object classification, precise localization, and segmentation at the instance level.

The model employs a two-stage processing pipeline, as illustrated in Fig. 1. Initially, the Region Proposal Network (RPN) [22] identifies candidate object regions within the input image, generating a set of preliminary bounding boxes. These proposals are subsequently refined in the second stage, where features corresponding to each RoI are extracted using the RoIAlign operation. This operation is critical for maintaining spatial alignment between the input feature map and the sampled features, which directly contributes to the precision of the segmentation output. Utilizing these aligned features, the network proceeds to classify each object, adjust the bounding box coordinates, and produce a binary segmentation mask delineating the object's spatial boundaries.

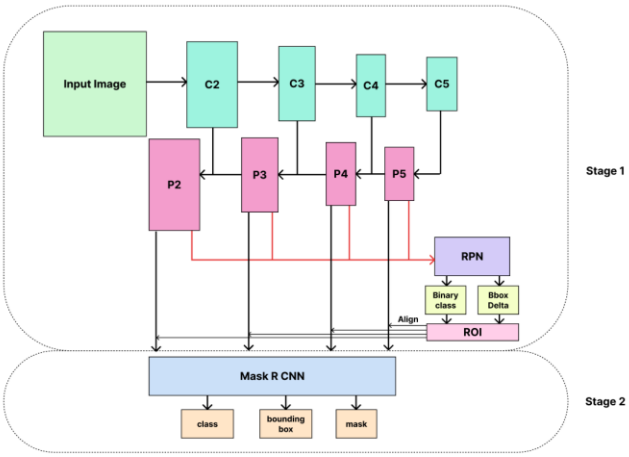

Fig. 1. Architecture of Mask R-CNN.

A key advancement in Mask R-CNN is the replacement of the RoIPool layer with RoIAlign. RoIPool's quantization step often introduces spatial misalignments that compromise mask accuracy. RoIAlign mitigates this issue by avoiding quantization, preserving the exact spatial information during feature extraction. This refinement substantially improves both detection precision and the quality of the generated masks.

Since its introduction, Mask R-CNN has consistently demonstrated cutting-edge performance across prominent visual recognition benchmarks, particularly the COCO (Common Objects in Context) dataset [23]. Its exceptional accuracy has contributed to its broad adoption in diverse computer vision applications, extending well beyond its original roles in instance segmentation and object detection to encompass more advanced tasks, including human pose estimation.

The operational workflow of the Mask R-CNN architecture is organized into two main phases. Initially, a deep convolutional neural network—typically a ResNet variant—serves as the backbone to derive hierarchical feature maps from the input image. The extracted features are then passed to the RPN, which identifies potential object-containing regions. In the subsequent phase, the RoIAlign mechanism is employed to extract accurately aligned features corresponding to each proposed region. These refined features are subsequently utilized to simultaneously carry out object categorization, refine bounding box coordinates, and generate segmentation masks at the pixel level for individual instances.

In first stage, backbone network typically ResNet produces multi-scale feature maps denoted as C2 through C5, corresponding to different levels of convolutional hierarchy. These maps capture progressively abstract representations, with

deeper layers encoding semantic information and shallower layers retaining fine-grained spatial details.

To address scale variation among objects, Mask R-CNN integrates a Feature Pyramid Network (FPN) [24]. FPN constructs a multi–level feature hierarchy (P2–P5) by combining high-level semantic features from deeper layers with spatially detailed information from earlier layers through a top–down pathway and lateral connections. This multi–scale representation enhances the model`s ability to accurately detect and segment objects of various sizes within the same image.

Once the feature map is formed, RPN generates proposals for areas potentially containing objects. Each area proposal is assessed based on two main outputs:

- Binary Class: Determines whether the area contains objects or not.
- Bounding Box Delta: Correction of the bounding box on the proposal area to improve the accuracy of object position prediction.

Next, the area proposals generated by RPN are processed using ROI Align, a technique that aims to extract features with a fixed size, even though the size of the area proposals varies. ROI Align improves the shortcomings of the ROI Pooling method, which tends to produce quantization errors in the detection process.

During the second phase, the region proposals produced by the Region Proposal Network (RPN) are further processed by the Mask R-CNN head, which simultaneously carries out object classification, refines bounding box coordinates, and generates segmentation masks. This stage produces three principal outputs:

- Object Classification: The model assigns a category label to each detected object based on its learned features.
- Bounding Box Regression: The system adjusts the coordinates and dimensions of the bounding boxes to more accurately enclose the detected objects.
- Mask Prediction: In addition to detecting objects, Mask R–CNN produces a binary mask for each identified instance. This mask delineates the specific pixels associated with the object, enabling precise instance-level segmentation within the image.

This stage enables Mask R–CNN to provide outputs like bounding boxes, class labels, and binary masks that map object areas more accurately. Thus, Mask R–CNN is not only able to detect the position of objects but also provide detailed segmentation for each detected object. Final result of Mask R–CNN visualized by displaying the bounding box, class label, and mask on the input image.

B. Measurement Upper Arm Circumference (MUAC)

MUAC serves as a simple yet effective anthropometric measure for evaluating the nutritional status of pregnant women, particularly in screening for CED. Measure value below 23.5 cm is recognized as indicative of elevated CED risk, which is associated with adverse maternal outcomes and an increased likelihood of delivering infants with LBW.

Traditionally way assessed using manual measuring tapes, MUAC in this study is estimated through a digital method that leverages upper arm image segmentation. The approach begins with Mask R-CNN, which detects and accurately segments the upper arm within the image. From the segmentation mask's bounding box, specific geometric features—namely diagonal and horizontal lengths—are extracted to estimate MUAC.

For images captured from a frontal view, MUAC is inferred from the length of a diagonal line extending from the top-right to the bottom-left corner of the bounding box. In lateral view images, estimation is based on the horizontal distance from the midpoint of the left vertical edge of the bounding box to its geometric center. This view-dependent measurement technique is adapted from established methodologies [16], which also employed diagonal and horizontal representations to approximate upper arm dimensions. The proposed automated method aims to enhance the precision and consistency of MUAC estimation in digital anthropometric analysis.

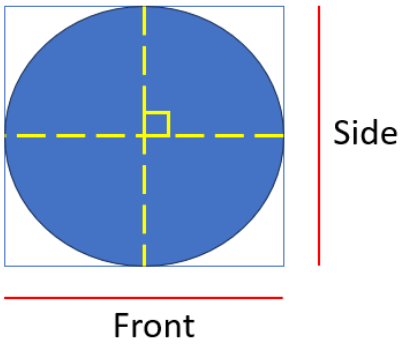

Fig. 2. A method for measuring MUAC.

The calculation method for MUAC is shown in Fig. 2. The front is the result of MUAC measurement with the picture taken from the front, and the side is the result of MUAC measurement with the picture taken from the side. Because the shape of the MUAC is closer to an ellipse than a circle, we will use the elliptical equation [see Eq. (1)]:

$$\text{Circumference} = 1/2\pi\ (\text{Front} + \text{Side}) \quad (1)$$

C. Mean Absolute Error (MAE)

MAE is one of the most frequently used evaluation metrics to measure the error rate in a regression or forecasting model. MAE quantifies the average magnitude of the absolute differences between observed values and corresponding model predictions, providing a straightforward indication of the model's predictive accuracy [26].

MAE is a commonly used performance metric that quantifies the average magnitude of errors between predicted values ($\hat{y}_i$) and actual ground truth values (y_i). It calculates the absolute differences without taking into account the direction of the errors, thereby providing a clear and intuitive interpretation in the same units as the original data. Due to this property, MAE is particularly well-suited for image-based measurement applications, such as those investigated in this study. The mathematical formulation of MAE is presented as follows [see Eq. (2)]:

$$MAE = \frac{1}{n} i + \sum_{i=1}^{n} (yi - \hat{y}i) \quad (2)$$

where,

- yi is the manual measurement value (reference)
- $\hat{y}i$ is the system measurement value
- n is the amount of data

D. Dataset

This study collected the dataset in person at the Faculty of Public Health, University of North Sumatra. Pictures were taken while the individual stood upright, with the left hand unobstructed by clothing and raised slightly, while the right hand was pointed straight down, as shown in Fig. 3. There was a total of 392 images, as shown in Fig. 4, but only 144 images were suitable for MUAC measurement. The reason is three-fold: i) Four pictures were taken from different angles during data collection. Only two images per individual were used in this study, so the remaining two were discarded. ii) The profile data of the individual in the image was not found, making the image unusable. iii) The captured image does not conform to the image standard.

Fig. 3. A dual-angle picture in-pose for MUAC measurement.

Fig. 4. The annotated set of images.

Images that do not meet the image standard cannot be included in this study because testing results will differ significantly from those that meet the image standard. Also, the measurement results will not match because the images that do not meet the image standards have different camera-to-object distances. The image standard detail such as Dimension: 2340 × 4160 pixel; Resolution:72 DPI; File Type: JPG; Camera to object distance: 180 cm. The collected data set was manually annotated on the Roboflow platform [27]. Annotation is done by marking bounding areas and bounding boxes to the objects to be detected in the image. The images in this dataset are put into three classes: person, hand, and upper arm. One hundred forty-four images were manually annotated. Each person has two images: a front-view image and a side-view image. The data labeling is done on a total of 72 individuals.

After annotating the images, a standard dataset suitable for model training was built. The dataset creation process was performed using the same annotation platform. This dataset is generated in JSON format, which is adapted to the COCO (Common Objects in Context) format so that it can be used directly in the Mask R-CNN architecture.

We used an in-house, task-specific dataset—rather than public corpora—because generic scene datasets lack MUAC-specific labels, paired front/side views, and the controlled capture conditions described above that are required for reliable pixel-to-centimeter scaling. These properties align with our method's needs (upper-arm detection/segmentation and dual-view geometry) and enable a faithful end-to-end evaluation with Mask R-CNN. We acknowledge the modest dataset size and controlled setting as limitations and plan to expand to more diverse populations and capture conditions in future work.

E. Reference Object Method

To establish a scale for measurements within the image, we employ a reference object method by using a known object—a standard power plug- in this study—as a reference for scaling. This approach relies on the known dimensions of the reference object to infer measurements within the image. The power plug is a standard object because its dimensions are typically standardized and can be reliably measured.

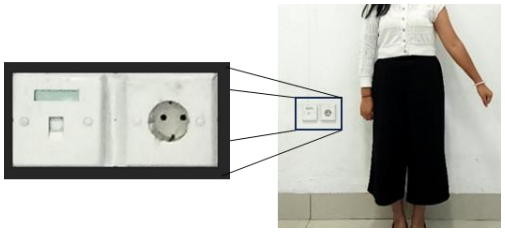

Fig. 5. (Left) Locating the power plug on the left side of the wall, and (Right) cropping the power plug with an image editor.

In Fig. 5, two images are presented to illustrate the process. The Right image shows an MUAC individual standing in front of a wall with a power plug visibly mounted on it. This initial image captures the scene as it appears naturally, with the power plug as the calibration reference object. The Left image in Fig. 5 shows the result after the power plug has been isolated by cropping the original image using Adobe Photoshop. This cropping step focuses on the power plug, removing extraneous elements from the image to allow for precise measurement.

Fig. 6. Determining the power plug's height using a measuring tape.

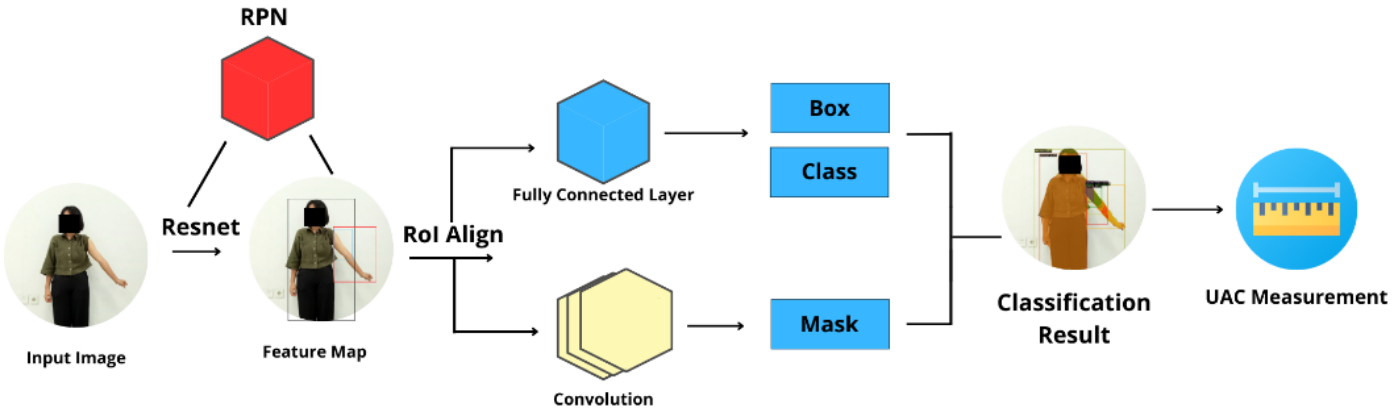

Fig. 7. General architecture of proposed system.

Fig. 6 shows the physical measurement of the actual power plug using a measuring tape, which determines its height to be 8.5 cm. Together, the equivalent height in pixels after measuring the power plug with digital imaging software is the width 297 pixels and height 136 pixels. These measurements are critical for calculating the scale factor that relates pixel dimensions in the image to real world dimensions.

The scale is calculated using the following equation:

$$Scale = y : \hat{y} \tag{3}$$

The variable y refers to the physical height of the power plug (8.5 cm, and the variable $\hat{y}$ refers to the height of the power plug in pixels (136 pixels). After plugging the values measured beforehand into the equation, the scale is computed: Scale = 8.5 cm: 136 px.

Simplifying this ratio, we divide both sides by 8.5, yielding 1 : 16. This means that 16 pixels in the image correspond to 1 cm in the real world. In other words, the pixel-to-centimeter conversion factor is 16 pixels/cm [see Eq. (3)]. This scale factor is then applied to all object detection and segmentation results obtained from the image. For example, if an object detected in the image has a height of 48 pixels, its real-world height would be 48 / 16 = 3 cm.

IV. Implementation and Results

This section presents the implementation and empirical findings: dataset preparation and training on Google Colab using Detectron2 with Mask R-CNN-FPN, the end-to-end system architecture, and a performance study across training iterations (1000 versus 2000). We then report testing and evaluation results—including IoU-based detection accuracy, MUAC measurement comparisons with the resulting MAE, and the accuracy distribution—and illustrate the top-down panoptic segmentation outputs that underpin the measurements.

A. Dataset and Training

In this study, the dataset was prepared and processed using the Roboflow platform, a tool specifically developed to optimize workflows in computer vision applications. During the data collection phase, relevant images were gathered and subsequently organized within Roboflow to ensure compatibility with model training requirements. This preparation process likely encompassed several key steps, including image annotation (e.g., labeling objects within images), data augmentation (e.g., applying transformations such as rotation or scaling to enhance dataset variability), and partitioning the dataset into training, validation, and test subsets. Roboflow's integrated functionalities—such as automated preprocessing and annotation tools—facilitate the creation of well-structured and machine learning-ready datasets.

Following the completion of dataset preparation, model training was conducted using Google Colab (Google LLC). Cloud-based platform offers access to significant computational resources, including Graphics Processing Units (GPUs), at little to no cost. Google Colab was using as the training environment primarily due to its robust GPU support, which is essential for efficiently accelerating the computationally intensive process of training deep learning models. The training efforts within this environment centered explicitly on the Mask R-CNN model, a novel architecture renowned for its efficacy in object detection and instance segmentation.

This research employs Detectron2 [28], a comprehensive library developed by Facebook AI Research (FAIR). Detectron2 facilitates the execution of complex, high-precision inference tasks, a capability leveraged in this study for model evaluation on the prepared dataset. For the specific architectural implementation herein, the Detectron2 framework was configured to utilize the Mask R-CNN model in conjunction with FPN.

B. System Architecture

The diagram depicts the data flow through the system, starting from the input images, followed by feature extraction using a backbone network. The system then branches into two main tasks: 1) a box classification and regression head, which predicts the object class and refines the bounding box coordinates, and 2) a mask prediction head, which generates a segmentation mask for each detected object. The final output is designed to produce measurements for the MUAC using the aforementioned algorithms. Fig. 7 illustrates the general architecture of the proposed system, providing a visual overview of the workflow.

C. Model Performance Evaluation with Varying Iterations

To evaluate the impact of training iterations on model performance, we compare the total loss and classification loss of different models trained for 1000 and 2000 iterations, as shown

in Table I. Total loss is a comprehensive metric that measures the overall error of the model, encompassing components such as classification, bounding box regression, segmentation, and object proposal. Classification loss quantifies the model's error in assigning objects to their correct classes. Lower values for both metrics indicate improved model performance.

TABLE I. PERFORMANCE COMPARISON FOR ALL TESTED MODELS

Model	Accuracy (P)	Total Loss	Class Loss
Faster R–CNN R50-FPN-3x (1000 iterations)	0.96	0.33	0.08
Faster R–CNN R50-FPN-3x (2000 iterations)	0.98	0.19	0.05
Mask R–CNN R50-FPN-3x (1000 iterations)	0.96	0.41	0.08
Mask R–CNN R50-FPN-3x (2000 iterations)	0.98	0.26	0.04
Mask R–CNN R101-C4 (1000 iterations)	0.98	0.40	0.04
Mask R–CNN R101-C4 (2000 iterations)	0.99	0.26	0.02

Table I provides a comparative summary of performance results for multiple models, including Faster R–CNN and Mask R–CNN variants. For instance, as illustrated by data also visualized in Fig. 8, extending the training of the Mask R–CNN R50-FPN-3x model from 1000 to 2000 iterations led to a reduction in total loss from 0.41 to 0.26 and in classification loss from 0.08 to 0.04. Similarly, for the Faster R-CNN R50-FPN-3x model, an identical increase in training iterations (from 1000 to 2000) yielded a decrease in total loss from 0.33 to 0.19 and classification loss from 0.08 to 0.05. This trend of improved loss metrics with more extensive training was consistent across other evaluated models. For example, the Mask R-CNN R101-C4 model exhibited a drop in total loss from 0.40 to 0.26 and in classification.

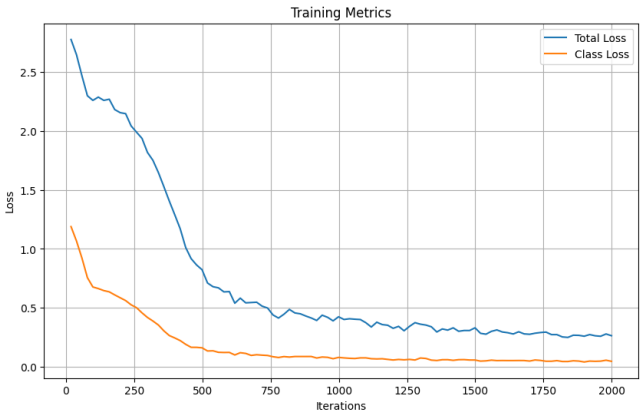

Fig. 8. Training loss curves for Mask R-CNN R50-FPN-3x. The plot illustrates the decrease in total loss and class loss over 2000 training iterations. The continued reduction in both loss metrics suggests that training for 2000 iterations yields a more refined model compared to training for only 1000 iterations.

Consistent with the observed improvement in loss metrics, the accuracy (P)—the proportion of correct predictions—also increased with more training iterations. For example, the accuracy of the Mask R-CNN R50-FPN-3x model improved from 0.96 to 0.98 when its training was extended from 1000 to 2000 iterations. Similarly, the Mask R-CNN R101-C4 model's accuracy rose from 0.98 to 0.99 under the same increase in training duration.

The presented results demonstrate that increasing training iterations from 1000 to 2000 consistently reduces total and classification losses across all tested models. This reduction is indicative of enhanced model convergence and lower overall error. The concurrent improvements observed in accuracy further corroborate this finding. Therefore, predicated on these empirical observations, this study adopts models trained for 2000 iterations, as they exhibit demonstrably superior performance characterized by minimized error and heightened accuracy.

D. Testing and Evaluation

Following the completion of model training, evaluation and testing procedures are conducted within the Colab notebook environment, where inference results are visualized directly on the input images. This workflow is seamlessly integrated with cloud storage services, which are utilized to manage both the datasets and the trained model files. To assess the accuracy of object detection, the IoU metric is employed as a key performance indicator. The IoU results for all evaluated images are presented in Table II.

TABLE II. IOU CALCULATION RESULTS

Individual	IoU for front-view image	IoU for side-view image

72	0,83	0,80

After inference, the output is extracted to the CPU for easier processing. From here, the bounding boxes, masks, class labels, and prediction scores are extracted from the results. The class indices corresponding to the objects to be detected are then identified, namely "person", "hand", and "upper arm".

Next, iterations are performed on each class to find the best detection based on the highest score value of each detected object. If the processed class is "upper arm", then the mask's diagonal and horizontal lengths are calculated using the CalculateDiagonalLength and HorizontalCutLength algorithms. The best mask for each class is then saved for further visualization. The saved information includes the bounding box, mask, score, and class label of the detection result. Subsequently, after measuring the MUAC of 72 individuals, the results obtained can be seen in Table III.

TABLE III. COMPARISON OF MUAC MEASUREMENTS

The overall system accuracy can be seen in Table IV, which provides a breakdown of the system's accuracy when tested on a dataset of 72 individuals using Google Colab as the training and inference platform.

TABLE IV. ACCURACY DISTRIBUTION

Total Data	72 Individuals
0 - 1 cm Results	21 Individuals
1 - 2 cm Results	20 Individuals
Results > 2 cm	31 Individuals

The distribution of results presented in Table IV elucidates the system's overall accuracy profile and identifies key limitations. While a substantial proportion of MUAC predictions achieve high accuracy (29.2% exhibiting a 0–1 cm difference from actual values) and moderate precision (27.8% with a 1–2 cm difference), the considerable percentage (43.1%) of predictions deviating by more than 2 cm suggests a lack of uniform precision across the study population. This inconsistency in performance could plausibly arise from various factors. These may include disparities in lighting conditions during image acquisition, instances of occlusion affecting the arm region, or natural variations in the anatomical appearance of the MUAC region across individuals, all of which can adversely affect the performance of the underlying Mask R–CNN model responsible for object detection and segmentation.

An evaluation was conducted using the Mean Absolute Error (MAE) metric, as defined in Eq. (2), to assess system performance quantitatively. This metric computes the mean absolute deviations of the system-generated measurements and the manual (ground truth) measurements for all individuals in the dataset. The analysis yielded an MAE of 2.31 cm. This result, representing the average discrepancy between the system's estimates and the actual values, highlights the necessity for additional improvements to improve the system's measurement precision.

E. Top-Down Panoptic Segmentation Approach

The system's measurement process was visualized using Detectron2's Visualizer, a dedicated utility for illustrating the outcomes of object detection and segmentation procedures. This tool graphically depicts the boundaries and masks of detected objects (specifically the upper arm in this context), superimposing key measurement indicators, such as diagonal and horizontal lines, onto the segmented areas. Such visual outputs are invaluable for qualitatively evaluating the system's detection and segmentation performance. Furthermore, they play a critical role in validating quantitative measurements by enabling direct comparison with ground truth data, which ultimately supports the assessment of the system's output reliability.

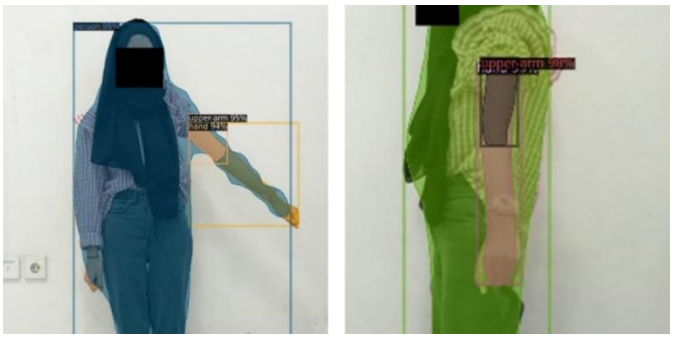

Fig. 9. Top-down detection and segmentation results for individual 52.

Fig. 9 is an example case with an estimated MUAC measurement that is the closest to the ground truth. The length of the diagonal line intersecting the detected mask area is 84 pixels. Meanwhile, the horizontal line bisecting the mask is 120 pixels long. The measurement results in pixel units are then

converted into centimeter (cm) units using a conversion factor, where 1 cm is equivalent to 16 pixels [derived from Eq. (3)].

After the conversion, it is found that the length of the diagonal line intersecting the mask (from the front image) is 5.25 cm, while the length of the horizontal line intersecting the mask (from the side image) is 7.5 cm. Next, these values are used in, as shown in Eq. (1), the elliptical formula to calculate the overall MUAC, which is 20.0175 cm.

For further examples, the following two instances are system MUAC measurements with a significant difference from the corresponding ground truth MUAC.

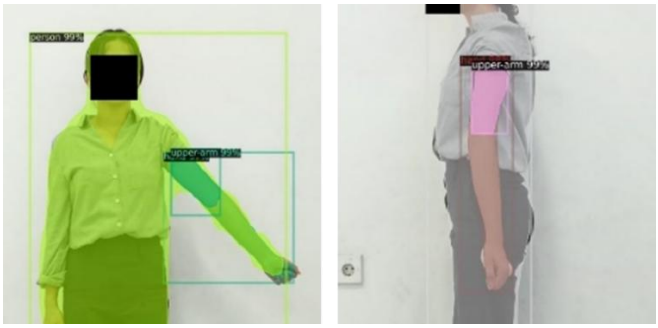

Fig. 10. Top-down detection and segmentation results for individual 48.

Fig. 10 illustrates an example of an image showing the result of a MUAC measurement that deviates by 1 to 2 cm from the ground truth value. In the image, the length of the diagonal line intersecting the detected mask area is 98 pixels (converted to 6.125 cm). Meanwhile, the length of the horizontal line bisecting the mask is 140 pixels (converts to 8.75 cm). Based on the data presented in Table III, the ground truth of individual 48 is 24.5 cm. Thus, the difference between the computed result and the ground truth is 1.15 cm.

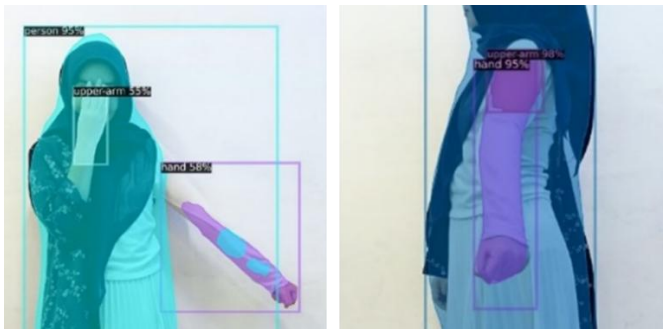

Fig. 11. Top-down detection and segmentation results for individual 13.

In another case, Fig. 11 is an example of images with the results of a MUAC measurement with a difference of > 2 cm compared to the actual MUAC measurement. The diagonal line intersecting the mask is 346 pixels (converts to 21.65 cm), while the horizontal line intersecting the mask is 209 pixels (converts to 13.06 cm). Plugging these values into the elliptical formula, we get the circumference measurement of 54.46 cm.

V. Discussion

The results of the IoU calculation in Table I shows that the model achieves reasonably good accuracy. The average for IoU calculation results for images taken from the front reaches 0.82, which is quite close to 1. The average IoU calculation results for images taken from the side reach 0.77, shows that the model is better at detecting pictures taken from the front than those taken from the side.

In Table III, the actual MUAC of individual 52 is 20 cm. So, the calculation result in this case has a difference of about 0.15 cm with the ground truth. The difference is not too high due to the person doing a moderately good pose where the arm is raised high enough so that the system can detect the upper arm well. The person also raises their sleeves, so that the upper arm is more straightforward to detect.

In some cases, as seen with individual 13, there is a notable variation between the estimated MUAC and the ground truth. In the case of individual 13, the size difference reaches 25.96 cm. This size difference is important because the system does not detect the upper arm correctly. As can be seen in Fig. 11, the system detects the upper arm on the person's left hand. This detection error is caused by the individual wearing a white shirt that resembles the background color of the picture. Furthermore, the participant's sleeve remained unraised, a circumstance that posed an additional challenge to the system's ability to perform accurate detection and segmentation of the target region.

Future Work: Building on our error analysis—evidenced by the front- versus side-view IoU gap (0.82 vs. 0.77) and failures such as individual 13, where clothing–background similarity and unraised sleeves led to mis-segmentation—we outline four concrete directions with measurable targets: 1) Robustness to clothing – background similarity and atypical poses: targeted augmentations (color/texture jitter, occlusion/cutout, pose perturbation), hard-negative mining, and boundary-refinement heads; target $\geqslant$ +0.03 absolute IoU on side view and $\geqslant$ 20% reduction in MUAC errors > 2 cm. 2) Calibration beyond site-specific objects: ablate the current outlet-based scaling against portable fiducials (checkerboard/ArUco) and reference-free/self-calibrating options; target $\leqslant$ 1.5$\times$ variance relative to the best method and < 5% catastrophic scale failures. 3) View fusion and measurement modeling: benchmark the current ellipse formulation against (a) robust statistics over multiple per-view cuts and (b) a small interpretable regressor from per-view mask features; target $\geqslant$ 0.3 cm MAE reduction without sacrificing interpretability. 4) Real-time, on-device deployment and prospective validation: compress the model (pruning/quantization), profile on mobile hardware, and run a head-to-head study against trained operators using standardized MUAC tapes; target $\leqslant$ 200 ms end-to-end latency per view with $\leqslant$ +0.2 cm MAE degradation versus desktop, intraclass correlation $\geqslant$ 0.9, and Bland – Altman limits of agreement within $\pm$3 cm [29].

VI. Conclusion

The Mask R-CNN model accurately detects the upper arm and other body parts. This shows good potential for object segmentation, especially in the case of MUAC measurement. Based on the IoU calculation, 0.82 was obtained for images taken from the front angle and 0.77 for pictures taken from the side. These high IoU values indicate that the applied Mask R-CNN model can produce segmentations close to the annotated ground truth mask, especially in images that meet the image

standards. This value also indicates that the model can detect upper-arm objects better when the image is taken from the front. This result supports the effectiveness of the system for MUAC measurement.

The MUAC measurement results obtained through the digital imaging system show variations in accuracy depending on the quality of the image. As seen in Fig. 9, when the photos are taken with closer compliance to the image standard, the system measurements can closely resemble the manual measurements (higher accuracy). However, significant differences between system measurements and manual measurements can occur, as shown in Fig. 10 and Fig. 11, indicating that the system's accuracy will decrease, if the individual does not show the upper arm clearly and the color of the sleeve matches or resembles the background color.

Capturing images with a frontal viewing angle, proper distance, and adequate lighting tends to produce more accurate measurement results. This emphasizes the importance of quality and consistency in the image capture process to ensure that the automated measurement system can provide accurate and reliable results.

Evaluation using the Mean Absolute Error (MAE) metric resulted in an average error of 2.31 cm between system measurements and manual measurements. Of the 72 image samples tested, 21 individuals (29.2%) had measurement differences of 0-1 cm, 20 individuals (27.8%) had differences of 1-2 cm, and 31 individuals (43.1%) had differences of more than 2 cm. Thus, further development is expected to overcome the problems found in this study and improve the performance and accuracy of the MUAC detection and measurement system.

This study has several limitations. The dataset is modest and was collected under a standardized imaging protocol, which may limit generalizability. Pixel-to-centimeter calibration depends on a wall power-outlet reference that may not be available or standardized across sites. MUAC estimation fuses paired front- and side-view measurements via an ellipse approximation, making the final circumference susceptible to view-specific errors. The pipeline is also sensitive to clothing/background similarity and pose. Future work will expand data diversity and size, explore reference-free calibration, and strengthen the robustness of the segmentation and measurement pipeline.

Ensemble Learning for Multi-Class Android Malware Detection: A Robust Framework for Family Level Classification

Mana Saleh Al Reshan
Department of Information System-College of Computer Science and Information Systems, Najran University, Najran 61441, Saudi Arabia
Emerging Trends and Technologies Lab (ETRL)-College of Computer Science and Information Systems, Najran University, Najran 61441, Saudi Arabia

***Abstract*—The widespread popularity of Android devices has made them a prime target for sophisticated and evolving malware threats. Traditional malware detection techniques rely on binary classification (malicious vs. benign), which fails to capture the nuanced behavioral differences between malware families, critical for threat intelligence and incident response. To address this limitation, we propose a robust multi-class classification approach for Android malware family detection, leveraging ensemble learning and advanced feature selection methods. Our system uses a hybrid feature extraction strategy that combines Chi-Squared and Mutual Information techniques to eliminate low-utility features and retain the most discriminative attributes. These include flow-based metrics, inter-arrival time (IAT), and session duration, key indicators of malicious behavior. We evaluated five baseline classifiers (Random Forest, Gradient Boosting, XGBoost, Extra Trees, and Decision Trees) across three ensemble strategies (bagging, voting, and stacking). Among these, the Stacking ensemble achieved the highest overall performance, with 83% across all evaluation metrics, accuracy, precision, recall, and F1-score, and a True Negative Rate (TNR) of 93.34%. The framework also improves the detection of minority malware families in imbalanced datasets. These findings highlight the advantages of ensemble learning for building scalable and reliable Android systems suitable for real-world deployment.**

***Keywords*—Malware detection; cyber threat; ML models; feature selection; ensemble methods**

I. Introduction

The rapid proliferation of intelligent mobile devices has established Android as the dominant smartphone computing platform. In 2020, global smartphone production reached approximately 1.24 billion units, with Android accounting for around 78.45% of the market share [1]. This dominance can be attributed to its open-source architecture, affordability, and extensive connectivity options, including Wi-Fi, Bluetooth, and GPS. Additionally, Android's support for third-party application installation significantly enhances device functionality.

However, this openness introduces critical security vulnerabilities. Unlike Apple's tightly controlled ecosystem, Android's decentralized app distribution model facilitates the spread of malicious applications beyond the official Google Play Store. Despite Google's integrated malware scanning systems, many harmful apps still manage to evade detection [2]. The fragmented nature of the Android ecosystem further compounds security challenges, increasing exposure to threats such as data breaches and system-level attacks. In the third quarter of 2021, the Kaspersky Security Network reported over 9.5 million blocked incidents involving mobile malware, adware, and riskware. Common infection vectors include malicious MMS messages, phishing emails, and compromised applications. Users are particularly at risk when installing unverified apps that embed malicious code or exploit system vulnerabilities [3]. With Android powering approximately 70% of global mobile devices, it remains a prime target for various cyberattacks, including malware, ransomware, and spyware. Frequently used apps like WhatsApp, Facebook, mobile banking tools, and games are often exploited, placing user data such as photos, contacts, messages, and financial information at significant risk. This underscores the urgent need for intelligent and reliable malware detection systems to safeguard user privacy and device security.

Machine learning (ML), particularly ensemble learning techniques, has shown great promise in malware classification [4]. These methods enhance detection accuracy and offer robustness against evasion techniques. Ensemble techniques such as bagging, voting, and stacking combine the predictive power of multiple classifiers, mitigating the weaknesses of individual models and improving overall performance [5].

Unlike traditional single-classifier methods, such as Decision Trees or Gradient Boosting, which are prone to overfitting and poor generalization on large and varied malware datasets, our ensemble learning methodology provides tangible enhancements. For example, in a stacking ensemble research on the AndMal 2020 dataset, the authors obtained 83% accuracy and a TNR of 93.4% for multi-class classification, which beat traditional models hands down. Similarly, recent deep-learning-based ensembles combining CNN variants (ResNet, SENet, SEResNet) in "MFEMDroid" have also yielded superior detection performance owing to their complementary strengths. These results further substantiate that ensemble methods, specifically stacking, bagging, and voting, not only enhance detection precision and reduce false positives but also are more robust against evasive

attacks. Further, in contrast to most existing research centering on binary classification only, our framework contributes more by allowing multi-family detection (Adware, Spyware, SMS_Malware, Benign), enabling richer threat identification and improved real-world applicability.

This research proposes and evaluates an Android malware detection framework that employs various ensemble learning methods to classify malware samples into families. The primary objective is to enhance detection reliability, reduce false positives, and bolster mobile cybersecurity.

Given the widespread use of Android smartphones, this study addresses a critical challenge in mobile security. By applying ensemble learning to classify malware into families, the proposed framework facilitates early threat identification and contributes to the development of intelligent, automated defense mechanisms. The findings are valuable to researchers, cybersecurity professionals, and mobile developers aiming to enhance the security of mobile environments.

Key Contributions:

- We obtained an Android malware dataset from the Kaggle repository. We utilized the Android Malware Dataset from Kaggle, consisting of 355,630 records with 85 features. Categorized into four families: Spyware, Adware, SMS_Malware, and Bengin.
- The dataset was preprocessed by handling null values, removing duplicates and irrelevant data, and applying label encoding to categorical features.
- Feature selection was performed using Chi-square and Mutual Information (MI) techniques to retain the most relevant features.
- We trained and evaluated five baseline machine learning classifiers: Random Forest (RF), Gradient Boosting (GB), Extreme Gradient Boosting (XGB), Extra Trees (ET), and Decision Tree (DT). In addition, we implemented and assessed three ensemble methods: stacking, bagging, and voting.
- This study presents a reproducible framework that can serve as a foundation for future research in mobile cybersecurity and intelligent malware detection.

The remainder of the study is structured as follows: Section II reviews related work on Android malware and Machine learning approach. Section III describes the dataset, preprocessing steps, and feature selection used in this study. Section IV presents the experimental results and provides comparative studies. Section V concludes the study and outlines the future direction.

II. Related Work

An algorithm for malware detection was proposed in this work [6]. Two Android malware datasets, including CICAndMal2017 and Drebin, were selected for conducting research. To detect malware attacks, the researchers implemented support vector machine (SVM), K-nearest neighbors (KNN), Linear Discriminant Analysis (LDA), Long Short Term Memory (LSTM), and Conventional Neural Network-Long Short Term Memory (CNN-LSTM). The highest accuracy rate, which is 100% was obtained by the SVM model using the CICAndMal2017 dataset.

This research conducted a systematic literature review to examine deep learning for malware attack detection. Their research spans 2014 to 2021, and they identified a total of 123 studies. They found 40.1% (53) of studies were deep learning-based. To fulfill their goal, some research questions were established [7].

Malicious pattern analysis can help reverse the misuse of online applications, such as banking and various social media apps. In study [8], an IOS malware categorization model was proposed, which is capable of detecting 30 patterns of phylogenetic. Out of 150mobile apps, only 7 apps were identified by the classifier.

Android Malware grayscale image representation visualization methods were proposed [9]. The authors utilize both global and local features for better performance. It was observed that local features such as manifest, dex-arc, produce poor accuracies between 65.16% and 93.56%. However, orb features take low computational time for feature selection, training extraction model training, and malware sample detection.

With the growing popularity of Android smartphones, malware threats are receiving increased attention. This study [10] introduces MLDroid, a web-based framework for detecting Android malware through dynamic analysis. MLDroid identifies relevant features using feature selection techniques and trains models using various machine learning approaches. The system was evaluated on over 500,000 real-world apps. Results show that integrating four techniques, such as deep learning, Farthest First Clustering, Y-MLP, and a nonlinear ensemble decision tree forest, along with rough set-based feature selection, achieved a high malware detection rate of 98.8%.

The growing use of Android devices has led to the emergence of sophisticated malware that employs complex obfuscation techniques, making static analysis alone inadequate for effective detection. Although dynamic analysis can uncover evasive behaviors, it is resource-intensive and limited in execution path coverage. To overcome these limitations, a hybrid detection approach combining static and dynamic analysis was proposed. A publicly available dataset containing 352 static and 323 dynamic features was developed to support both binary and multiclass classification. Irrelevant features were removed using the Information Gain algorithm. Experimental results demonstrated that the hybrid method significantly outperformed individual analyses, with the Random Forest classifier achieving 98.53% accuracy for binary classification and 90.1% for multiclass classification [11].

Android malware is a persistent and growing threat, affecting industries like healthcare, banking, transportation, government, and e-commerce. It became challenging to classify malicious apps. This study [12] proposed two ML-enabled dynamic analysis methods: one to categorize malware by category and the other by family. With the CCCS-CIC-

AndMal2020 dataset that contains 14 malware categories and 180 families, the proposed models were more than 96% accurate in detecting categories and more than 99% accurate in detecting families.

As Android devices gain popularity, malware detection and family categorization have become the most important research topics. Although static and dynamic analysis are most commonly used, they are based on complicated processes. In this work [13], the researchers present a hybrid approach optimized for multi-feature data to detect and categorize Android malware. Static analysis makes use of permissions and intents, three feature selection techniques being tested, with the best results from Chi-Square, yielding a 95.04% detection rate using a Random Forest classifier. Main static features were also tested for more information. In dynamic analysis, as opposed to previous methods involving one-way HTTP or transport-layer traffic, the researchers maintained complete session-level protocol layers. The Res7LSTM model was subsequently used to further classify uncertain samples. Experimental results indicate that the proposed method enhances malware family classification accuracy from 71.48% (previous work) to 99% by taking advantage of session-based, multi-layer traffic analysis with high accuracy using fewer static features.

Malware family classification categorizes similar malware instances into families to determine their behavioral patterns and facilitate recovery. A permission-based classification technique with both native and native/custom Android permissions is proposed [14]. Experiments were performed on the DREBIN dataset with various classifiers and tested using accuracy, macro F1-score, balanced accuracy (BAC), and Matthews correlation coefficient (MCC), the latter two measures being appropriate for imbalanced datasets. The results indicated that: i) tailor-made permissions enhanced classification performance, ii) accuracy and BAC varied up to 3.67% despite having the same model, and iii) LightGBM and AdaBoost performed better than other classifiers.

The detection and categorization of Android malware families must be automated to reduce the workload of security analysts. While various machine learning and deep learning techniques exist, the rapid growth of mobile applications necessitates faster and more accurate solutions. This study proposes a scalable method that significantly improves both detection accuracy and analysis speed. Evaluated on large-scale datasets, the proposed approach achieves an F-measure of 99.71%, a low false positive rate of 0.37%, and processes 300,000 samples in just 3.3 hours. For malware family classification across 28 families, it achieves an F-measure of 97.5%, a precision of 96.55%, and a recall of 98.64%. Comparative results demonstrate that our approach outperforms previous methods in both efficiency and effectiveness [15].

III. Research Methodology

This section presents a detailed description of the entire pipeline employed for Android Malware families' classification, comprising dataset preprocessing, feature selection, data splitting, training and testing of baseline classifiers, and the ensemble methods, as shown in Fig. 1.

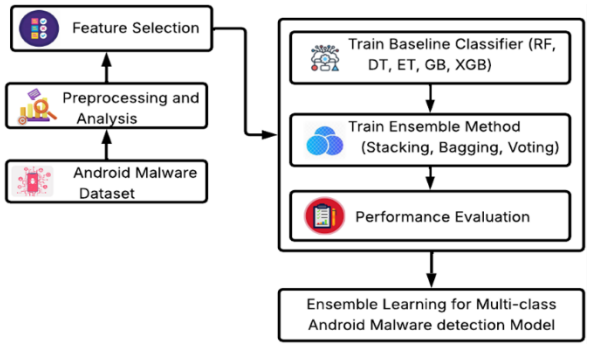

Fig. 1. Proposed research methodology.

A. Dataset

We downloaded the Android Malware dataset from Kaggle [16]. The dataset was comprised of (355630 x 85) records. The dataset contains four families, such as Adware, Spyware, SMS_malware, and Bengin, as depicted in Fig. 2.

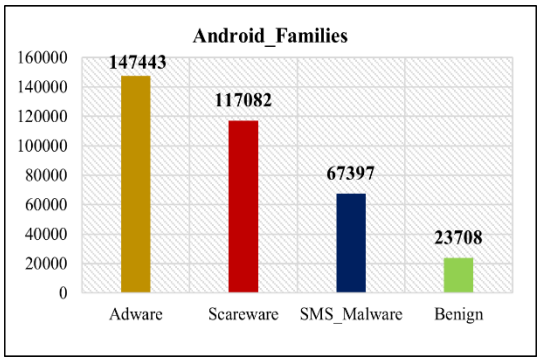

Fig. 2. Android families.

B. Preprocessing and Analysis

A non-informative timestamp column was removed, as it did not contribute any meaningful value to the training process. To prepare the dataset for machine learning algorithms, categorical features were encoded using the Label Encoding technique. Each categorical column was converted into a numerical format by assigning a unique integer to every distinct category. Missing values were either filled or removed, as appropriate, to maintain consistency and data integrity. After encoding, the dataset was separated into feature variables (X) and target labels (y). A final check for missing values in the feature set was conducted to ensure data completeness before model training and feature selection. These preprocessing steps ensured that the data was clean, fully numeric, and suitable for both statistical analysis and machine learning applications [17].

C. Feature Selection

To enhance model performance and reduce computational complexity, feature selection was performed using two statistical techniques: the Chi-Squared Test and Mutual Information.

1) Chi-Square test: The Chi-Squared test is a statistical hypothesis test used to assess the independence between categorical features (attributes) and the target class. In the context of feature selection, it assesses whether the actual

frequency distribution of a feature significantly differs from the expected distribution assuming that the feature is statistically independent of the target variable [18]. Mathematically, the Chi-Squared statistic for a feature f is defined, as shown in Eq. (1):

$$Z^2 = \sum_{i=1}^{t} \sum_{k=1}^{d} \frac{(M_{ik} - P_{ik})^2}{P_{ik}} \quad (1)$$

where,

M_{ik}: Signifies the observed frequency of category i of features f with class labels k

P_{ik} characterizes the expected count of frequency assuming independence.

$\boldsymbol{k}$: Depicts the number of feature categories

$\boldsymbol{d}$: Shows the number of class labels

Fig. 3 demonstrates the selected features by their Chi-Squared scores, highlighting their relevance for classification. Top features such as Flow Bytes/s, Flow IAT Std, and various Inter-Arrival Time (IAT) metrics are essential for distinguishing normal traffic from anomalies or attacks. The prominence of IAT-related features (e.g., Fwd IAT Total, Bwd IAT Mean) underscores the importance of packet timing in detecting abnormal patterns linked to malicious activity. Metrics like Flow Bytes/s and Packet Length Variance help identify unusual data rates and packet sizes, often seen in network intrusions. Active and Idle time features further reveal session-level behavior, aiding in the detection of stealthy threats. The high Chi-Squared values (up to 10th) reflect the strong discriminatory power of these features. These statistically selected features provide a solid foundation for enhancing intrusion detection and traffic classification through machine learning.

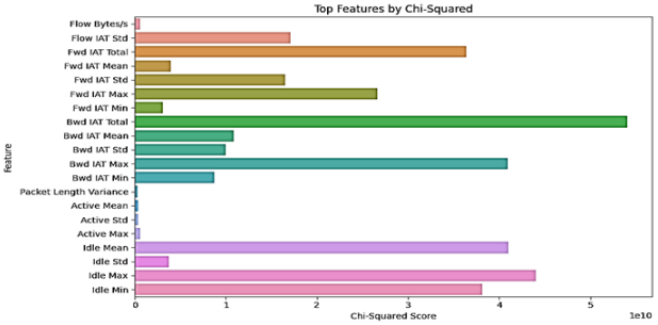

Fig. 3. Selected features using the Chi-Square method.

To enhance feature selection beyond the limitations of Chi-Squared analysis, Mutual Information (MI) was employed to capture both linear and non-linear dependencies between features and the target variable. This approach helps optimize the feature set by removing less informative attributes, particularly in scenarios involving complex network traffic patterns.

2) Mutual information feature selection: Mutual Information (MI) was used to quantify the amount of shared information between each feature and the target variable. Unlike the Chi-Squared test, MI can capture both linear and non-linear relationships. MI scores were computed for all features, and the top 20 with the highest scores were selected [19].

Fig. 4 presents a hierarchical listing of network traffic features sorted by their Mutual Information scores, indicating their predictive relevance to the target variable (e.g., intrusion detection). The top-ranked feature is Flow ID, followed by key metrics such as Fwd Avg Bytes/Bulk, Packet Length Mean, and Avg Bwd Segment Size, each with related sub-features indented beneath. These attributes represent various aspects of network behavior, including flow identifiers, packet size distributions, data transfer characteristics, and traffic dynamics. A supporting (though currently blank) tabular structure appears to outline threshold-based MI scores, likely intended to guide the selection of highly informative features. This step plays a critical role in building more accurate and robust machine learning models for network traffic classification and security analysis.

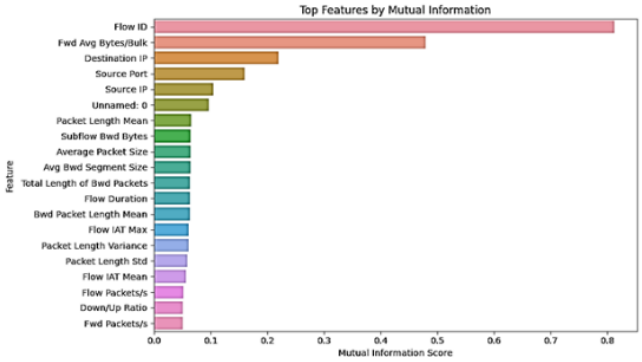

Fig. 4. Selected features using the MI method.

D. Model Development

We trained and evaluated four baseline classifiers, such as RF, ET, GB, XGB, and DT. To enhance predictive accuracy and robustness, we also implemented ensemble methods including stacking, bagging, and voting. Algorithm 1 demonstrates the training and testing mechanism of baseline and ensemble methods.

Algorithm-1: Training and Evolution of Baseline Classifiers

Input: Selected features set
Output: evaluation metrics for each baseline classifier
Begin:

1. Split the dataset into features (X) and Target label (Y)
2. Apply train_test_split on X and Y with stratification
3. Define baseline classifiers
   - RF
   - DT
   - ET
   - GB
   - XGB
4. For each baseline classifier:
   - Train model
   - Compute evaluation metrics:
     - Accuracy, precision, recall, F2 score, TNR
     - Confusion matrix
5. Train ensemble methods on trained baseline classifiers
6. Repeat Step 4 for each ensemble method

end

IV. Results and Discussion

The experiments in this study were performed on Windows 10 using Kaggle Notebook. The dataset was divided into training (70%) and test (30%) sets, with stratification to maintain the original label distribution, as depicted in Table I below.

TABLE I Division of Samples

Training Samples	Testing samples	Total Samples
248938	106688	355626

TABLE II Performance Evaluation of ML Models

ML models	Accuracy	Precision	Recall	F1 score	TNR
RF	81%	81%	81%	80%	92.37%
GB	70%	70%	70%	66%	87.95%
ET	79%	79%	79%	79%	91.72%
DT	79%	79%	79%	79%	91.92%
XGB	77%	77%	77%	77%	91.05%
Stacking	83%	82%	80%	8%	93.34%
Bagging	80%	89%	80%	80%	92.13%
Voting	82%	82%	82%	82%	92.95%

Table II presents the comparative performance of various machine learning models evaluated on a multi-class classification problem. Among the evaluated models, the Stacking classifier demonstrates the best overall performance, achieving 83% across accuracy, precision, recall, and F1 score, along with the highest true negative rate (TNR) of 93.34%. This reflects its strong generalization and balanced class discrimination, likely due to its ability to aggregate diverse base learners and optimize their combined predictions. Voting (82%) and RF (81%) also perform well across all metrics, benefiting from ensemble techniques that reduce variance and enhance stability. Bagging, while showing slightly lower accuracy (80%), achieves the highest precision (89%), indicating confident positive predictions, albeit with a trade-off in recall. ET (79%), DT (79%), and XGBoost (77%) yield moderate, balanced results but are outperformed by more advanced ensemble methods. GB exhibits the weakest performance, with 70% accuracy and the lowest F1 score (66%), possibly due to overfitting or suboptimal parameter tuning. Overall, ensemble approaches, especially stacking and voting, offer superior predictive performance and robustness, while single models and simpler boosting methods lag in capturing complex class relationships.

TABLE III Cross-Validation

ML models	Accuracy (CV =5)	Mean Std
RF	87%	± 0.0008
GB	88%	± 0.0011
ET	86%	± 0.0007
DT	83%	± 0.0007
XGB	84%	± 0.0009
Stacking	89%	± 0.0003
Bagging	84%	± 0.0009
Voting	85%	± 0.0012

To ensure the robustness of the ML model, 5-fold stratified cross-validation was performed. Table III describes the performance of ML classifiers and ensemble methods. The analysis illustrated that ensemble methods outperformed individual learners consistently. Among the baseline classifiers, GB (88%), RF (87%), and ET (86%) demonstrated robust predictive accuracy, while the lone DT ranked lower at 83% because of its greater overfitting tendency. XGBoost (84%) performed competitively, but could not surpass GB within this dataset. Ensemble methods improved results even more, with the highest accuracy achieved by the Stacking Classifier (89%) and lowest variance (±0.0003), performing superior generalization through diverse base learners via a meta-model. Bagging (84%) and Voting (85%) produced incremental improvements over single classifiers, but were inferior to stacking. The uniformly low standard deviations between models reflect consistently stable and dependable performance, and stacking proves to be the most stable and dependable means for deployment.

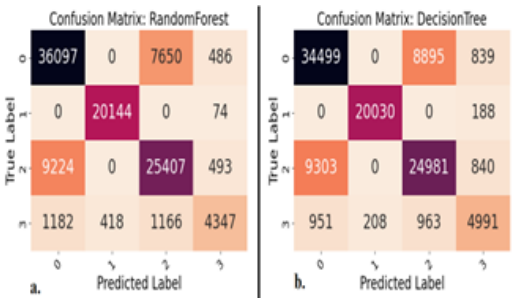

Fig. 5. Confusion matrix for ML models.

Fig. 5 represents the performance of the RF and DT models over unseen test data using confusion matrices. In Fig. 5(a), the RF model correctly classified 85995 out of the total samples (106688) with 20693 misclassifications, demonstrating high predictive accuracy. Similarly, Fig. 5(b) shows the DT model's confusion matrix, with 84501 correct predictions and 22187 misclassifications. The superior performance of the RF model compared to the DT model is expected, given RF's ensemble nature. By combining the predictions of multiple decision trees through bootstrap aggregation (bagging) and random feature selection, RF reduces variance and improves generalization to unseen data. In contrast, a single DT is more prone to overfitting, often capturing noise in the training set. The confusion matrix results further demonstrate that the RF model more effectively handles class boundaries, resulting in fewer misclassifications than the DT model.

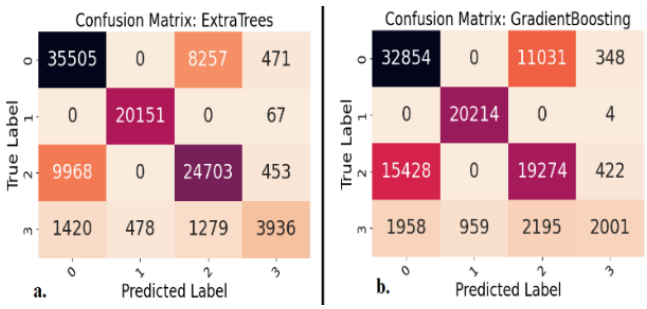

Fig. 6. Performance evaluation of classifiers.

Fig. 6(a) presents the confusion matrix for the ET classifier. The model demonstrated high predictive accuracy for class 1 and class 2, with 20,151 and 24,703 correct predictions, respectively. However, it showed significant misclassification between class 0 and class 2: 8,257 class 0 instances were incorrectly predicted as class 2, and 9,968 class 2 instances were misclassified as class 0, indicating notable overlap between these two classes. Fig. 6(b) shows the confusion matrix for the GB model. It correctly identified 20,214 class 1 and 19,274 class 2 samples, but exhibited greater confusion between class 0 and class 2 than Extra Trees, misclassifying 15,428 class 2 instances as class 0 and 11,031 class 0 instances as class 2. Both models performed poorly on class 3, with substantial dispersion across incorrect classes, indicating limited discriminative power for this class. Both models consistently underperform on class 3, with predictions for this class dispersed across the other categories. This suggests that class 3 may be underrepresented in the training data or lacks sufficiently distinctive features, making it difficult for the models to learn clear decision boundaries. The consistently poor classification performance for class 3 underscores a fundamental limitation in the dataset, either in terms of class imbalance or inadequate feature representation for this class.

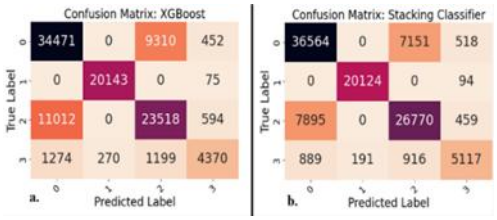

Fig. 7. Performance evaluation of ML models over unseen data.

Fig. 7(a) and Fig. 7(b) compare the performance of XGBoost and the Stacking classifier. XGBoost performs well on classes 1 and 2, with 20,143 and 23,518 correct predictions, respectively, as depicted in Fig. 7(a). However, in Fig. 7(b), it shows significant confusion between class 0 and class 2, misclassifying 9,310 class 0 instances as class 2 and 11,012 class 2 instances as class 0. This indicates overlapping feature space or weak decision boundaries between these classes. In contrast, the Stacking classifier demonstrates stronger overall performance. It substantially increases correct predictions for class 0 (36,564) and class 2 (26,770), while reducing misclassifications between them. Additionally, it improves classification for class 3, correctly identifying 5,117 instances, suggesting better generalization and improved handling of minority classes through ensemble learning. Overall, the Stacking model achieves more balanced classification and effectively addresses the limitations observed in XGBoost.

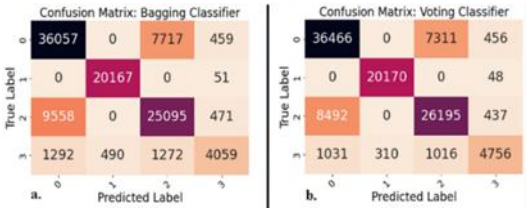

Fig. 8. Confusion matrix for ensemble methods.

The confusion matrices compare the bagging and voting classifiers. Fig. 8(a) shows the confusion matrix for the Bagging Classifier, where the classifier is showing high accuracy for class 0 (36,057 correct predictions) with fewer overall misclassifications. The Voting Classifier slightly improves correct predictions for class 0 (36,466) but introduces greater confusion, notably misclassifying 7,311 class 0 instances as class 1, as represented in Fig. 8(b). Diagonal entries indicate correct classifications, while off-diagonal entries represent errors. Bagging uses bootstrap aggregation to reduce variance and produce stable predictions. In contrast, voting combines outputs from diverse models, enhancing generalization but sometimes increasing misclassification between closely related classes. These results illustrate the trade-off between model diversity and predictive stability in ensemble methods.

The baseline classifier comparison provides key insights into performance across standard evaluation metrics, as represented in Fig. 9. Among the five models, RF, GB, ET, DT, and XGB. The XGBoost demonstrates the strongest performance, achieving the highest accuracy (92.37%) along with solid precision (81%), recall (81%), and F1 score (80%). This is largely due to its advanced regularization, gradient-based optimization, and ability to capture complex patterns while mitigating overfitting. All ensemble methods (RF, GB, ET, and XGB) outperform the single Decision Tree, which shows the lowest accuracy (87.95%) and reduced precision, recall, and F1 scores (all around 70%). This highlights the benefit of ensemble learning in enhancing generalization by combining multiple learners. ET (91.92%) and Random Forest (91.05%) also perform well, leveraging random feature selection and ensemble averaging to improve robustness. GB (91.72%), while slightly behind XGBoost, still delivers strong performance but lacks some of XGBoost's advanced optimization features, which likely explains the gap. In summary, XGBoost emerges as the most effective classifier, though other ensemble methods remain competitive. While the Decision Tree model is simple and interpretable, it lacks the predictive power needed for applications requiring high accuracy.

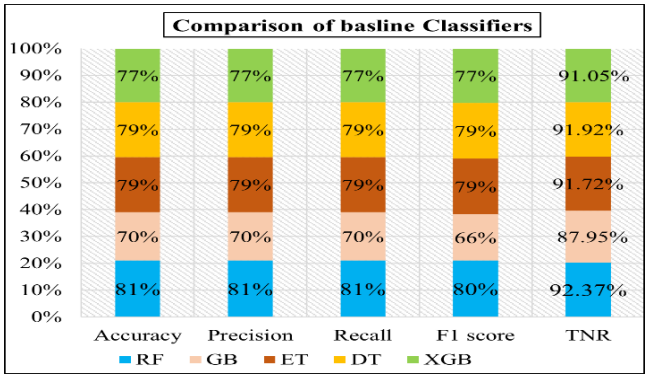

Fig. 9. Comparison of ML classifiers.

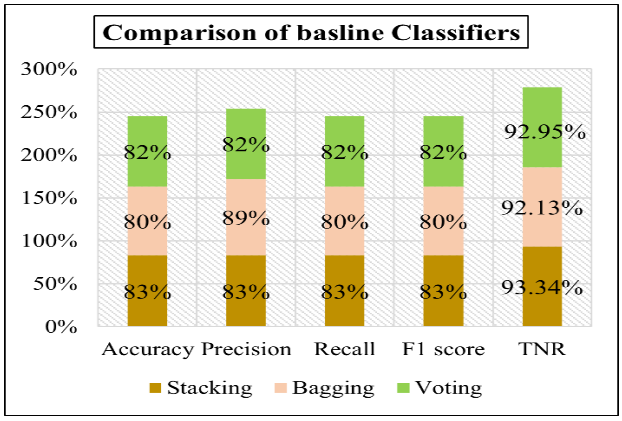

Fig. 10. Comparison of ensemble methods.

Fig. 10 depicts the comparison of three ensemble methods to determine the most effective approach. Key metrics, including accuracy, precision, recall, F1 score, and true negative rate (TNR), are used to evaluate performance, with values such as 92.95%, 92.13%, and 93.34% indicating strong results in individual configurations. Ensemble techniques, namely stacking, bagging, and voting, are also assessed for their ability to enhance model robustness by combining multiple classifiers. The inclusion of varying percentages (e.g., 30%, 25%, 20%) suggests an investigation into data split ratios or classifier weighting, aimed at further optimizing performance. Consistent precision values, such as 82%, 80%, and 83% across different ensemble methods, highlight the stability and reliability of these approaches. Overall, the analysis underscores the importance of selecting appropriate evaluation metrics and ensemble strategies to maximize classifier accuracy and predictive performance.

A. Discussion

The increased popularity of Android phones made them a favorite target among malicious applications, thus rapidly increasing malware on Android. Traditional detection systems typically perform binary classification (malicious vs. benign), overlooking the nuanced distinctions between malware families and differences that are crucial for threat intelligence, incident response, and forensic analysis [20] [21]. Addressing this gap, our study introduces a multi-class classification framework to differentiate between Android malware families using ML and ensemble-based models. As indicated in Table II, ensemble methods, specifically stacking, consistently outperformed baseline standalone models. The Stacking classifier obtained 83% in all the evaluation metrics (accuracy, precision, recall, F1-score) and a maximum TNR of 93.34%, validating its better generalization ability. Confusion matrix analyses also reveal the virtues and vices of separate classifiers. Models such as Random Forest and Extra Trees performed well with high accuracy for dominant families (e.g., Class 1 and Class 2), but struggled with minority classes (e.g., Class 3), revealing an ongoing class imbalance problem. Interestingly, Stacking demonstrated better performance with underrepresented classes, correctly classifying 5,117 examples of Class 3 and illustrating that it was capable of detecting intricate, non-linear relationships. Feature selection had an essential impact on model performance. Employing a hybrid technique incorporating Chi-Squared and Mutual Information algorithms, we found discriminative features like Flow Bytes/s, inter-arrival time (IAT) metrics, and session-based duration corresponding to behavioral patterns of various malware families. The dual-method strategy allowed dimensionality reduction to be done in an efficient manner without losing interpretability and enhancing model accuracy. Decision Trees were the worst-performing classifiers among all because of overfitting and the poor learning capacity of complex data patterns. Conversely, Voting classifiers and XGBoost yielded close-to-optimal performance, further supporting the efficacy of aggregation and boosting on high-variance, imbalanced datasets, such as Android malware. Ensemble learning supplemented with careful feature selection is an effective approach to steady multi-class Android malware detection, especially in real-world environments where data imbalance and intricate decision boundaries are prevalent.

V. Conclusion

This work presents an efficient and scalable machine learning architecture for multi-class Android malware family classification, addressing the limitations of traditional binary detection approaches. By leveraging ensemble learning, specifically the stacking method and a hybrid feature selection strategy combining Chi-Squared and Mutual Information techniques, the system achieves high accuracy, strong generalizability, and robustness to data imbalance. Empirical results demonstrate that the Stacking classifier outperforms both individual models and other ensemble techniques, achieving 83% across all evaluation metrics and the highest TNR of 93.34%. Notably, it significantly improves the detection of minority malware families, making it well-suited for real-world threat environments characterized by imbalanced class distributions and complex behavioral patterns. These findings validate the effectiveness of ensemble-based approaches and principled feature engineering in malware detection and provide a solid foundation for advancing automated and intelligent mobile security systems. Future work will focus on expanding the dataset, incorporating dynamic analysis features, and integrating deep learning models to further enhance detection accuracy and threat response capabilities.

VI. Future Work

While the present study demonstrates the efficacy of ensemble learning for Android malware detection, various promising research directions remain unexplored. To begin with, expanding the dataset to include newer and varied malware samples, such as zero-day attacks, would make the model more robust against changing threats. Second, the incorporation of dynamic analysis capabilities like system calls, network traffic, and runtime activity might supplement the static capabilities employed in this research to give a better understanding of malware activity. Third, combining ensemble techniques with deep learning frameworks (like CNNs, RNNs, or combination models) might further enhance detection rates, particularly in dealing with intricate temporal and behavioral patterns. Additionally, future efforts need to tackle adversarial robustness, as malware developers more and more use evasion and obfuscation mechanisms to defeat machine learning-based

detectors. Research on federated and distributed learning methods is also a promising direction, enabling collaborative malware detection on devices without compromising user privacy. Finally, using explainable AI (XAI) techniques would add more transparency and trust in detection outcomes, which is extremely essential for cybersecurity professionals when deploying tools in critical real-world settings.

Analyzing Cyber Attack Detection in IoT Healthcare Environments Using Artificial Intelligence

Rawan Marzooq Alharbi, Muhammad Asif Khan
Department of Information Systems-College of Computer Science and Engineering, Taibah University, Madina, Saudi Arabia

***Abstract*—The rapid growth of the Internet of Things (IoT) has significantly increased its integration into daily life. In recent years, the integration of IoT technologies in healthcare has significantly enhanced patient care and operational efficiency. One of the most promising areas for using IoT devices in healthcare or interconnecting medical devices is known as the Internet of Medical Things (IoMT). IoMT supports various healthcare services, e.g., remote patient monitoring. However, there are serious cyber-security concerns, as various attacks have targeted these IoMT devices in recent years. This research presents an analytical approach to understanding how Artificial Intelligence (AI) can improve the detection of cyber-attacks within IoT healthcare environments. The main goal of this research is to provide an AI-based model to detect cyber-attacks in IoMT in the healthcare environment. Many researchers have worked on developing a framework in this field to address critical cybersecurity threats. However, these efforts often fall short of covering other important aspects such as data privacy and interoperability. In this study, a model and framework are proposed to monitor IoT networks, and detect potential security breaches in real-time to help in mitigating risks while maintaining healthcare services. The key findings contribute to strengthening cybersecurity protocols in healthcare IoT environments in order to ensure the protection of sensitive information against emerging cybersecurity vulnerabilities.**

Keywords*—*IoT healthcare security; cyber-attack detection; healthcare security; AI in healthcare; smart medical systems

I. Introduction

The Internet of Things (IoT) is a network of our daily life physical objects (things) that surround us and are connected together to send or receive data over internet without human intervention to ease human life. These things range from a wrist watch to home appliances and these are embedded with sensors which are smarter and more interactive with both us and the surrounding. The IoT promises to revolutionize our industries and economies by connecting billions of devices across the world. The IoT offers unparalleled opportunities to organizations for automation and novelty. As the technologies become established and matured, the IoT will be an integral part of industrial digital transformation. In future we will see spread of IoT from a smart highway to smart airports, smart home to smart cities, smart building to smart hospitals etc. There are various objects or things which have sensors such as car, door, lights, air conditioner etc. in different sectors can be connected through internet [1].

A survey conducted by Statista Inc [2] depicts there were 7.74 billion devices connected around the world in 2019 which could exceed 25 billion by 2030.

The exponential use of IoT devices in our daily lives has revolutionized various sectors including the healthcare sector. Thus, IoT is enabling the seamless connection of devices and systems to improve patient monitoring, diagnosis, and treatment [3]. Smart medical devices, and wearables have become integral components of modern healthcare, providing clinicians with real-time data and enhancing patient outcomes. Using IoT devices in healthcare or interconnecting medical devices is known as the Internet of Medical Things (IoMT) [4]. IoMT now supports various healthcare services, e.g., remote patient monitoring. However, this increased connectivity has also led to heightened vulnerabilities, making healthcare environments attractive targets for cyber-attacks [5].

The threats of a cyber-attack to target IoT healthcare systems mainly include data breaches, ransomware attacks, and denial-of-service (DoS) attacks [6]. The consequences of these attacks on IoT healthcare systems can be severe, ranging from compromised patient data to disruptions in critical healthcare services [7]. Since healthcare organizations strive to protect sensitive information and maintain operational integrity, traditional cybersecurity measures often fall short due to the complexity and scale of IoT networks. In this context, Artificial Intelligence (AI) emerges as a powerful tool for enhancing cybersecurity in IoMT environments. By leveraging advanced algorithms and machine learning techniques, AI can analyze vast amounts of data, identify patterns, and detect anomalies that may indicate potential threats.

With incessant growth in use and adoption of the IoT devices many IoT devices are found to have inherent security issues. The manufacturers of the devices focus on device functions and cost rather than the security features which in turn create security concerns and vulnerabilities in the devices. Wide spread of IoT devices and the information these devices need to provide features may be compromised, therefore, in this context cyber security has been extreme critical. A lot of research has tried to mimic a variety of hypothetical threats to enhance IoT security. Since more novel, and serious threats are being developed, requiring further work in this field especially in the healthcare sector. Moreover, the IoT devices only have limited amount of memory, computational capacity, and power. In such a situation, any communication issue caused by a cyber-attack might have hazardous consequences on a patient's health, and may even result in death.

Due to the rapid growth of infrastructure of IoT devices in recent years, IoT-based healthcare systems have become vital for detecting cyberattacks. Any attack may have a significant impact on the life of the patient. Therefore, the use of Artificial Intelligence (AI) is one of the finest solutions available to

improve the efficiency of detecting cyber-attacks in IoT healthcare environments. The aim of this research is to analyze the effectiveness of AI in detecting cyber-attacks within IoT healthcare environments, exploring both the current landscape and the future potential of AI-driven security solutions. In order to accomplish it, we have formulated the following research questions and we strive to address them in this research study:

RQ1: How integration of AI and Internet of Things (IoT) technologies can enhance cyberattacks detection and prevention capabilities in healthcare systems?

RQ2: What strategies can be employed to optimize AI cybersecurity model for scalable, cost effective and security compliant healthcare systems?

RQ3: How can AI improve the accuracy of cyberattack detection in IoT healthcare environment?

In order to find the answers of the research questions following hypotheses have been formed:

H_0 - AI Models improve the accuracy of cyberattack detection

H_1 - AI Model has the potential to enhance the detection of cyberattacks on IoT network in healthcare systems

The research study aims to develop an effective AI model to protect IoT healthcare systems by detecting cyberattacks in IoT healthcare networks and to provide an AI-based model that enhances the findings of existing research on an IoT healthcare security dataset. The proposed model aims to provide more accurate results from attack types compared to the relevant research of IoT healthcare datasets. The proposed model will get an optimum performance time compared to current strategies in relevant research of IoT healthcare datasets.

This research contributes to the body of knowledge by providing an efficient AI-based cybersecurity model for protecting IoT healthcare environment and for improving the accuracy and precision of cyber-attacks classification. Moreover, the model will show a potential to improve the sustainability of IoT systems by reducing the wastage of resources in identifying the cyber-attacks on time.

II. Literature Review

Due to the rapid advancement of technology, various communication and information technology-based solutions are being used in healthcare environments to facilitate both healthcare professionals and patients. These technologies mainly include the Internet of Things (IoT), artificial intelligence (AI), virtual reality (VR) and multi-agent systems. With the help of IoT technology, various gadgets having sensors and actuators are integrated to remotely monitor patients and provide different medical services like diagnosis, consultation, treatment, and information through on-ground healthcare staff [8]. Authors in study [9] proposed an IoT-based system to monitor the heartbeat and body temperature of a patient over a remote location through sensors and Bluemix technology. Similarly, authors in study [10] worked on a patient's activity recognition by analyzing the speech and movement patterns of a patient at home. They used a camera, breath sensor, and ECG for patient health monitoring. Likewise, researchers in study [11] developed a smartphone application to provide early medical assistance to elderly people at home.

With the progress of AI technology, healthcare data is now being analyzed and predicted through AI-based expert systems which help healthcare experts to make fast and efficient decisions for remote patients' healthcare. The AI models efficiently process the real-time sensor data and provide helpful information to healthcare professionals for better treatment decisions [12]. Similarly, VR technology is also used in telemedicine to improve the interaction between local healthcare staff and remote expert physicians for real-time patient healthcare including surgeries. Many recent research experiments have revealed that augmented reality (a type of VR) can improve the live motion-based interaction of remote healthcare experts for better diagnosis and treatment [13, 14].

Despite a lot of technological progress in healthcare environments, cybersecurity is a serious concern in IoT-based healthcare environments. Over the past few years, many researchers have worked on improving the security of IoMT-based healthcare systems. Authors in study [15] worked on detecting cyberattacks in IoT healthcare environments. The authors proposed an anomaly detection approach along with machine learning to detect cyberattacks in remote patient monitoring environments. The authors used the CICIoT dataset which contains 33 types of IoT attacks divided into seven main categories. The authors first pre-processed the CICIoT dataset for a balanced sample representation of each class. They further applied features- eliminating methods and features dimensionality reduction methods. Afterwards, they trained various machine learning models including Random Forest (RF), Logistic Regression (LR), Artificial Neural Network (ANN), and Adaptive Boosting (AB). Their proposed model achieved the highest accuracy based on Random Forest (RF), reaching up to 99.55%in binary and multiclass classification.

Similarly, researchers in [16] worked on detecting anomalies in IoT smart hospital environments. The authors proposed a low-latency anomaly detection system (ADS) and implemented it in the Contiki Cooja simulator. The authors achieved on average 80% accuracy in detecting three types of anomalies attacks including Rank and flooding attacks.

A study in [17] proposed an access control system for the privacy preservation of healthcare data in IoT healthcare architecture. The authors proposed a deep learning approach to secure IoT healthcare systems from unauthorized access by users and attackers. They also proposed a secure access control module by focusing on user attributes to protect IoT healthcare systems from cyberattacks caused due to unauthorized access. Their proposed model is based on a convolutional neural network (CNN) and it achieved 98% accuracy and 95% precision and F1-score.

In a study researchers [18] worked on improving the privacy and interoperability issues in IoT healthcare systems. The authors applied various data pre-processing techniques and trained a deep learning model that consists of a convolutional neural network (CNN) and Long Short-Term Memory (LSTM). Their proposed model achieved more than 80% accuracy, precision and recall on various datasets including PhysioNet, MIMIC, and eICU datasets.

In another study [19] proposed the cognitive machine learning based Cyber-Physical healthcare attack detection model to transmit healthcare data mules firmly. The collected data stored over the cloud platform where machine learning algos analyze the cyberattack patterns and predict their behavior accordingly. The proposed Cyber Machine Learning Anomaly Detection Framework (CML-ADF), can detect the cyberattacks over the edge nodes at the physical layer. The experimental results depict, CML-ADF framework achieving an accuracy of 98.2 % with an efficiency ratio of 97.8 % respectively. Moreover, it also outburst the delay and communication cost parameter over existing models with the ratio of 21.3 % and 18.9 % respectively.

The researchers in [20] demonstrate the Intrusion Detection System (IDS) under the umbrella of Internet of Medical Things (IoMT) based on Deep Recurrent Neural Network (DRNN) and supervised Machine Learning (SML) classifiers to forecast the unknown cyberattacks. In order to optimize features, the authors used the bio-inspired particle swarm approach which determines the outstanding results since its inception in the real-world optimization challenges. Under rigorous test beds and experimentation, the proposed SML model outperformed the existing approaches while attaining the accuracy of 99.76 %.

In a study, researchers [21] worked on the AI assisted IoT-CPS framework to diagnose patient diseases such as Diabetes, Heart anomalies and Gait disorders. Each disease has its own set of detection parameters with respect to patient gender, age and complexity. The author used the openly available dataset, acquired from Kaggle repository for the execution of proposed AI-enabled IoT-CPS methodology. The experimental tests showed that the proposed framework outperformed the existing studies with an accuracy of 86.4 % indeed.

A research study [22] proposed the framework to generate IoT based normal and malicious data in order to develop the IoT assisted context aware security solutions for malicious traffic detection in various use cases. The author named the proposed open-source IoT data generator as IoT-Flock. It not only generates the traffic but also converts the captured data into a particular dataset for further analysis and recommendation. While using the proposed framework, the author generates the IoT-healthcare dataset which comprises both normal and IoT attack affected data which is ultimately being detected with the help of multiple ML based classifieds to protect the healthcare system from cyberattacks. The proposed context aware IoT based data generator is very effective to analyze the sensory IoT healthcare use cases in terms of cyber security.

The authors in [23] developed the cyber-attack inclusion with anomaly detection methodology accompanying recursive feature elimination (RFE) and multi-layer perceptron (MLP) approach. Both of these approaches are very effective to identify optimal feature selection and performance evaluators. The proposed model was tested on various IoMT cyber security datasets with an average accuracy of 98.08 % respectively.

In a study [24] proposed the AI assisted Artificial Fish Swarm-driven Weight normalized Adaboost (AF-WAdaBoost) model for the optimization of accuracy and sustainability parameters to identify cyberattacks in IoT healthcare systems. The proposed AF-WAdaBoost mechanism fiercely adjusts the ML classifiers to enhance accuracy and persistence against evolving threats. The experimental study shows the proposed model outperformed traditional IoT- healthcare cyberattack detection approaches with an accuracy of 98.69 %, F-measure and Precision with 94.86 % and 95.72 % respectively.

Researchers in study [25] worked on the novel cyberattack healthcare anomaly detection technique based on Cyber Physical System (CPS) to enhance network security. A quantum cloud Federated learning mechanism has been implemented on the CPS in order to build an IoT healthcare network. Existing approaches lack to achieve reasonable values for Round Trip Time (RTT) using Transmission control Protocol (TCP) packets and are ineffective on the large number of packets. Our proposed model attained network efficiency of 92 %, security analysis with 89 %, training and validation loss of 79 % and 49 % respectively.

A research study [26] suggested the novel approach for assessing the cybersecurity of e-healthcare applications i.e., assistance of quantum machine learning. In this approach the author proposed the deep variational adversarial network encoder with fuzzy Gaussian quantile neutral network to identify and classify the useful characteristics of user activity data patterns to identify the vicious user to enhance the overall network security. The implementation of the proposed approach shows vigorous results in terms of learning rate, prescient misfortune, transmission influence, jitter, throughput and dynamic serverless response time. Moreover, the proposed system attained the random accuracy of 98%, F-1 score of 75 %, Mean Average Precision of 65 % and the kappa Coefficient of 69% which outperformed the existing server based E-healthcare security approaches.

In a study [27] illustrated the comparison between various AI-driven threat detection approaches to enhance security and to mitigate cyber threats in the IoT Healthcare environment. In the world of AI-driven cyber security solutions, the most prominent are transformer based models, federated learning and blockchain integration to step into the real-time threat detection systems. The most prominent approach to mitigate cyberattack in the Enhanced AI-based Network intrusion Detection using Generative Adversarial Networks (GANs) which attained the accuracy of 98.2 % which exceeded the preceding resilient intrusion detection system and multi-domain trojan detection framework which were at 97.8 % and 97.1 % respectively.

The authors in [28] illustrated how future healthcare hubs and proactive smart devices implement their own cybersecurity models to ensure full proof AI assisted healthcare communication channels. The proposed AI based healthcare communication cyber security model set the digital healthcare communication IEEE standards interviewing the cybersecurity policies. Moreover, the Joint Optimized Infrastructure for Network Empowered Research (JOINER) came into existence to ensure secure future communication in the healthcare sector. Now each AI-driven emerging cybersecurity policy relies on JOINER architecture. The proposed approach outperformed the existing communication trends, in terms of data rate, mobility, latency, connectivity gap, and reliability.

A study [29] introduced the framework of trustworthiness and decision-making support mechanism within the internet of

medical things (IoMT) use cases. Keeping in view the shortcomings of risk management and management approaches to accessed the IoMT context aware scenarios in the existing models, lack proper automation and inability to mitigate the various security risks in the healthcare system, the proposed (MLRA-Sec) framework integrate the Hybrid Risk Assessment (RA) model with ML-based anomaly detection technique to ensure and evaluate cumulative IoMT risk. Experimental study shows effective outcome as compared to the state of the art intrusions detection IoT-ML based models.

A research study conducted by study [30] focused on addressing the problem of cyber risk assessment in IoT healthcare environments. The authors proposed a lightweight, efficient and dynamic approach for risk assessment of security events in IoT healthcare infrastructure. The authors generated synthetic data and then executed multiple simulation scenarios on it while mapping the attack surface and applying threat models. The proposed approach not only highlight the security risks but also provides some helpful information to mitigate the cyber threats.

Authors in study [31] highlighted the challenges in the healthcare security system with the advancement of energy constraint communication devices. Considering the severity of the issue, the author developed the monitoring frequency-based detection and dynamic threshold mitigation method using Temporal Convolutional Networks (TCNs) in the 5G healthcare IoT (H-IoT) environment. The proposed approach calculates the H-IoT node's incoming and outgoing data mules counts for five seconds with respect to overall data traffic. This dynamic approach provides adaptive security by taking the mean value of detected malicious data across all nodes to evaluate the threshold cap to enhance the classification accuracy and restricts the true DDos attacks. The experimental test beds conducted under two communication protocols i.e., Message Queuing Telemetry Transport (MQTT) and User Datagram Protocol (UDP) in a realistic 5G based healthcare environment. The proposed model attained the average accuracy of 99 % on MQTT datasets and 99.99 % on UDP dataset with 80 % mitigation.

A research work carried out by study [32] showed the impact and comparison of AI-driven existing IoMT security models. With recent advancement in IoMT, in spite of its effectiveness, it also becomes the easy corner for hackers to breach the patient's sensitive information and use it for their own evil desires. To resiliate these attacks, novel taxonomy of AI based intrusions detection IoMT schemes have been highlighted in this article. Moreover, tasks and processes are carried out over Cloud-Fog-Edge architectures to reduce the overall latency and efficient use of computational resources in real-time to enhance the efficiency of the system, also being a part of its comparison approaches.

Authors in study [33] focused on the vulnerabilities to cyberattacks in the IoT healthcare system. Along with the rapid use of heterogeneous smart devices becomes a more severe concern as the time proceeds. In this paper, author proposed the deep neural network assisted cyberattack detection model to accompanying the unknown cyberattacks in IoT healthcare environment. An AI based proposed anomaly cyber threats have been tested on latest ECU-IoHT dataset and attained the accuracy of 99.85% under the average area receiver characteristic cure is at 0.99 with the false positive is 0.01 that highlights the effectiveness of the proposed cyberattack detection system as compared to the state of the art approach.

Researchers in study [34] worked on preventing cyber threats in IoT healthcare environments. The authors proposed a framework to detect different types of cyberattacks in IoT healthcare networks. The authors used four different types of dataset related to cybersecurity attacks for having maximum cyberattacks coverage and getting a more generalized AI model. The authors applied different data pre-processing techniques like data cleaning, data imputation, and dimensionality reduction. Afterwards, they trained the pre-processed data over an attention-based bi-LSTM deep convolved network to detect the cyber-attacks in IoT healthcare environments. Overall, the authors achieved around 99% accuracy on all datasets.

A research study [35] proposed a hybrid approach to detect cyber-attacks in internet of medical things (IoMT) environment. In order to efficiently detect the cyber-attacks, the authors integrated three AI models which include K-nearest neighbors (KNN), long-short term memory (LSTM), and principal component analysis (PCA). Both the LSTM and PCA models were used for data pre-processing. Afterwards, they trained and tested KNN model for detect cyber-attacks in IoMT environment. The authors tested the proposed hybrid framework over four datasets which include TON-IoT, ECU-IoHT, ICU, and WUSTL-EHMS dataset. Overall, the proposed approach resulted 99% accuracy for detecting cyber-attacks in IoMT environment.

Similarly, researchers in study [36] worked on efficiently detecting the intelligent detection of intrusions in IoMT environment. The authors integrated two deep learning models which include convolutional neural network (CNN) and LSTM for efficient detection of intrusions. The CNN was mainly used for features extraction whereas the LSTM was used sequential network traffic flows prediction. The authors referred the proposed intrusion detection system (IDS) as hybrid deep learning-based IDS solution for IoMT (HIDS-IoMT). The proposed approach was also tested in a fog computing environment where the proposed HIDS-IoMT model was deployed on a Raspberry Pi device which not only demonstrated an accurate detection of intrusions but also reduced the detection latency as the IDS was deployed on an edge device.

Likewise, authors in study [37] designed a framework for intrusion detection in IoMT environments. The authors proposed a stacking ensemble approach by stacking machine learning and deep learning models into two groups to effectively secure the IoMT network. The authors used ECU-IoHT dataset. They first pre-processed the dataset by applying data cleaning, data normalization, data balancing and features selection techniques. The proposed framework combined both machine learning and deep learning classifiers to detect various cyber-attacks in IoMT environment. Moreover, in order to deploy the proposed AI-based IDS in real-time [38], the authors implemented Kappa architecture which helped to update data streams with low latency. The proposed approach resulted 99.1%accuracy for binary class classification and 99.3%accuracy for multi-class classification to detect four types

of cyber-attacks including spoofing, denial of service, scanning, and Smurf attack.

Authors in study [39] proposed a hybrid deep learning framework to enhance the security and quality of service (QoS) in IoT healthcare systems. The authors introduced a novel software-defined network (SDN) based architecture and integrated it with a security module that is responsible to detect cyberattacks in healthcare network. The secure module was mainly developed by training and testing a Bidirectional LSTM model over CICDDoS2019 dataset. In order to improve the QoS by reducing transmission, the authors used CNN model in SDN controller to find the best fog node integrated with SDN which further improved the overall network life. The proposed hybrid deep learning framework resulted 99.59% accuracy, 99.53% F1-score, and 3 ms delay in order to detect cyber-attacks in IoT healthcare environments.

The literature reviewed above provided us information of some datasets used to detect, train and test AI model in healthcare environment. Table I shows short description of these datasets:

TABLE I. DATASETS USED TO DETECT, TRAIN AND TEST AI MODEL IN HEALTHCARE ENVIRONMENT

Dataset	Reference	Description
CICIoT	Khan & Alkhathami, 2024	This dataset consists of real-time normal and cyberattacks traffic. It is widely used to train and test AI models to efficiently detect cyberattacks. It includes real-time network traffic of 105 real IoT devices. It contains mainly 156 features and covers 33 types of cyber-attacks data
Aegean AWID	Pimple & Sharma, 2025	This dataset contains the network attacks traffic of Wi-Fi attacks. It has 156 features
IoT-ICU	Hussain et al., 2021	This dataset mainly focused on ICU environment where different sensors and actuators are connected over a Wi-Fi. It contains different types of cyberattacks and normal traffic
NSLKDD	Saheed & Arowolo, 2021	It is an updated version of KDD intrusion detection dataset. It has some class imbalance issues
ECU-IoHT	Kilincer et al., 2023	This dataset was mainly developed to analyze the vulnerabilities in IoT healthcare environment
CICIDS2017, UNSW-NB15	Alsulami, 2024	These are basically general cyberattack dataset. But these are also used in healthcare environment
IoT-23, LINET 2020, NetML	Prabakar et al., 2024	This dataset mainly contains IoT malware related data to detect and figure out the potential attacks in healthcare environments
Bot-IoT	Ksibi et al., 2025	This dataset mainly contains botnet attack traffic

III. RESEARCH METHODOLOGY

In order to conduct research for finding out solution of the research questions stated earlier, we adopted design science research methodology which consists of five major stages. The Fig. 1 shows the five stages including data collection, data preprocessing, feature selection, AI models training and performance comparison.

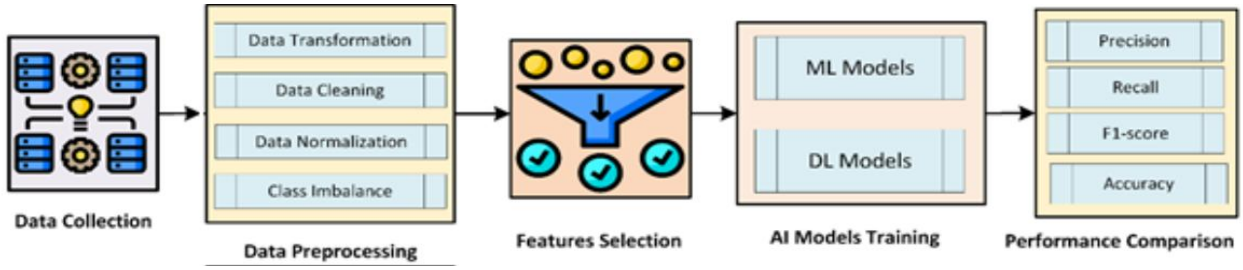

Fig. 1. The proposed methodology for cyber-attacks detection using AI in IoT healthcare environments.

A. Data Collection

The data collection is a primary step of our proposed methodology. To go through further steps to recognize cyber-attack detection using AI in IoT healthcare environments, we first need to collect a dataset. A few researchers have worked on detecting cyber-attacks in IoT healthcare environments. Therefore, we reviewed existing datasets and then selected the dataset with a vast variety of cyber-attacks. The IoT healthcare security dataset named as CIC IoMT dataset (Dadkhah et al., 2024) contains eighteen (18) types of cyber-attacks traffic including spoofing, scanning, TCP, UDP, and MQTT attacks. These eighteen (18) types of cyber-attacks are categorized into five classes which include spoofing, reconnaissance (RECON), MQTT, denial of service (DoS) and distributed DoS (DDoS) attacks. The complete mapping of eighteen (18) types of cyber-attacks along with their classified category are shown in Table II.

TABLE II. CYBERATTACKS WITH CLASSIFIED CATEGORIES

Category	Cyber-attacks
SPOOFIN	ARP Spoofing
RECON	Ping Sweep, Recon VulScan, OS Scan, Port Scan
MQTT	Malformed Data, DoS Connect Flood, DDoS Publish Flood, DOS Publish Flood, DDoS Connect Flood
DOS	DOS TCP, DOS ICMP, DOS SYN, DOS UDP
DDOS	DDoS SYN, DDOS TCP, DDOS ICMP, DDOS UDP

The CIC IoMT healthcare security dataset (Dadkhah et al., 2024) is mainly saved in packet capture (.pcap) file format collected via WireShark tool. A few .pcap files are also converted into the .csv file format. The CIC IoMT dataset (Dadkhah et al., 2024) contains network traffic of 40 IoMT devices including 25 real devices and 15 simulated devices. The dataset contains three types of communication protocols used by

healthcare devices which include Wi-Fi, Bluetooth, and MQTT devices. The MQTT-based healthcare devices are simulated devices whereas the Bluetooth and Wi-Fi-based healthcare devices are real devices integrated into a real-time network. The CIC IoMT dataset (Dadkhah et al., 2024) has 45 features in each .csv file without labels. These features are enlisted and briefly described in Table III. In summary, the CIC IoMT dataset (Dadkhah et al., 2024) is big dataset contains multiple .pcap and .csv files and each .csv file contains samples in range 5000 to 80,000 samples. There is a minor issue of class imbalance if look at it from the perspective of binary or multi-class classification.

TABLE III. LIST OF FEATURES WITH BRIEF DESCRIPTION IN CIC IOMT DATASET (DADKHAH ET AL., 2024)

Feature	Description
Header Length	Mean of the header lengths of the transport layer
Time-To-Live	Time-to-live
Rate	Speed of packet transmission within a window in packets/sec
fin flag number	Proportion of packets with FIN flags in the window
syn flag number	Proportion of packets with SYN flags in the window
rst flag number	Proportion of packets with RST flags in the window
psh flag number	Proportion of packets with PSH flags in the window
ack flag number	Proportion of packets with ACK flags in the window
ece flag number	Proportion of packets with ECE flags in the window
cwr flag number	Proportion of packets with CWR flags in the window
syn count	Count of Syn flag occurrences in packets
ack count	Count of Ack flag occurrences in packets
fin count	Count of Fin flag occurrences in packets
rst count	Count of Rst flag occurrences in packets
IGMP	Average number of IGMP packets in the window
HTTPS	Average number of HTTPS packets in the window
HTTP	Average number of HTTP packets in the window
Telnet	Average number of Telnet packets in the window
DNS	Average number of DNS packets in the window
SMTP	Average number of SMTP packets in the window
SSH	Average number of SSH packets in the window
IRC	Average number of IRC packets in the window
TCP	Average number of TCP packets in the window
UDP	Average number of UDP packets in the window
DHCP	Average number of DHCP packets in the window
ARP	Average number of ARP packets in the window
ICMP	Average number of ICMP packets in the window
IPv	Average number of IPv packets in the window
LLC	Average number of LLC packets in the window
Tot Sum	Total packet length within the aggregated packets (window)
Min	Shortest packet length within the aggregated packets (window)
Max	Longest packet length within the aggregated packets (window)
AVG	Mean packet length within the aggregated packets (window)
Std	Standard deviation of the packet length within the aggregated packets (window)
Tot Size	(Avg.) Length of the packet
IAT	Interval mean between the current and previous packet in the window
Number	Total number of packets in the window
Variance	Variance of the packet lengths in the window
Protocol Type	Mode of protocols in the window

B. Data Preprocessing

Once we are done with data collection, the next step is to pre-process the dataset in order to pass a refined dataset to AI models for better training. As shown in Fig. 2, the first step in data pre-processing is data transformation, i.e., to transform the categorical values to numeric integer values because the AI models only work on number values. So, to perform data transformation, we used the one-hot encoding technique After the data transformation, we performed data cleaning to remove missing values, null values or infinite values from the dataset. Once the dataset is cleaned, we then need to normalize the dataset to scale the feature values in a comparable range. For this purpose, we used Min-Max normalization which scales the feature values in the range [0, 1].

We noticed that there was a class imbalance issue in the dataset. To fix the class imbalance issue, we used the down-sampling technique as there were some attacks where samples were less than 5000. So, when we combined the data-frames of such attack samples based on same class, we came to know that minimum 18000 samples were present in a class. Therefore, to fix the class imbalance issue, we dropped down the samples from other attack classes by randomly selecting 18000 samples from each class via down-sampling technique. Eventually, after the down-sampling, we had 18000 samples from each of five attack classes as mentioned in Table II which in total leads to 18,000 x 5 = 90,000 attack samples. Similarly, we randomly selected 18000 samples from benign, i.e., normal class samples as well. So in total, we had 90,000 (attack samples of five classes) + 18000 (benign samples of 1 class) = 108,000 samples for training and testing AI models.

C. Features Selection

Although the dataset is pre-processed, we further need to perform features selection to provide the most useful features to machine learning models for better performance. For this purpose, we applied four commonly used features selection techniques, i.e., Anova, Chi2, mutual information, and extra tree features selection method to select only useful features from the dataset. Using these four features selection techniques, we tried different numbers of features i.e., 20, 30 features out of total 45 features and check on which feature set the machine learning models yield better performance by comparing the results with the performance achieved while training AI models on all features. Therefore, we considered three scenarios.

- Training and testing AI models on all features.
- Training and testing AI models on 20 features selected via features selection methods.

- Training and testing AI models on 30 features selected via features selection method.

D. Models Training

Before starting training to AI models, we first need to divide the dataset into a training set and a testing set. To split the dataset, we use the 80:20 ratio, i.e., 80% dataset were split randomly into training-set and 20% data were used for testing-set. As shown in Fig. 2, we trained both machine learning models and deep learning models for cyber-attacks detection in IoT healthcare environments. Therefore, we trained five commonly used machine learning models, i.e., decision tree (DT), random forest (RF), Naïve Bayes (NB), k-nearest neighbors (KNN), and logistic regression (LR). Similarly, we trained two commonly used deep learning models, i.e., multi-layer perceptron (MLP), and convolutional neural network combined with long-short term memory (CNN+LSTM) model, for cyber-attacks detection in IoT healthcare environments.

E. Performance Comparison

We compared the performance of all trained models to decide the best-performing model. We used four commonly used performance metrics including accuracy, precision, recall and F1-score. These evaluation metrics are defined in the next results and discussion section.

IV. Results

In order to conduct experiment, we acquired publicly available dataset and proceeded with further stages. For the data preprocessing, data transformation and training and testing of the AI models for cyber-attacks detection in IoT healthcare environments, we used Python programming language and some standard AI models and libraries, such as numpy, pandas, scikit-learn, and tensorflow.

To begin with experimentation, we considered three scenarios in which seven AI models are trained for cyber-attacks detection in IoT healthcare environments. These seven commonly used AI models include decision tree (DT), random forest (RF), Naïve Bayes (NB), k-nearest neighbors (KNN), logistic regression (LR), multi-layer perceptron (MLP), and convolutional neural network combined with long-short term memory (CNN_LSTM) model. All these models were trained with their default parameters set in Python's scikit-learn library except MLP and CNN_LSTM. For MLP and CNN_LSTM, we used tensorflow library. We further used Adam optimizer, set learning rate = 0.001, defined four hidden layers. After training these models, we then need to evaluate their performance on test data for cyber-attacks detection. For this purpose, we used four commonly used performance evaluation parameters, i.e., precision, recall, F1-score, and accuracy. These performance matrices are defined as follows:

1) Precision (PR): It tells us about the capacity of a system to accurately recognize an attack upon the happening of an actual cyber-attack. It presents a correlation between accurately anticipated attacks and actual outcomes. Mathematically, precision is expressed as:

$$PR = \frac{True\ Positives}{\text{True Positives } + \text{ False Positives}} \times 100$$

2) Recall (RE): It tells us about the correctly identified cyber-attack events upon its existence in the network. Mathematically, recall is written as:

$$RE = \frac{True\ Positives}{\text{True Positives } + \text{ False Negatives}} \times 100$$

3) Accuracy (AC): It tells us about how many attack events are categorized as attacks and how many regular network packets are categorized as normal traffic. It also indicates the proportion of accurate predictions relative to the total number of samples. Mathematically, it is expressed as:

$$AC = \frac{\text{True Positives } + \text{ True Negatives}}{\text{Total Samples}} \times 100$$

*4) F1- score:*It is defined as a harmonized average of recall and precision. It tells us about the percentage of correctly predicted testing samples as cyber-attacks. Mathematically, it is expressed as:

$$F1\ score = 2 \times \frac{PR\ x\ RE}{PR + RE}$$

In order to evaluate the best performance among the AI models, we have three scenarios as we mentioned earlier and will find out the best-performing model to recognize cyber-attacks in each scenario.

B. Scenario 1 - Training and Testing AI Models on All Dataset Features

We applied the data preprocessing techniques stated earlier and after cleaning and normalization of the data, we selected all features to test and compare performance of the seven AI models. Table IV shows overall performance of seven AI models for cyberattacks detection in IoT healthcare networks over the test data.

TABLE IV. Performance of All Seven AI Models when All Features Selected

Classifier	Accuracy	Precision	Recall	F1 score
DT	0.97	0.9	0.97	0.97
RF	0.98	0.98	0.98	0.98
NB	0.45	0.41	0.46	0.35
KNN	0.94	0.94	0.94	0.94
LR	0.36	0.40	0.36	0.32
MLP	0.52	0.56	0.52	0.49
CNN_LSTM	0.84	0.85	0.84	0.84

It can be observed that RF classifier efficiently identified critical cyberattacks whereas the LR classifier poorly performed. Overall, the RF classifier resulted 98% accuracy, 98% precision, 98% recall and 98% f1 score for cyberattacks detection IoT healthcare environments. Fig. 2 shows the performance of all the seven models when all features were selected.

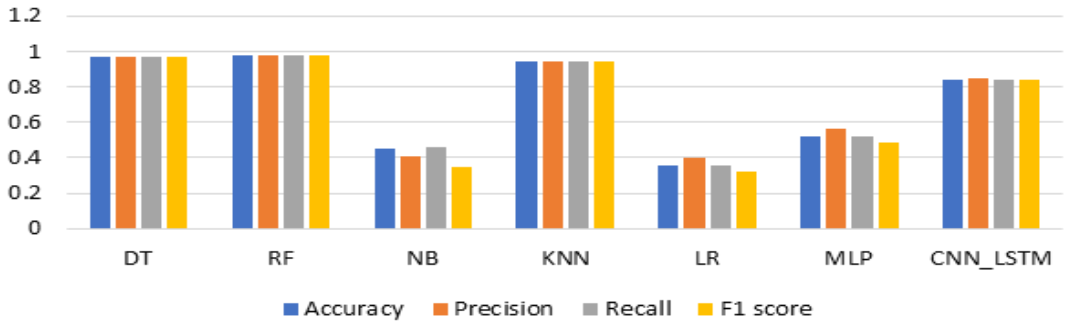

Fig. 2. Test results of all seven AI models when all features selected.

C. *Scenario 2 - Training and Testing AI Models on Top 20 Features*

After the data preprocessing, we selected top 20 features to test and compare the performance of AI models on all features vs. a subset of features according to proposed methodology for cyberattacks detection in IoT healthcare environments. We applied four features selection techniques including Anova, Chi^2, Mutual information and Extra tree using scikit-learn library in Python programming language. Table V shows the accuracy and recall scores of seven AI models for cyberattacks detection in IoT healthcare networks over the test data.

It can be observed that for Accuracy, the RF classifier efficiently identified critical cyberattacks whereas the LR classifier poorly identified cyber-attacks. Overall, the RF classifier resulted 98% accuracy for Anova, 97% accuracy for Chi2, 97% accuracy for Mutual information and 97% accuracy for Extra Tree features selection technique for cyberattacks detection IoT healthcare environments. Similarly, for Recall, the RF classifier efficiently identified critical cyberattacks whereas the LR classifier poorly performed. Overall, the RF classifier resulted 89% recall for Anova, 98% recall for Chi^2, 98% recall for Mutual information and 98% accuracy for Extra Tree features selection technique for cyberattacks detection IoT healthcare environments. Fig. 3 shows accuracy and recall of the seven AI models on top 20 selected features.

We obtained data of Precision and F1 scores for all AI models when 20 features were selected. Table VI shows the data.

TABLE V. ACCURACY AND RECALL SCORES OF SEVEN AI MODELS WHEN 20 FEATURES SELECTED

Classifier	Accuracy				Recall			
	Anova	Chi2	Mutual_Info	Extra_Tree	Anova	Chi2	Mutual_Info	Extra_Tree
DT	0.86	0.97	0.96	0.96	0.87	0.97	0.97	0.97
RF	0.98	0.97	0.97	0.97	0.89	0.98	0.98	0.98
NB	0.37	0.45	0.45	0.45	0.38	0.46	0.46	0.45

CNN_LSTM	0.84	0.83	0.84	0.84	0.84	0.85	0.84	0.84

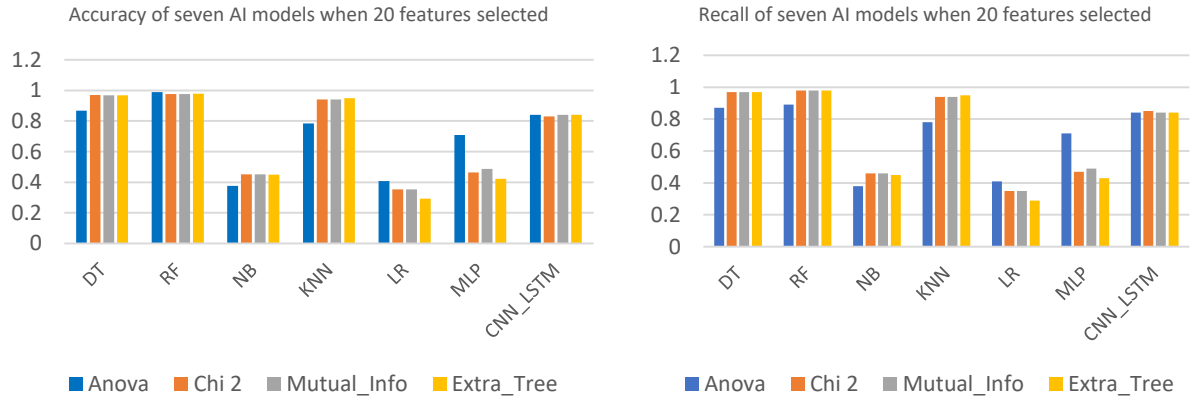

Fig. 3. Test results of Accuracy and Recall of seven AI models when 20 features selected.

TABLE VI. PRECISION AND F1 SCORES OF SEVEN AI MODELS WHEN 20 FEATURES SELECTED

Classifier	Precision				F1 score			
	Anova	Chi2	Mutual_Info	Extra_Tree	Anova	Chi2	Mutual_Info	Extra_Tree
DT	0.47	0.97	0.97	0.97	0.87	0.97	0.97	0.97
RF	0.89	0.98	0.98	0.98	0.89	0.98	0.98	0.98
NB	0.38	0.41	0.41	0.42	0.33	0.36	0.36	0.36
KNN	0.79	0.94	0.94	0.95	0.78	0.94	0.94	0.95
LR	0.26	0.39	0.39	0.29	0.30	0.29	0.29	0.25
MLP	0.77	0.64	0.53	0.44	0.70	0.43	0.46	0.37
CNN_LSTM	0.84	0.85	0.84	0.84	0.84	0.85	0.84	0.84

It can be observed that the RF classifier efficiently identified critical cyber-attacks whereas the LR classifier poorly identified cyber-attacks. Overall, the RF classifier resulted 89% precision for Anova, 98% precision for Chi^2, 98% precision for Mutual information and 98% precision for Extra Tree features selection technique for cyber-attacks detection IoT healthcare environments. Similarly, F1 scores show that RF classifier efficiently identified critical cyber-attacks whereas the LR classifier poorly identified cyber-attacks. Overall, the RF classifier resulted 89% f1-score for Anova, 98% f1-score for Chi^2, 98% f1-score for Mutual information and 98% f1-score for Extra Tree features selection technique for cyber-attacks detection IoT healthcare environments. Fig. 4 shows Precision and F1 scores of the seven AI models on top 20 selected features.

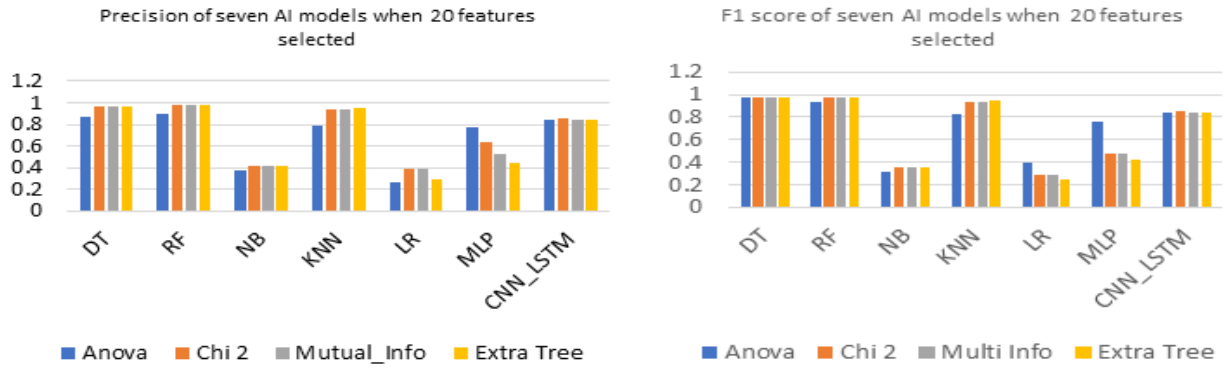

Fig. 4. Test results of Precision and F1 scores of seven AI models when 20 features selected.

D. Scenario 3 - Training and Testing AI Models on Top 30 Features

In this scenario, we selected top 30 features to test and compare the performance of AI models on all features vs. a subset of features according to the proposed methodology for cyber-attacks detection in IoT healthcare environments. Table VII shows the accuracy and recall scores of seven AI models for cyberattacks detection in IoT healthcare networks over the test data.

It can be observed that RF classifier efficiently identified critical cyberattacks whereas the LR classifier poorly identified the cyberattacks. Overall RF resulted 93% accuracy and recall for Anova, 98% accuracy and recall for Chi^2, 98% accuracy and recall for Mutual_Info and 98% accuracy and recall for Extra_Tree features selection techniques for cyberattacks detection in IoT healthcare environments. Fig. 5 shows the Accuracy and Recall scores metrics of seven AI models for 30 features selected.

TABLE VII. ACCURACY AND RECALL SCORES OF SEVEN AI MODELS WHEN 30 FEATURES SELECTED

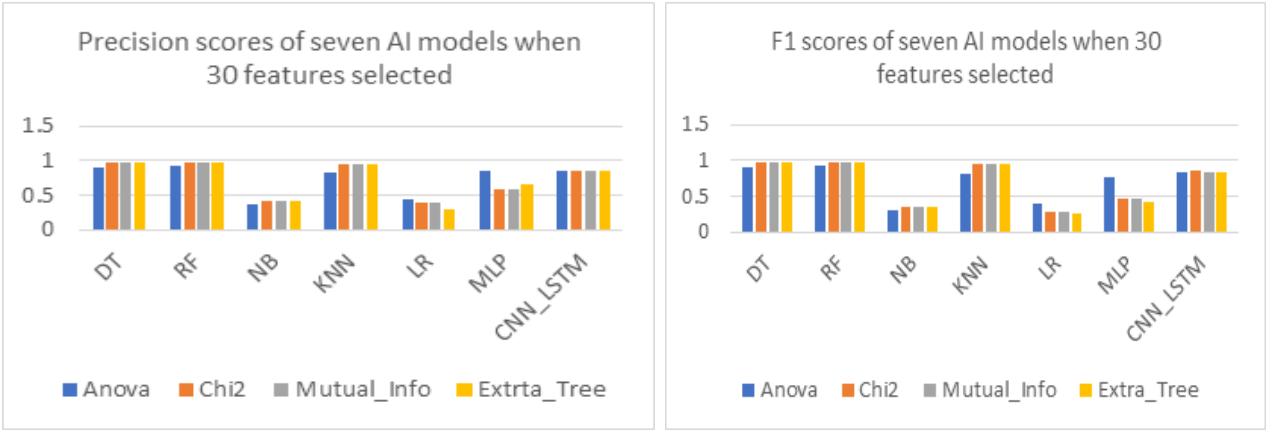

Fig. 6. Test results of Precision and F1 scores of seven AI models for 30 features selected.

V. DISCUSSION

The overall results in all three scenarios revealed that the RF classifier outperformed all other AI models for cyber-attacks detection in IoT healthcare environments. The RF classifier resulted the highest scores in terms accuracy, precision, recall, and F1-score for all three scenarios and across all four features selection techniques. In contrary, the LR classifier resulted the lowest scores in terms accuracy, precision, recall, and F1-score for all three scenarios and across all four features selection techniques. The experimental results support that both our hypothesis H0 and H1 are true since it is proved that the AI models improve the accuracy of cyber-attacks detection in IoT healthcare environments which eventually leads to prove that AI models has potential to enhance the detection of cyber-attacks in IoT healthcare environments.

VI. CONCLUSION AND FUTURE WORK

With the rapid application of IoT devices in healthcare environments, the cyber-attacks are surging in IoT healthcare environment due to limited security features such as limited

memory and processing power integrated in IoT devices. The healthcare environment is highly sensitive and any malfunction of IoT healthcare devices due to cyber-attacks can lead to severe implications even death. Therefore, it is highly essential to secure IoT healthcare devices from cyber-attacks. Hence, in this research, we proposed a methodology for cyber-attacks detection in IoT healthcare environments using AI. The proposed methodology consists of five major stages including data collection, data pre-processing, features selection, AI models training and performance comparison. We acquired a publicly available CIC IoMT dataset for training & testing of the AI models for cyber-attacks detection in IoT healthcare environments using Python language and some standard AI models and libraries. We used four commonly used features selection methods and trained and tested five commonly used machine learning models and two deep learning models. Furthermore, we considered three scenarios in which all seven AI models are trained for cyber-attacks detection in IoT healthcare environments. The experimental results revealed that the Random Forest (RF) classifier outperformed all other AI models for detecting 18 types of cyber-attacks—mapped into five attack classes—and normal traffic in IoT healthcare environments having 98% accuracy, 98% precision, 98% recall and 98% F1-score. Likewise, the best results were achieved on selecting 20 features out of 45 features using mutual information features selection method.

In future, we aim to increase the attack coverage to enable AI model to detect more types of cyber-attack. Furthermore, we aim to deploy the proposed solution in real-time environment in order to test its performance in real-time use case.

***Abstract*—The economy of today's world is a data-driven knowledge economy, as electronic devices are mostly used for our day-to-day activities, through which organizations collect data actively or passively. The dimensionality of the dataset is also increased, along with the volume of data, because of the advancements in digital devices and communication technology. The feature selection becomes a crucial preprocessing step in big data analytics as a dimensionality reduction technique to eliminate redundant and noisy features. Studying the fluctuations in feature selection results is a vigorous area of research, as it is positively related to data utility, as fluctuations in feature selection results confuse the data analysts' minds about their research outcomes. Privacy preservation is a major concern in big data analytics to protect sensitive individuals' data. Application of privacy preservation techniques to modify the dataset will affect the stability of feature selection, as it has recently been proven that it mostly depends on the dataset's physical characteristics. This study analyses the performance of the proposed Scalable Reversible Randomization Algorithm (SRRA) in terms of privacy preservation, change in characteristics of the dataset, information loss, stability of feature selection, and data utility in big data scenarios.**

Keywords*—Big data; data analytics; high dimensionality; feature selection; selection stability; privacy preservation; information loss

I. Introduction

Big data is a keyword for organizations, as everyday mountains of customer data (including social media, education, healthcare, finance, business, and more) accumulate in organizations that are mostly unstructured and semi-structured. Because of the technological advancements and outsourcing of cloud computing, the dimensionality, i.e., the number of features of the dataset, is also increasing along with volume, i.e., samples. Organizations get an edge over their competitors by analyzing the data for mining patterns and getting insights, and applying the knowledge for business strategic decision-making and improved customer relationship management. However, feature selection is a vigorous preprocessing step of dimensionality reduction as it eliminates the "curse of high dimensionality" by selecting the most relevant subset of features for better comprehension of the model, higher efficiency in terms of processing time, improved accuracy of data analytics results, elimination of possible redundant and noisy attributes which may be quasi identifier attributes leading to better privacy preservation than the full set of features.

Unstable feature selection results confuse the researcher, as feature selection is related to data utility. Previously, data scientists believed that fluctuations in feature selection results depend on feature selection algorithms. However, lately, it has been proven that fluctuations in feature selection results depend mostly on changes in the physical characteristics of the dataset but are not completely independent of algorithms [1-6]. Feature selection instability is caused by minor changes in the dataset, which may select different subsets of features and may affect the accuracy of data analytics results, leading to doubts in the minds of researchers about their conclusions of research findings. Sensitive data like monetary data or disease, or marital status of individuals should be prevented from disclosure to third parties in data analytics. The application of privacy-preservation techniques affects the physical characteristics of the dataset, which will be reflected in fluctuations in feature selection results, which will be related to the accuracy of big data analytics results. Hence, there is a need to develop privacy preserving big data analytics algorithms with minimal change in the physical characteristics of the dataset for better feature selection stability results, lesser information loss, and higher data utility without compromising on privacy preservation.

All the privacy conserving methods like slicing, t-closeness, l-diversity, and k-anonymity have been practiced for a long time, but in the big data era, their applications have practical complications resulting in processing overheads because of the enormous volume, several varieties, and continuous velocity of arriving data. Traditional security mechanisms are inadequate in handling data analytics in big data and cloud computing scenarios. The tools for big data, like Hadoop, MapReduce, Pig, and Spark, work on distributed parallel processing in the Hadoop Distributed File System, leading to complications in employing privacy-conserving methods in terms of scalability and implementation overheads. It is practically very complex to implement and time-consuming in terms of processing efficiency, and it is very difficult to implement these privacy conserving methods in terms of scalability, as the data and processing algorithm are distributed in thousands of data nodes,

and also results in a diminution of the accuracy of outcomes of big data analytics, i.e., data utility.

Information security and privacy protection are very challenging in the big data and cloud computing era. To address the issues, the proposed algorithm, SRRA, is based on the randomization technique, which can be applied to the preprocessing stage itself; hence, it is highly scalable and efficient in terms of processing time for big data privacy preservation. At the preprocessing stage, the data are collected from different sources and go through data extraction, data cleansing, transformation procedures, and anonymization of sensitive and quasi-identifiers by SRRA to annihilate personal identifying information and safeguard private sensitive data, followed by feature selection as a dimensionality reduction technique.

In this research study, Section II provides the related work, and Section III describes the proposed privacy preserving big data analytics algorithm, the Scalable Reversible Randomization algorithm (SRRA). Section IV presents the methodology, results and discussion. Finally, Section V provides the conclusion.

II. Related Work

Big data analytics is vital for organizations in today's data-driven economy. However, sensitive data of individuals' records shouldn't be re-identified by the data analyst, as it can be misused. Privacy is a data owner-oriented concept and a privacy preservation method in which the dataset is under the control of a custodian called PPDM (Privacy Preserving Data Mining), and the data owner is responsible for the privacy of the individuals' data. The second one is the anonymization method, and also in this method, the dataset is not under the control of a custodian called PPDP (Privacy Preserving Data Publishing).

In PPDM, like differential privacy techniques is interactive, the dataset is under the control of the data owner, and the big data analyst analyses the dataset. However, these techniques are not appropriate for the big data era and are practically very difficult to implement because of the three v's, i.e., velocity, variety, and volume of big data, and also the data is collected from different sources. The PPDP methods like generalization, bucketization, perturbation, and anonymization techniques like k-anonymity (quasi identifiers are generalized to at least k number of alike attribute values for different records in each equivalence class), l-diversity (improved model of the k-anonymity technique, the sensitive attributes are at least l distinct domain feature values for each equivalence class that includes both generalized k number quasi identifier values and l distinct sensitive feature values to avoid both background knowledge and similarity attack), t-closeness (to eliminate skewness attack on l-diversity model), slicing, and randomization methods are non-interactive, the dataset is anonymized and published for any research works as it is not under the control of a custodian. However, these techniques are practically very difficult to implement in the distributed processing environment of big data and the cloud computing era of Hadoop, Spark, or Pig, as they are not directly applicable and also not very scalable.

The differential privacy method [7] is an interactive query made to a database using a randomized response mechanism by adding calculated noise to the outcome of the query. This method shares data to permit inferences about groups of persons while preventing someone from learning information about an individual through a rigorous mathematical foundation. It gives strong security for sensitive data even if the adversary has robust background knowledge, but less data utility because of added noise. Because of the three v's: variety, velocity, and volume of big data, the differential privacy technique is not appropriate for cloud computing and big data environments. In the Hadoop Distributed File System environment of big data, along with the distributed processing environment of the MapReduce algorithm, it is very complex and difficult to implement differential privacy in big data.

The important PPDP methods are t-closeness, l-diversity, k-anonymity, and slicing. The k-anonymity method anonymizes the data to eliminate re-identification, as every quasi-identifier is anonymized with a k number of feature values by the generalization technique [8, 9]. In the k-anonymity algorithm, the value of k of 23 means ensuring 23 blurry tuples when an effort is made to recognize a specific individual's private sensitive data. It is difficult to prevent re-identification of individuals' records by quasi-identifiers, and so disclosure of sensitive data cannot be prevented in k-anonymity. In the k-anonymity technique, record linkage attacks like homogeneity attacks and background knowledge attacks compromise the de-identification of an individual's record if there is insufficient diversity of sensitive attributes.

The l-diversity method was introduced to eliminate the attacks that compromise the k-anonymity model. There must be l well-represented sensitive feature values like disease, marital status, and monetary values in each equivalence class, in the l-diversity method [10]. Because of the different varieties and huge volume of data in big data, l-diversity is not possible at all times, and implementing l-diversity in big data is very complex and difficult. The feature disclosure cannot be safeguarded when the global distribution of data in the dataset is tilted into a few equivalence classes. Nevertheless, de-identification is compromised by the skewness attack in the l-diversity model, as in the equivalence class, one value emerges as frequently leading to the possibility for the opponent to deduce the value of another entity having a similar value with the information of real time global dispersal of data.

The t-closeness model is introduced to avoid the skewness attack in the l-diversity model. If the distance between the distributions of sensitive feature values in the class is no more than a threshold of the real skewness of the distributed data, the equivalence class is measured to have 't-closeness' in the t-closeness model [11]. These techniques have limitations and practical difficulties in big data and cloud computing scenarios. Applying these techniques is very difficult and complex in big data and clouds because of the huge volume and multiple varieties of data, and also inefficient due to long processing time, resulting in being very difficult to implement in big data frameworks like Hadoop, MapReduce, Pig, and Spark.

Slicing is the model of splitting the dataset column-wise or row-wise, i.e., splitting feature values and/or tuples where

extremely correlated features are a group and dissimilar features are sliced into different groups [12]. Slicing models are more appropriate for big data datasets with high dimensionality. Nevertheless, it is very complex to implement and also has practical limitations.

The randomization method adds calculated noise to the particular feature values [13]. Randomization methods have disadvantages in big data due to processing time efficiency and reduction in data utility, i.e., the accuracy of outcomes of big data analytics. However, the randomization method can be applied in the preprocessing step itself, and then it eliminates anonymization overhead.

Cryptographic methods such as secure multiparty computation (MPC) and homomorphic encryption are used to encrypt the data before the transfer of it for big data analytics [14]. In this method of secure multiparty computing, multiple parties can analyze the dataset together without revealing their data. It is very complex to implement cryptographic methods in big data. If multiple parties are involved in integrated big data analytics, managing the complexity is more challenging in big data. In this technique, data utility is considerably reduced by the application of encryption. Also, it is not easy in the big data and cloud computing scenario to encrypt all data.

The recent developments in privacy-conserving methods in the big data era are MapReduce-based anonymization (MRA) [15]. In this method, the dataset is considered as a single equivalence class, and in each iteration, tuples are selected for subclasses for k-anonymization. A global file is needed among the data nodes to share the updated equivalence class information with all nodes is a major drawback of the method. In the updated version of MRA, instead of a single global file, a chunk of files is used to update the equivalence class information. In this method, the drawbacks are multiple files to share equivalence class information and multiple iterations. The Scalable k-anonymization (SKA) model for MapReduce in [16]. This method has better processing time in comparison with similar existing scalable algorithms. In this method initial file is converted into a sorted equivalence class. The SKA algorithm results in considerable information loss. In the improved SKA, the columns are rearranged so that the distance between consecutive records is less, resulting in minimum information loss.

The privacy preserving big data analytics algorithm in [17] uses cryptographic techniques like homomorphic encryption schemes, attribute-based encryption schemes, and order-preserving encryption schemes in untrusted cloud environments. It is very difficult to implement this method in big data and cloud computing environments, as applying cryptographic techniques is a huge implementation overhead. This method has improved the preservation of privacy compared to other methods. The application of encryption algorithms for privacy preservation drastically reduces the utility of data.

Privacy preserving big data analytics algorithm in [18] uses two phases Named Entity Recognition (NER) approach called Conditional Random Field (CRF) to annotate unstructured data into the structured form, along with ImpSKA, an extension of the Scalable k-Anonymity (SKA) model using the Apache Pig framework. This method can be used for semi-structured and unstructured data. Practically, it is complex to implement in a big data distributed processing environment, leading to huge implementation overhead.

The improved scalable l-diversity approach in [19] is the scalable anonymization approach for privacy preserving big data publishing, and Apache Pig is used for the implementation. In this method, the input data are sorted for the creation initial equivalence class. In improved scalable l-diversity (ImSLD), both quasi-identifier attributes and sensitive attributes are used to generate an equivalence class from the sorted columns, and then the table is first k-anonymized and then l-diversified. In ImSLD, along with k-anonymization, l-diversity is also used to improve the preservation of privacy. There will be information loss and decreased data utility in comparison to the previous anonymization methods. It is a complex and time-consuming model in a big data scenario, as the required columns are arranged in ascending order of several unique values. This model also has a marginally higher processing time in comparison to similar models.

Along with generalization, anonymization (l-diversity and k-anonymity), slicing, and a method analogous to a one-way hash function called privacy view generation are used in the proposed system in [20] to safeguard the sensitive data and to avoid privacy incursions. In feature partitioning using the slicing method, extremely interrelated features are sliced as a subset of records. An equivalence class is formed for each slice of records and is anonymized by k-anonymity. Quasi identifiers are susceptible to background knowledge attacks, and hence sensitive feature values are l-diversified. However, this model is very complex to implement as it is very time-consuming in big data scenarios, leading to increased processing time and data utility is also drastically reduced.

The privacy-conserving big data analytics methods are not effective in terms of scalability, and applying these methods in big data distributed frameworks like Hadoop, MapReduce, Pig, or Spark is very intricate and time-consuming, and data utility is considerably reduced. The proposed Scalable Reversible Randomization Algorithm (SRRA) in this research study is suitable for the distributed parallel processing of big data frameworks, as it can be applied in the preprocessing stage itself, and so it is extremely scalable. It fills the gap, as the existing privacy preserving techniques are unsuitable in a big data scenario. The SRRA is practically not very difficult to implement in big data compared to the similar methods and with better fluctuations in feature selection results, lesser information loss, and higher data utility without compromising privacy preservation.

III. Proposed Scalable Reversible Randomization Algorithm (SRRA)

There will be four types of features in the dataset: non-sensitive features, indirect or quasi-identifiers, sensitive features, and direct identifiers.

Non-sensitive features are the features other than the above three types that are not sought by the intruder.

Indirect identifiers or quasi-identifiers are features like date of birth, occupation, religion, location, and zip code that can be

indirectly used for the re-identification of a record of an individual using linkage attacks.

Sensitive features are features like disease or monetary values targeted by the intruder. Privacy preservation techniques should be applied to quasi-identifiers and sensitive features to safeguard the privacy of individuals' records.

Direct Identifier attributes uniquely identify the record, like employee ID or social security number. Identifier attributes are generally anonymized before being sent for big data analytics.

The proposed reversible privacy conserving algorithm, i.e., Scalable Reversible Randomization Algorithm (SRRA), is shown in Fig. 1. SRRA is explained in [21]. Big data analytics is challenging for computational resources in terms of storing and processing, and also for machine learning algorithms in terms of efficiency and performance. Also, it is difficult to identify quasi-identifier and sensitive data in big data. The efficiency, i.e., performance of algorithms, and data utility, i.e., accuracy of results of the analysis, will be closer or the same because, with sampled versions, for the reduced samples selected by attribute selection optimization algorithms such as the ant-colony, Pareto-front, particle swarm optimization, and similar other algorithms. However, we should not be able to outperform the model of the 100% data. The privacy-conserving alteration by the proposed algorithm SRRA is scalable and efficient, along with better stability of feature selection and accuracy results.

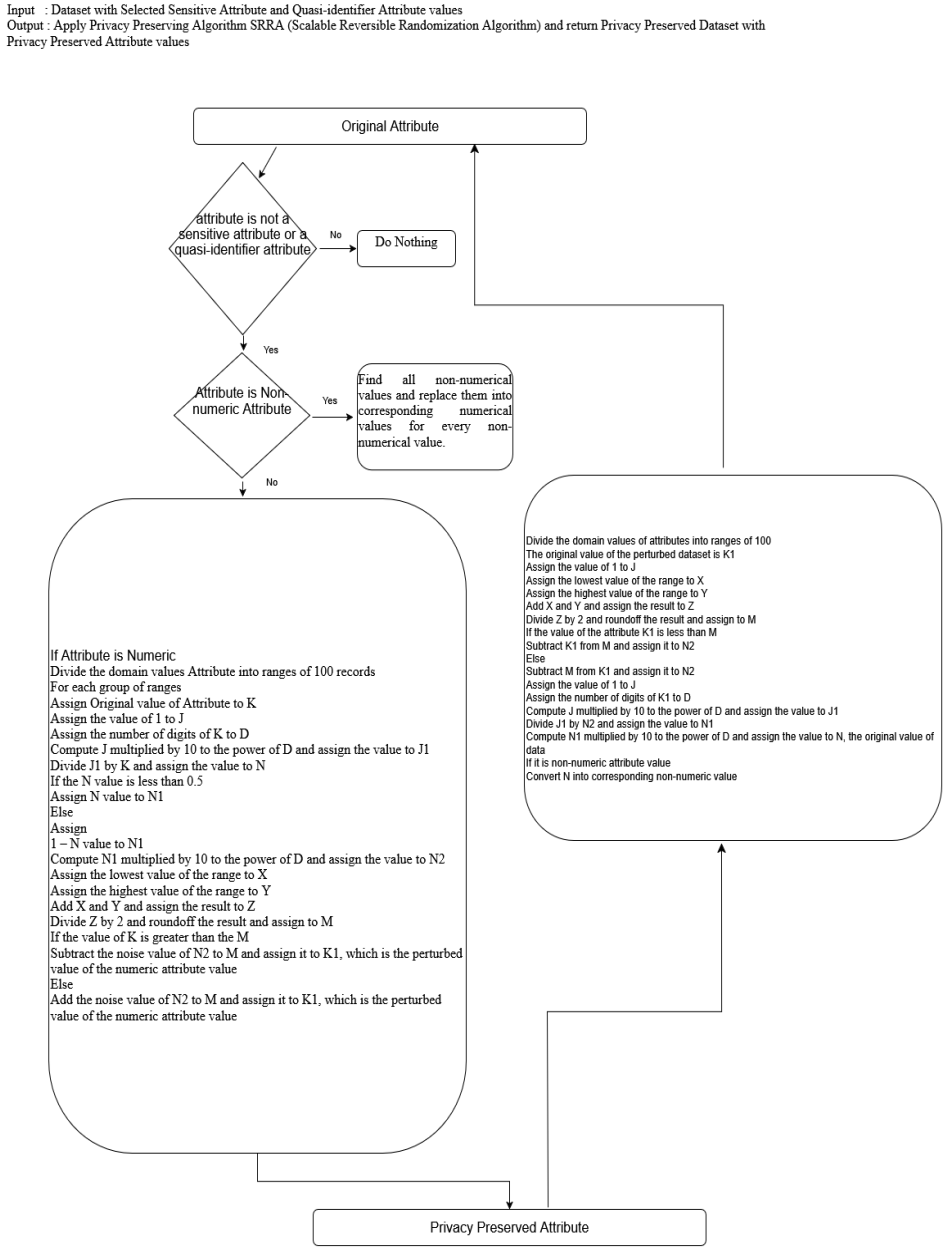

Fig. 1. Pseudocode of the proposed reversible privacy preserving algorithm of SRRA.

The selected sensitive and quasi-identifier attributes are perturbed by the proposed SRRA for privacy preservation. The application of SRRA in big data, which contains numeric and non-numeric data converted into definite sizes or formats, is suitable for the application of feature selection methods. The feature selection algorithm applied on the privacy conserved dataset, which is an important preprocessing step, will select an almost similar set of attributes, as the privacy conserving perturbation does not much affect the statistical characteristics of the experimental dataset.

The privacy-preserved dataset is used for big data analytics to get insights and hidden patterns from it. The application of SRRA results in the change in statistical characteristics of attribute values of the experimental dataset is negligible with less information loss, leading to better stability of feature selection and improved big data analytics results in terms of accuracy and error rate, along with robust privacy preservation of individuals' records. The SRRA processing time is reduced to around 15% in comparison to other similar methods in big data scenarios. The reversible privacy conserving algorithm of SRRA can be used to get the original dataset from the privacy-preserved dataset.

IV. Experiments

A. Methodology

The methodology of research is diagrammatically shown in the block diagram, in Fig. 2.

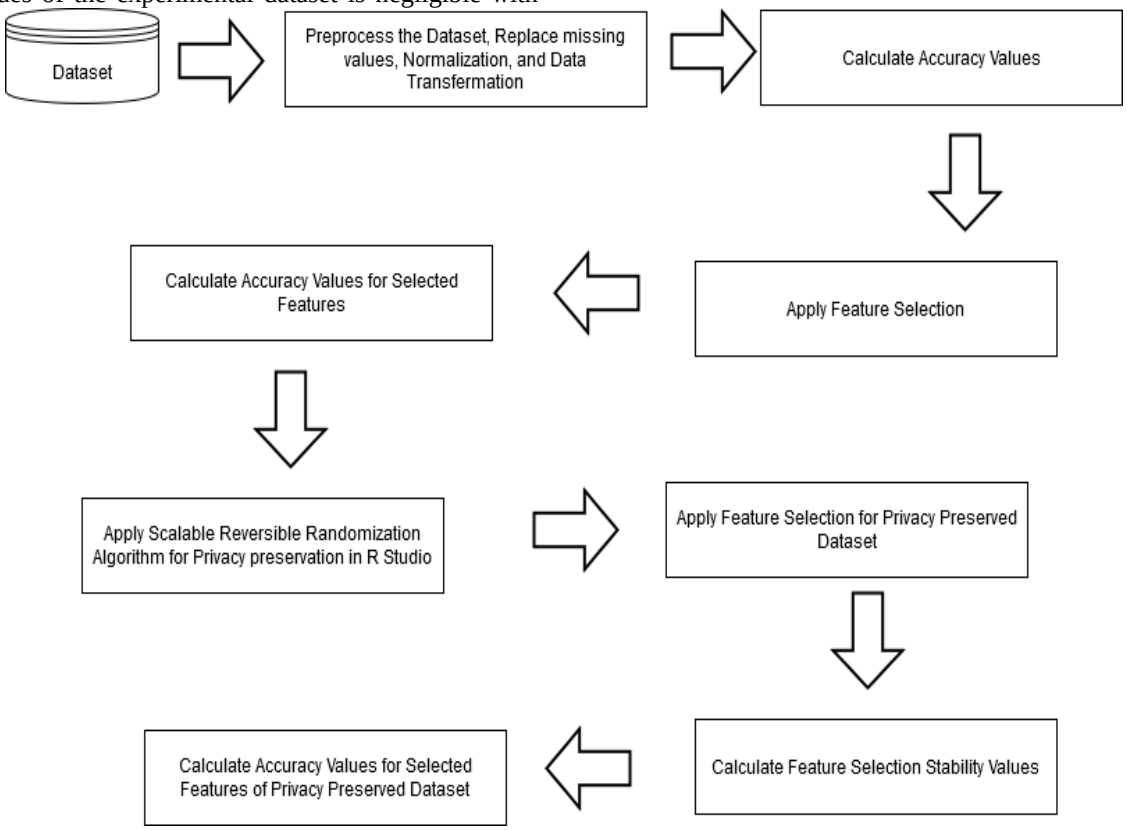

Fig. 2. Methodology.

B. Experimental Setup

The experiments are carried out in R-Studio. The application of privacy preserving modification by SRRA is implemented as a preprocessing step on the experimental datasets. The privacy-preserved datasets are harnessed in the Hadoop Distributed File System. The Hadoop distributed processing is implemented with three data nodes and one name node. The dataset used in the experiments is the Census Income dataset of the UCI repository.

C. Normalized Cardinality Penalty NCP

The metric to measure the information loss due to the manipulations of privacy-preservation is Normalized cardinality penalty (NCP) [22]. Information loss is an important parameter for the performance of the privacy preserving big data analytics algorithm. NCP is the metric of information loss in percentage, and hence it is suitable for big data scenarios. NCP for an equivalence class G for numeric attribute A is defined in Eq. (1):

$$NCP_A(G) = \frac{MAX_A^G - MIN_A^G}{MAX_A - MIN_A} \quad (1)$$

where, numerator MAX and MIN represent the range of attributes of class G, and denominator MAX and MIN represent the entire table.

D. Correlation-Based Feature Selection CFS

By seeing the degree of redundancy among them, along with the distinctive prophetic capability of each feature, the value of the attribute subsets is evaluated by CFS. The subsets of features that are prominently correlated within the class, with the inter-

correlation among classes, will be scanter preferences are taken by CFS [23]. Authors have GA, as a search method, with CFS as a fitness function. CFS selects the best feature subset and can be supplied with alternative search mechanisms. In Eq. (2), CFS is specified.

$$r_{zc} = \frac{k\, r_{zi}}{\sqrt{k + (k-1)\, r_{ii}}} \quad (2)$$

where, k refers to the number of subset features, r_{ii} refers to the mean inter-correlation between subset features, r_{zi} refers to the mean correlation between subset features and the class variable, and r_{zc} provides the correlation between other subsets of features and the class variable [23].

E. Dice's Coefficient

In [24], the Dice coefficient is the similarity measure used to measure the stability of feature selection, i.e., to calculate the overlap between two subsets. It included the Jaccard index. Dice takes a value between zero and one, where zero suggests no overlap and one suggests that the two subsets are identical. Dice, Jaccard, and Tanimoto are measures of similarity among them to calculate fluctuation in feature selection results. The Dice's coefficient is represented in the given Eq. (3):

$$\text{Dice}(F'1, F'2) = \frac{2\,|F'1 \cap F'2|}{|F'1| + |F'2|} \quad (3)$$

F. Results

In the experiments, four algorithms from Table I are used. Dice's coefficient is a metric used to measure fluctuations in feature selection results. The feature selection algorithm used in the experiment is CFS. Table I shows the relationship between changes in the physical characteristics of the dataset by privacy preserving perturbation effects on information loss, the fluctuations in feature selection results, and the accuracy of big data analytics outcomes.

In [20], privacy preservation is implemented in the HDFS distributed file system environment of real-time huge datasets. A secure map-reduce layer is introduced in MapReduce distributed processing for privacy preserving implementation. The methodologies used are generalization, slicing, anonymization (k-anonymity followed by l-diversity), and a one-way hash function, as privacy view generation in a parallel processing environment of distributed processing. In this method, the l value is kept constant for changing values of k for different anonymization views and processing time combinations for optimum configuration values. However, by using NCP, it is proven that information loss in 48% results in decreased data utility.

The algorithm is a combination of techniques like slicing, generalization, k-anonymity, l-diversity, one way hash function resulting in better privacy-preservation, but implementing this algorithm in the Hadoop distributed file system is very complex and time consuming, resulting in increased processing overhead in big data scenario. Stability of feature selection is 0.72 as it is drastically reduced along with data utility value for overall accuracy as 63.27% and accuracy of selected features as 68.59%.

TABLE I PERFORMANCE COMPARISON OF DIFFERENT TECHNIQUES

Privacy Preserving Technique Ref. No.	Information loss by NCP	Feature Selection Stability	Overall Accuracy		Accuracy of Selected Features	
			Before Privacy Preservation	*After Privacy Preservation*	*Before Privacy Preservation*	*After Privacy Preservation*
[20]	48%	0.72	74.51%	63.27%	79.68%	68.59%
[19]	35%	0.86	74.51%	69.68%	79.68%	75.51%
[18]	41%	0.77	74.51%	65.89%	79.68%	73.23%
[17]	59%	0.67	74.51%	61.87%	79.68%	65.86%
SRRA	26%	0.91	74.51%	72.28%	79.68%	77.41%

The privacy preserving algorithm by the authors in [19] is an improved scalable l-diversity approach, which has a higher stability of feature selection value of 0.86 and accuracy of overall feature as 69.68% and accuracy of selected features as 75.51% but it has lower privacy preservation compared to other methods. The information loss by NCP is 35%. The algorithm by [18] can be applied for semi-structured data using tagging techniques followed by scalable k-anonymity. The model is optimum in stability value of feature selection as 0.77, information loss by NCP as 41% and data utility of overall features as 65.89% and for selected features as 73.23%.

The algorithm by [17] is a cryptographic method, and it has the lowest stability of feature selection value of 0.67 and an overall accuracy value of 61.87% along with the accuracy of selected features as 65.86%, as it uses encryption methods, but it has better privacy preservation. In this method, the information loss by NCP is 59%, which is the highest among the listed methods.

The SRRA algorithm in [21] uses a randomization technique of calculating noise addition. The algorithm is applicable for both numeric and non-numeric data and hence suitable for big data. If the data is categorical or non-numeric, the attribute values are converted into equivalent numeric values before applying the algorithm. The proposed algorithm SRRA has the highest stability of feature selection value of 0.91 compared to other algorithms, an overall accuracy of 72.28%, and an

accuracy of selected features of 77.41%, which is higher than other algorithms. The information loss by NCP is also a minimum value of just 26%. This is because the change in statistical properties by SRRA is minimal compared to other algorithms, as the change in physical characteristics of the trial dataset is positively related to fluctuations in feature selection results and accuracy.

G. Discussion

The method in [20] is superior in terms of safeguarding private sensitive data. This method is very complex to implement in terms of implementation and computing cost, i.e., execution time. Implementation of the algorithm in [19], in the Hadoop distributed file system, using the MapReduce algorithm, is also easy compared to other models. This model in [18] is difficult to implement compared to other models used in the experiments.

Encryption methods in [17] are difficult to implement in big data scenarios, and data utility is also drastically reduced. So, there will be a relationship among privacy preserving perturbation, information loss, fluctuations in feature selection results, and accuracy.

As the characteristics of the dataset are related to the fluctuations in feature selection results and accuracy, the statistical characteristics of the dataset have minimal modification because of the privacy-conserving alteration by SRRA in [21]. Hence, SRRA give better results in terms of stability of feature selection, accuracy values of privacy-preserved dataset in terms of overall accuracy, and accuracy of selected features.

Information loss by NCP is also minimum, compared to other similar methods, as the change in characteristics of the dataset is minimal. Another advantage of SRRA is its suitability in big data scenarios, as the privacy preserving algorithm is a simple calculated noise addition technique and can be implemented in the preprocessing stage itself with less overhead, i.e., processing time, compared to similar privacy preserving algorithms without compromising on privacy-preservation.

V. Conclusion

The SRRA has higher stability of feature selection and accuracy values because the change in characteristics of the physical properties of the experimental dataset is minimal. However, the algorithm has better privacy preservation as there is a trade-off among variation in physical characteristics of the dataset, information loss, efficiency, fluctuations in feature selection results, as it is related with data utility, i.e. accurate data analytics results.

In the proposed privacy preserving big data analytics algorithm SRRA, both quasi-identifiers and sensitive features are anonymized by the randomization technique of calculating noise addition efficiently with minimal practical overheads in the preprocessing stage itself, and hence, because of the practical advantages, the implementation overhead is minimal compared to similar other algorithms in big data and cloud environments.

General privacy preserving algorithms are not working in a big data scenario. Hence, developing privacy-preservation algorithms in a big data scenario is very much challenging because of the implementation overhead and hence there will be a tradeoff among lesser information loss, better privacy preservation, improved stability of feature selection as it is directly linked with data utility, as selected features are used for data analytics for better efficiency, i.e. processing time and improved accuracy of data analytics results.

Shared API Call Insights for Optimized Malware Detection in Portable Executable Files

Mehdi Kmiti, Jallal Eddine Moussaoui, Khalid El Gholami, Yassine Maleh
LaSTI Laboratory-National School of Applied Sciences Khouribga, Sultan Moulay Slimane University, Beni Mellal, Morocco

***Abstract*—Malware analysis is essential for understanding malicious software and developing effective detection strategies. Traditional detection methods, such as signature-based and heuristic-based approaches, often fail against evolving threats. To address this challenge, this study proposes a static analysis–based malware detection system that employs thirteen classifiers, including Logistic Regression, K-Nearest Neighbors (KNN), Support Vector Machine (SVM), Naive Bayes, Decision Tree, Linear Discriminant Analysis (LDA), Quadratic Discriminant Analysis (QDA), Random Forest, Extra Trees, Gradient Boosting, AdaBoost, and LightGBM. The framework is built on a balanced dataset of 1,318 Windows Portable Executable (PE) files (674 malware, 644 benign), where the features are derived from shared API calls between benign and malicious files to ensure relevance and reduce redundancy. Experimental results show that the Extra Trees classifier achieved the highest accuracy of 98.14%, highlighting its effectiveness in detecting malware. Overall, this study provides a robust, data-driven approach that enhances static malware detection and contributes to strengthening cybersecurity against emerging threats.**

***Keywords*—Malware detection; static analysis; portable executable (PE) files; API calls; extra trees classifier**

I. Introduction

Malware, short for "malicious software", represents a major threat to digital systems, ranging from financial losses and privacy breaches to operational disruptions in critical infrastructure [1]–[4]. Modern malware is increasingly sophisticated, driven by profit, espionage, and cyber warfare, and includes forms such as viruses, worms, trojans, ransomware, and spyware [5], [6]. Recent statistics highlight its scale: more than 90% of digital threats target the Windows operating system, with AV-TEST reporting 1.17 billion threats by mid-2024, while global cybercrime costs are projected to reach $10.5 trillion annually by 2025 [7], [8]. These figures underscore the urgent need for effective malware detection strategies.

Traditional methods, such as signature-based and heuristic-based detection, struggle to keep pace with polymorphic and zero-day malware [9]–[11]. As a result, static analysis, which inspects executables without execution, has emerged as a promising alternative, particularly when combined with machine learning for classification.

Research Gap: Despite promising results, many prior static analysis methods rely on large and redundant feature sets, which increase computational overhead and reduce interpretability. Deep and ensemble learning models achieve high accuracy, but often lack scalability in real-world or resource-constrained environments. There is thus a need for lightweight and interpretable approaches that preserve strong detection performance while reducing redundancy.

To address this gap, we propose a malware detection framework based on shared API calls, which represent the intersection of calls found in both benign and malicious Portable Executable (PE) files. This refined feature space highlights the most relevant behaviors, reduces dimensionality, and supports efficient classification. Using a balanced dataset of 1,318 PE files (674 malware, 644 benign), we evaluate thirteen classifiers and demonstrate that the Extra Trees ensemble achieves the highest accuracy of 98.14%. The contributions of this work lie in constructing a refined dataset of shared API calls that enhances interpretability and efficiency, conducting a comparative evaluation of multiple classifiers, and showing that Extra Trees provides the best trade-off between accuracy and computational cost, making it suitable for practical deployment.

The remainder of this study is organized as follows: Section II reviews related work, covering metadata-based techniques, ensemble and hybrid approaches, and recent deep learning and graph-/transformer-based solutions, followed by the positioning of this study. Section III describes the proposed methodology, including dataset construction, API call extraction, shared-feature representation, preprocessing, the employed machine learning models, training and evaluation protocols, and the computing environment. Section IV presents the experimental results and provides a comprehensive discussion, including a comparative assessment against state-of-the-art (SOTA) approaches, limitations of the proposed method, practical applicability, and future research directions. Finally, Section V concludes the study by summarizing the key findings and outlining directions for future research.

II. Related Work

Research on static malware detection has explored a wide range of features and machine learning models. Existing approaches can be grouped into three main categories: metadata-based methods, ensemble and hybrid models, and deep learning methods, including recent transformer and graph-based solutions.

A. PE Header and Metadata Features

Balram et al. [12] evaluated six classifiers, including Support Vector Machine, Logistic Regression, Random Forest, and XGBoost, on string-based and PE header features. Their findings showed that string features, when combined with XGBoost and hybrid models, provided superior accuracy.

Similarly, Baldangombo et al. [13] analyzed PE headers, DLL names, and API calls, reporting that PE header features alone could achieve up to 99% accuracy with the J48 classifier while maintaining low computational overhead. These studies highlight the effectiveness of handcrafted metadata features but also underscore their limitations in scalability and adaptability to evolving threats.

B. Ensemble and Hybrid Models

Azeez et al. [14] proposed an ensemble framework that integrated fully connected dense Artificial Neural Networks (ANNs) and 1D-CNNs, with Extra Trees serving as a final-stage classifier. Their approach outperformed conventional classifiers in accuracy and robustness. Shijo and Salim [15] combined static and dynamic analysis, using Printable Strings Information (PSI) along with API call sequences extracted from the Cuckoo Sandbox, and achieved 98.7% accuracy with Support Vector Machine (SVM) and Random Forest. Yousuf et al. [16] further improved performance by integrating multiple feature sets, including DLL names, API calls, PE headers, and section attributes, and applying ensemble techniques such as Majority Voting, Stack Generalization, and AdaBoost, achieving 99.5% accuracy. These works demonstrate the benefits of combining diverse features and models, though often at the cost of increased complexity.

C. Deep Learning and Graph-/Transformer-Based Methods

Deep learning techniques have also been widely adopted in malware detection. Bensaoud and Kalita [17] proposed a CNN–LSTM model trained on 8-gram sequences, achieving an SOTA accuracy of 99.91%. More recent studies (2021 to 2025) have introduced advanced architectures based on transformers and graph neural networks (GNNs). Trizna et al. [18] applied a Transformer model with self-attention to dynamic API-call behaviors, improving detection accuracy while enhancing interpretability through attention visualization. Similarly, Seneviratne et al. [19] leveraged Vision Transformers in a self-supervised setup on image-based malware representations, achieving around 97% accuracy.

In the graph-based domain, GNNs are increasingly used to capture structural relationships in executables. Mohammadiana et al. [20] combined graph reduction techniques with GNNExplainer to enable efficient and interpretable malware detection on function and control-flow graphs. Shokouhinejad et al. [21] proposed a stacked GNN framework where multiple base learners are trained on PE control-flow graphs and integrated via an attention-based meta-learner, significantly improving both classification accuracy and explainability. Additionally, Tang [22] introduced a hybrid GNN-based model that fuses static and dynamic features, reporting a 4 to 7% performance gain over existing baselines on the EMBER and VirusShare datasets.

These works demonstrate the potential of deep learning, transformers, and GNNs for achieving high detection accuracy while also improving interpretability. However, their computational requirements are often high, making them less practical for deployment in resource-constrained environments.

D. Positioning of this Work

While prior studies demonstrate that traditional machine learning, ensembles, and deep learning can achieve high malware detection accuracy, they often rely on large or redundant feature sets or demand high computational resources. In contrast, the proposed framework focuses on a lightweight subset of shared API calls between benign and malicious executables. This design reduces redundancy, improves interpretability, and provides a practical balance between accuracy and efficiency, making it suitable for real-world deployment in static malware detection.

III. Methodology

This section details the data sources and selection criteria, the API-call extraction pipeline, the construction of the shared-call feature space, the preprocessing steps, the learning models and hyperparameters, and the training and evaluation protocol used in this study. The objective is to provide a complete and reproducible description of the static-analysis workflow. Table I presents the dataset overview.

A. Data Sources and Selection Criteria

The corpus comprises 1,318 Windows PE files: 674 malware samples obtained from VirusShare (2012 to 2024) and 644 benign executables collected from the C:\Windows\System32 directory of a Windows 10 installation. Duplicates at the file and feature-vector levels were removed. To limit class bias and facilitate clear performance estimation, the dataset was balanced via random undersampling of the majority class, yielding 714 unique samples (357 benign, 357 malware). The final feature matrix contains 559 columns: 558 binary API-call indicators and one label column. Rationale: a balanced setting supports robust classifier comparison without prevalence-driven bias, while focusing on static features enables scalable, execution-free analysis [23]-[27].

TABLE I Dataset Overview

_c_exit	SetLastError	VariantUnit	CopyFileW	…	Class
1	0	0	1	…	1
0	0	1	0	…	1
1	1	0	1	…	0
0	1	1	1	…	0
0	0	1	0	…	1

B. API-Call Extraction Pipeline

API calls were obtained through a two-stage static workflow:

1) Import table parsing using pefile to enumerate imported functions and their DLLs; normalization unified function aliases (e.g., CopyFileA/W) and handled forwarded exports.

2) Disassembly using the Capstone framework to scan code sections for call instructions and resolve additional API references not declared in the import table (e.g., late binding, indirect calls). Extracted names were canonicalized to DLL.Function form (e.g., KERNEL32.CopyFileW), lower-cased, and filtered to exclude non-WinAPI stubs and compiler intrinsics. The output of this stage is a per-file multiset of API

call identifiers [28]-[35]. Fig. 1 shows the steps of data collection process.

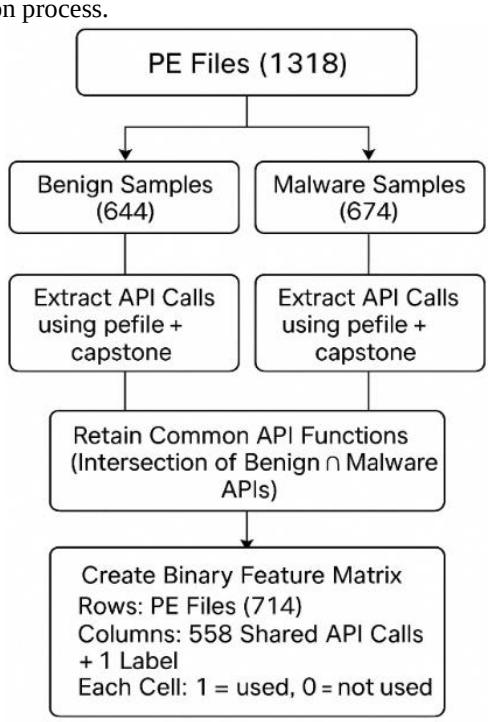

Fig. 1. Data collection process steps.

C. Shared-Call Feature Construction

Let B and M denote the sets of unique API calls observed in benign and malware subsets, respectively. The shared feature set is defined as:

$$S = B \cap M$$

Each file i is represented by a binary vector $x_i \in \{0,1\}^{|S|}$, where $x_{i,j} = 1$ if API $s_j \in S$ appears in file i, and 0 otherwise. Stacking all N files yields $X \in \{0,1\}^{N \times |S|}$. Limiting features to S reduces redundancy and emphasizes behaviorally relevant calls common to both classes.

Pseudo-code (shared-call construction)

1) Extract API sets A_f for each file f
2) Compute $B = \bigcup_{f \in \text{benign}} A_f$, $M = \bigcup_{f \in \text{malware}} A_f$
3) Set $S = B \cap M$
4) For each file f, form $x_f[j] = 1\{s_j \in A_f\}$ for all $s_j \in S$
5) Concatenate all x_f to obtain X.

a) Practical advantage: This representation filters out API calls unique to one class, thereby reducing dimensionality, mitigating dataset sparsity, and emphasizing behaviorally significant features. Compared with using the full API space, this method enhances computational efficiency, supports faster training, and highlights generalizable patterns for malware detection.

D. Preprocessing

Duplicate vectors were removed to ensure one instance per unique API profile. Missing indicators were treated as absence (0). The dataset was then shuffled and split into 70% training / 30% testing with stratification by class. No numerical scaling was applied to binary indicators. Where appropriate (e.g., SVM, LR), class weights were set to balanced [36]-[42]. Fig. 2 presents the data preprocessing steps.

E. Machine Learning Models and Parameters

To evaluate the effectiveness of shared-API-call-based static malware detection, a diverse set of classification algorithms was implemented, covering traditional learners, ensemble methods, and neural networks. Each classifier was trained on the binary feature vectors derived from Section III-C, with performance assessed via 5-fold stratified cross-validation and a 30% independent test set. Hyperparameters were selected based on widely adopted defaults or light grid search to balance performance and computational efficiency.

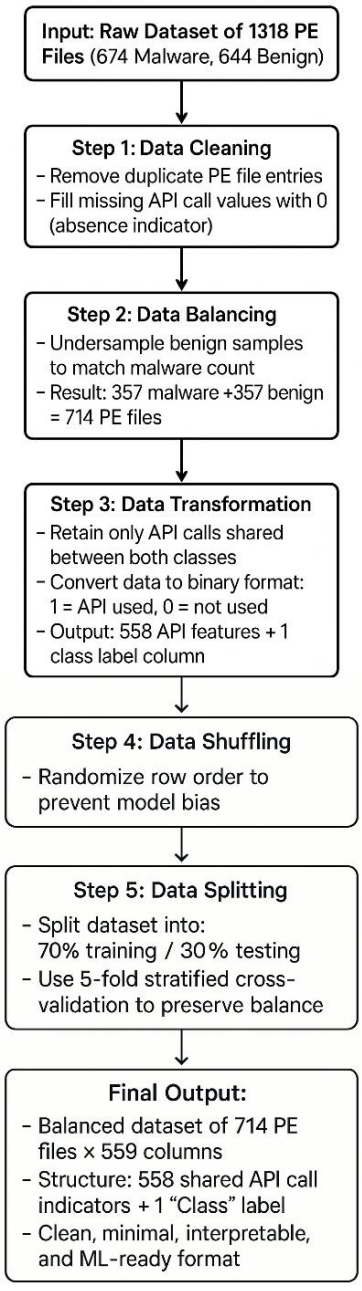

Fig. 2. Data preprocessing steps.

The classifiers are grouped into three categories: traditional baselines, ensemble learners, and deep learning models. A summary of libraries and configurations are presented in Table II to Table IV.

1) Traditional machine learning models: These models serve as interpretable baselines, providing insight into linear separability and low-complexity decision boundaries.

TABLE II TRADITIONAL MACHINE LEARNING MODELS

Model	Library	Hyperparameters / Notes	Practical Rationale
Logistic Regression	scikit-learn	solver='liblinear', penalty='l2', C=1.0, random_state=42	Robust linear baseline; efficient on sparse binary features
K-Nearest Neighbors (KNN)	scikit-learn	n_neighbors=5, weights='uniform', metric='minkowski'	Captures local neighborhoods; sensitive to feature sparsity
SVM	scikit-learn	C=1.0, kernel='rbf', gamma='scale'	Strong nonlinear decision boundary; benchmark for high-dimensional data
Naive Bayes	scikit-learn	Default parameters	Probabilistic, fast baseline for binary data
Desicion Tree	scikit-learn	criterion='gini', random_state=42	Provides interpretability; prone to overfitting
Linear Discriminant Analysis (LDA)	scikit-learn	Default parameters	Tests linear discriminants; assumes Gaussian feature distribution
Quadratic Discriminant Analysis (QDA)	scikit-learn	Default parameters	Quadratic boundary; serves as generative baseline

2) Ensemble learning models: Ensembles aggregate multiple weak learners to improve generalization. These models are particularly suited for binary, high-dimensional spaces, like API call vectors.

TABLE III ENSEMBLE LEARNING MODELS

Model	Library	Hyperparameters / Notes	Practical Rationale
Random Forest	scikit-learn	n_estimators=100, random_state=42	Reduces variance via bagging; robust baseline
Extra Trees	scikit-learn	n_estimators=100, random_state=42	Increased randomization; faster training
Gradient Boosting	scikit-learn	n_estimators=100, learning_rate=0.1, random_state=42	Strong baseline for structured data; balances bias/variance
AdaBoost	scikit-learn	n_estimators=50, learning_rate=1.0, random_state=42	Emphasizes difficult samples; reduces bias
LightGBM	LightGBM	Default parameters	Gradient boosting optimized for large sparse binary features

3) Deep learning models: Deep learning models are increasingly applied in malware detection due to their ability to capture complex, nonlinear relationships among features. In this study, a feedforward ANN was implemented as a representative deep learning baseline. The ANN directly ingests binary API-call feature vectors, enabling it to learn higher-order dependencies beyond the capacity of linear or tree-based classifiers.

TABLE IV DEEP LEARNING MODELS

Model	Library	Hyperparameters / Notes	Practical Rationale
ANN	Keras / TensorFlow	• Input: 559 nodes (one per API call) • Hidden layers: [256, 128], activation='relu' • Dropout: 0.5 • Output: 1 node, activation='sigmoid' • Optimizer: Adam • Loss: Binary Crossentropy • Epochs: 50 • Batch size: 32	Baseline neural network for binary feature vectors

F. Training and Evaluation Protocol

The dataset was partitioned into 70% training and 30% testing with stratified sampling to preserve class balance. Model selection and stability were assessed using 5-fold stratified cross-validation on the training portion; final results were reported on the independent test set. Unless otherwise stated, a fixed threshold of 0.5 on the predicted probability/score was used to compute threshold-dependent metrics (OA, TNR, FPR). AUC was computed from the ROC curve and is threshold-independent. All experiments used identical splits and fixed random seeds for reproducibility.

Metrics. Four complementary measures were reported:

a) Overall Accuracy (OA): proportion of correctly classified samples.

b) True Negative Rate (TNR): proportion of benign files correctly identified as benign.

c) False Positive Rate (FPR): proportion of benign files misclassified as malware.

d) Area Under the ROC Curve (AUC): probability that a randomly chosen malware sample receives a higher score than a randomly chosen benign sample; operationally computed from the ROC via the trapezoidal rule.

All equations are referenced:

$$OA = \frac{\mathrm{TP} + \mathrm{TN}}{\mathrm{TP} + \mathrm{TN} + \mathrm{FP} + \mathrm{FN}} \quad (1)$$

$$TNR = \frac{\mathrm{TN}}{\mathrm{TN} + \mathrm{FP}} \quad (2)$$

$$FPR = \frac{\mathrm{FP}}{\mathrm{FP} + \mathrm{TN}} = 1 - TNR \quad (3)$$

$$AUC = \int_0^1 TPR(\tau) \times \mathrm{dFPR}(\tau) \ , With\ TPR = \frac{\mathrm{TP}(\tau)}{\mathrm{TP}(\tau) + \mathrm{FN}(\tau)} \quad (4)$$

G. Reproducibility and Computing Environment

The experiments were conducted on a workstation equipped with an Intel Core i5-12450H CPU (8 cores, up to 4.4

GHz), 16 GB DDR4 RAM, an NVIDIA RTX 2050 GPU (4 GB), and a 512 GB SSD, running Windows 11.

The malware detection pipeline was implemented in Python 3.9. Key libraries and frameworks included:

pefile for parsing PE headers and extracting imported functions.

Capstone disassembly engine for recovering additional API call references from executable code sections.

pandas for data handling and feature structuring.

scikit-learn for implementing classical machine learning classifiers and evaluation procedures.

TensorFlow/Keras for training and evaluating the ANN.

All random seeds were fixed across experiments to ensure reproducibility. Identical training or test splits were maintained for all models to guarantee fair comparison.

IV. Results and Discussion

A. Results

Thirteen classifiers were evaluated to identify the most effective algorithms for malware detection using shared API-call features. Table V summarizes the performance across four key metrics: Overall Accuracy (1), True Negative Rate (2), False Positive Rate (3), and Area Under the ROC Curve (4) [43]-[46].

The Extra Trees classifier achieved the highest overall accuracy (OA = 98.14%) and a strong AUC of 98.19%, confirming its suitability for handling high-dimensional, sparse binary feature vectors. The ANN achieved the highest AUC (99.50%), reflecting excellent discriminatory power between benign and malicious samples, although its OA was slightly lower at 97.67%.

Other strong performers included Logistic Regression (OA = 97.67%, AUC = 97.75%) and AdaBoost (OA = 97.67%, AUC = 97.69%). Gradient Boosting also performed competitively (OA = 97.21%, AUC = 97.31%), while Random Forest and LightGBM both reached OA = 96.74%. Traditional classifiers such as Naïve Bayes, LDA, and QDA underperformed, with OA below 85%, highlighting their limitations in modeling nonlinear feature interactions.

Notably, the Decision Tree classifier achieved an FPR of 0% (3), although its OA and AUC (95.35% and 95.61%) were lower than ensemble-based methods.

Table V shows the performance comparison of classifiers using FPR (3), TNR (2), OA (1), and AUC (4).

TABLE V Performance Comparison of Detectors

Algorithm	FPR (%)	TNR (%)	AUC (%)	OA (%)
Naïve Bayes	3.25	13.49	83.82	83.26
Logistic Regression	0.46	1.86	97.75	97.67
LDA	20	17.67	62.05	62.33
SVM	0.93	2.79	96.38	96.28
QDA	19.06	14.42	66.11	66.51
KNN	0.93	4.18	95.06	94.88
Decision Trees	0	4.65	95.61	95.35
ANN	0.93	1.39	99.50	97.67
Random Forest	0.46	2.79	96.87	96.74
Extra Trees	0.46	1.39	98.19	98.14
AdaBoost	0.93	1.39	97.69	97.67
Gradient Boosting	0.46	2.32	97.31	97.21
LightGBM	0.46	2.79	96.87	96.74

To evaluate the contribution of the proposed approach relative to prior studies, Table VI presents a comparative analysis. It contrasts the performance of the shared API-call-based Extra Trees classifier results with traditional string- and header-based approaches, as well as recent SOTA methods such as deep ensembles, hybrid static–dynamic frameworks, and attention-based models.

TABLE VI Comparative Analysis of the Proposed Method and Existing Malware Detection Approaches

Study	Features used	Model / Architecture	OA (%)	Interpretability	Complexity	Notes
Proposed Method (Extra Trees)	Shared API call vectors	Extra Trees Classifier	98.14	High	Low	Lightweight and fast; effective for sparse binary features
Balram, et al. [12]	String	Hybrid (LR/XGB)	98	Moderate	High	Highest accuracy; longer execution time
Baldangombo et al. [13]	PE Headers	J48	99	High	Moderate	Best standalone feature set; uses PCA
Azeez et al. [14]	PE Headers	Ensemble (7 NNs + ExtraTrees)	100	Low	Very High	Best performance; requires stacked ensemble training
Shijo and Salim [15]	Integrated (PSI + API 3/4-grams)	SVM	98.7	Low	Very High	Best accuracy; combines static/dynamic strengths
Yousuf et al. [16]	PE Header + PE Section (Integrated)	Random Forest, Stack Gen	99.5	Medium	Moderate-High	Uses IG/PCA for feature selection; combines static structural features.
Bensaoud and Kalita [17]	API Calls + Opcodes (8-grams)	CNN-LSTM-3	99.91	Medium	High	Combines CNN for spatial features and LSTM for sequential patterns.
Trizna et al. [18]	Dynamic API call traces	Self-Attention (Nebula)	99.8	Medium	High	SOTA dynamic analysis; resource-intensive
Seneviratne et al. [19]	Malware images (transformed binaries)	Vision Transformer (Self-Supervised)	97	Low	Very High	Requires GPU-heavy training; less interpretable

Mohammadian et al. [20]	Graph-based API dependency features	Graph Reduction + Explainable Learning	95.4	High	High	Improves explainability; complex preprocessing
Shokouhinejad et al. [21]	Graph-based features	Explainable Ensemble Learning	86.14	High	High	Balances interpretability with high accuracy
J. Tang [22]	Static + Dynamic fusion	Hybrid ML Ensemble	> 95	Medium	Very High	Strong accuracy but requires both runtime and static environments

The Receiver Operating Characteristic (ROC) curve for the Extra Trees classifier is shown in Fig. 3, illustrating its balance of high OA and AUC with low FPR.

Fig. 3 presents the ROC curve of the Extra Trees classifier, evaluated with OA (1), AUC (4), TNR (2), and FPR (3).

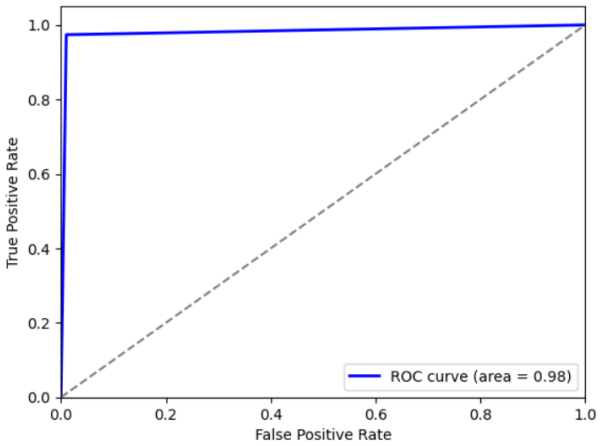

Fig. 3. ROC curve using extra trees classifier.

B. Discussion

The results confirm the effectiveness of tree-based ensemble models for static malware detection in sparse, binary feature spaces. The Extra Trees classifier offers the best balance between accuracy and interpretability, while the ANN model demonstrates superior AUC performance, suggesting that deep learning techniques can better capture subtle feature interactions.

In comparison with existing studies, the proposed framework offers several practical advantages, notably in terms of lightweight architecture, reduced feature redundancy, and improved computational efficiency. For instance, Azeez et al. [14] employed a complex ensemble of seven neural networks combined with Extra Trees to attain near-perfect detection accuracy, resulting in significant training overhead and deployment challenges. In contrast, the present approach circumvents such complexity, enhancing scalability and ease of integration. Furthermore, while Shijo and Salim [15] relied on sandboxed environments to extract dynamic behavioral features, the proposed static-only methodology eliminates the need for runtime execution, thereby simplifying implementation while maintaining competitive detection performance.

Balram et al. [12] and Baldangombo et al. [13] reported strong results using string- and header-based features but did not emphasize interpretability or feature reduction. Yousuf et al. [16] achieved an impressive 99.5% accuracy through feature fusion and advanced ensemble techniques; however, this came at the cost of increased system complexity.

More recent advances, such as self-attention models [18], [19] and explainable graph-based frameworks [20], [21], achieve high accuracy and improved interpretability but require significant computational resources, making them less suitable for lightweight or real-time deployments. Hybrid feature fusion approaches, such as that proposed by Tang [22], demonstrate the value of combining static and dynamic features but introduce additional integration challenges.

Overall, the proposed method achieves high accuracy (98.14% overall accuracy) and excellent discrimination (99.50% AUC) while using a compact and interpretable feature set of 558 shared API calls.

LIMITATIONS

As with most static approaches, the method may be less effective against heavily obfuscated or polymorphic malware and could face challenges related to concept drift, where emerging malware families exhibit behaviors not represented in the training data. Additionally, the moderate dataset size may limit generalization to large-scale, real-world scenarios.

PRACTICAL APPLICABILITY

Despite these limitations, the proposed framework is fast, lightweight, and interpretable, making it suitable for endpoint security systems and resource-constrained environments, where dynamic analysis is infeasible.

FUTURE WORK

Future research should focus on extending the analysis to larger and more imbalanced datasets would provide stronger evidence of generalizability. Moreover, integrating hybrid static–dynamic features could enhance resilience against obfuscation and adversarial evasion. Finally, exploring advanced architectures, such as CNN-LSTM hybrids or transformer-based models, may offer additional improvements in robustness and scalability.

V. CONCLUSION

This study presented a lightweight and interpretable malware detection framework that leverages shared API call behaviors extracted from benign and malicious PE files. Thirteen classifiers were systematically evaluated on a balanced dataset of 1,318 samples, demonstrating that high detection accuracy can be achieved with carefully selected static features. Among the evaluated models, the Extra Trees classifier achieved the best overall accuracy (98.14%), while maintaining high interpretability and computational efficiency. The ANN reached the highest AUC (99.50%), highlighting the ability of shallow deep learning models to capture nonlinear feature interactions. Overall, tree-based ensemble methods proved most effective for high-dimensional binary API-call features, offering a strong balance between detection power, efficiency, and interpretability.

In comparison with recent SOTA approaches such as hybrid CNN-LSTM models, graph-based learning, and transformer-based architectures, the proposed framework provides a more practical and resource-efficient solution. While those models often achieve higher accuracy on larger datasets, they typically introduce greater computational overhead and reduced interpretability. In contrast, the presented framework achieves competitive results while remaining lightweight, making it suitable for deployment in resource-constrained or real-time environments.

Despite these strengths, the study has several limitations. The exclusive reliance on static analysis may reduce robustness against highly obfuscated or adversarial malware, while the use of a moderately sized, balanced dataset limits generalizability to real-world malware distributions, which are often large-scale and highly imbalanced. Issues such as concept drift, adversarial evasion, and scalability in high-volume environments remain open challenges.

Future work should extend this research by validating the framework on larger and more diverse datasets, integrating dynamic and hybrid features, and investigating advanced ensemble or deep learning architectures such as CNN-LSTMs and transformer-based models. Additional directions include enhancing resilience against adversarial evasion techniques, addressing concept drift in evolving threat landscapes, and optimizing scalability for high-throughput detection scenarios. These improvements would strengthen both the theoretical and practical impact of the proposed approach, ensuring its continued relevance in modern malware detection.

Intrusion Detection Using Machine Learning and Deep Learning

Fatima Jobran ALzaher, Asma AlJarullah
Department of Informatics and Computer Systems, King Khalid University, 61421, Alfara, Abha, Saudi Arabia

***Abstract*—As cyberattacks grow in prevalence, Intrusion Detection Systems (IDS) have become critical for securing network infrastructures. This study proposes an efficient IDS framework utilizing both machine learning (ML) and deep learning (DL) algorithms. The framework is evaluated on the "NF-UNSW-NB15-v2" dataset, which comprises a blend of normal and malicious traffic. A diverse set of advanced models—including Deep Neural Networks (DNN), Long Short-Term Memory (LSTM) networks, eXtreme Gradient Boosting (XGBoost), Random Forest (RF), and K-Nearest Neighbors (KNN)—is deployed for intrusion detection. The approach encompasses both binary classification (normal vs. malicious) and multi-class classification (specific attack categories). Preprocessing steps include feature standardization using StandardScaler, class imbalance correction via SMOTE, and dimensionality reduction through Principal Component Analysis (PCA). Results show that Random Forest and XGBoost models achieve high accuracy in binary classification with F1-scores approaching 0.97, while XGBoost attains the best macro F1-score (0.71) in multi-class tasks. Additionally, RF and XGBoost demonstrate the fastest inference times, underscoring their suitability for real-time deployment. This work contributes a scalable and optimized IDS pipeline for enhancing cybersecurity resilience.**

***Keywords*—Cybersecurity; cyber-attack; intrusion detection system; machine learning; deep learning**

I. Introduction

In recent years, the cyber world witnessed the most phenomenal increase ever of cyber threats that targeted individuals, businesses, and governments. The cost of cybercrime at the global level is anticipated at $9.5 trillion by 2024, which amounts to $26 billion per day or $18 million per minute [1]. The growing rate of cybercrime emphasizes the need for proper cybersecurity controls.

Small and medium-sized businesses are most vulnerable with 69% of these experiencing at least one cyber-attack within the past year [1]. Yet 80% of the SMBs are largely unimplemented with the utilization of Privileged Access Management solutions while fewer than 60% of the enterprises are using vital cybersecurity practices of password managers, two-factor authentication, and cybersecurity education [1]. The shift toward remote work amplified the fear of security since 72% of businesses are concerned about the danger it presents and 80% of cybersecurity professionals confirm that the danger increased since 2020 [1].

Phishing and ransomware attacks grew more complex and more numerous. Security professionals saw 62% more phishing assaults within the recent years with 79% of account takeover attacks originating from the type of phishing attack that occurs with the use of phish emails [1]. The ransomware attacks grew with 70% of the attacks focusing on the small business market and the number of ransomware teams actively present more than doubling year over year [1].

Adversaries now leverage automation and AI to accelerate reconnaissance, weaponization, and evasion, fueling an arms race that compels defenders to adopt more adaptive, data-driven countermeasures [2].

Traditional intrusion detection systems (IDS) that rely on static signatures or hand-crafted rules struggle with previously unseen or rapidly morphing threats [3]. Machine learning (ML) and artificial intelligence (AI) enable dynamic threat modeling, anomaly detection, and behavioral analysis, allowing IDSs to generalize to novel attacks while reducing false positives [3].

Despite notable advancements in IDS research, a critical limitation persists across most studies: the insufficient handling of class imbalance, which leads to poor detection rates for minority attack types. Previous works have primarily focused on maximizing overall accuracy, often at the expense of rare class detection, resulting in inflated performance metrics dominated by frequent categories. Furthermore, inconsistencies in preprocessing pipelines, a lack of standardized evaluation on modern NetFlow-based datasets like NF-UNSW-NB15-v2, and the limited integration of a diverse set of both machine and deep learning techniques within a single, optimized framework limit the robustness and practical applicability of existing IDS solutions. This study aims to bridge these gaps by proposing an integrated pipeline that combines SMOTE-based class balancing, PCA-driven feature reduction, and a comprehensive evaluation of multiple ML and DL models to enhance minority class detection and overall performance on the NF-UNSW-NB15-v2 dataset.

The remainder of the paper is organized as follows. Section II reviews related work on ML/DL-based IDS. Section III details the methodology, including the dataset, preprocessing (standardization, imbalance handling, dimensionality reduction, and train–test split), model specifications, and evaluation metrics. Section IV reports the experimental results for both binary and multi-class settings and examines inference-time performance for real-time applicability. Section V discusses key findings, practical implications, and limitations. Section VI concludes and outlines directions for future research.

II. Related Work

Kasongo and Sun [4] conducted a performance analysis of Intrusion Detection Systems (IDS) by applying a feature

selection algorithm to the UNSW-NB15 dataset. They emphasized the importance of reducing feature dimensionality to enhance IDS accuracy. The study used five machine learning classifiers—SVM, KNN, Logistic Regression, Artificial Neural Networks (ANN), and Decision Trees (DT)—and showed that XGBoost-based feature selection significantly improved model performance, especially for DTs. However, the study did not address class imbalance, which led to lower F1-scores for minority classes.

Kumar et al. [5] proposed an integrated rule-based IDS using both the UNSW-NB15 and RTNITP18 datasets. Their approach employed Decision Tree classifiers (C5, CHAID, CART, and QUEST) to detect five attack types: Generic, Probe, DoS, Exploit, and Normal. The study reported improved accuracy and reduced false alarm rates through rule-based modeling and information gain-based feature selection. Nonetheless, it lacked proper handling of class imbalance and yielded low precision and recall for critical attack types.

More et al. [6] compared several supervised ML techniques for identifying deceitful emails with filtering approaches and through use of the WEKA toolset. The work identifies a weakness in conventional Bayesian filtering, effective in spam filtering but not in high false positive cases. To counteract, several classifiers, such as RF and SVM, have been incorporated and utilized for enhancing accuracy and minimizing false positives in classification. In its use, feature extraction via Naïve Bayes and an evaluation tool developed in WEKA facilitated testing of numerous algorithms for classification in a thorough manner. Experimental tests showed that RF and SVM performed better in enhancing positive and negative actual values and overall accuracy over 96%. The work identifies the use of hybrid classification approaches in improving deceitful message detection and minimizing security threats posed through spammers.

Tahri et al. [7] have designed an IDS with ML algorithms for enhancing network security. As communications through electronic means have increased, IDS proves to be a useful tool for discovering hostile activity in network communications. In the current work, three classifiers, Naïve Bayes, SVM, and KNN, have been compared for performance with two benchmark datasets, namely, “NSL-KDD” and “UNSW-NB15”. In part one of work, three classifiers have been compared with the use of “UNSW-NB15”, and then for a proper analysis, best-performing algorithm is utilized for testing with “NSL-KDD”. As per work, SVM outperforms all classifiers in terms of accuracy consistently, with 97.77% accuracy for “UNSW-NB15” and 97.29% accuracy for NSL-KDD. In conclusion, SVM proves to be an effective intrusion detection classifier, and future work will attempt to make its processing efficient and integrate it in real-time security tools such as a firewall.

Musa et al. [8] review the application of ML algorithms in IDS for enhancing network security through observation of traffic and intrusion activity, and IDS is distinguished between anomaly-based and signature-based detection, with the first identifying abnormalities in behavior and the second employing predefined attack signatures. Various types of ML approaches, including single, hybrid, and ensemble classifiers, are contrasted and compared over seven datasets, with the consequence that single classifiers fall below both ensemble and hybrid classifiers in terms of accuracy and detection performance. Comparison between algorithms including SVM, DTs, RF, and Neural Networks identifies that ensemble approaches, including stacking classifiers, have a significant impact in intrusion detection improvement. Challenges include feature selection improvement, testing over a range of and updated datasets, and minimizing false positive values. Optimizing hybrid models, minimizing computational overload, and enhancing real-time intrusion capabilities have been suggested for future work, according to the authors.

Samantaray et al. in [9] conducted a comparative study on ML model implementation in intrusion detection in IoT-based networks. The research is centered on increasing threats in the security of IoT networks and the need to utilize efficient IDS in order to mitigate them. The research uses the “UNSW-NB15 (DS-1)” and “NF-UNSW-NB15 (DS-2)” datasets in comparing models based on ML like SVM, KNN, Logistic Regression, Naïve Bayes, DT, and RF. The feature scaling is based on a method involving the usage of the MaxAbsScaler algorithm in order to increase efficiency in classification. The results highlight the usage of the RF classifier in achieving the highest precision in generating the most accurate outcome with a gain in the rate of detection from 60% to 94% in the DS-2 dataset. The research focuses on efficiency in ML usage in intrusion detection and supports future research on implementation with improved feature selection and DL.

Sayed et al. in [10] conducted research with a focus on optimizing the efficiency of DNN-driven IoT intrusion detection systems (IDS). Because the IoT devices are under threat and there is a limitation in the process ability and in features in security, the researchers provided two CNN models, namely IoTCNN and MyCNN, with a purpose to classify intrusion in the network. The "NF-UNSW-NB15-v2" dataset was used in the research, and the stream network data was converted into RGB images in order to train the models. Results indicated the efficiency of the models in the detection of various intrusion types, and in the majority of intrusion categories, the precision of the models improved. The research confirms the efficiency of anomaly-based IoT security based on DL and calls for improvement in the handling of imbalances in the class and the optimization of the hyperparameters.

Table I provides a structured summary of key related studies, highlighting the datasets, methodologies, and performance metrics used, which helps position the present work within the broader landscape of IDS research.

Despite notable advancements in IDS research, a recurring limitation across most studies is the insufficient handling of class imbalance and the resulting poor detection of minority attack types. Previous works primarily focused on improving overall accuracy without explicitly addressing the critical challenge of rare class detection, often leading to inflated performance metrics dominated by frequent attack categories. In addition, inconsistencies in preprocessing, lack of standardized evaluation on newer datasets, and limited integration of deep learning techniques further limit the robustness of existing IDS solutions. Building on these gaps, this research proposes an

integrated approach combining SMOTE-based class balancing, PCA-driven feature selection, ML/DL modeling to enhance minority class detection and overall intrusion detection performance on the NF-UNSW-NB15-v2 dataset [20].

TABLE I. SUMMARY OF RELATED WORK

Year	Research Title	Dataset	Machine Learning / Deep Learning Model(s)	Preprocessing	Classification Type	Performance Metrics	Findings	Limitations	Ref
2020	Performance analysis of IDS using a feature selection method on UNSW-NB15	UNSW-NB15 [21]	SVM, KNN, Logistic Regression, ANN, Decision Tree	Min-Max normalization; Feature selection with XGBoost	Binary and Multi-class	Binary: Accuracy 90.85%, Precision 80.33%, Recall 98.38%, F1-score 88.45% Multi-class: Accuracy 77.51%, Precision 79.50%, Recall 77.53%, F1-score 77.28%	Feature selection (XGBoost) improved ML model performance.	No class imbalance handling; poor F1-scores for minority classes.	[4]
2020	An integrated rule-based intrusion detection system on UNSW-NB15 and RTNITP18	UNSW-NB15 [21], RTNITP18 [5]	Decision Trees (C5, CHAID, CART, QUEST)	Feature selection using Information Gain; K-Means clustering	Multi-class	Accuracy 84.83%, Approximate F1-score 68.13%	Rule-based modeling reduced false alarms in IDS.	No class imbalance handling; low precision and recall for critical attacks.	[5]
2015	Evaluation of deceptive mails using filtering & WEKA	SpamBase [22], Ling-Spam [23], Enron [24], PU1 [25], PU2 [25]	Random Forest, SVM, Naïve Bayes	Tokenization; Feature extraction; Term Frequency normalization	Binary	Accuracy: RF 98.9%, SVM 98.4%, NB 93.2%	Ensemble models (Random Forest) achieved high classification accuracy.	No class imbalance handling; no minority class evaluation.	[6]
2022	Intrusion Detection System using machine learning algorithms	UNSW-NB15 [21], NSL-KDD [26]	SVM, KNN, Naïve Bayes	Feature selection using mutual information;	Binary and Multi-class	Binary: SVM Accuracy 97.78% Multi-class: SVM Accuracy 97.29%	SVM achieved high accuracy on IDS datasets without heavy feature engineering.	No class imbalance handling; no minority class evaluation.	[7]

No class imbalance handling; no minority class evaluation.	[8]
2024	Comparative assessment of ML algorithms in IoT-based network intrusion detection	UNSW-NB15 (DS-1), NF-UNSW-NB15 (DS-2) [20]	SVM, KNN, Logistic Regression, Naïve Bayes, Random Forest	MaxAbsScaler normalization	Multi-class	Accuracy: RF 60% (DS-1), 94% (DS-2)	Feature scaling (MaxAbsScaler) improved IDS model stability.	No class imbalance handling; no minority class evaluation.	[9]
2022	Augmenting IoT intrusion detection system performance using deep neural networks	NF-UNSW-NB15-v2 [20]	CNN	FFT-based NetFlow transformation to RGB images; Image normalization	Multi-class	Accuracy ~99% (frequent classes); poor F1-scores for minority classes	CNNs using NetFlow-to-image transformation achieved high accuracy for frequent attacks.	No class imbalance handling; poor F1-scores for minority classes.	[10]

III. METHODOLOGY

The methodology for this project is structured into several essential steps, as depicted in Fig. 1.

The proposed method for intrusion detection using deep learning (DL) and machine learning (ML) follows a structured pipeline:

1) Dataset: The NF-UNSW-NB15 dataset is used, comprising a combination of normal and malicious network traffic. It provides a realistic foundation for evaluating intrusion detection models.

Preprocessing Steps:

- Standardization: Normalizes the data to have the same feature scaling.
- PCA (Principal Component Analysis): Reduces dimensionality in a way that maximizes computational efficiency while retaining significant features.
- Oversampling: Balances the dataset and treats imbalances in classes, optimizing performance on minority attack classes.

2) Model training: Preprocessed data is fed to ML (e.g., XGBoost, RF, KNN) and DL (e.g., DNN, LSTM) models for training.

3) Evaluation metrics: Model performance is evaluated using conventional metrics, including accuracy, precision, recall, F1-score, and AUC-ROC, to ensure robust and comprehensive assessment of intrusion detection effectiveness.

B. Dataset

The NetFlow-based variant of the UNSW-NB15 dataset, referred to as NF-UNSW-NB15, incorporates additional flow-level features and is labeled according to specific attack categories. The original dataset comprises 2,390,275 network flow records, including 95,053 attacks (3.98%) and 2,295,222 benign flows (96.02%). These attack records are further divided into nine subtypes, as summarized in Table II [19]. For this study, the dataset was obtained from Kaggle, where the official version was uploaded by the author after removing duplicate rows, reducing the total count to 1,986,745. Therefore, the dataset used in this research is consistent with the original release, except for the exclusion of duplicates to improve data integrity and processing efficiency.

Mohanad Sarhan et al. [20] proposed a standardized feature set for network intrusion detection datasets to improve detection performance through the application of machine learning techniques. Their approach leverages NetFlow v9 features, which are widely supported by network devices and proven to be effective for traffic analysis. The proposed feature set includes 43 numerical, flow-based attributes designed to facilitate accurate and consistent detection of security events. By promoting dataset standardization, this feature set simplifies model evaluation, enhances compatibility for dataset merging, and supports real-world deployment of intrusion detection systems.

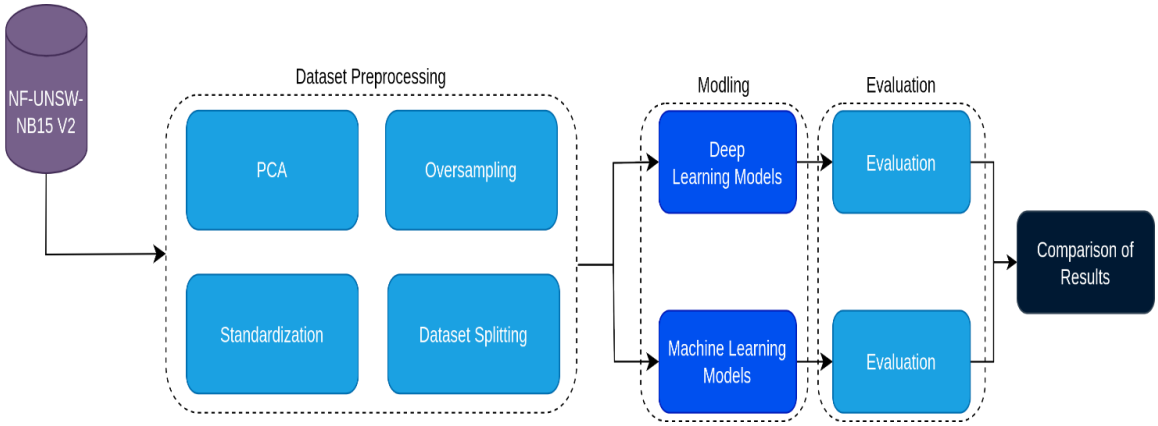

Fig. 1. Proposed method.

TABLE II. ATTACK TYPES IN "NF-UNSW-NB15"

Class	Count	Description
Benign	2295222	Normal, non-malicious network traffic.
Fuzzers	22310	An attack where large volumes of random data are sent to a system to cause crashes and identify security vulnerabilities.
Analysis	2299	A category of threats targeting web applications through ports, emails, and scripts.
Backdoor	2169	A method that bypasses security mechanisms by responding to specially crafted client requests.
DoS	5794	An attack that overwhelms a system's resources to disrupt access to its data or services.
Exploits	31551	Sequences of commands used to manipulate a system by exploiting known vulnerabilities.
Generic	16560	A cryptographic attack that causes collisions in block cipher encryption.
Reconnaissance	12779	Also known as probing, this technique involves gathering information about a network host.
Shellcode	1427	Malicious code designed to take control of a victim's system.
Worms	164	Self-replicating attacks that spread across multiple computers.

TABLE III. FEATURES IN "NF-UNSW-NB15"

	Field Name	Data Type	Description
1	IPV4_SRC_ADDR	String	Source IPv4 address
2	IPV4_DST_ADDR	String	Destination IPv4 address
3	L4_SRC_PORT	Integer	Source port number for IPv4
4	L4_DST_PORT	Integer	Destination port number for IPv4
5	PROTOCOL	Integer	Byte value representing the IP protocol identifier
6	L7_PROTO	Integer	Numeric identifier for the Layer 7 protocol
7	IN_BYTES	Integer	Total incoming bytes
8	OUT_BYTES	Integer	Total outgoing bytes
9	IN_PKTS	Integer	Count of incoming packets
10	OUT_PKTS	Integer	Count of outgoing packets
11	FLOW_DURATION_MILLISECONDS	Float	Duration of the flow in milliseconds
12	TCP_FLAGS	Integer	Aggregated TCP flags
13	CLIENT_TCP_FLAGS	Integer	Aggregated TCP flags from the client side
14	SERVER_TCP_FLAGS	Integer	Aggregated TCP flags from the server side
15	DURATION_IN	Float	Duration of the client-to-server stream (in milliseconds)
16	DURATION_OUT	Float	Duration of the server-to-client stream (in milliseconds)
17	MIN_TTL	Integer	Minimum Time-to-Live (TTL) value observed in the flow
18	MAX_TTL	Integer	Maximum Time-to-Live (TTL) value observed in the flow
19	LONGEST_FLOW_PKT	Integer	Size (in bytes) of the longest packet in the flow
20	SHORTEST_FLOW_PKT	Integer	Size (in bytes) of the shortest packet in the flow
21	MIN_IP_PKT_LEN	Integer	Length of the smallest observed IP packet in the flow
22	MAX_IP_PKT_LEN	Integer	Length of the largest observed IP packet in the flow
23	SRC_TO_DST_SECOND_BYTES	Float	Rate of bytes sent from source to destination (bytes per second)
24	DST_TO_SRC_SECOND_BYTES	Float	Rate of bytes sent from destination to source (bytes per second)
25	RETRANSMITTED_IN_BYTES	Integer	Count of retransmitted TCP bytes from source to destination
26	RETRANSMITTED_IN_PKTS	Integer	Count of retransmitted TCP packets from source to destination
27	RETRANSMITTED_OUT_BYTES	Integer	Count of retransmitted TCP bytes from destination to source
28	RETRANSMITTED_OUT_PKTS	Integer	Count of retransmitted TCP packets from destination to source
29	SRC_TO_DST_AVG_THROUGHPUT	Float	Average throughput (bps) from source to destination
30	DST_TO_SRC_AVG_THROUGHPUT	Float	Average throughput (bps) from destination to source
31	NUM_PKTS_UP_TO_128_BYTES	Integer	Number of packets with an IP size of 128 bytes or less
32	NUM_PKTS_128_TO_256_BYTES	Integer	Number of packets with an IP size between 128 and 256 bytes
33	NUM_PKTS_256_TO_512_BYTES	Integer	Number of packets with an IP size between 256 and 512 bytes
34	NUM_PKTS_512_TO_1024_BYTES	Integer	Number of packets with an IP size between 512 and 1024 bytes
35	NUM_PKTS_1024_TO_1514_BYTES	Integer	Number of packets with an IP size between 1024 and 1514 bytes
36	TCP_WIN_MAX_IN	Integer	Maximum TCP window size from source to destination
37	TCP_WIN_MAX_OUT	Integer	Maximum TCP window size from destination to source
38	ICMP_TYPE	Integer	ICMP type combined with ICMP code (ICMP Type * 256 + ICMP Code)
39	ICMP_IPV4_TYPE	Integer	ICMP type identifier for IPv4
40	DNS_QUERY_ID	Integer	Transaction ID of a DNS query
41	DNS_QUERY_TYPE	Integer	Type of DNS query (e.g., 1 = A, 2 = NS, etc.)
42	DNS_TTL_ANSWER	Integer	Time-to-Live (TTL) value of the first A record, if available
43	FTP_COMMAND_RET_CODE	Integer	Return code for an FTP client command

Table III lists the feature set of the NF-UNSW-NB15 dataset, detailing the flow characteristics captured for intrusion detection analysis.

Fig. 2 illustrates the significant class imbalance in the dataset, with benign (normal) traffic overwhelmingly dominating all categories of malicious traffic. Among the attack types, "Exploits" and "Fuzzers" appear most frequently, while others such as "Reconnaissance," "DoS," and especially "Worms" occur far less often. This imbalance poses challenges for accurate model training and may necessitate the use of resampling methods or advanced techniques to improve detection performance, particularly for minority attack classes.

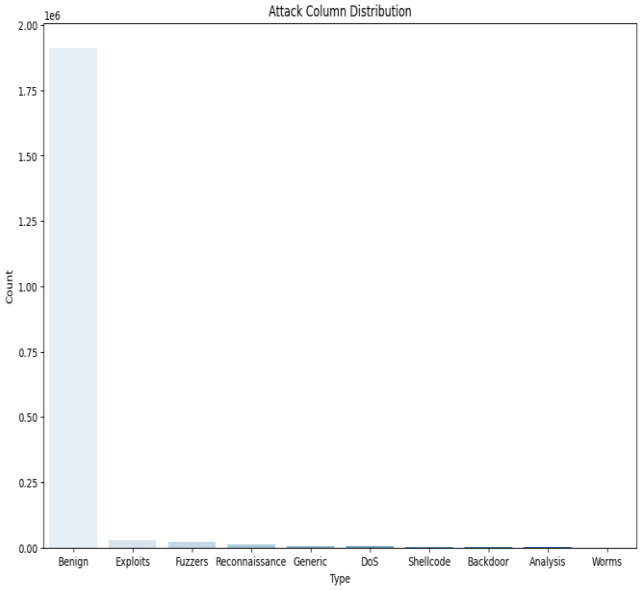

Fig. 2. Attack column distribution.

Fig. 3 displays how normal and malicious flows are distributed in the dataset, revealing a pronounced class imbalance: legitimate traffic vastly outweighs attack traffic.

Such skew can hamper model effectiveness, so remedies like SMOTE oversampling or class-weight adjustment are advisable to achieve more reliable classification.

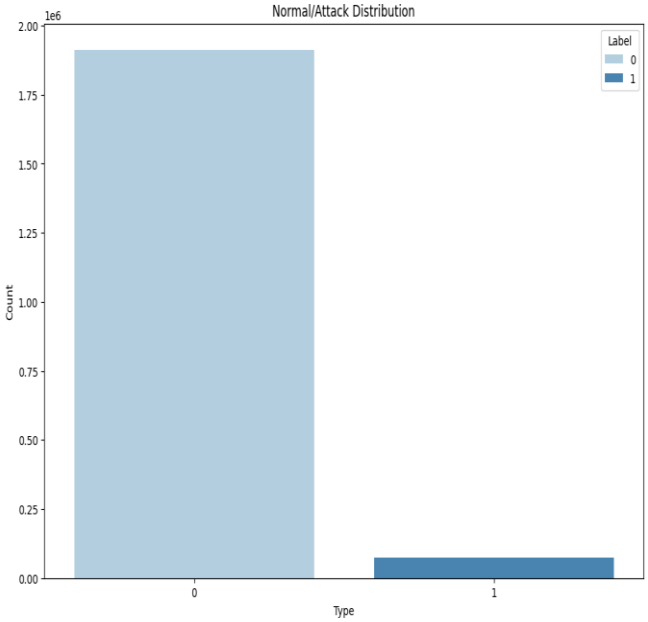

Fig. 3. Label column distribution.

Fig. 4 shows the distribution of different types of attacks in the dataset. "Exploits" is the highest frequency type, with "Fuzzers" and "Reconnaissance" following, and "Worms" and "Analysis" are the least frequent. The imbalanced distribution among attack types implies the need for careful model training in order to correctly identify in every category.

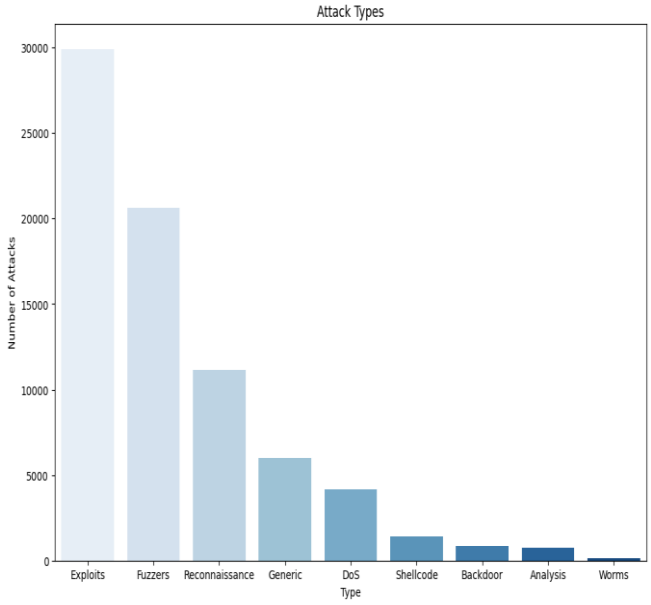

Fig. 4. Count of every attack type.

C. Dataset Preprocessing

To ensure high-quality input for model training, the NF-UNSW-NB15-v2 dataset undergoes a series of preprocessing steps designed to enhance learning efficiency and model performance.

1) Standardization: Standardization was applied using the StandardScaler, which transformed each numerical feature to have a mean of zero and a standard deviation of one. This normalization process ensured that all features contributed proportionally to the learning process, preventing any single feature with a large magnitude from disproportionately influencing the model. Standardization was particularly important for algorithms sensitive to feature scale, such as K-Nearest Neighbors (KNN) and Deep Neural Networks (DNN), which rely on distance-based calculations and gradient-based optimization, respectively. This approach follows best practices outlined in prior literature and common implementations such as scikit-learn [11].

2) Handling class imbalance: To address the class imbalance issue in the dataset, the Synthetic Minority Over-sampling Technique (SMOTE) [32] was applied exclusively to the training set after splitting the data into 70% for training and 30% for testing. This approach was intentionally adopted to prevent data leakage and to ensure an unbiased evaluation of the model's performance on unseen data.

SMOTE generates synthetic samples for minority classes by interpolating between existing instances rather than simply duplicating them. For each minority sample in the training set, the algorithm identifies its k-nearest neighbors (commonly k=5) within the same class. It then selects one neighbor at random and creates a new instance by generating a point along the feature-space line segment connecting the original sample and its neighbor. This synthetic instance inherits the statistical

characteristics of both points, resulting in a new example that is both realistic and non-redundant [32].

By enriching the training set with these synthetic examples, the class distribution becomes more balanced. This allows learning algorithms to be exposed to a wider variety of patterns and variations within the minority classes, which enhances their ability to generalize and improves detection of rare attack types. The test set was left untouched to preserve the original distribution and maintain the integrity of the evaluation.

3) Dimensionality reduction: To address the high dimensionality of the dataset, which consists of 43 flow-based NetFlow features, Principal Component Analysis (PCA) was employed as an effective dimensionality reduction technique. PCA transforms the original feature set into a smaller number of uncorrelated components while retaining the majority of the data's variance. This transformation reduces computational complexity, accelerates model training, and mitigates the risk of overfitting by eliminating redundant or less informative attributes [13].

An initial correlation analysis of the raw NetFlow features revealed strong linear relationships among several variables. For instance, IN_PKTS and OUT_PKTS exhibited a Pearson correlation coefficient of approximately 0.99, while FLOW_DURATION_MILLISECONDS was highly correlated with both DURATION_IN and DURATION_OUT. Similarly, MIN_TTL and MAX_TTL showed correlations exceeding 0.90. These relationships, visualized in Fig. 5, support the application of PCA to reduce multicollinearity and noise within the dataset.

To validate the independence of the PCA components, a correlation matrix was generated to examine the relationships between the extracted components. As shown in Fig. 6, the components are effectively uncorrelated, demonstrating that PCA successfully transforms the original feature space into a set of orthogonal, linearly independent dimensions. This orthogonality reinforces PCA's suitability for improving model robustness and reducing feature redundancy.

Overall, PCA proved especially beneficial for ensemble models such as Random Forest and XGBoost, which can be negatively affected by irrelevant or highly correlated features. Its use enhanced model focus, reduced overfitting, and improved interpretability within the intrusion detection pipeline.

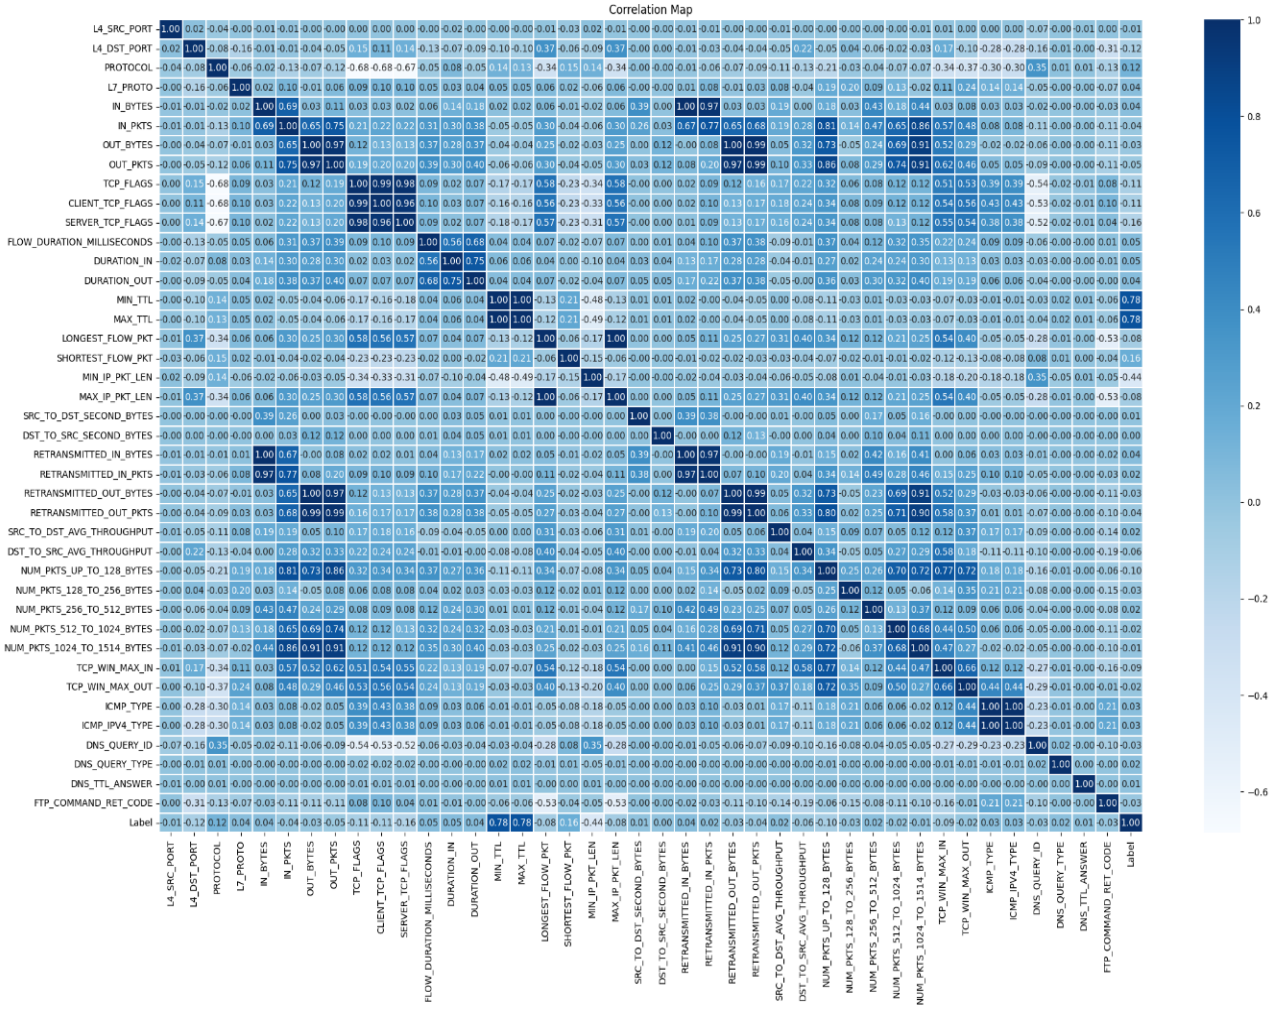

Fig. 5. Correlation heatmap of original NetFlow features.

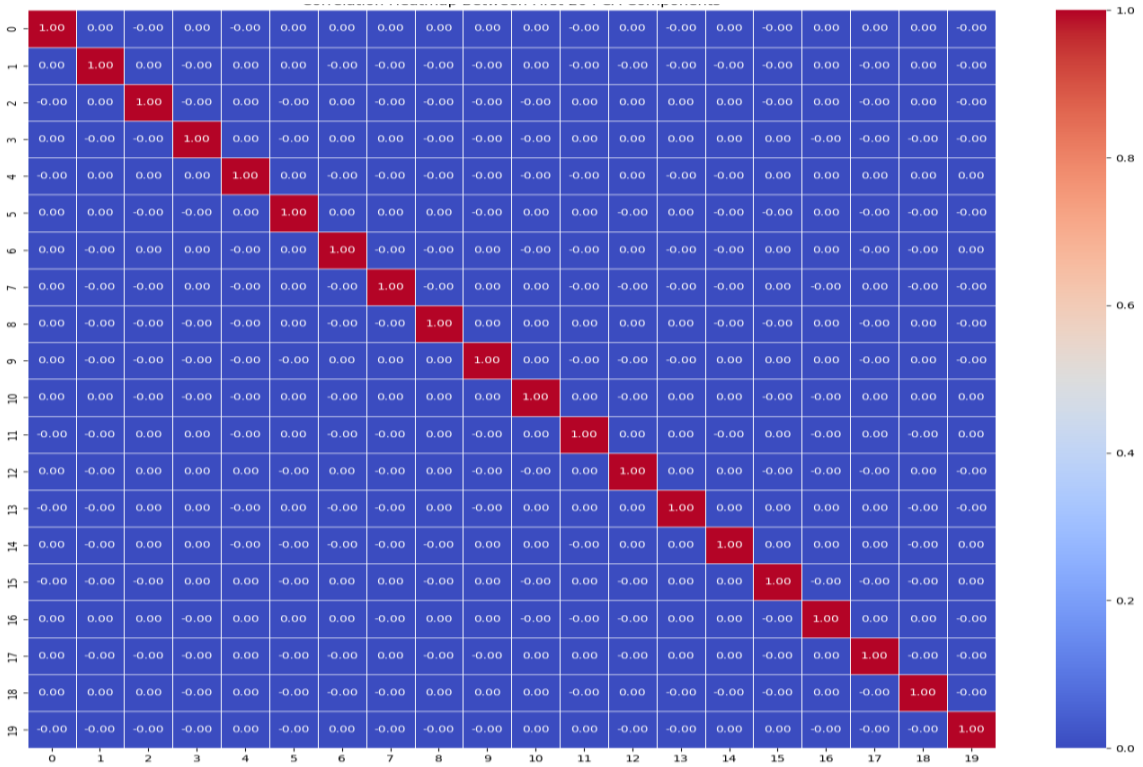

Fig. 6. Correlation between PCA Components (with self-correlation).

4) Train-test split: To evaluate model performance fairly, the dataset is divided into distinct subsets. For traditional machine learning models, the dataset is partitioned into 70% for training and 30% for testing to evaluate generalization performance on unseen data. In the case of deep learning models such as LSTM and DNN, the dataset is further divided into 70% for training and 30% for testing, enabling effective monitoring during training and ensuring robust model evaluation.

D. Modeling

1) Machine learning models: Random Forest (RF), KNN, XGBoost, and SVM are the most effective ML models for the detection of intrusions. The models are good for classification with feature-extracted input but are inefficient with complex temporal relationships within sequential input.

a) K-Nearest Neighbor (KNN): The KNN algorithm is a supervised algorithm in ML most commonly used to classify tasks [11]. It identifies the unlabeled data by considering the label and the available training data's features. The algorithm identifies the data by determining the point's nearest neighbors and the final label by majority voting. Among all the algorithms in ML, the algorithm in the case of the KNN algorithm is unique in terms of ease and interpretability and, in turn, acts to be a commonly used algorithm to classify tasks [12]. Even despite the ease, the algorithm performs exceptionally in the case of solving the classification and the regression problems in different datasets, regardless of size, label distribution, the datasets' noise, and the datasets' ranges [12].

b) Random Forests (RF): RF is a versatile algorithm in ML, famous for reducing the effect of overfitting, a prevalent problem in decision trees (DTs). It performs tasks such as classification, regression, and others by building many DTs during the training period. The algorithm works by evaluating multiple distinct decision trees (DTs) and making the prediction through a voting mechanism. Unlike in the case of a standard DT, in which each internal node gets partitioned by the optimal attribute, RF uses the optimal attribute from a random subset of predictors at each internal node. This randomization serves to enhance model generalization and resistance, and the resulting algorithm is a versatile tool in numerous applications in ML.

c) XGBoost (XGB): XGBoost (XGB) is a Gradient Tree Boosting algorithm powerful enough to solve heavy-scale ML problems in an efficient and effective manner. It possesses great prediction precision and model training speed, and it's the leading performer in all the competitions at Kaggle. The mechanism in XGB lies in the addition of trees in an iterative fashion and the division of the features during the course of the expansion in the tree. The model learns to fit the residuals from the last prediction each time a new tree gets added [13]. Given an input x_i, a true label y_i, and a raw prediction z_i before applying the sigmoid function, according to [14], the XGBoost model defines its objective function in the following equation:

$$L^{(t)} = \sum_{i=1}^{n} \quad l\left(y_i, Z_i^{(t-1)} + f_t(x_i)\right) + \Omega(f_t) + c \quad (1)$$

Where $l(.,.)$ represents the loss function, t denotes the t-th tree, and Ω serves as a penalty for model complexity. The term $\Omega(f_t)$ refers to the regularization penalty, while c is a constant.

The second-order Taylor expansion is given by:

$$f(x+\Delta x) \approx f(x) + f'(x)\Delta x + 1/2\, f''(x)\Delta x^2 \quad (2)$$

By substituting Eq. (2) into Eq. (1), we can obtain the following result.

$$L^{(t)} \approx \sum_{i=1}^{n}\left[l\left(y_i + Z_i^{(t-1)}\right) + g_i f_t(x_i) + \frac{1}{2}h_i\left(f_t(x_i)\right)^2\right] \quad (3)$$

where $g_i = \partial\, L/\partial\, z_i$, and $h_i = \partial^2\, L/\partial\, z_i^2$. By eliminating the constant terms, we derive the following simplified objective at step t.

$$L^{(t)} \approx \sum_{i=1}^{n}\left[g_i f_t(x_i) + \frac{1}{2}h_i\left(f_i(x_i)\right)^2\right] + \Omega(f_t) \quad (4)$$

The terms g_i and h_i play a vital role in optimizing the XGBoost training process. For binary classification, the model typically employs cross-entropy (CE) as its default loss function.

$$L = -\sum_{i=1}^{n}[y_i log(\acute{y}_i) - (1-y_i)log(1-\acute{y}_i)] \quad (5)$$

In Eq. (5), $\acute{y}_i = 1/[1+exp(-z_i)]$, that is sigmoid is selected as activation. Therefore, we can get:

$$\partial\, \acute{y}_i/\partial\, z_i = \acute{y}_i(1-\acute{y}_i) \quad (6)$$

2) Deep learning models: Deep-learning methods often fall under the umbrella of unsupervised pre-trained networks—architectures that stack many more layers and parameters than typical machine-learning neural nets, earning them the designation "deep."

a) Deep Neural Network (DNN): An Artificial Neural Network (ANN) is a model based on the structure and function of the brain [15]. Since neural networks (NN) are powerful nonlinear discriminators in the event of problems in classification, because they are able to describe any decision boundary in the feature space [16]. In recent years, Deep Neural Networks (DNNs) gained significant interest in intrusion detection research and evolved from Shallow Neural Networks (SNNs). The feature abstraction ability in DNNs and the ability to represent highly complex patterns make them extremely useful in applications in DL. Because of their ability to represent data in a good way, DNNs are in high demand in order to design efficient and robust solutions.

The results are produced in a DNN based on the connection weights and activation functions in the neurons. The DNN is composed of multiple processing layers, and every layer contributes to decision-making and feature extraction. Several hyperparameters dictate the operation of a DNN and are to be determined in advance, including the number of units, number of layers, weights and bias initializers, activation function, regularizer's coefficient, learning rate, and the optimizer. In this DNN model, ReLU activation is applied in the input layer and in every hidden layer. The ReLU function is a piecewise linear function and returns the same input in the situation where the input is a positive number and a value of zero in the situation where the input is a negative number [17]. The neurons activated by this function are also rectified linear activation units.

$$ReLU(x) = max(0, x) \quad (7)$$

b) Long Short-Term Memory (LSTM): The LSTM layer is a special kind of [18] RNN, and the main job of the LSTM layer is to handle sequence data with temporal relationships, such as text and relation data. The LSTM layer consists of three gates, the forget gate, the output gate, and the input gate, and the shared state. The use equation and the LSTM layer's detailed working are presented in the following equations:

$$f_s = \sigma\left(W_f \cdot [h_{s-1}, x_s] + b_f\right) \quad (8)$$

$$i_s = \sigma\left(W_f \cdot [h_{s-1}, x_s] + b_i\right) \quad (9)$$

$$\acute{C} = tanh(W_c \cdot [h_{s-1}, x_s] + b_C) \quad (10)$$

$$C_s = f_s \cdot C_{s-1} + i_s \cdot \acute{C} \quad (11)$$

$$o_s = (W_o[h_{s-1}, x_s] + b_C) \quad (12)$$

$$h_s = o_s \cdot tan(C_s) \quad (13)$$

The input gate controls how the LSTM cell state acquires the information, in Eq. (9). The forget gate controls how the LSTM cell state forget the information, in the Eq. (8). The cell state updates by the Eq. (10) and Eq. (11).

Output Layer:

The output layer generates the predicted sentiment classification of the comment. The final output vector is scaled using the softmax activation function to produce a probability distribution across each class. The equation is as follows:

$$y = softmax\left(W h_{fc} + b\right) \quad (14)$$

E. Evaluation Metrics

1) Confusion matrix: It's a matrix to represent how model classify dataset, also to use to check how good the model's performance of classification. It's comprised by four components.

In a confusion-matrix context, true positives (TP) are cases where an instance is genuinely positive and the model correctly labels it as such, whereas true negatives (TN) are instances that are truly negative and rightly classified as negative. By contrast, false positives (FP) occur when a genuinely negative instance is mistakenly flagged as positive, and false negatives (FN) arise when a genuinely positive instance is incorrectly marked as negative.

2) ROC Curve (Receiver Operating Characteristic Curve): A graph that shows classification performance across all thresholds by plotting the true-positive rate (TPR) against the false-positive rate (FPR), illustrating the trade-off between sensitivity and specificity.

3) Score: The harmonic mean of precision and recall; a single, balanced metric that is especially informative when class distributions are unbalanced. It ranges between 0 and 1, and 1 in the event of optimal precision and recall.

$$\text{F1 Score} = \frac{2 * \text{Precision} * \text{Recall}}{\text{Precision} + \text{Recall}} \quad (15)$$

4) Accuracy: The rate of correctly classified observations over the total observations. It is a helpful indicator in the situation where false positives and false negatives are equally distributed.

$$\text{Accuracy} = \frac{\text{Number of Correct Predictions}}{\text{Total Number of Predictions}} \quad (16)$$

5) Precision: The proportion of the total predicted positives actually being positives. The higher the precision, the lower the rate of the incorrect positives, and the lowest the incorrect positives.

$$\text{Precision} = \frac{\text{True Positives}}{\text{True Positives} + \text{False Positives}} \quad (17)$$

6) Recall: The ratio of correctly predicted positive instances to all actual positive instances. A higher recall indicates fewer missed positives and a lower rate of false negatives.

$$\text{Recall} = \frac{\text{True Positives}}{\text{True Positives} + \text{False Negatives}} \quad (18)$$

IV. Results

This section presents how a range of ML and DL models performed on binary and multi-class intrusion-detection tasks using the "NF-UNSW-NB15" dataset. Before training, we applied PCA to cut dimensionality and boost both speed and accuracy. Every model was tuned with the same hyper-parameter settings to keep the comparison fair. Their effectiveness was gauged with a full suite of metrics—accuracy, precision, recall, F1-score, AUC, and confusion matrices—so we could see each algorithm's strengths and weaknesses in detail. Results are split into two categories: binary detection of normal versus malicious traffic, and multi-class detection that pinpoints the exact attack type.

A. Hyperparameter Configuration

All deep learning models (LSTM and DNN) were trained using a fixed set of hyperparameters to ensure a fair and consistent comparison. For binary classification tasks, the loss function employed was binary crossentropy, while sparse categorical crossentropy was used for multi-class classification. Model optimization was performed using the Adam optimizer with a learning rate of 0.001. Both tasks were trained over 20 epochs with a batch size of 128. Additionally, early stopping was applied based on validation loss to prevent overfitting and ensure optimal generalization performance.

Table IV presents the hyperparameter settings used for model training, including learning configuration, optimization strategy, and loss functions for both binary and multi-class tasks.

B. Binary Classification Results

Before applying SMOTE, all models achieved high overall accuracy (0.99); however, recall and F1-scores—particularly for the minority class—were comparatively lower. For instance, the LSTM model achieved a recall of 0.92 and an F1-score of 0.94, while the DNN model recorded a recall of 0.90. These results indicate reduced sensitivity to minority class detection due to the dataset's class imbalance.

Moreover, AUC scores, which evaluate a model's ability to distinguish between classes, were also affected. Deep learning models such as DNN and LSTM yielded relatively lower AUCs in the range of 0.90–0.92, suggesting less reliable separability between benign and malicious traffic. In contrast, ensemble models like Random Forest and XGBoost performed better, achieving AUC scores around 0.98. Nevertheless, even these models demonstrated measurable improvements after applying SMOTE.

These findings confirm that SMOTE plays a critical role not only in enhancing recall and F1-scores but also in improving the overall discriminative power of classifiers, as reflected in AUC metrics. Table V summarizes the performance of LSTM, DNN, Random Forest, KNN, and XGBoost on the binary classification task prior to applying SMOTE.

After applying SMOTE, all models demonstrate strong performance, with Random Forest and KNN achieving high accuracy and F1-scores. While LSTM and DNN yield slightly lower precision for the Attack class, they still achieve perfect recall, indicating high sensitivity to positive cases. The AUC score of 0.99 or higher across all models confirms excellent separability between classes. Among all models, RF achieved the best overall performance with an F1-score of 0.97, and highly balanced precision and recall values, especially for class 1 (Attack class). Its confusion matrix is very high, showing low misclassificationwith 2308 false positives and 199 false negative, Fig. 7 shows Random Forest confusion matrix that effectively classified both Normal and Attack classes, making it the most reliable model for the binary classification task.

TABLE IV. Hyperparameter Settings

Parameter	Value
Epochs	20
Batch Size	128
Learning Rate	0.001
Optimizer	Adam
Loss Function (Binary)	Binary Crossentropy
Loss Function (Multi)	Sparse Categorical Crossentropy
PCA Components (Binary and Multi)	20

TABLE V. Binary Classification Performance without SMOTE

Model	Accuracy	Precision	Recall	F1-score	AUC
LSTM	0.99	0.97	0.92	0.94	0.92
DNN	0.99	0.97	0.90	0.93	0.90
RF	0.99	0.97	0.98	0.98	0.98
KNN	0.99	0.95	0.95	0.94	0.95
XGBoost	0.99	0.96	0.97	0.97	0.98

Fig. 8 shows LSTM confusion matrix for classifying both Normal and Attack classes.

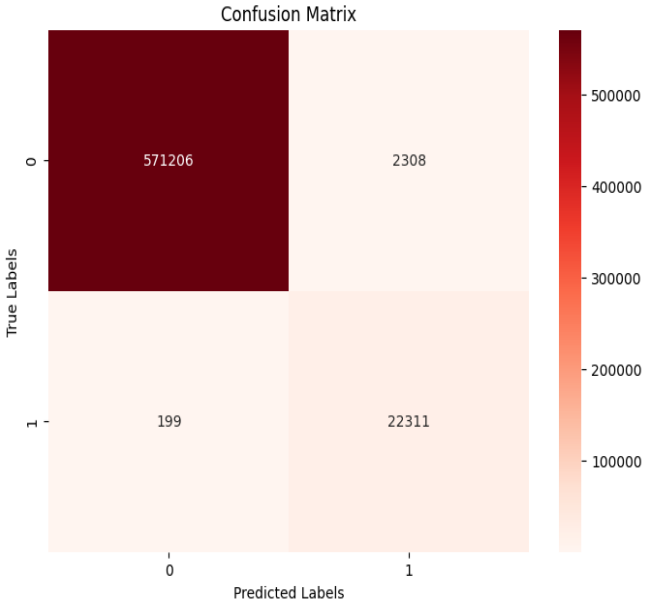

Fig. 7. RF confusion matrix.

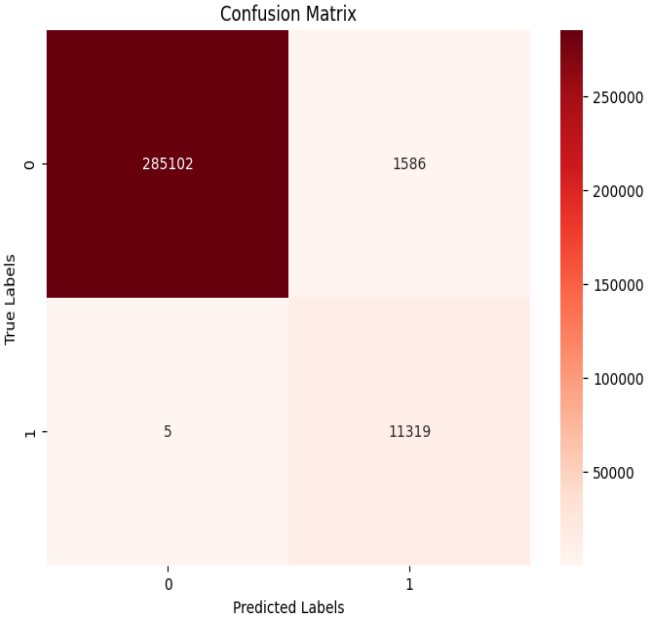

Fig. 8. LSTM confusion matrix.

The confusion matrix of the LSTM model reveals strong sensitivity in detecting attacks, although a slight increase in false positives indicates a trade-off in precision.

Fig. 9 shows DNN confusion matrix for classifying both Normal and Attack classes.

This matrix illustrates the DNN model's good performance, with solid detection capability and also slight false alarm rate, reflecting effective learning of attack patterns.

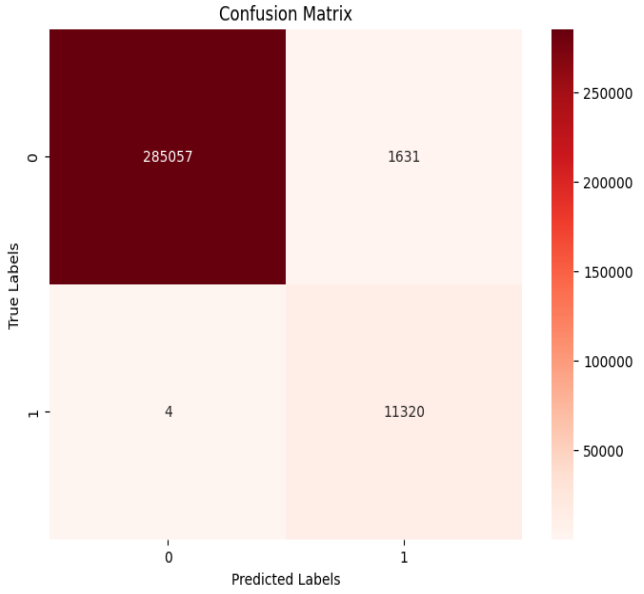

Fig. 9. DNN confusion matrix.

Fig. 10 shows KNN confusion matrix for classifying both Normal and Attack classes.

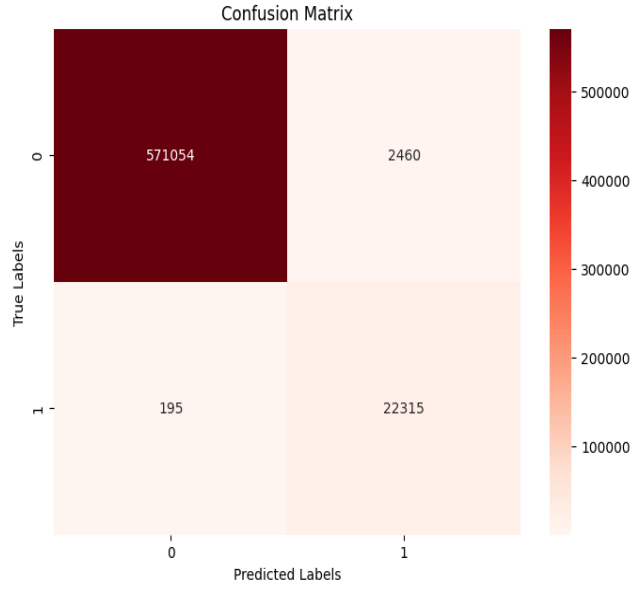

Fig. 10. KNN confusion matrix.

The KNN confusion matrix indicates good accuracy, with slightly higher misclassification of Normal status.

Fig. 11 shows XGBoost confusion matrix for classifying both Normal and Attack classes.

XGBoost exhibits high precision and recall, evident in its compact and clearly defined confusion matrix blocks with 2164 false positives and 239 false negatives, signifying high discriminative power.

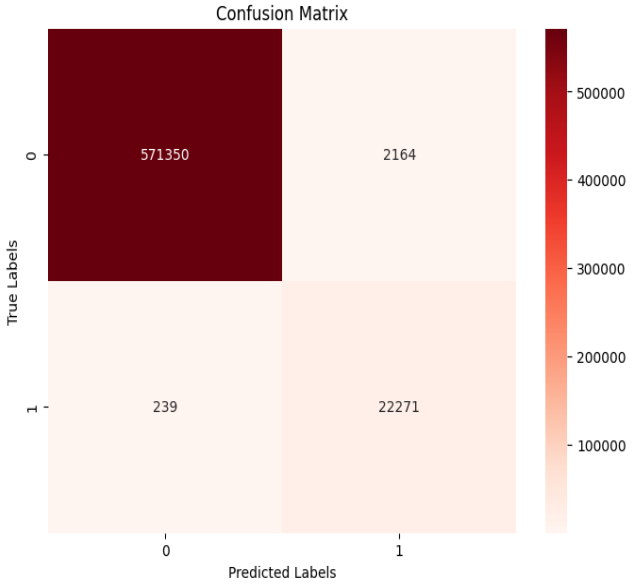

Fig. 11. XGBoost confusion matrix.

Table VI summarizes the performance of LSTM, DNN, RF, KNN, and XGBoost on the binary classification task.

TABLE VI. BINARY CLASSIFICATION PERFORMANCE WITH SMOTE

Model	Accuracy	Precision	Recall	F1-score	AUC
LSTM	0.99	0.94	0.99	0.97	0.99
DNN	0.99	0.94	0.99	0.96	0.99
RF	0.99	0.95	0.99	0.97	0.99
KNN	0.99	0.95	0.99	0.97	0.99
XGBoost	0.99	0.95	0.99	0.97	0.99

C. Multi-Class Classification Results

Unlike binary classification, the multi-class classification task suffered from noticeable performance degradation in the absence of SMOTE, especially in models like DNN, which recorded extremely low precision, recall, and F1-score (all = 0.10) despite an overall accuracy of 0.99. This illustrates that accuracy alone is misleading under class imbalance.

Similarly, LSTM showed moderate metrics (F1 = 0.52), while Random Forest and XGBoost performed relatively better (F1 = 0.64 and 0.62 respectively). AUC scores also reflected this trend—DNN had a poor AUC of 0.50, while XGBoost reached 0.98. These results demonstrate the limitations of models when trained on highly imbalanced data and reinforce the need for resampling methods like SMOTE to achieve fair multi-class performance across all attack types.

Table VII summarizes the performance of LSTM, DNN, RF, KNN, and XGBoost on the multi-class classification task before applying SMOTE.

Table VIII details the multi-class classification performance across the same set of models after SMOTE.

Model performances vary more noticeably in the multi-class setting. LSTM and DNN, while achieving high overall accuracy due to class imbalance in test set, show lower macro-averaged F1-scores, indicating challenges in learning minority classes. In contrast, Random Forest and XGBoost perform robustly across all classes, benefiting from ensemble-based learning. KNN also performs competitively but with slightly lower recall. The XGBoost classifier emerged as a competitive performer in the multi-class setting, achieving a macro F1-score (0.71), reflecting moderate performance across most classes, including minority ones. The confusion matrix of XGBoost reflects moderate performance on minority classes such as 6, 7, 8, and 9 with misclassifications, e.g., 919 false negatives for class 2 and 1455 for class 4 as shown in Fig. 12.

LSTM's multi-class confusion matrix (Fig. 13) shows robust classification for dominant classes but reveals some difficulty in differentiating among minority attack types.

TABLE VII. MULTI-CLASS CLASSIFICATION MACRO-AVERAGED SCORES WITHOUT SMOTE

Model	Accuracy	Precision	Recall	F1-score	AUC
LSTM	0.99	0.57	0.53	0.52	0.92
DNN	0.99	0.10	0.10	0.10	0.50
RF	0.99	0.66	0.62	0.64	0.94
KNN	0.99	0.61	0.58	0.59	0.87
XGBoost	0.99	0.66	0.60	0.62	0.98

TABLE VIII. MULTI-CLASS CLASSIFICATION MACRO-AVERAGED SCORES

Model	Accuracy	Precision	Recall	F1-score	AUC
LSTM	0.99	0.62	0.56	0.56	0.99
DNN	0.99	0.66	0.57	0.59	0.99
RF	0.98	0.68	0.71	0.63	0.99
KNN	0.99	0.69	0.66	0.63	0.89
XGBoost	0.99	0.73	0.80	0.71	0.99

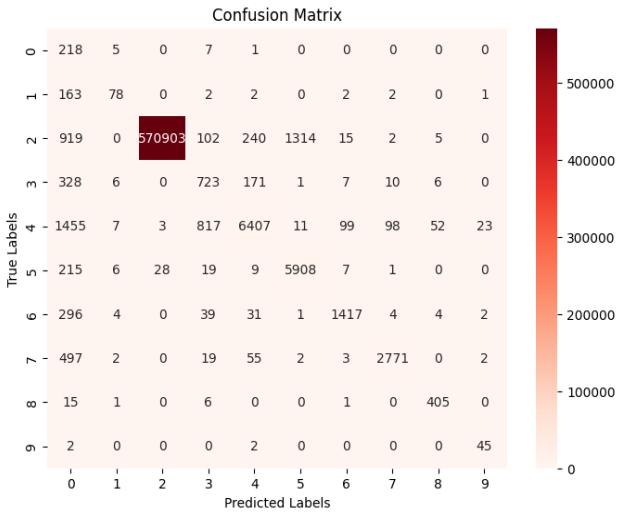

Fig. 12. XGboost confusion matrix in multi-classification.

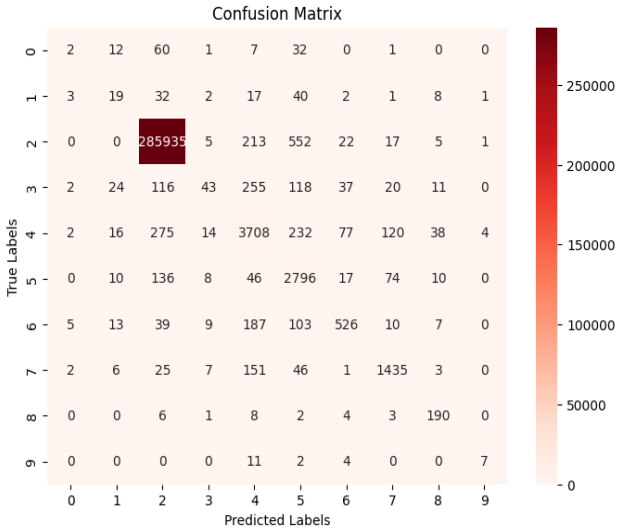

Fig. 13. LSTM confusion matrix in multi-classification

The DNN model performs well across several classes, but the confusion matrix reflects misclassification among minority classes as shown in Fig. 14.

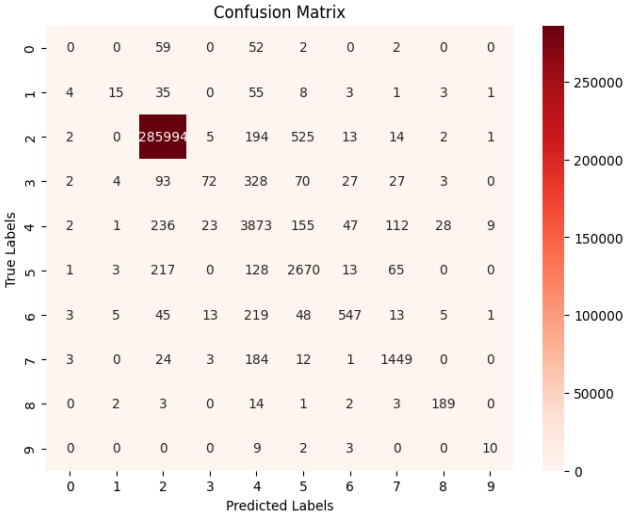

Fig. 14. DNN confusion matrix in multi-classification.

The confusion matrix of KNN (Fig. 15) shows good effectiveness, better than LSTM and DNN, but still less than Xgboost.

Random Forest delivers a compact and efficient confusion matrix, excelling at distinguishing between multiple attack types, especially frequent ones, while showing some overlap in less-represented classes as shown in Fig. 16.

D. Inference Time Evaluation for Real-Time Applicability

In addition to classification performance, prediction time is a critical consideration for real-world deployment, particularly in systems requiring real-time or near-real-time responses. Table IX presents both the total and average prediction times (per 1,000 records) for each model across binary and multi-class classification tasks, providing insight into their computational efficiency.

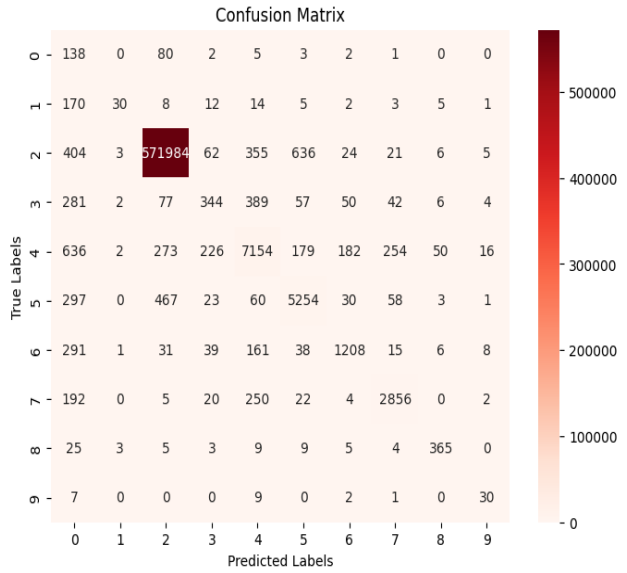

Fig. 15. KNN confusion matrix in multi-classification.

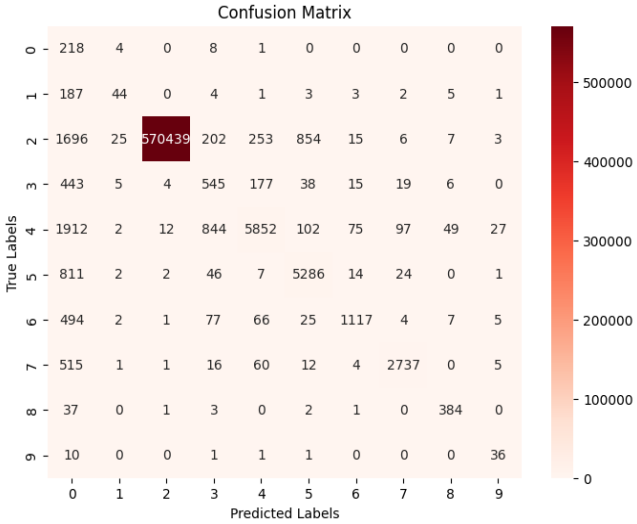

Fig. 16. Random forest confusion matrix in multi-classification.

TABLE IX. PREDICTION TIME FOR EACH CLASSIFIER

Model	Task	Total Time (s)	Avg. Time per 1000 Records (s)
LSTM	Binary	25	0.3575
DNN	Binary	20	0.0700
RF	Binary	4.519	0.0076
KNN	Binary	73.4142	0.1232
XGBoost	Binary	14.323	0.0240
LSTM	Multi-class	22.8	0.07
DNN	Multi-class	20.5489	0.0690
RF	Multi-class	5.0694	0.0128
KNN	Multi-class	39.0577	0.0983
XGBoost	Multi-class	26.7887	0.0449

Random Forest exhibited the fastest prediction times in both binary and multi-class tasks, making it highly suitable for real-time applications. Random Forest also demonstrated strong efficiency, whereas deep learning models, particularly LSTM and KNN, had the longest processing times.

V. Discussion

This study presents a comprehensive evaluation of multiple machine learning (ML) and deep learning (DL) classifiers for both binary and multi-class network intrusion detection using the NF-UNSW-NB15 dataset. The results demonstrate that the proposed models—particularly XGBoost and Random Forest—achieved superior performance, with macro-averaged F1-scores and accuracy exceeding 99% in binary classification. These models also maintained robustness in multi-class scenarios, achieving macro F1-scores of up to 0.71.

In contrast, the recent work by Samantaray et al. [9], which employed traditional ML algorithms on the same dataset, reported significantly lower macro F1-scores—only 0.26 with Logistic Regression and 0.17 with Random Forest—despite using MaxAbsScaler for feature scaling. Although their approach achieved relatively high overall accuracy (up to 94%) in multi-class classification, the low macro-averaged metrics reflect poor generalization across minority classes, indicating that class imbalance was not sufficiently addressed.

TABLE X. Comparative Results of Best Classifiers Across Studies

Study	Model	Dataset	Type	Accuracy	Macro Precision	Macro Recall	Macro F1-Score
This Work	RF	NF-UNSW-NB15-v2	Binary	0.99	0.95	0.99	0.97
This Work	XGBoost	NF-UNSW-NB15-v2	Multi-class	0.99	0.73	0.80	0.71
Kasongo and Sun [4]	XGBoost	NF-UNSW-NB15	Binary	0.91	0.80	0.98	0.88
Samantaray et al. [9]	RF	NF-UNSW-NB15	Multi-class	0.90	0.23	0.20	0.17
Samantaray et al. [9]	KNN	NF-UNSW-NB15	Multi-class	0.93	0.29	0.31	0.26
Sayed et al. [10]	IoTCNN	NF-UNSW-NB15-v2	Multi-class	~0.99	~0.42	~0.63	~0.44
Sharma et al. [33]	RF	UNSW-NB15	Binary	0.87	0.90	0.86	0.86

Similarly, the CNN-based models proposed by Sayed et al. [10], namely IoTCNN and MyCNN, demonstrated limited macro-level performance. For example, the IoTCNN model produced low precision and F1-scores in most attack categories, including F1 = 0.14 for Analysis and 0.13 for DoS, despite exhibiting high overall accuracy. These results suggest that while convolutional models may effectively capture local patterns, they often struggle with inter-class variance and generalization without advanced preprocessing or data augmentation strategies.

In addition to Samantaray et al. [9] and Sayed et al. [10], we include the study by Sharma et al. [33], which evaluates ensemble methods on UNSW-NB15 using a binary setting. Their best model (Random Forest) achieves Accuracy = 0.87, Macro Precision = 0.90, Macro Recall = 0.86, and Macro F1 = 0.86, whereas our binary IDS on NF-UNSW-NB15-v2 attains Accuracy ≈ 0.99 and Macro F1 ≈ 0.97. Thus, our approach improves binary macro-level performance by ≈ 11 points in F1 while also raising accuracy by ≈ 12 percentage points, reinforcing that the proposed SMOTE + PCA + diverse ML/DL pipeline generalizes better under class imbalance than strong ensemble baselines.

Overall, our findings highlight the effectiveness of ensemble models—such as XGBoost and Random Forest—in capturing complex feature relationships and addressing class imbalance. A comparative summary of results is provided in Table X.

VI. Conclusion

This work developed and empirically validated an end-to-end intrusion-detection pipeline that couples rigorous preprocessing (StandardScaler normalization, SMOTE oversampling, and PCA dimensionality reduction) with five classifiers (XGBoost, RF, KNN, DNN, and LSTM) evaluated on the "NF-UNSW-NB15-v2" dataset. The experiments covered both binary (normal vs attack) and nine-class attack identification tasks, using a unified hyper-parameter budget to ensure fair comparison.

Results underscore the strength of ensemble trees for tabular network-flow data: XGBoost and Random Forest achieved high metrics (≈ 0.9960 for accuracy, precision, recall, F1, and AUC) in binary detection, while XGBoost retained a competitive macro F1-score (0.71) and a balanced confusion matrix in multi-class testing. Deep models matched overall accuracy but lagged in macro scores, indicating residual sensitivity to minority classes. Crucially,RF and XGBoost's inference latency—on the order of milliseconds per thousand flows—demonstrates that top-tier accuracy can coexist with real-time throughput, making the approach deployable in production networks.

Although the pipeline raises the state of the art for this dataset, two limitations remain: extremely rare classes such as Worms and Analysis still risk misclassification despite SMOTE, and features were restricted to NetFlow attributes. Future work should explore cost-sensitive or generative resampling, integrate payload-level and temporal-correlation features, and test hybrid architectures (e.g., LSTM embeddings feeding XGBoost) under online-learning and edge-deployment constraints. Overall, the study provides a reproducible blueprint and a strong baseline for practitioners seeking accurate, low-latency, and resource-efficient intrusion detection in modern networked environments.

Comprehensive Analysis of Machine and Deep Learning Models for Stock Market Prediction

Hadi S. AlQahtani, Prof. Mohammed J. Alhaddad, Dr. Mutasem Jarrah
Department of Information Technology-Faculty of Computing and Information Technology,
King Abdulaziz University, Jeddah, Saudi Arabia

***Abstract*—Stock market prediction is a core task in financial engineering that requires sophisticated methods to extract subtle market and volatility trends. The increasing complexity of the stock market has led to the integration of advanced machine learning (ML) and deep learning (DL) techniques to improve accuracy beyond traditional statistical methods. This research provides a taxonomy of stock market prediction methods and reviews key regression-based models, including linear regression and advanced neural networks like recurrent neural networks (RNNs), long short-term memory (LSTM), and hybrid (CNN-LSTM) models. The study deploys and evaluates three specific models: Linear Regression, RNNs, and LSTMs. The models were trained and tested using modern data preprocessing procedures, including Z-score normalization and temporal sequencing. The findings show that the Linear Regression (LR) model performed better, with a Root Mean Square Error (RMSE) of 0.334 during training and 0.304 during testing, and a Mean Absolute Error (MAE) of 0.203 and 0.207, respectively. This contrasted with the deep learning models, which had higher error rates. The LSTM achieved a training RMSE of 0.355, while the RNN model had a training RMSE of 0.383. These results provide empirical evidence that increased model complexity does not necessarily translate into better forecasting accuracy in financial applications, and that model selection is both context-sensitive and data-driven. The findings mentioned the challenge of nonstationarity in stock market data and the need to periodically retrain models on recent data.**

Keywords—Deep learning; machine learning; prediction methods; stock market; regression; taxonomy

I. Introduction

Predicting stock prices accurately is crucial for investors, financial markets, and economy decision makers because of its profound implications for investment decisions. Two traditional approaches are used for forecasting stock trends, fundamental analysis and technical analysis. Fundamental analysis consists of the assessment of the actual value of securities based on the company's financial reports and other macroeconomic factors [1]. This method is more suitable for strategic long-term investment. Technical analysis, on the other hand, involves the use of price movements, volumes, and charts to determine the prognosis of future prices. This method is applied for short-term trading and help determine tendencies and the right time for trading operations [2].

The financial forecasting industry, particularly stock market prediction, has been greatly impacted by AI technologies as it continues to evolve rapidly. Traditional financial time series and time series analysis techniques often fail to analyze the market's complex nonlinear data, which made researchers shift their focus to more sophisticated AI technologies [3]. These include Recurrent Neural Networks (RNNs), Long Short-Term Memory networks (LSTMs), and even hybrid models such as LSTM-CNNs [4]. RNNs provide the most basic method to model temporal dependencies in sequential data, while LSTMs improve upon RNNs by introducing memory cell architectures to mitigate the vanishing gradient problem [3]. More recently, LSTM-CNN models have been developed which combine LSTMs with Convolutional Neural Networks (CNNs), leveraging both temporal and spatial feature extraction capabilities. This research focuses on the stock price forecasting AI models and aims to analyze their performance comparatively and identify the most optimal model for practical usage [4].

The traditional forecasting methods struggle to capture the complexities and uncertainties inherent in stock markets. However, AI technologies are modern methods that offer promising ways for enhancing prediction accuracy [13]. The algorithms offer the ability to automatically detect patterns, adapt to changing market conditions, process large volumes of data, including historical prices, technical indicators, financial news, social media sentiment, leveraging large datasets and detecting intricate patterns, especially machine learning (ML) and deep learning (DL) techniques [5]. By employing ML and DL algorithms such as linear regression, logistic regression, RNNs, LSTM, and LSTM-CNN, researchers have attempted to exploit the vast amount of market data to uncover hidden relationships and forecast future price movements [6]. This paper mentions stock market prediction methods taxonomy, with recent advancements in stock market prediction achieved through possible methods that can assist in stock market prediction. Generally, this paper provides insights into the effectiveness and reliability of the most important approaches in stock market prediction, informing stakeholders about their potential benefits and challenges in real-world and prediction applications.

The reminder sections of this paper are: proposed previous work in Section III as a literature review. Section IV discussed methodology, results and findings are evaluated in Section V, Critical analysis is given in Section VI and Section VII is the conclusion.

II. Stock Market Prediction Methods Taxonomy

Stock market prediction methods are divided into three categories: fundamental analysis, technical analysis, and algorithmic approaches.

A. Fundamental Analysis

Fundamental analysis relies on economic indicators, company performance metrics, and financial reports to assess the intrinsic value of a stock [1].

B. Technical Analysis

Technical analysis focuses on historical price patterns, trading volumes, and chart indicators to forecast future price movements [12].

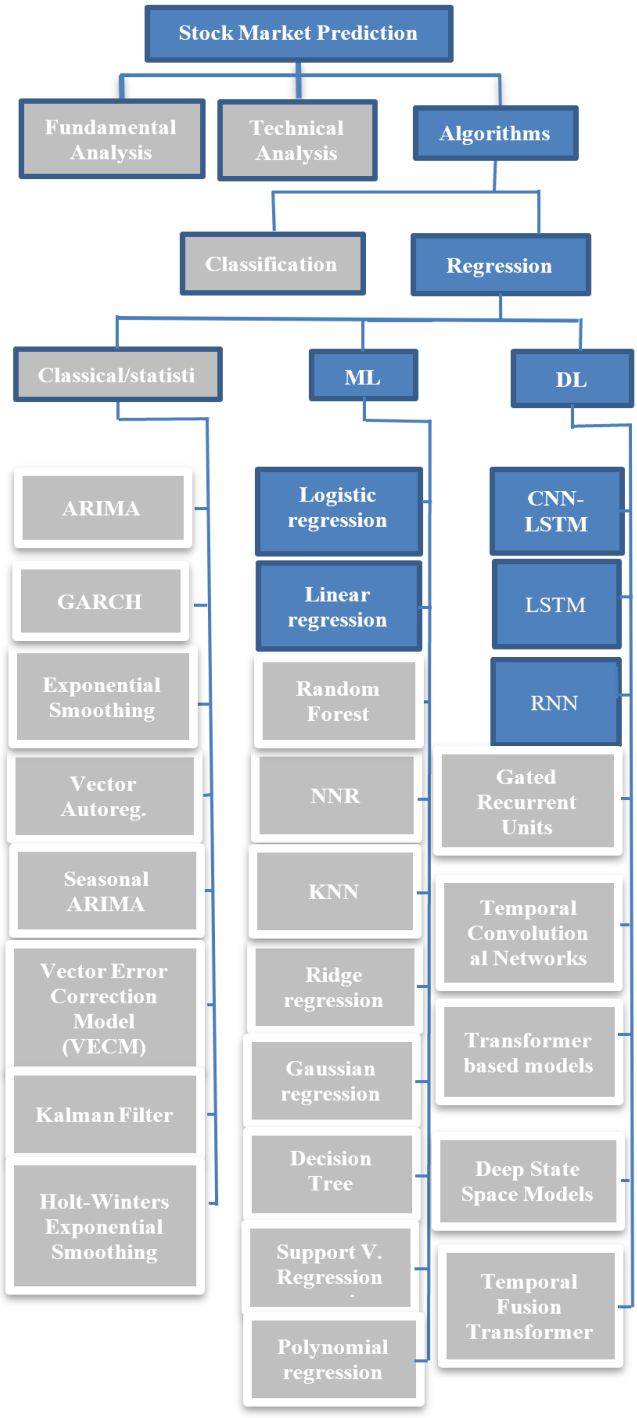

Fig. 1. Taxonomy of stock market prediction methods.

C. Algorithmic Approaches

Algorithmic approaches employ computational models and artificial intelligence techniques to identify patterns and generate predictions. Within algorithmic approaches, methods are typically organized into two main tasks: classification (e.g., predicting whether a stock will rise or fall) and regression (e.g., forecasting the exact stock price or return value) [6].

Since the present study is concerned with continuous stock price forecasting [15], the focus is placed on regression methods. These can be further classified into three different categories [14]:

- Classical/Statistical models (e.g., ARIMA, GARCH), which provide simple yet interpretable baselines.
- Machine Learning (ML) models (e.g., Linear Regression, Logistic regression, Support Vector Regression, Random Forests), which capture nonlinear relationships and improve predictive performance.
- Deep Learning (DL) models (e.g., RNN, LSTM, CNN-LSTM), which are designed to learn complex temporal dependencies and deliver state-of-the-art results for sequential financial data.

This hierarchical taxonomy provides a structured view of stock prediction methods, showing how approaches range from traditional econometric techniques to advanced AI-driven models. It also clarifies the scope of this study, which emphasizes regression-based methods across statistical, ML, and DL Models. These three categories contain more techniques, as shown in Fig. 1.

III. Literature Review

Predicting the stock market has attracted much interest from the scientific community, financial experts, and computer scientists. Future market prices and movements are likely to show complex nonlinear relationships with time that differ. Due to their availability and increased computational power, most technological tools are incredibly precise and elaborate.

The reviewed studies in this paper are organized into a taxonomy that highlights how stock market prediction methods are structured along the key dimensions: algorithm type

The discussed literature is limited to important machine learning (ML) approaches and deep learning (DL) approaches:

A. Machine Learning

1) Linear regression: Linear regression is treated as a supervised learning algorithm for regression tasks. It is an elementary method of predictive modeling, a subset of artificial intelligence, used to establish a relationship between an outcome variable and one or several predictor variables. It assumes that the best fit is a straight line that best predicts the errors between the predicted and actual values. The conditional assumptions are linearity, the absence of multicollinearity, and the normality and homoscedasticity of residuals. Research in [7] discussed regression methods used for prediction models in machine learning. The researchers overviewed definitions of the models, metrics for model

evaluation, assumptions, and methods of attribute selection. Some of the issues that were raised in the study include issues related to overfitting and the fact that while regression is a very powerful tool, it is, however, quite restricted in its ability to solve very complicated problems. Reference [8] designed a website that employed linear regression for stock price prediction. The researchers concluded that the performance on two years of historical prices provided reasonable accuracy. Authors of study [16] also noted that it is crucial to consider nonstationarity when dealing with stock data for production use. The model must be periodically retrained using more recent data to enhance its predictive ability. Research in [9] discussed how the linear regression model is trained for stock prediction using Python. The researchers explored exploratory data analysis, formulating a model, evaluating it, and incorporating it into trading strategies. Generally, they proved the existence of its kind but pointed out the dangers of oversimplification and the use of predictive modeling. Moreover, regression coefficients introduce interpretability measures to identify useful indicators [9]. Nonstationarity is one of the challenges faced by models and may be addressed by retraining on more recent sliding stock data. In general, literature supports the application of regression for stock prediction but simultaneously raises concerns about using it without proper precaution [8]. Important features are cross-validation, integration with other techniques, repetitiveness with retraining, interpretability and integration with human decision-making [14]. The greatest value is achieved when prescriptive analytics include predictions and insights into the trading systems.

2) Logistic regression: In machine learning and for classification tasks, logistic regression is a supervised learning algorithm. It is a specific feature of neural networks is that they require many training data points for accurate predictions. Neural networks can be used when making predictions based on binary outcomes. Logistic regression is one of the most frequently used in machine learning and can be utilized to predict a binary outcome point given predictor variable [14]. The study in [10] evaluated the abilities of logistic regression as a machine learning algorithms, including random forest and neural networks. This study revealed that logistic regression was not inferior to other algorithms after the method of choosing the number of features through the area under the ROC curve was applied [10]. This is where logistic regression proves to be a helpful interpretable baseline model. The study in [11] employed logistic regression and logitboost algorithms to build churn prediction models. Logit had a slightly better performance than logistic regression, although this came at the cost of performing hyperparameter tuning. Logistic regression provides an excellent and less complex solution to the model. Authors of [17] considered the rationale for employing logistic regression or linear regression analysis when analyzing treatment effects in experimental research with binary data. The study in [11] concluded that logistic regression was reasonable for disentangling treatment impact from risk profiles relevant to the outcome, even in situations of imbalanced randomization. Generally, the reviewed research proves the suitability of the logistic models for causal conclusions. Logistic regression has several benefits, namely, interpretability, efficiency, and reliability of the results. Coefficients of logit show how each predictor is associated with the outcome variable [11]. Fewer tuning parameters are needed than in other complex machine learning methods. Logistic regression also performs well when analyzing small datasets and has no overfitting issue. In fact, research [10] has demonstrated that it can do so to estimate treatment effects while also accounting for confounding factors. However, the assumptions accompanying most logistic regression models, such as linearity and multicollinearity, may be violated in real-world data [10]. The algorithm cannot, in the process, model multiplicative complex nonlinear effects or high-order interactions as with tree-based methods. Another disadvantage is that logistic regression is very sensitive to the choice of the classes where the classes are imbalanced. Even if more variables are added to the model, the algorithm may not increase its predictive accuracy if the relationship is not linear or, in other words, if it is nonlinear in nature [11]. These limitations justify the need for superior sampling and variable selection techniques in the study designs. Machine Learning techniques reviewed sources of Linear Regression and Logistic Regression are summarized in Table I.

TABLE I. EVALUATION SUMMARY OF MACHINE LEARNING TECHNIQUES

Ref.	Methodology	Performance metrics	Strengths	Limitations	Result
[7]	Support vector polynomial regression algorithm	Mean absolute error (MAE)	Used number of transactions missing to calculate its performance	Used algorithms may not increase its predictive accuracy and need test it on other algorithms	SVM accuracy: 93%
[8]	Linear regression, basic but fundamental	Mean absolute error (MAE), root mean square error (RMSE)	Simplicity, easy to implement	Limited complexity in modeling	Exceeded 85%
[9]	Regression analysis	MSE, RMSE, R-squared	Practical application	Limited to simple models	Accuracy 76%
[10]	Comparative study of logistic regression and ML	Recall, F1 Score, AUC	Simple and Direct comparison	Algorithm not work as expected with nonlinear models, in addition to that, it is very sensitive to the choice of the classes	N/A
[11]	Logistic regression and Logit boost	Recall, F1 Score, Area Under the Curve (AUC)	Focused on binary classification	The algorithm may not increase its predictive accuracy if the relation is not linear	Accuracy more than 85%

B. Deep Learning

1) Recurrent Neural Networks (RNN): RNNs are a type of deep neural network that is very useful when processing data in a sequence, such as time series data such as stock prices [17]. The recurrent connections allow RNNs to capture temporal dependencies within the series of observations. The study in [18] discussed deep learning stock forecasting models and noted that RNNs/LSTMs can identify temporal dependencies that are not extractible by other models. The inherent recurrent structure of RNNs allows the design of a model of sequential correlations unavailable to feedforward networks. Nonetheless, it is difficult for vanilla RNNs to handle longer sequences because these models have issues with exploding/vanishing gradients [19]. RNNs with memory solve this problem using gated memory cells that help with long-term dependency. In conjunction with recent techniques in deep learning, RNNs offer the best performance in modeling most sequence data. Due to their ability to identify temporal relationships, RNNs with memory models are useful for predicting the next values of time series such as stock prices. RNNs with memory networks for stock price prediction are rooted in enhanced capacity to handle time series data appropriately. The study in [20] compared RNN LSTM with other models, such as linear models and random forests, especially from the perspective of stock price forecasts. The source takes up the problem of a lack of effective tools for risk forecasting in the context of the fluctuating financial market, as well as implementing sound research methods to determine the efficiency of the models [20]. A weakness with all recurrent neural networks is the vanishing gradient problem, but LSTMs are especially lauded for their performance with long-term dependencies in data, which is useful since stock price data are a sequence. This model is even better than regular RNNs because it has memory cells that control the flow of data, and the cells have gates that control the addition and accumulation of data, which tend to solve problems such as vanishing gradients, which are common with regular RNNs.

2) Long Short-Term Memory (LSTM): LSTM is a type of recurrent neural network that might be most effective in modeling time series data. Since their introduction, LSTMs have been implemented in the financial field, where they have been used in stock price prediction, algorithm trading, risk control, and fraud identification. Reference [19] discussed various prediction methods employed in stock markets, including LSTMs. They discovered that LSTMs are more effective for variable financial time series where the data contain nonlinear trends and are nonstationary. They enhance the algorithm to increase its accuracy. Authors of study [21] introduced a four-layer architecture of a dual-LSTM model using past prices and technical indicators to forecast multiple-day-ahead stock prices. The author's approach offers one of the best solutions for benchmark datasets. Accordingly, LSTMs have significant advantages and are suitable for modeling financial time series. It can remember long-range dependencies missing in feedforward networks through their memory cells. Some of the main issues that are particularly relevant to LSTM-based financial applications include data noise, model interpretability, and the model's ability to generalize to distribution shifts with respect to the time series. Research has provided a new mixed option comprising long short-term memory (LSTM) and an adaptive genetic algorithm (AGA) for the prediction of stock indices, further stressing innovation in the spheres of financial forecasting [12]. The study in [22] motioned progressive developments in predictive analytics in financial markets and, thus, considered the current state of the markets. From a methodological perspective, the integration of LSTM with AGA is focused on optimizing the networks' structures and parameters to improve the forecast's accuracy accordingly [22]. Performance metrics such as the mean square and absolute percentage errors are used to check the model's effectiveness. One of the advantages of this study is the authors' effective method of tracking changes in data from one period to another and adjusting for such changes in the analysis, thus enhancing the forecast accuracy. However, the requirements of the components to work out the model result in a more complex design and higher processing needs, which may become an issue of practical application [22]. The results show that it has better accuracy than traditional models do, making it possible to fine-tune investment portfolios [22].

3) CNN-LSTM: The combination of CNNs and LSTM produced a new model that uses both a convolutional neural network (CNN) and LSTM networks to benefit from each other's strengths and make a proper model for time series forecasting. The CNN down samples the input time series to extract local spatial relations, whereas the LSTM learns long-term temporal relations. The CNN is used to extract features, and the output sequence is taken from the CNN and passed to the LSTM at the back end, which is considered for temporal analysis. The CNN features in the network act as translation invariants, and the LSTM capability is used to store the temporal state. A few recent studies have implemented the CNN-LSTM architecture across different fields, such as stock market prediction and electricity load forecasting [20]. Authors of study [23] used a CNN-LSTM to input multivariate financial time series data and established that this improves the performance of a pure LSTM.

4) Analysis of the CNN-LSTM method shows that the CNN-LSTM method for financial time series forecasting takes advantage of convolutional neural networks and long short-term memory networks [23]. It can identify spatial correlations in the data and temporal correlations to make the best prediction. One advantage is that the weights of a CNN are made regular before feeding the LSTM layer, which increases its ability to resist variations [24]. Long-term dependencies may remain a task for a model that can still be challenging compared with more straightforward methods of statistics. Thus, CNN-LSTM has the potential to refine the accuracy of forecasts; however, further studies are still needed in terms of interpretability, versatility for different datasets,

and optimization of feature extraction strategies. Further tweaking and testing it on live data would help achieve its real-life applicability. Simple modifications in the structural design of models and training algorithms could effectively unlock the benefits of this integrated deep learning approach to modeling financial series. Deep Learning techniques reviewed sources of RNN, LSTM, and CNN-LSTM are summarized in Table II.

TABLE II. EVALUATION SUMMARY OF DEEP LEARNING TECHNIQUES

Ref.	Methodology	Performance Metrics	Strengths	Limitations	Result
[21]	Dual-LSTMs, advanced for real-time data	RMSE, Mean Absolute Deviation (MAD)	Capable of handling complex patterns	Complexity in tuning and training	Best average prediction errors of LSTM = 0.05
[19]	Etaheuristic Optimization on RNN–LSTM	MAE, R-squared, Accuracy, Precision	Wide scope by using more datasets	Lacks specific practical insights	Accuracy after using RNN–LSTM increment of 4–6%
[23]	Multivariate CNN-LSTM model	MSE, RMSE, MAE	Handles multiple data streams	Complexity and implementation difficulty	CNN-LSTM Average value of RMSE = 0.0162
[22]	Uses LSTM with sentiment analysis from social media. (TLSTM)	RMSE, MAE, Accuracy, Precision	Combines technical analysis with sentiment analysis for better predictions	Model Complexity	RMSE= 2.147, 82.19 and F-measure = 89%

IV. METHODOLOGY

A. Research Design and Framework

The study employs a quantitative experimental design to determine the performance of machine learning and deep learning techniques for stock market prediction. The methodology outlines the procedure as a six phase process: data collection, preprocessing, models implementation, model training/testing, and results evaluation. This study will only consider the performance of the Saudi Aramco (2222.SR) stock. Saudi Aramco is the largest oil company in the world, and it has considerable influence over the regional and global financial markets [1].

The experimental framework was structured to allow reproducibility and statistical reliability due to a comparison of three modeling approaches. The first Linear Regression model was used as a baseline model. The second, RNN, was a first-generation model based on basic sequential learning. The third, LSTM, was a first-generation model based on sequential temporal dependencies. This multi-model approach allows for assessing performance at different levels of complexity and computational overhead. In addition, it provides a better understanding of how machine learning methods perform compared to the more up-to-date deep learning architectures in forecasting applications within finance.

B. Data Collection and Acquisition

Historical stock data for Saudi Aramco was collected systematically using Yahoo Finance API (yfinance) Python library over a total of last five years. The dataset captures daily trading activity which includes opening price, closing price, high-low range for the day, volume of trades and is therefore complete in terms of transaction history. Since the target stock symbol was 2222.SR, it ensured that the data collected and returned was specifically from the Saudi Stock Exchange (Tadawul). Generally, error handling and data validation were built into the data collection process to capture concerns regarding completeness and integrity of the data returned. Missing values were identified and subsequently addressed using forward and backward interpolation as appropriate, when generating daily averages from weekly averages. Outliers were identified through statistical measures and determined whether to keep/discard outliers based on trading volumes and more importantly, where the trades were made with respect to the market, bid-ask and consensus price at that point in time. Overall, the comprehensive dataset provides a great way to train a model, and based on the extensive and complete dataset provided, all empirical results should reflect the actual market conditions and trading behaviors observed in the Saudi Arabian equities market.

C. Preprocessing

The preprocessing stage included many data standardization methods to improve how well the model converges with optimal performance. The data standardization techniques included standardization of the input features utilizing Z-score normalization method to standardize all input features using the equation, as shown in Eq. (1):

$$Z = (X - \mu) / \sigma \quad (1)$$

Where Z is the standardized value of X, the original value, μ is the mean, and σ is the standard deviation of the feature. The standardization of the input features is important in optimizing a neural network as it allows the converging of the cost function to occur more efficiently [14]. This ultimately reduces the required number of epochs to train the model and improves model reliability. The preprocessing pipeline developed the temporal sequences for the sliding window techniques in RNN and LSTM models. The construction of temporal sequence input patterns using sliding windows, enabled the models to learn from historical price movements. All numerical features underwent feature scaling to develop an ability to separate features within differing magnitude therefore preventing bias to larger magnitude features. The dataset was divided into a training and testing dataset, the training dataset consisted of 80% and the testing dataset consisted of 20% of the total data, used chronological splitting methods to prevent any leakage of future data which ensured the temporal characteristics of the dataset remained intact throughout the inception of the models.

D. Model Performance Evaluation Metrics

The model performance was assessed using two main evaluation metrics. The first evaluation metric was Root Mean Square Error (RMSE), which was calculated as shown in Eq. (2):

$$RMSE = \sqrt{(\Sigma(y_i - \hat{y}_i)^2 / n} \quad (2)$$

The second evaluation metric was Mean Absolute Error (MAE), calculated as shown in Eq. (3):

$$MAE = \Sigma|y_i - \hat{y}_i| / n \quad (3)$$

where y_i represents the actual values, $\hat{y}_i$ represents the predicted values, and n is the number of observations that were captured each day. After evaluating all models, meaningful differences in predictive performance were observed across models, with results systematically recorded to analyze prior to determining the best approach for predictive modeling.

E. Model Implementation and Architecture

The Linear Regression model is the baseline with which everything else can be compared. It implements the simplest relationship in the literature, which is shown in Eq. (4):

$$Y = \beta_0 + \beta_1 X_1 + \beta_2 X_2 + ... + \beta_n X_n + \varepsilon, \quad (4)$$

has easy-to-interpret coefficients, and is easy to compare with this work. The Linear Regression model was implemented using scikit-learn's Linear Regression class with all parameters set to the default (that is, no user-supplied input / adjusted parameters for this baseline model) to standardize the evaluation conditions. The implementation of the RNN architecture was carried out using the TensorFlow/Keras framework. It defines sequential data with the appropriate number of timesteps in the input layer, an RNN layer that has 50 hidden units, a dense layer that contains the predicted closing price, an Adam optimizer with a default learning rate set to 0.001, and finally a Mean Squared Error loss function. The RNN model used a basic architecture which was capable of looking at (and capturing) some short-range temporal dependencies, which may still have inherent issues with long range dependencies due to vanishing gradient issues before the learner reaches the next timestep [21]. The LSTM structure uses memory cells and gating mechanisms to solve RNN issues. It has an LSTM layer containing 50 memory units, a dropout layer (0.2) to regularize, and a dense final output layer for prediction. It also has the same optimizer and loss function as RNN. The LSTM design allows for learning long-term dependencies using a more sophisticated gating architecture, including forget gates, input gates, and output gates [21].

F. Statistical Validation, Robustness Testing, and Computational Environment

This study employed a rigorous method to implement and test machine learning models, including linear regression, with machine learning versus strictly statistical. The intention was to determine models that yield the most stable predictive accuracy to be used specifically in the Saudi Arabian equity market. Cross-validation tested the generalization capacity of each model by maintaining training and test data distinct to avoid leakage and attain a realistic performance estimation. Sensitivity analysis tested model stability against small to moderate perturbations in hyperparameters. Statistical significance testing determined whether differences observed in performance were statistically significant, for example, linear regression versus other models. Robustness testing assessed the performance of models under different market conditions and volatility regimes to assess generalizability. The performance of the models were assessed using the same computational resources; all experiments used Python 3.8+ with the same libraries (TensorFlow 2.x, scikit-learn, pandas, and numpy). Random seeds were established and hyperparameter values were recorded as well as calculated to ensure reproducibility. Each model had the same hardware specifications, details of all training modalities were finalized and recorded to allow full transparency and facilitate future model improvements.

V. Results and Evaluation

The investigation findings provide a comparative evaluation among three predictive methods for forecasting Saudi Aramco stock prices: Linear Regression, Long Short-Term Memory (LSTM), and Recurrent Neural Network (RNN). The training and testing datasets were evaluated using two relevant regression measures: Root Mean Squared Error (RMSE) and Mean Absolute Error (MAE). In the training phase, Linear Regression was again the best-performing method with the lowest RMSE (0.334) and MAE (0.203). For these metrics, linear regression was performed comparably on a direct comparison basis with the actual price. LSTM at RMSE 0.355 and MAE 0.266 for the remaining predictive methods, and RNN at RMSE 0.383 and MAE 0.263. Training Results prediction performance for Aramco Stock Market is summarized in Table III.

Thus, although the RNN and LSTM are deep learning computational models that model temporal dynamics such as time series data and patterns over time, and deeper network connections will provide better mathematical representation, they did not outperform the Linear regression-based training performance.

More importantly, during the testing phase, which indicates how the model performs on unseen data, Linear Regression (LR) remained ahead of the pack, with an RMSE of 0.304 and MAE of 0.207, as shown in Table IV and drawn in Fig. 2. LSTM's RMSE was 0.346 and MAE of 0.237, as shown in Table IV and drawn in Fig. 3, while RNN performed the worst with an RMSE of 0.415 and MAE of 0.329, as shown in Table IV and drawn in Fig. 4. Testing results analysis for Aramco stock market are summarized in Table IV.

TABLE III. Training Results Prediction Performance of Aramco Stock Market

Model Name	RMSE	MAE
Linear Regression	0.334	0.203
LSTM	0.355	0.266
RNN	0.383	0.263

TABLE IV. Testing Results Analysis of Aramco Stock Market

Model Name	RMSE	MAE
Linear Regression	0.304	0.207
LSTM	0.346	0.237
RNN	0.415	0.329

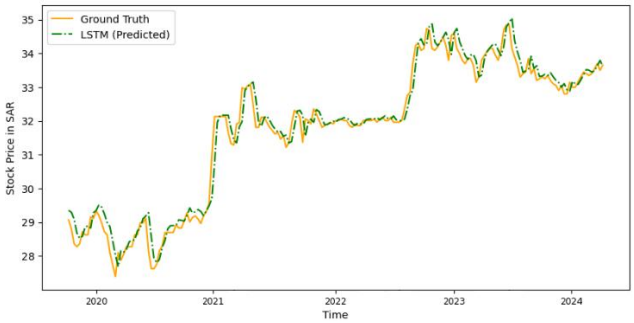

Fig. 3. LSTM prediction performance of Aramco stock market.

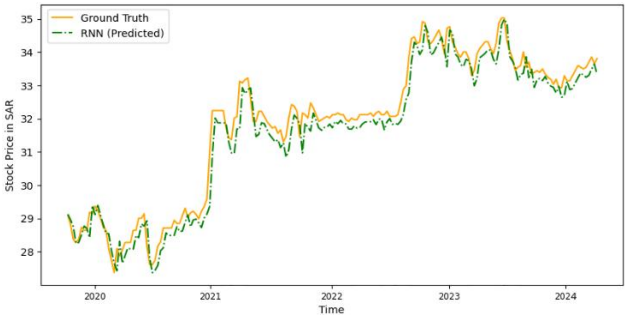

Fig. 4. RNN prediction performance of Aramco stock market.

A. Discussion

The study evaluated three specific models: Linear Regression (LR) from Machine learning, Recurrent Neural Networks (RNNs), and Long Short-Term Memory (LSTM) networks from Deep learning.

1) Linear Regression (LR): The study found that LR performed better than the deep learning models. This demonstrates that a less complex model can offer better forecasting accuracy, which is a significant finding. However, LR is limited in its ability to solve very complicated problems.

2) Long Short-Term Memory (LSTM) Networks: LSTMs are an advanced form of RNNs that address the vanishing gradient problem by using memory cells. The study found that LSTMs had a higher RMSE error compared to LR and performed better than RNNs. Its issues in this experiment are related to its complexity.

3) Recurrent Neural Networks (RNNs): The study's evaluation showed RNNs with the highest RMSE. A key weakness of standard RNNs is their difficulty in handling longer sequences due to issues with exploding modeling time series data, especially with non-linear and non-stationary trends.

Ultimately, this indicates that when assumed as a machine learning model and thus trained and treated as such, Linear Regression will outperform more complex Deep learning models - like RNNs and LSTMs - on stock market prediction tasks particularly when sequential patterns are not overly prevalent in the data or when the dataset is smaller in size. In conclusion, the findings continue to emphasize how model selection should be based on understanding the data. DNNs can include hidden layers meant to learn complex patterns in data, but models (assumptions of the data/structure) can still reveal the best predictive accuracy. While there is an excellent opportunity for deep learning models, their performance is not always superior, particularly in cases where the simpler model reveals the best outcomes.

VI. Critical Analysis and Synthesis of Key Findings, Gaps, and Trends

A central finding of the research is that a simpler model like Linear Regression outperformed more complex deep learning models (RNN and LSTM) in terms of lower error rates. This contradicts the general trend in machine learning, where deep learning models are often lauded for their superior ability to handle complex, non-linear data. This finding suggests that while DL models are powerful, their effectiveness in stock market prediction is not guaranteed and is highly context-sensitive and data-driven. It could be that the specific dataset or preprocessing methods used in the study were more suited to a linear model, or that the deep models were not sufficiently optimized.

A. The Dominance of Deep Learning for Non-linear Data

Despite the specific findings of the study, the broader literature review consistently highlights the shift from traditional statistical methods to more sophisticated AI technologies (ML and DL) to analyze the market's complex and non-linear data. Deep learning models, particularly LSTMs, are specifically praised for their capacity to handle time series data and mitigate the vanishing gradient problem, making them suitable for the long-term dependencies inherent in financial data. The trend is also moving toward hybrid models, like CNN-LSTM, which aim to combine the strengths of different architectures to improve prediction accuracy by capturing both spatial and temporal features.

B. Data-Centric and Preprocessing Trends

The study explicitly mentions the use of "modern data preprocessing procedures," including Z-score normalization and temporal sequence, to ensure effective model training. The literature also notes the increasing use of large, heterogeneous datasets that go beyond historical prices to include technical indicators, financial news, and social media sentiment. This trend towards incorporating diverse data sources is a key advancement, as it enriches the models with more context and helps them adapt to changing market conditions.

C. Gaps and Underexplored Areas

The study identifies several limitations and areas for future research:

1) Model interpretability: While models like Linear Regression offer interpretability, deep learning models often have complex functions. The paper notes that model interpretability is a key issue, especially for LSTM-based financial applications.

2) Generalizability and robustness: The study highlights that a model's ability to generalize to "distribution shifts" over time is a significant issue. The non-stationary nature of stock data means models must be periodically retrained on recent data.

3) The "Human Element": This study mentions incorporating predictions and insights into trading systems for "prescriptive analytics" and "integration with human decision-making". This suggests a gap in current research, which often focuses solely on model accuracy, without fully exploring the integration of these AI systems with human expertise and trading strategies.

4) Real-world applicability: The paper mentions that further tweaking and testing on "live data" is needed to achieve real-life applicability for models like CNN-LSTM. This points to a gap between theoretical model performance and practical, real-world deployment.

The findings of this research extend beyond the performance of individual models, offering insights into core, ongoing challenges in computer science and its applications.

1) The most striking finding, where the simple Linear Regression (LR) model outperformed the more complex deep learning models (RNNs and LSTMs), the study provides experimental evidence that for financial forecasting, which is both context-sensitive and data-driven, a complex model is not always the optimal choice. This highlights the ongoing challenge for computer scientists to select, not just develop, the right algorithm for a specific problem and dataset rather than universally favoring the latest or most sophisticated architecture.

2) Adaptive systems for dynamic environments: The document repeatedly mentions the challenge of nonstationarity in stock data and the need to periodically retrain models on recent data. This is a central problem in computer science applications that deal with dynamic, evolving systems, from robotics to network security. The need for models to adapt to distribution shifts over time without manual intervention is a major research area. The findings from this study confirm that for financial data, which is highly sensitive to real-world events and changes, the ability of a model to generalize and remain robust is a critical, and often unfulfilled, requirement.

3) Hybrid architectures for complex problems: The research's focus on hybrid models like the CNN-LSTM directly reflects a major trend in modern computer science: the move toward multi-modal or hybrid architectures. By combining different types of neural networks, researchers aim to leverage the unique strengths of each component to solve more complex problems than a single model could alone. The CNN-LSTM architecture, for example, is designed to extract both spatial features and temporal relationships. This approach represents a shift from finding a single "best" algorithm to building composite systems that are better suited for the multifaceted nature of real-world data.

VII. Conclusion

From a practical perspective, the research has important guidance to provide traders and financial analysts on linear and non-linear models. A linear model has features such as interpretability, rapid calculation speed, and reliable performance that make it a practical choice for real-time trading systems. The work did reveal that some models used in the experiments produced reliable predictions in empirical tests and supported context-based model selection.

This research investigated the capacity of machine learning and deep learning models to predict prices for the consumed stock of Saudi Aramco. The results demonstrated that the simpler models such as the Linear Regression model were able to achieve lower RMSE and MAE errors than LSTM and RNN models. This suggests that simpler models can capture stock movements, which seem to be relatively linear. The lower performance of the deep-learning models suggests that they likely overfit the data, leading to the notion that not all complexities lead to better forecasting models. This study highlighted the relevance of regression models in financial forecasting. This is also highly applicable to emerging markets, where data characteristics are not conducive to complex neural architectures.

Future work should apply to a wider diversity of stocks, incorporate outside economic variables, and investigate ensemble models containing both linear and deep learning components. Future research also needs to focus on making complex models more transparent so that implementers can understand why a particular prediction was made. Further research is needed to create models that are more robust and adaptable to sudden and unexpected market changes. This is crucial for building trust and enabling human decision-making. All these then provide the basis for smarter and more efficient specific decision-making in algorithmic trading, risk management, and portfolio optimization

Consumer Adoption of Autonomous Vehicles in China: A Bibliometric Review of Intention Drivers and Perceptions

Yunluo Zou[1]*, Syuhaily Osman[2], Sharifah Azizah Haron[3]
Faculty of Human Ecology, Universiti Putra Malaysia, Selangor, Malaysia[1, 2, 3]
College of Economics & Management, Hubei University of Arts and Science, Xiangyang, China[1]

***Abstract*—Autonomous vehicles (AVs) are playing an increasing role in digitally enabled transportation systems with the dramatic emergence of related technologies. Consumer adoption is arguably a key factor in the deployment of AVs in China. In this study, bibliometric analysis was used to explore intention drivers regarding consumer adoption of AVs and the role of consumer perception in the decision-making process from the perspective of Chinese consumers. The results revealed that consumer perception is a highly critical factor influencing the adoption of AVs. Moreover, most Chinese consumers were more sensitive to perceived losses than to gains. In addition, the main public focus was on highly intelligent shared AVs rather than family-use vehicles. These findings could help governments and enterprises gain a deeper understanding of consumer behavior in the Chinese market, which could be used as a reference for implementing measures to better accelerate the diffusion of AVs.**

Keywords*—Autonomous vehicles; diffusion of AVs; consumer adoption; consumer perception; Chinese market; bibliometric analysis

I. Introduction

Autonomous vehicles (AVs) have become regarded as one of the most active and promising innovations in the global market in recent years [1]. AVs are vehicles with the capability to guide themselves without human control [2]. The Society of Automotive Engineers (SAE) classifies autonomous vehicles into six distinct levels of driving automation, ranging from none to full automation. At Levels 4 and 5, these vehicles are driven almost entirely by AI, a process also known as unmanned driving [3]. Although AV-related industries and technologies are still developing and at their initial stage, the application of these vehicles is regarded as having considerable potential. Governments and the public believe these vehicles can perform successfully in promoting safety, reducing energy consumption, and improving traffic efficiency [4]. For example, the World Economic Forum (WEF) predicted that AVs would shape future urban mobility [5].

It is believed that China is experiencing one of the most rapid diffusion of AVs worldwide, with the expectation being that around 250,000 AVs equipped with Level 4 intelligence will be sold in 2034 [6]. Undoubtedly, consumer adoption is an important variable influencing this diffusion. Scholars have found that consumer adoption of AVs is driven by several factors. However, these factors may vary across cultures, market conditions, and policies. For example, studies in the USA found that environmental concerns, safety concerns, and costs contributed most to consumer attitudes towards AVs [7]. Therefore, to accelerate the diffusion of AVs in China, this study aims to identify the factors influencing consumer adoption intention and the perception-driven decision-making mechanisms behind AV adoption.

Although the Chinese AV market has attracted extensive academic research, this has primarily focused on technology development. Relatively few articles have conducted literature reviews from the perspective of consumers. Thus, the current study can bridge this gap and help determine what consumers are thinking and pursuing, as well as what they hate. It could also provide practical methods to accelerate the diffusion of this technology in China.

This study is organized as follows: In Section II, the development status of the Chinese AV market, consumer adoption intention, factors influencing consumer intention, and decision-making mechanisms involving consumer perception are presented based on the existing literature. The research questions of this study are then proposed. In Section III, the research methodology, data sources, search strategies, and screening and inclusion criteria are introduced. In Section IV and Section V, the results of two bibliometric analyses on factors influencing consumer intention to adopt AVs and consumer perception of AVs are presented and discussed. In Section VI, conclusions and implications are provided.

II. Literature Review and Research Questions

A. Development of Autonomous Vehicles in China

In 2019, McKinsey & Company [8] predicted that China would likely become the world's largest autonomous vehicle market and that two trillion dollars would have been generated in this market by 2040.

In the timeline formulated by McKinsey for the Chinese autonomous vehicle market, the adoption of Level 4 AV technology would start in 2027. In reality, this market has developed at a speed exceeding McKinsey's expectations. In 2024, China embarked on numerous pilot programs involving unmanned buses and taxis equipped with Level 4 intelligence [9].

Apart from its application in shared mobility, the automation of passenger vehicles is transitioning from Level 2

*Corresponding Author.

(partial automation) to Level 3+ (conditional automation). According to a Counterpoint report in 2024 [10], China is going to become the primary driver in enhancing machine intelligence levels, with the number of its Level 3 passenger vehicles expected to exceed one million by 2026.

In the field of logistics, the unmanned delivery business in China is developing rapidly. During the Double 11 Shopping Festival in 2023, unmanned delivery vehicles equipped with L4 autonomous driving technology were introduced in multiple cities, such as Hangzhou, delivering around 800 parcels per car each day [11].

Based on a Renub Research report in 2025 [12], the Chinese autonomous vehicle industry is exhibiting a rapidly upward trend. In 2024, the AV market size reached 17.23 billion dollars. With a CAGR of 29.01%, it is predicted that the market size will increase to 170.57 billion dollars by 2033, as shown in Fig. 1.

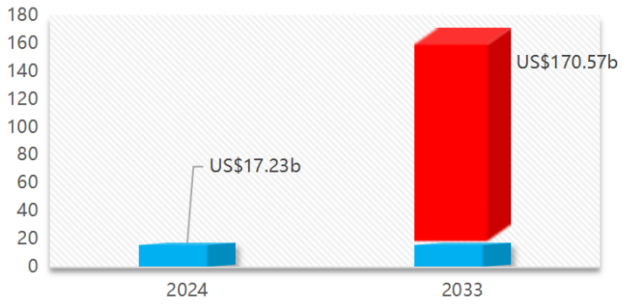

Fig. 1. Market size of autonomous vehicles in China (source: Renub Research).

B. Consumer Adoption Intention in the Chinese AV Market

Since autonomous vehicles are not yet widespread, it is challenging to obtain accurate and continuous data about the adoption intentions of consumers. However, by utilizing various commercial marketing company reports, it is possible to gain a basic understanding of consumers' attitudes in China.

Ipsos surveys from 2018 to 2022 [13], [14] demonstrated an obvious trend of increasing acceptance of autonomous vehicles in Asian countries compared to Western countries. Set against the global average, Chinese people have a higher intention to adopt autonomous vehicles. However, this intention is not exhibiting a significant upward trend.

According to these reports, the percentage of consumers in China who were willing to buy autonomous vehicles rose slightly from 46% to 51% between 2018 and 2022. This phenomenon is not an isolated case across Asia. In Malaysia, the proportion was 48% in 2018, so this country ranked second among all those surveyed. However, in 2020, only 47% of Malaysians believed that AVs would be a part of everyday life [15], as shown in Fig. 2.

C. Factors Influencing Consumer Intention to Adopt AVs

Market expectations appear to be far greater than the speed at which consumer willingness is increasing. Therefore, certain reasons must be limiting the growth of consumer adoption of AVs in China. Scholars have found that consumer adoption of AVs is influenced by many factors, including internal and external aspects.

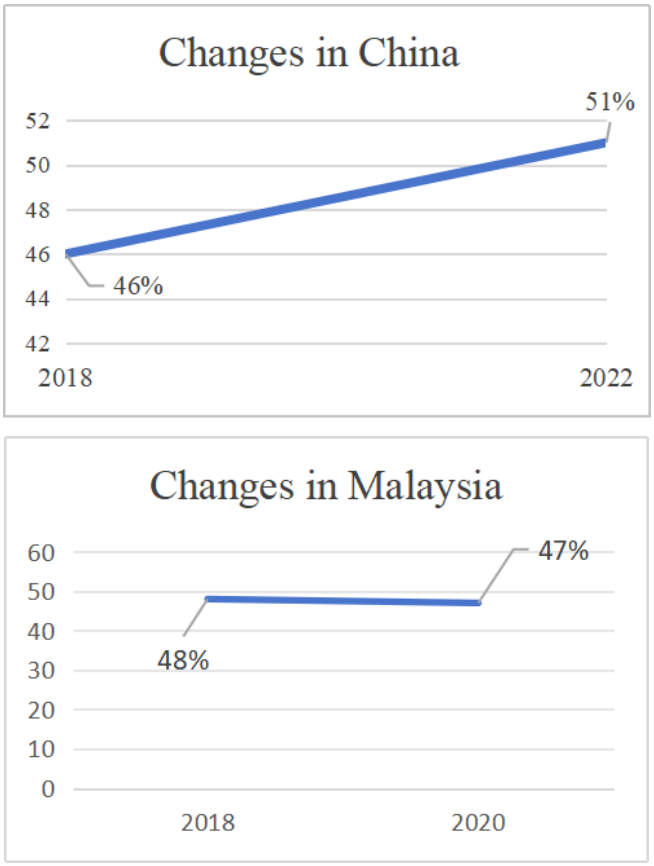

Fig. 2. Changes of intention in China and Malaysia (Source: Ipsos).

Topol š ek, Babić, Babić, and Cvahte Ojster š ek [16] revealed that the widespread adoption of autonomous vehicles was inevitable. Their research suggested that a series of factors influence consumer adoption intention of AVs, including safety, age, education levels, social influence, and consumer perceptions. Jing, Xu, Chen, Shi, and Zhan [17] investigated and compared the status of Europe and Asia, discovering that 13 factors, such as safety, influence acceptance of autonomous vehicles. On the other hand, Islam, Abdel-Aty, Lee, Wu, Yue, and Cai [18] showed that demographic traits appear to have no significant effect on consumer adoption intentions related to AVs.

A series of studies have revealed that consumer perception can explain how consumers make adoption decisions in the autonomous vehicle market. Chikaraishi, Khan, Yasuda, and Fujiwara [19] conducted a survey of public perceptions of AVs in Japan, finding that residents cared significantly more about perceived gains rather than losses in this market. This perception mechanism had obviously influenced AV acceptance in Japan. Meanwhile, Cai and Xiong [20] focused on AV-related privacy issues, revealing that when consumers faced these issues, they usually made a trade-off between perceived safety and perceived privacy risk. The scholars discovered that if consumers believed they were sharing data to improve safety, they would perceive more benefits than risks.

D. Decision-Making Mechanism with Consumer Perception

Scholars have developed a series of theories to explain the decision-making mechanisms with perceptions. Perceived Value Theory explores how humans determine their behavior based on the perceived value of goods or services, which is influenced by perceived gains and costs [21]. Bauer proposed Perceived Risk Theory, whose core idea is that any purchasing behavior involves uncertainty that makes consumers feel negatively, such as experiencing anxiety, worry, or discomfort, because individuals cannot predict the consequences of their decisions [22]. This theory focuses on the negative perceptions of consumers and how they function. The Value Acceptance Model (VAM) proposed by Kim, Chan, and Gupta clearly explains the decision-making mechanism as a trade-off between positive and negative perceptions. Its core concept is perceived value, which is determined by positive and negative perceptions [23], as shown in Fig. 3. These have been classified as perceived benefits and perceived sacrifices. The former include usefulness and enjoyment, while the latter include technicalities and fees.

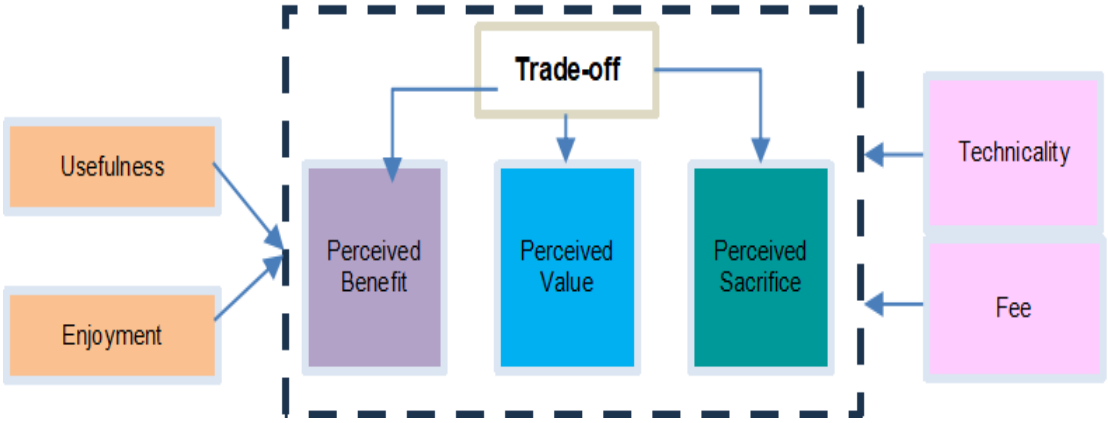

Fig. 3. Schematic representation of the VAM model.

To discover the decision-making mechanism of Chinese consumers in regard to autonomous vehicles, a deeper understanding of their perceptions is necessary. To explore the perceptions of these consumers, a bibliometric analysis was conducted.

E. Contributions of the Paper and Research Questions

The objectives of this study are to identify the intention of drivers regarding consumer adoption of AVs and understand the decision-making mechanisms behind AV adoption in China from the perspective of consumer perceptions, which would be achieved through bibliometric analysis. The study should enhance the understanding of Chinese consumer behavior within the government and enterprises, which can then propose better strategies to accelerate the diffusion of AVs.

Based on the research objective, the following research questions were proposed:

- What factors influence consumer intention to adopt AVs in China?
- In China, what are the consumer perceptions of autonomous vehicles?
- How can these perceptions influence the decision-making process of consumers?

III. Methodology

To determine the influencing factors of adoption intention and consumer perceptions of AVs in China, two bibliometric analyses were conducted using Bibliometrix [24].

A. Sources and Search Strategy

The data for both studies were extracted from the SCOPUS and IEEE Xplore databases, covering a 10-year period from 2016 to 2025. The following search keywords and rules were established for use in SCOPUS and IEEE Xplore, as shown in Fig. 4 and Fig. 5 for the two bibliometric analyses. The search string and keywords from Fig. 4 were applied to the bibliometric analysis of factors influencing consumer intention to adopt AVs in China; likewise, the search string and keywords from Fig. 5 were applied to the bibliometric analysis of consumer perception of AVs.

Database: Scopus

B. Screening and Inclusion Criteria

To ensure the selected literature focused specifically on: 1) factors influencing consumer adoption intention regarding AVs and 2) consumer perceptions, with all the studies conducted in the Chinese context, the PRISMA model was employed for systematic literature screening. The final analysis included 107 and 87 qualified publications for Study 1 and Study 2, respectively.

C. Process for Extracting Records from Databases for Study 1

Initial searches yielded 1,027 publications, with 800 from SCOPUS and 227 from IEEE Xplore. To perform a preliminary screening of the literature, restrictions were applied based on the publication year, research area, document type, and language. Only studies published in English between 2016 and 2025 and within specific document types were included. Similarly, by limiting the research areas, studies that were highly relevant to the review topic were included. According to the inclusion criteria, the number of studies was 661 from SCOPUS and 192 from IEEE Xplore. The process and results are shown in Table I.

TABLE I. PRELIMINARY SCREENING OF LITERATURE FOR STUDY 1

Filter	SCOPUS	IEEE Xplore
Publication Year	2016-2025 (n = 800)	2016-2025 (n = 227)
Research Area	Computer science; Social sciences; Engineering; Business, Management and accounting; Decision sciences; Economics, econometrics and finance; Psychology (n = 744)	Autonomous Vehicles; Human Drivers; Self-driving; Automated Vehicles (n = 192)
Document Type	Article; Conference paper; Review; Book chapter (n = 739)	Journals ; Conferences; Early Access Articles; Magazines (n = 192)
Language	English (n = 661)	English (n = 192)

To further filter out less appropriate literature, the preferred reporting items for systematic reviews and meta-analyses (PRISMA) model was employed, the process of which is shown in Fig. 6.

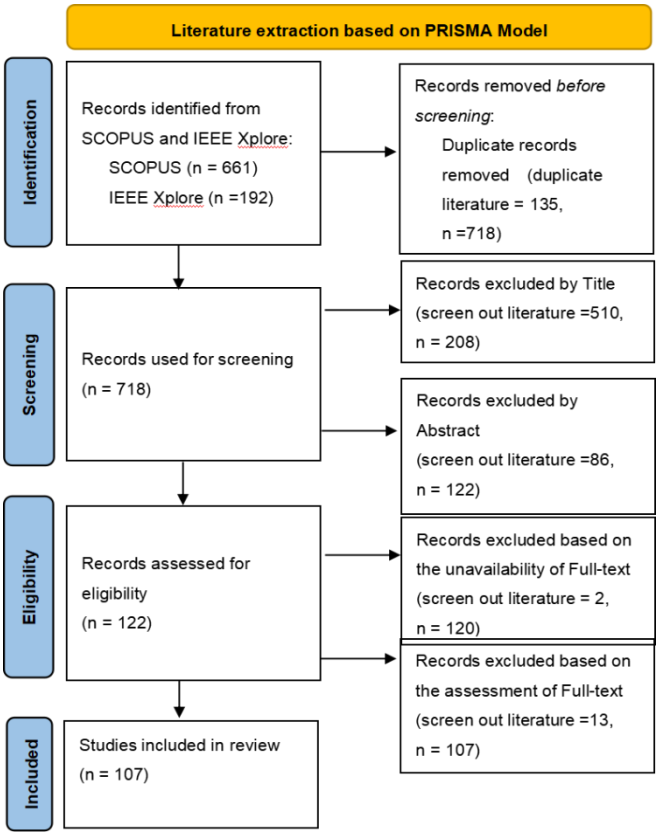

Fig. 6. Literature extraction based on PRISMA model for Study 1.

In the PRISMA Model, there were three crucial stages: identification, screening, and eligibility. At the identification stage, the records were imported into Zotero for identifying duplicate records. During the screening stage, the titles and abstracts of these studies were reviewed. Those that were not highly relevant to the review topic were excluded. At the eligibility stage, based on a full-text review, the studies were assessed. The studies of high quality were included.

After the screening process, 107 studies were selected and included in the subsequent analysis. Conducted over the past 10 years, they focused on factors influencing Chinese consumer adoption intention regarding autonomous vehicles.

D. Process for Extracting Records from Databases for Study 2

Initial searches yielded 890 publications (753 from SCOPUS and 137 from IEEE Xplore). Based on the publication year, research area, document type, and language, the literature was subjected to preliminary screening. We included studies published in English between 2016 and 2025 and within specific document types. Likewise, we selected studies highly relevant to the review topic by applying restrictions on research area. According to these inclusion criteria, 627 studies from SCOPUS and 123 from IEEE Xplore were selected. The process and results are shown in Table II. The PRISMA model was utilized to further screen for appropriate literature, with the process shown in Fig. 7.

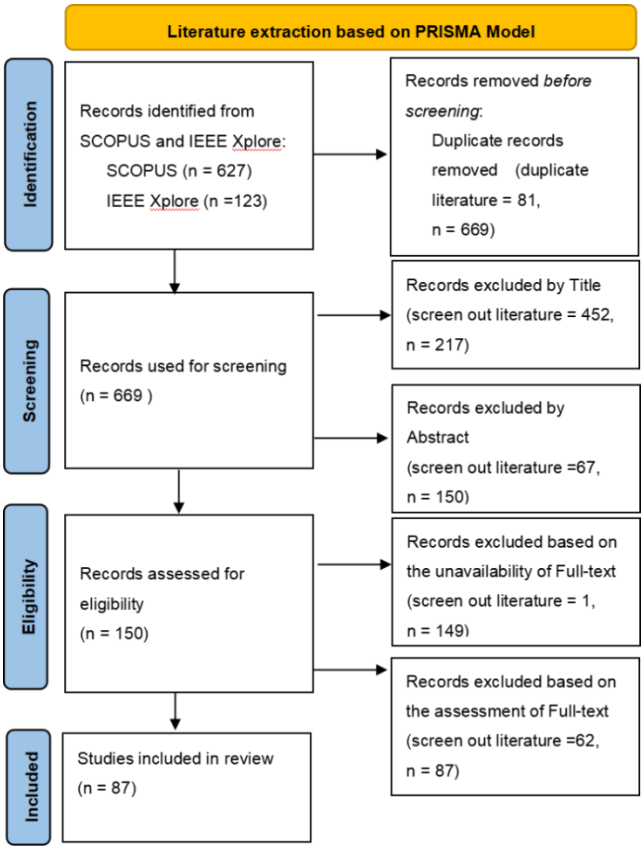

Fig. 7. Literature extraction based on PRISMA model for Study 2.

The studies were selected through three phases: identification, screening, and eligibility. At the identification stage, 750 records were imported into Zotero, and the duplicate records were excluded. During the screening stage, we reviewed the titles and abstracts of these studies and excluded those that were not highly relevant to the review topic. During the eligibility phase, we assessed the quality of these studies based on a full-text review.

After filtering, 87 studies were included in the following analysis. Conducted over a decade, they focused on Chinese consumers' perceptions of autonomous vehicles.

TABLE II. PRELIMINARY SCREENING OF LITERATURE FOR STUDY 2

Filter	SCOPUS	IEEE Xplore
Publication Year	2016-2025 (n = 753)	2016-2025 (n =137)
Research Area	Computer science; Engineering;social sciences; Business, management and accounting; Decision sciences; Economics, econometrics and finance; Psychology Neuroscience (n = 717)	Autonomous Vehicles;Human Drivers;Self-driving;Automated Vehicles(n = 124)

IV. BIBLIOMETRIC ANALYSIS: FACTORS INFLUENCING CONSUMER INTENTION TO ADOPT AVS

A. Word Frequency Analysis

Table III shows the frequency and ranking of keywords related to the factors influencing the intention to adopt AVs in the existing literature. According to the results, perception plays a crucial role in influencing consumer adoption intention. The keywords related to perception appear more than 20 times, especially “perceived risk”, which is mentioned 10 times.

The high academic attention devoted to shared autonomous vehicles in China (related concepts were mentioned 13 times, as shown in Table III) demonstrates that consumers have begun to try specific categories of AVs.

The intelligence level of AVs, which is decided by the artificial intelligence with which a car is equipped, proved to be a key factor in consumer adoption intention (“highly autonomous vehicle” appears five times and “artificial intelligence” appears three times). However, AI is not merely a promoting factor in the consumer decision-making mechanism. On the one hand, it can improve consumers’ interest in AVs by making these vehicles smarter and more useful; on the other hand, Chinese consumers are concerned about the effects of anthropomorphism, which may confirm the existence of the uncanny valley theory [24], [26] in the field of autonomous vehicles.

TABLE III. MOST FREQUENT KEYWORDS RELATED TO INFLUENCING FACTORS FOR ADOPTION INTENTION

Words	Occurrences
Shared autonomous vehicle	13
Perceived risk	10
trust	8
Perceived safety	6
Highly autonomous vehicle	5
Perceived value	5
Artificial intelligence	3
Anthropomorphic	2
Covid-19	2
Culture and psychology	2
Mass media	2
Perception	2
Safety	2
Self-efficacy	2
Social influence	2

To increase the intention to adopt AVs among Chinese consumers, internal factors such as building trust (“trust” appeared eight times) and improving self-efficacy (“self-efficacy” was mentioned twice) are very important.

External factors also play an important role. The adoption intention regarding AVs can change due to specific situations, such as the COVID-19 pandemic. Moreover, Chinese culture and psychology, publicity from mass media, and social

influence considerations can influence consumers' behaviors toward AVs.

B. Trend Topic Analysis

According to the changing research trends on topics related to influencing factors shown in Fig. 8, consumer perception emerged as the most extensively researched topic in recent studies examining factors influencing consumer intentions, especially in relation to perceived risk, value, and safety.

Shared autonomous vehicles maintained high popularity and peaked in 2023, but they showed a declining trend in the following year. In contrast, discussions about highly autonomous vehicles have been steadily gaining momentum. This might be a result of recent large-scale pilots of Level 4 autonomous public transportation systems, which have helped change AVs from a concept to reality in consumers' cognition. Many forms of shared autonomous vehicles in China have high intelligence, such as unmanned buses, unmanned taxis and shared school buses. Due to their capacity to reduce driver costs and parking demands, these options are predicted to become the main transportation modes of the future [25].

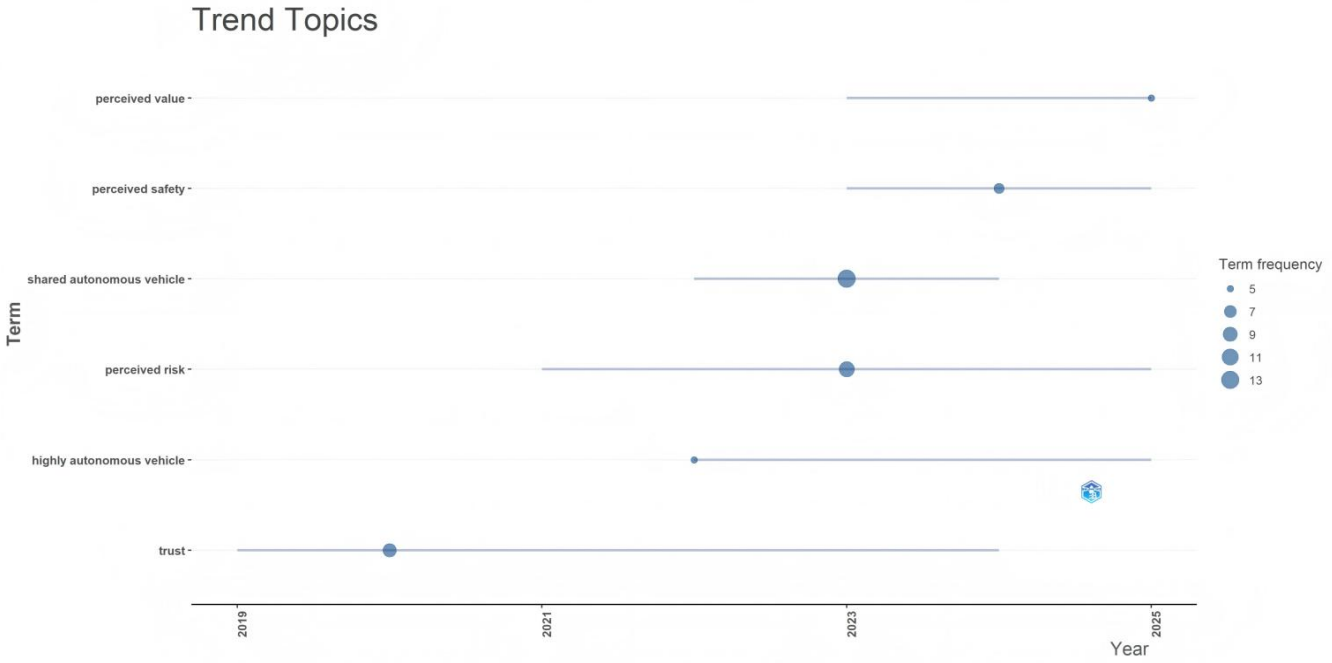

Fig. 8. Trend topics of influencing factors for adoption intention.

V. Bibliometric Analysis: Consumer Perception of AVs

A. Word Cloud Analysis

Fig. 9 shows that for articles related to China published between 2016 and 2025, a large number of consumers' perceptions were related to perceived risk. Words like "perceived usefulness" and "perceived benefit" are also mentioned frequently, according to Fig. 9, but at significantly lower frequency than "perceived risk". The figure also reveals that perceived safety is the category considered most among all the perception dimensions.

The Word Cloud Analysis of keywords also reveals that both internal and external factors are correlated with perceptions. From the perspective of internal factors, attitudes, trust, and demographic characteristics (terms such as 'female,' 'male', and 'adult') contribute the most. From the perspective of external factors, the most important roles are played by social media, as well as economic and social impacts.

Fig. 9 also indicates that current academic research mainly relies on surveys and questionnaires as research tools.

B. Frequency of Words over Time

To better explore how Chinese consumers make decisions based on perceptions, the synonym tool in the Bibliometrix was used to categorize keywords by theme. Frequency analysis over time was conducted related to consumer perceptions in the Chinese autonomous vehicle market, as shown in Fig. 10. This study grouped words about negative factors (like "perceived risk", "perceived cost", and "perceived loss") as "perceived loss", while positive words (like "perceived benefit", "perceived usefulness", and "perceived gain") were grouped as "perceived gain".

This analysis demonstrates a clear relationship between perceived gain and perceived loss. Although the frequencies of these two concepts were close to each other in 2018, they indicated different trends thereafter. The cumulative occurrence of "perceived gain" remained stable from 2020, while that of "perceived loss" obviously increased during the same period, surpassing that of "perceived gain" in 2022. Perceived safety, as the most-frequently considered dimension of perceptions, also revealed a significant upward trend since 2020, surpassing "perceived gain" in 2024.

Fig. 9. Word cloud of keywords related to consumer perception.

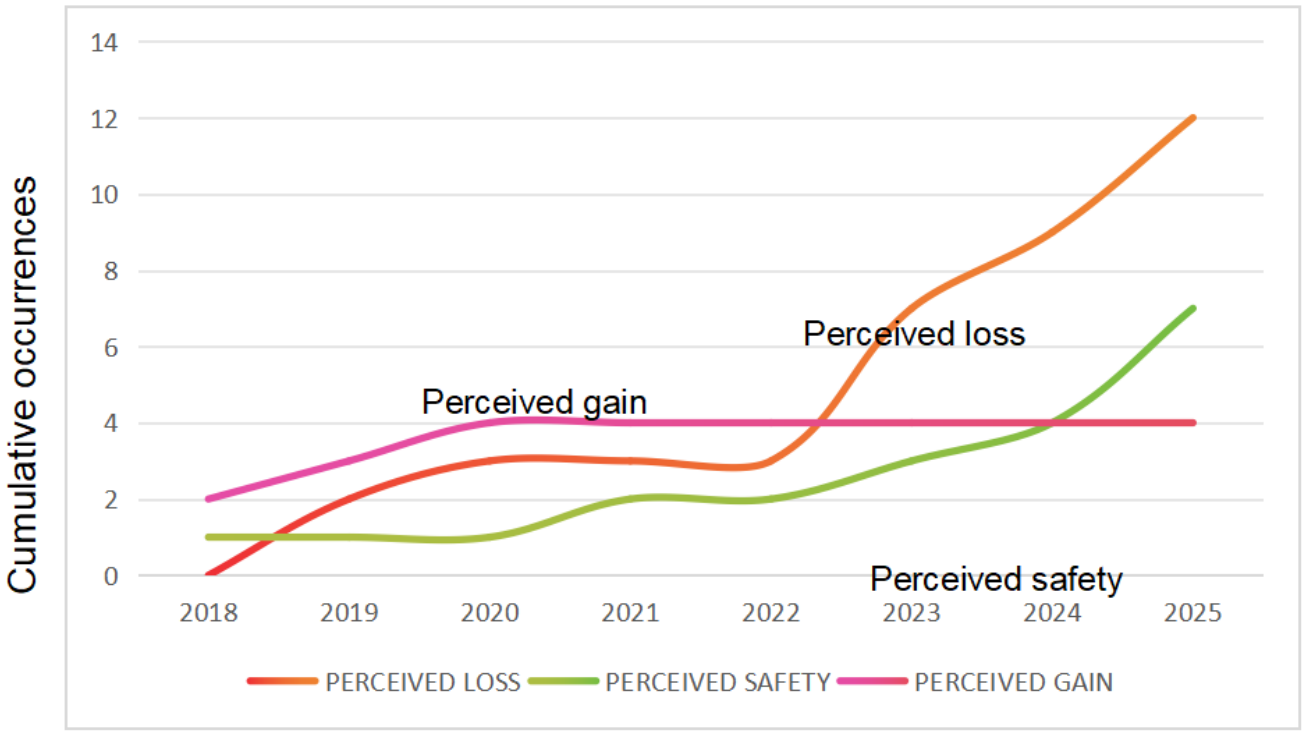

Fig. 10. Keywords' frequency over time related to consumer perception.

C. *Keyword Co-occurrence Network*

Fig. 11 shows a co-occurrence network related to Chinese consumers' perceptions of the autonomous vehicle market. On the one hand, it demonstrates strong relationships among perceived loss, perceived safety, traffic accidents, and demographic characteristics. The results suggest that Chinese residents, including different gender and age groups (female, male, young adults, middle-aged adults, and aged people), are more concerned about traffic risks caused by AVs than the safety they bring. This result is also an evidence proving that Chinese consumers are more sensitive to losses than to gains.

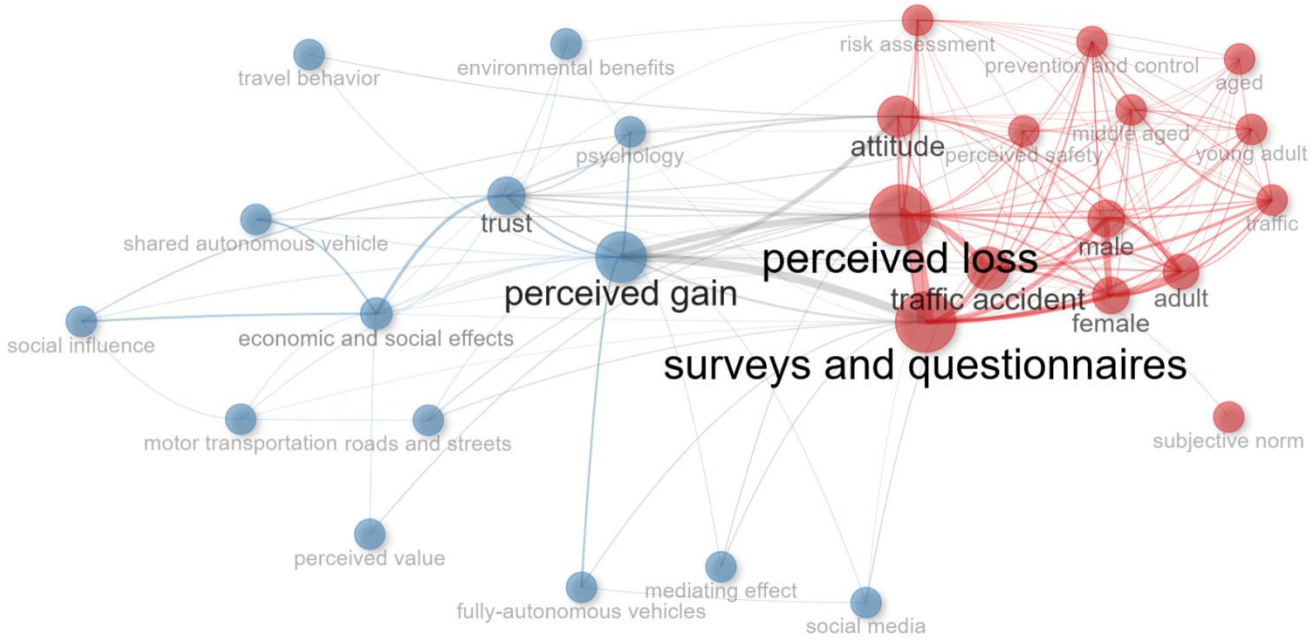

Fig. 11. Co-occurrence network related to consumer perception.

Furthermore, Fig. 11 shows that perceived gain has deep connections with economic and social effects, environmental benefits, and social influence in China. The term "share autonomous vehicle" is also in this category. This means that Chinese consumers develop more positive perceptions if they believe that, first, AVs can benefit society and the environment and, second, that taking shared autonomous vehicles is a reasonable and attractive option.

VI. Conclusion and Implications

In conclusion, the study has resolved all the research questions and demonstrates several points.

Through bibliometric analysis, numerous factors were found to influence Chinese consumers' adoption intention regarding AVs, including perception, intelligence level, trust, and certain external factors. Consumer perception seems the most important factor. The subsequent bibliometric analysis indicated the perception mechanism of Chinese consumers. The results showed that they judged perceived loss to be more serious than perceived gain. These consumers also showed significant concerns about perceived safety and the influence of AVs on both society and the environment.

Theoretically, this study systematically integrates literature on consumer adoption of AVs in the specific area of China, thus bridging a knowledge gap. In practical terms, this study can improve how governments and enterprises understand the behaviors and decision-making mechanisms of Chinese consumers in the autonomous vehicle market, thereby accelerating the diffusion of autonomous vehicle technology.

By reviewing the existing literature, we have identified the main trends and significant research gaps in the autonomous vehicle field in China.

First, there is a strong focus on shared autonomous vehicles. As one of the crucial application scenarios of AVs, it has received significant academic attention. However, based on the diffusion of innovation theory, purchasing and owning private AVs are also vital factors influencing the development of the Chinese AV market. Moreover, there is a need to expand the use cases for shared autonomous vehicles, not limited to school buses or robo-taxis.

Second, most empirical methods and tools for measuring consumer perceptions remain surveys and questionnaires. However, overreliance on this method could introduce biases, such as self-report bias, intention-behavior gap, and social desirability bias. Higher quality scales need to be developed, and additional empirical methods need to be applied in this field.

This study proposes that future research should expand the application scenarios of AVs, especially for private AVs and use cases for shared AVs, such as applications in rural areas. Additionally, other empirical methods, such as longitudinal studies and mixed methods, should also be used in this area to reduce bias.

Due to the limitations caused by the brief development duration of the autonomous vehicle industry and the geographical scope of this research, the number of documents included in the two bibliometric analyses were relatively small. Future research will aim to add other relevant documents, such as government reports, to provide stronger support for the conclusions. Additionally, empirical methods will be used to strengthen the conclusions in the future.

RA-ACS_net Network: A Quantum Optical Reconstruction Method for Ultra-high Resolution Bioimaging

Lin SHANG*
School of Electronics and Information Engineering, Wuhan Technical College of Communications, Wuhan 430065, Hubei, China

***Abstract*—Ultra-high resolution bioimaging based on quantum optics offers high sensitivity at relatively low cost, yet conventional reconstruction algorithms face challenges of excessive sampling time, long computation, and artifacts that limit imaging quality. To overcome these issues, this study proposes a novel quantum optical bioimaging reconstruction method termed RA-ACS_net, which integrates a ripple algorithm with a hybrid attention mechanism network. The ripple algorithm provides global optimization for network parameter adjustment, while the attention mechanism enhances feature extraction and information fusion. Furthermore, a differentiated loss function (ALoss) is designed to preserve fine structural details and improve visual fidelity compared with conventional MSE loss. A large-scale dataset of quantum optics-based bioimages is employed for training and validation. Experimental results demonstrate that RA-ACS_net achieves superior reconstruction performance, with significantly higher PSNR and SSIM across both low and high sampling ratios, when compared to iterative algorithms (TVAL3) and existing deep learning models (DR2-Net, DPA-Net). The proposed approach exhibits robustness under sparse data conditions, reduces blocking artifacts, and accelerates convergence, thereby addressing critical limitations of current methods. This study highlights the potential of combining quantum optics with advanced deep learning optimization strategies to establish a practical and efficient framework for ultra-high resolution bioimaging.**

Keyword*—*Ultra-high resolution bioimaging; quantum optics; computer vision; ripple algorithm; attention mechanism

I. Introduction

Bioimaging techniques are the cornerstone of modern biological and medical research, enabling us to observe and understand the structure and function of living systems at the molecular, cellular and tissue levels [1]. However, traditional imaging techniques, such as fluorescence microscopy and electron microscopy, are limited by diffraction limits and imaging speeds, making it difficult to meet the demand for high-resolution and highly dynamic imaging of biological systems [2]. In recent years, the rapid development of quantum optics and computer vision technology has provided the possibility to break through these limitations [3]. Quantum optics, especially single-photon detection technology and quantum entanglement, provides a means for bioimaging to go beyond the traditional diffraction limit; while computer vision technology, on the other hand, shows great potential in processing and analysing massive biological image data [4]. Therefore, it is very meaningful to study the integration method between ultra-high resolution bio-imaging, quantum optics and computer vision techniques, especially the use of deep learning techniques to generate models for ultra-high resolution bio-imaging image reconstruction [5].

With the application and development of quantum optics and computer vision technology in the field of bio-imaging, the research on quantum optics and computer vision technology for ultra-high resolution bio-imaging has also attracted the attention of experts and scholars in the field [6]. Currently, the research on the application and integration of quantum optics and computer vision technology in the field of bio-imaging mainly includes the application of quantum optics in bio-imaging, bio-imaging reconstruction based on machine vision, and bio-imaging image feature extraction and recognition [7]. This study focuses on the ultra-high resolution bio-imaging reconstruction problem by fusing quantum optics, and analyses a large number of literature. Currently, there are three main methods for sampling and reconstruction of quantum optics bio-imaging systems: 1) Under-sampling using a random measurement matrix or an orthogonal fixed matrix first, and then using iterative algorithms to reconstruct the images. Chong and Pramanik [8] use Gaussian measurement matrices to undersample the bioimaging, and orthogonal matching tracking method is used to reconstruct the image; Wanas et al, [9] use the full-variance generalised Lagrangian alternating direction algorithm as an iterative algorithm to reconstruct the bioimaging; 2) using Gaussian random measurement matrices or orthogonal fixation matrices for under-sampling, but using the deep learning-based reconstruction network to reconstruct the image. Yao et al. [10] proposed DR2-Net based on ReconNet, which solves the problem of degradation of reconstructed image accuracy due to the excessive depth of the network; Sun et al. [11] proposed a dual-path attentional network DPA-Net for compressed perceptual image reconstruction, which consists of a structural path, a texture path, and a texture-attentional module; and 3) using a deep learning network that integrates sampling and reconstruction. A sampling and reconstruction integrated residual codec network SRIED_Net was proposed in the literature [12] and used in a quantum optical bio-imaging system, where the results showed that the network reconstructs quickly and obtains better reconstruction performance. The current network reconstructs the image resulting in blocking of the reconstructed image, which reduces the reconstruction accuracy of quantum optics-based high-resolution bioimaging.

Aiming at the problems of the current high-resolution bio-imaging reconstruction network based on quantum optics, this study proposes a ripple algorithm to optimise the attention mechanism network for quantum optics high-resolution bio-imaging reconstruction method. Firstly, the problem of quantum optics application for ultra-high resolution bio-imaging, secondly, combining the ripple algorithm [13] and attention mechanism [14], the RA-ACS_net reconstruction network is proposed, and finally, the effectiveness and efficiency of the RA-ACS_net reconstruction network are verified by using high-resolution bio-imaging data based on quantum optics.

The main novelty of this study lies in the integration of the ripple algorithm with a hybrid attention mechanism network to address the limitations of existing quantum optical bioimaging reconstruction methods. Unlike traditional iterative algorithms and standard deep learning frameworks that often suffer from long reconstruction times, blocking artifacts, and limited robustness, the proposed RA-ACS_net model introduces an optimized parameter adjustment process guided by ripple-based global search. In addition, a novel differentiated loss function, ALoss, is designed to preserve structural details and enhance perceptual quality beyond the performance of conventional MSE. Experimental results on quantum optical bioimaging datasets demonstrate that the RA-ACS_net network significantly outperforms state-of-the-art models under both low and high sampling ratios, achieving higher PSNR and SSIM values. This methodological advancement not only improves reconstruction accuracy and robustness but also offers a practical pathway for bridging quantum optics and advanced computer vision in ultra-high resolution bioimaging.

The full study is structured as follows: firstly, the application of quantum optics in bio-imaging is analysed in detail in Section II, including single photon detection technology, quantum entanglement imaging and its practical application in biological systems. The design and realisation of the quantum optical bio-imaging system is presented, focusing on the core devices of the system and their working principles. In Section III, the RA-ACS_net reconfiguration network is proposed, and the reconfiguration network is optimised by combining the ripple algorithm and the attention mechanism. The bio-imaging reconstruction approach is presented in Section IV. Section V verifies the performance enhancement of the method proposed in this study in quantum optical bio-imaging through experimental comparison, and finally, Section VI summarises the research results of this study and provides an outlook on the future research direction.

II. Quantum Optics for Ultra-High Resolution Bioimaging Analysis

A. Quantum Optics in Biological Imaging

1) Single-photon detection technology: Single-photon detection technology takes advantage of the quantum properties of photons and is able to detect a single photon as a unit, thus achieving high-precision imaging under very low light intensity conditions [15], as shown in Fig. 1. In biological imaging, this technique is particularly suitable for fluorescently labelled single-molecule imaging, which can obtain high-resolution structural information while maintaining cellular activity.

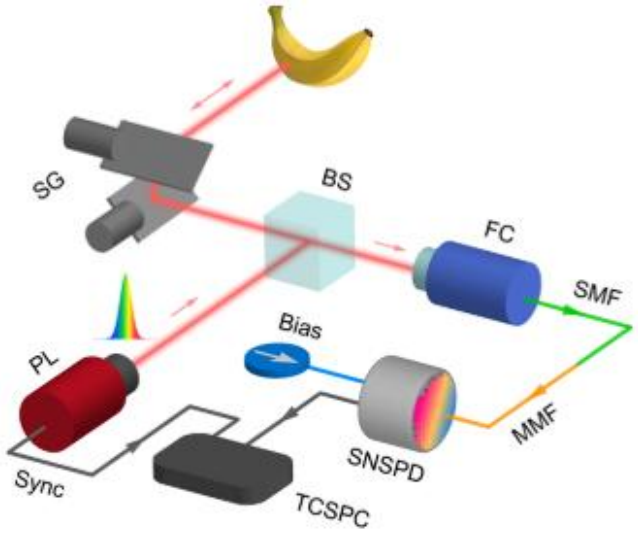

Fig. 1. Single-photon detection technology.

2) Quantum entanglement and imaging: Quantum entanglement [16] is a fundamental concept in quantum optics, where two or more particles are interdependent on each other in their quantum states, and even if there is a great distance between them, measurements on one of the particles will instantly affect the state of the other, and the schematic diagram of the principle of quantum entanglement is shown in Fig. 2.

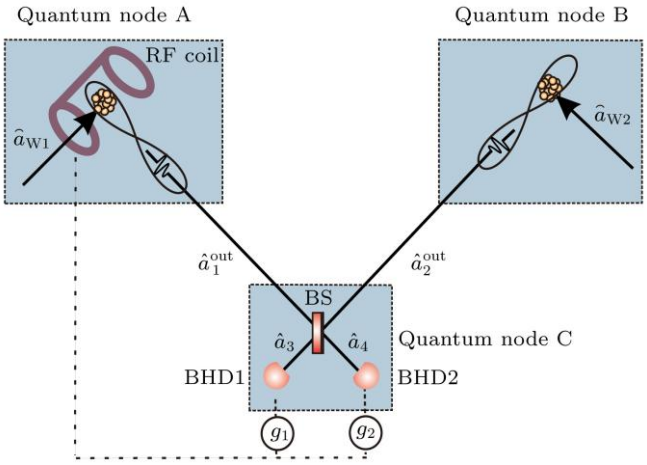

Fig. 2. Quantum entanglement.

Using the properties of quantum entanglement, a super-resolution quantum imaging system can be designed (Fig. 3) to achieve high-resolution imaging beyond the diffraction limit.

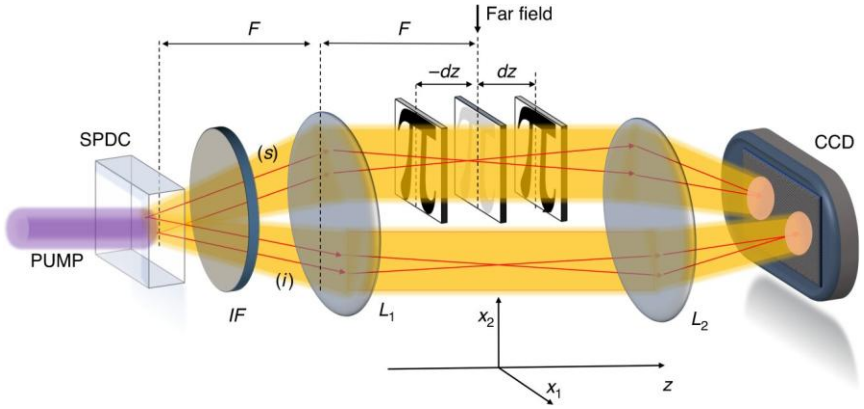

Fig. 3. Quantum imaging system.

3) Quantum optics in bioimaging: Quantum optical techniques show great potential in the field of bio-imaging due to their unique quantum coherence and entanglement effects. These techniques can significantly improve the resolution and sensitivity of imaging beyond the limits of conventional optical physics. Quantum imaging techniques using entangled photon pairs and single-photon detection can enable the observation of virus-sized cellular tissue structures as well as nanoscale defects in insulator materials, with specific applications analysed, as shown in Fig. 4.

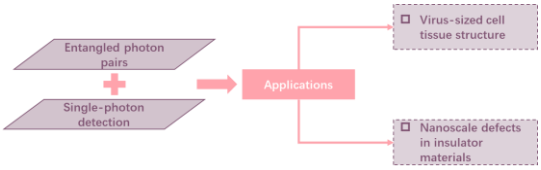

Fig. 4. Application of quantum optics in bio-imaging.

B. Quantum Optical Bio-Imaging System

Quantum optical bio-imaging systems utilise quantum coherence and entanglement effects to improve the resolution and sensitivity of imaging beyond the limits of conventional optical physics [17]. The research object of this study is the quantum optical single-pixel imaging system, which is shown in Fig. 5.

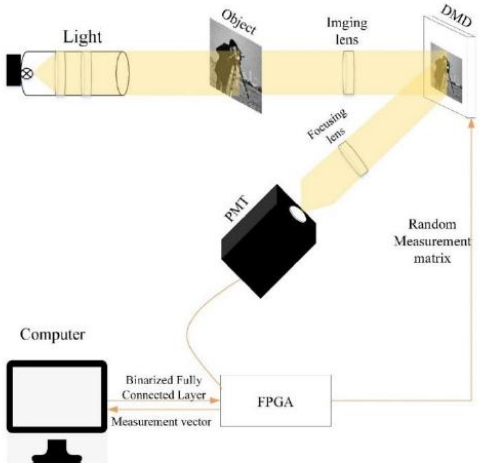

Fig. 5. Quantum optical single-pixel imaging system.

This study builds a quantum optical bio-imaging system whose core devices mainly contain a parallel single-photon source, a digital micromirror device DMD, and a single-photon detector PMT.

1) Parallel single photon source: In order to reduce the impact of light source scattering on the imaging results, this study designs a parallel single-photon source that can output a very weak parallel light, with a specific structure principle, as shown in Fig. 6.

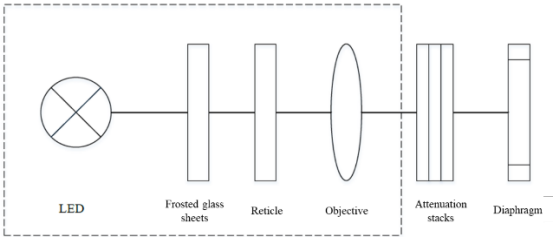

Fig. 6. Structure of parallel single-photon source.

2) Digital micromirror device DMD: Photonic single-pixel imaging schemes mainly implement spatial light modulation technology through spatial light modulators [18]. The electrically addressed spatial light modulator DMD used in this study has the advantages of high brightness, high reliability, simplified working circuit and high contrast, and its specific structure is shown in Fig. 7. The parameter settings of the DMD development board used in the experimental system of this study are shown in Table I.

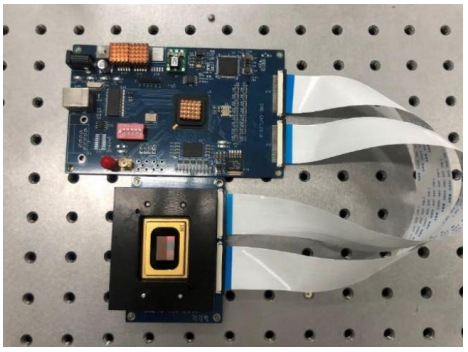

Fig. 7. Structure of DMD development board.

TABLE I DMD OPERATING PARAMETERS

Sports event	Setting parameters
resolution (of a photo)	1024×768
Micromirror size	13.68μm×13.68μm
Flip angle	±12°
frame rate	3000Hz
degree of contrast	2000:1
operating band	350nm~2700nm
synchronisation	Internal synchronisation, external synchronisation
random access memory (RAM)	DDR2

3) Single-photon detector PMT: The photon-counting single-pixel imaging system utilises a detector with a single-photon response to achieve the quantification of modulated light intensity. In this study, PMT is chosen as a single-photon detector, which is mainly composed of a photocathode, a collection anode and an electron multiplier pole, and its internal structure is shown in Fig. 8:

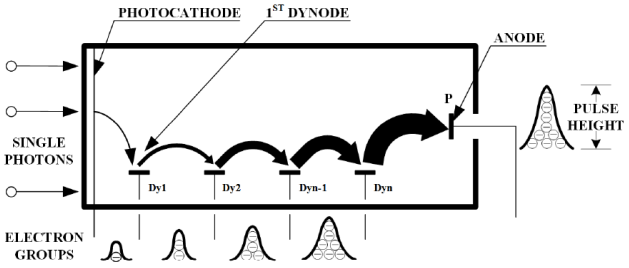

Fig. 8. PMT schematic.

C. Quantum Optical Bioimaging Reconstruction

In quantum optical bio-imaging systems, the traditional iterative reconstruction algorithms, although capable of accurately reconstructing the target image, have high time complexity, especially for large resolution images, where the reconstruction time is exponentially multiplied. In order to improve the efficiency of image reconstruction, ReconNet, as a neural network for reconstructing compressed perceptual images, was introduced into the quantum optical bioimaging reconstruction problem [19].

The structure of the ReconNet network is shown in Fig. 9. ReconNet consists of an upsampling module and an image enhancement module. The upsampling module contains one fully connected layer, and the image enhancement module contains six convolutional layers, each of which is post-positioned with a ReLU activation function to perform a nonlinear transformation.

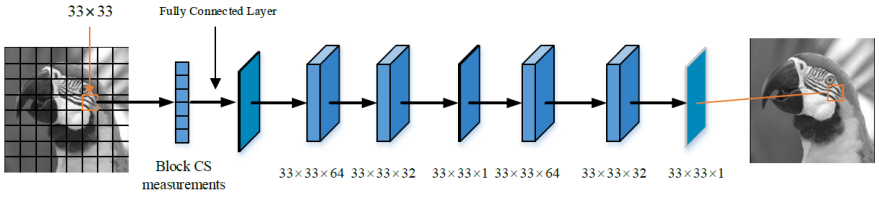

Fig. 9. ReconNet structure.

III. RA-ACS_NET RECONFIGURATION NETWORK

In order to improve the accuracy and efficiency of ultra-high resolution bio-imaging reconstruction based on quantum optics, this study uses the ripple algorithm to optimise the attention mechanism network and construct the RA-ACS_net reconstruction network.

A. Network of Attention Mechanisms

In order to reduce the computational burden of the reconstruction network and make full use of the image summary to give important information, this study adopts the attention mechanism [20] to construct the image reconstruction network and improve the image reconstruction effect. Attention mechanism network is divided into Hard Attention mechanism (Hard Attention) and Soft Attention mechanism (Soft Attention). According to the classification of attention mechanism structure and function, the attention mechanism network can be divided into Channel Attention Mechanism, Spatial Attention Mechanism and Hybrid Attention Mechanism, and the specific structure schematic is shown in Fig. 10.

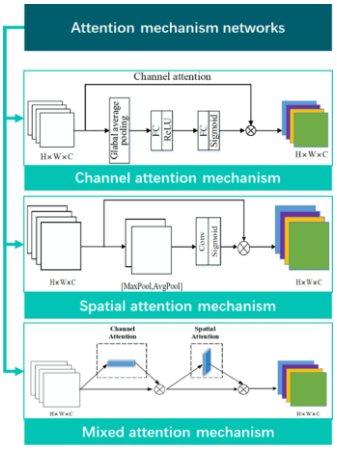

Fig. 10. Classification of attention mechanisms.

Inspired by the hybrid attention mechanism, this study adopts an attention mechanism network based on residual neural network, i.e., ACS_net, and the specific network structure is shown in Fig. 11. As can be seen from Fig. 11, ACS_net contains a picking sub-network and a deep reconstruction sub-network.

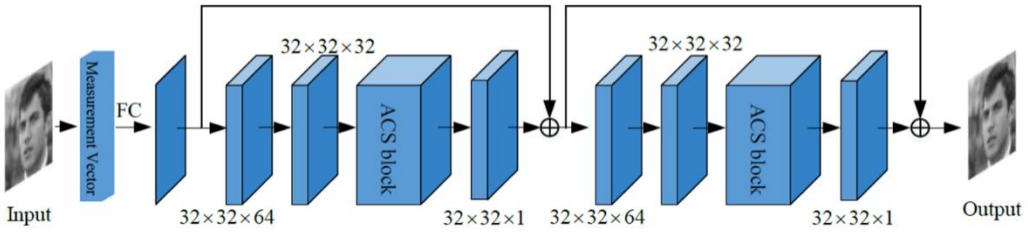

Fig. 11. ACS_net structure.

In the sampling network part, considering the screening of the input image information to ensure the completeness of the input information, ACS_net adopts the full connection layer to sample the original image to ensure the completeness.

In the deep reconstruction subnetwork part, ACS_net employs two residual blocks [21] to achieve the combination of lower-order features with higher-order features through jump connections. Each residual block contains a hybrid attention mechanism module (ACS_block) [22] and three convolutional layers. The structure of ACS_block is shown in Fig. 12, in which two convolutional layers are front-loaded, and then Batch Normalizaition is performed on these two convolutional layers, followed by a nonlinear transformation of the input feature maps through the activation function ReLU; finally, the input features are processed using the convolutional layers and the image reconstruction results are obtained.

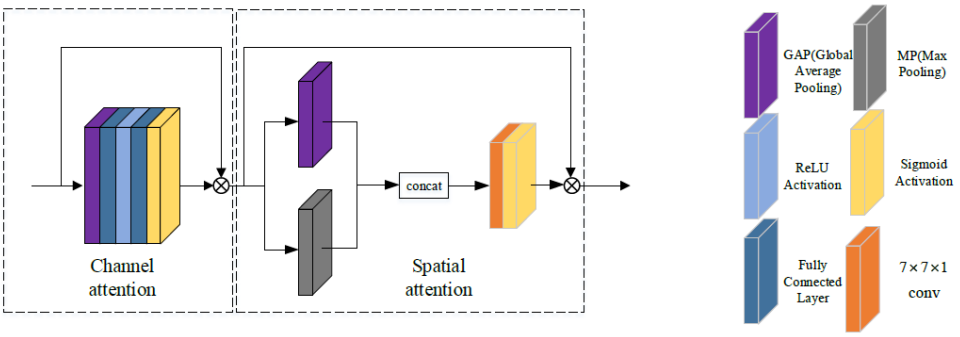

Fig. 12. Structure of the attention mechanism module.

In order to improve the overall performance of the model, this study designs a new loss function, namely ALoss (Attention Loss), which is calculated as follows, Eq. (1):

$$ALoss = \alpha \times \frac{1}{N}\sum_{i=1}^{N}\left\|x_i' - x_i\right\|^2 + \beta \times \frac{1}{N}\sum_{j=1}^{N}\left\|x_j'' - x_j\right\|^2 \quad (1)$$

where, x_i and x_j are the pixel values of the important and non-important regions of the original image block, x_i' and x_j'' are the pixel values of the important and non-important regions of the image recovered by the neural network, α and β are the scaling coefficients of the loss function, and N is the number of pixel points in the focal and non-focal regions of the image.

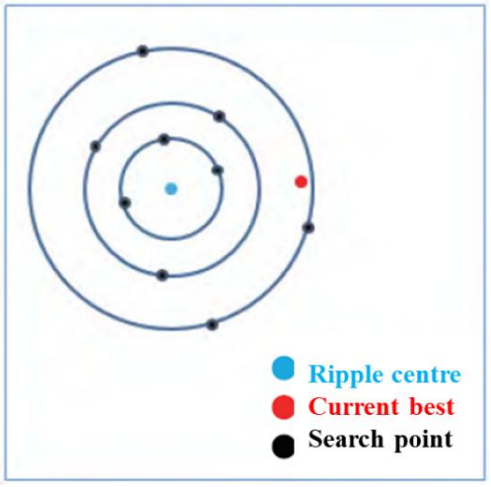
B. Ripple Algorithm

Ripple Algorithm (RA) is an optimization algorithm that simulates the phenomenon of ripple propagation in nature [13]. The RA algorithm has two features:

- The centroid adopts the ripple region search based on the current fitness and the global optimal fitness, which has stronger global search capability.
- The centroid searches relatively independently with the current optimal solution, and converges to the global optimal solution in a passive manner.

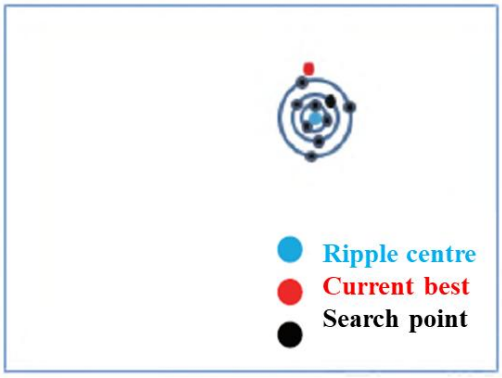
According to the characteristics of the ripple algorithm, this study performs a multi-layer ripple random point taking search with each centre point and calculates the random point adaptation value. The RA algorithm mainly includes two aspects of the search capability, i.e., exploration and exploitation, and the specific search schematic is shown in Fig. 13.

The multi-layer ripples are calculated by taking random points, as follows in Eq. (2):



$$X_i^{km} = X_i + r \times R_i^k \quad (2)$$

where, X_i^{km} denotes the mth random search point in the kth layer of the ith centroid, X_i is the ith centroid, R_i^k is the radius of the kth layer of the ith centroid, and r is an n-dimensional random unit vector.



The ripple radius of each centre point is based on the gap between the current fitness and the global optimal fitness, the larger the gap, the larger the ripple radius and the wider the search area, and the smaller the gap, the smaller the ripple radius and the smaller the search area. The equation for calculating the ripple radius is as follows in Eq. (3):

$$R_i^1 = \log_\alpha \left(\frac{\sigma_i}{\sigma_{\max}} \right) \times \beta \tag{3}$$

where, α is the base of the logarithmic function and $\alpha \in (0,1)$; $\sigma_{\max}$ denotes the global maximum fitness value.

(a) Exploration

(b) Development

Fig. 13. RA algorithm search.

Comparing each centroid with its corresponding random point in the ripple layer, the point with the best fitness value is retained to form a new centroid cluster. Each centroid searches for the optimal point relatively independently rather than actively approaching the current optimal point, and the centroid cluster eventually converges to the optimal point as the iteration proceeds with the shrinkage function decreasing. The centre point update is calculated as follows in Eq. (4):

$$X_i^{t+1} = opt\left(X_i^t, X_i^{11}, \cdots, X_i^{km}, \cdots, X_i^{3M} \right) \tag{4}$$

where, X_i^{t+1} is the ith centroid of the centroid cluster in generation t+1, X_i^t is the ith centroid of the centroid cluster in generation t, X_i^{km} is the mth search point in layer k corresponding to the ith centroid, and M is the number of randomly taken points for each layer of ripples.

C. RA-ACS_Net Network Model

In order to improve the efficiency of ACS_net network reconfiguration, this study adopts the RA algorithm to optimise the ACS_net network parameters. The RA algorithm takes the ACS_net network parameters as the optimisation variables, MSE as the optimisation fitness function, and adopts the iterative process of the RA algorithm as the optimisation strategy, and the specific model construction is shown in Fig. 14.

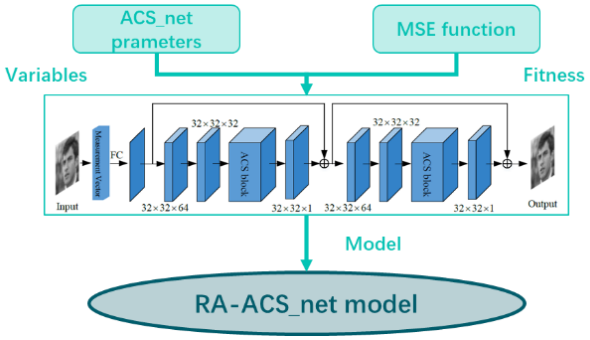


Fig. 14. RA-ACS_net network model construction diagram.

IV. BIO-IMAGING RECONSTRUCTION APPROACH

In order to improve the efficiency and accuracy of the fusion quantum optics ultra-high resolution bio-imaging reconstruction method [23], this study proposes a fusion quantum optics ultra-high resolution bio-imaging reconstruction method based on RA-ACS_net. The method combines quantum optics, constructs an ultra-high resolution bio-imaging system, optimises the ACS_net network parameters using the ripple algorithm, and constructs a bio-imaging reconstruction method based on the RA-ACS_net network model. The specific method flow is shown in Fig. 15.

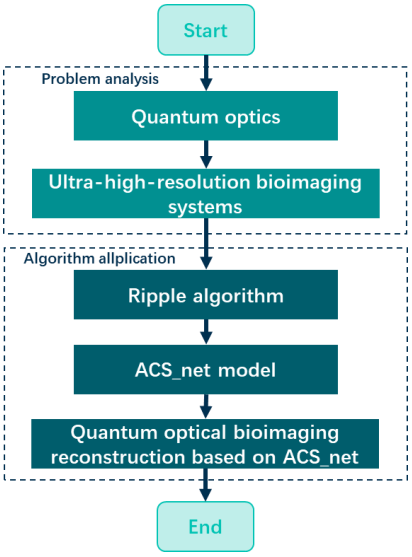

Fig. 15. Application of RA-ACS_net model in quantum optical bio-imaging.

V. Analysis of Results

In order to verify the efficiency of the RA-ACS_net reconstruction network proposed in this study, this study collects 19872 quantum optics-based bio-imaging images as the training set, and 128 bio-imaging images as the dataset for the training set to verify the performance of the network. For comparative analysis, this study firstly investigates the performance of different attention mechanism networks based on the RA algorithm in bio-imaging image reconstruction algorithms, secondly investigates the effect of different loss functions on reconstruction networks, and finally verifies the performance of the attention mechanism in quantum optics-based bio-imaging.

A. Comparative Experiments on Networks with Different Attention Mechanisms

In order to evaluate the effect of the attention mechanism on the reconstruction network models proposed in this study, controlled experiments are designed in this section to compare the reconstruction performance of the four reconstruction network models. The comparison algorithms used in the different attention mechanism network comparison experiments are shown in Table II. The results of the experiments of different attention mechanism network modules are shown in Fig. 16.

TABLE II Parameter Settings of the Algorithm

Arithmetic	Algorithm setup
RA-CS_net	Removal of the Attention Mechanism module and optimisation of the CS_net parameter using the RA algorithm
RA-ACS_net_V1	Contains only the Channel Attention Mechanism module, which uses the RA algorithm to optimise the ACS_net_V1 parameter
RA-ACS_net_V2	Contains only the Spatial Attention Mechanism module, which uses the RA algorithm to optimise the ACS_net_V2 parameter
RA-ACS_net	Contains a hybrid attention mechanism module with RA algorithm to optimise ACS_net parameters

Fig. 16 shows the performance comparison of the four models at different Measuring Ratio (MR). It can be clearly seen that as the Measuring Ratio increases, the PSNR of all the models gradually increases. This is in line with the principle of Compressed Sensing (CS): the higher the Measuring Ratio, the more raw data we acquire, the better the quality of the reconstructed image, and the PSNR rises.

The RA-CS_net model performs the worst over the entire range of measurement ratios, especially at low measurement ratios (e.g., 0.1), where its PSNR is only about 25 dB, which is significantly lower than the other models. Even though the PSNR of this model increases as the measurement ratio increases, it is smaller and eventually the PSNR is still below 30 dB at a measurement ratio of 0.5. This indicates that the RA-CS_net model is weak in reconstructing the image with limited information, probably because the architecture of the model loses a lot of information when dealing with high compression rates.

By comparing RA-ACS_net_V1 with RA-ACS_net_V2, we find that both versions of the improved model outperform RA-CS_net over the entire range of measurement ratios, especially at a measurement ratio of 0.1, where the PSNR already reaches about 28 dB. As the measurement ratio increases, their PSNR improves rapidly, and finally at a measurement ratio of 0.5, both of them reach a PSNR of about 32 dB, which significantly outperforms that of RA-CS_net, indicating that the ACS (Adaptive Compressed Sensing) architectures have a significant improvement in the image reconstruction task, and they can better recover the original image, especially at medium to high measurement ratios.

RA-ACS_net: the model has the most impressive performance, especially at higher measurement ratios (e.g. 0.4-0.5), where it achieves a PSNR of more than 34 dB and close to 35 dB. This suggests that RA-ACS_net is able to utilise more measurements more efficiently, further improving the quality of the reconstruction.

The different magnitudes of PSNR enhancement with measurement ratio for different models are also reflected in Fig. 16. RA-CS_net has a relatively flat enhancement, indicating that it is not efficient in utilising the additional data. RA-ACS_net_V1 and RA-ACS_net_V2 have faster enhancement rates, especially at measurement ratios from 0.1 to 0.3, and their PSNRs are rapidly enhanced, which indicates that these improved models have a greater increase in data utilisation.RA-ACS_net boosts the most, and its PSNR continues to increase at higher measurement ratios (0.3 to 0.5), indicating that it performs best in high measurement ratio scenarios.

At low measurement ratios (0.1), the differences between the models are more obvious, especially RA-CS_net is much lower than the other three models. This indicates that the traditional RA-CS architecture has been difficult to recover images effectively when the amount of data is extremely limited, whereas the ACS-based model is able to extract more useful information from a small amount of data by means of self-adaptation, which significantly improves the reconstruction quality.

When the measurement ratio reaches 0.5, RA-ACS_net performs the best, with a PSNR close to 35 dB, while RA-CS_net still stays at less than 30 dB.This suggests that, although the reconstruction quality of all the models improves at high measurement ratios, the architecture of RA-ACS_net is able to make better use of the additional measurements and show better reconstruction results. This may be due to the stronger feature extraction and information fusion capabilities of the model.

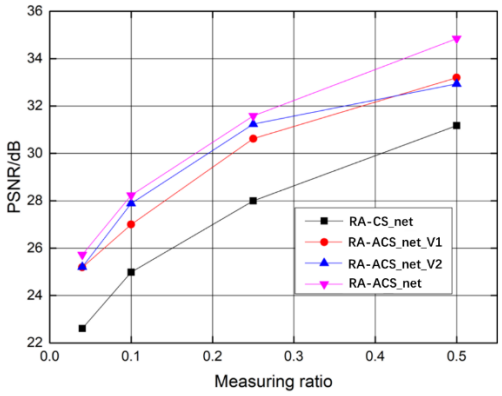

Fig. 16. Peak signal-to-noise ratio of reconstructed networks with different attention mechanism modules.

B. Comparison Experiment of Different Loss Functions

In order to evaluate the impact of the differentiated loss function ALoss designed in this study on the performance of the reconstructed network, a set of controlled experiments is designed in this section for validation, i.e., the comparison experiments between RA-ACS_net+MSE and RA-ACS_net+ALoss. The specific results are shown in Table III and Table IV.

From Table III, it can be seen that in terms of PSNR, the peak signal-to-noise ratio of the reconstructed network using the ALoss differentiated loss function is higher than the MSE loss function. From Table IV, it can be seen that the SSIM value of the reconstructed network using the ALoss differentiated loss function is higher than that of RA-ACS_net+MSE. It can be seen that the use of the ALoss function proposed in this study can greatly improve the performance of the reconstructed network RA-ACS_net_V2. The ALoss loss function improves the PSNR, as well as significantly improves the SSIM, which indicates that the loss function not only effectively improves the visual quality of the image but also better maintains the structural features of the image during the reconstruction process. MSE, although it also performs well, has limited performance enhancement when the measurement ratio is high, and especially performs significantly worse than ALoss in PSNR.

At low measurement ratios (MR=0.04), the performances of the two loss functions are relatively close, but the advantage of ALoss is gradually revealed when the measurement ratio increases, especially at high measurement ratios (MR=0.5), its image recovery is significantly better than that of MSE. If the application scenarios require a better reconstruction effect at high measurement ratios, the ALoss loss function is recommended. MSE can also be an option if the basic performance at low measurement ratios is pursued, but it is not as good as ALoss in terms of comprehensive performance.

The ALoss loss function outperforms MSE at all measurement ratios, especially at high measurement ratios, where it significantly improves the quality of the image reconstruction and exhibits greater applicability and effectiveness. Future studies can further explore the improvement of this loss function to enhance its performance under low measurement ratio conditions.

TABLE III PSNR (DB) RESULTS FOR DIFFERENT LOSS FUNCTION DESIGN METHODS

Aarithmetic	MR=0.04	MR=0.1	MR=0.25	MR=0.5
RA-ACS_net+MSE	22.788	25.050	28.230	30.617
RA-ACS_net+ALoss	22.986	25.467	28.632	31.950

TABLE IV SSIM RESULTS FOR DIFFERENT LOSS FUNCTION DESIGN METHODS

Arithmetic	*MR=0.04*	*MR=0.1*	*MR=0.25*	*MR=0.5*
RA-ACS_net+MSE	0.713	0.814	0.896	0.927
RA-ACS_net+ALoss	0.713	0.833	0.914	0.950

C. Quantum Optical Bio-imaging System Experiments

In order to verify the validity of the RA-ACS_net application, the reconstruction performance of RA-ACS_net in quantum optical imaging is analysed in this section, and the specific results are shown in Fig. 17.

Fig. 17 gives the results of the comparison of the PSNR metrics of the reconstructed images of RA-ACS_net and the traditional iterative algorithm TAVL3 at different measurement rates (MR=0.04, 0.1, 0.25, 0.5). From Fig. 17, it can be seen that the reconstruction performance of both RA-ACS_net and TAVL3 is improved as the measurement ratio increases; the PSNR metrics of RA-ACS_net are improved by 3.265 dB~6.71 dB compared with TAVL3. It can be seen that RA-ACS_net is well-suited to be applied for reconstructing images in a photo-quantum optics bio-imaging system. The TVAL3 algorithm gradually improves the PSNR when the measurement ratio increases, but the overall performance is relatively flat, and finally, the PSNR is about 23 dB at a measurement ratio of 0.5. The Proposed algorithm improves the PSNR significantly faster, outperforms TVAL3 in all measurement ratio conditions, and the PSNR is close to 30 dB at a measurement ratio of 0.5.

At a lower measurement ratio (0.1), the PSNR of TVAL3 is about 20 dB, while that of the Proposed algorithm is about 24 dB, showing a significant improvement in the reconstruction quality of the newly Proposed algorithm at low measurement ratios. This difference suggests that the Proposed algorithm is more effective than TVAL3 in dealing with sparse data, and may be structurally designed to be more adept at extracting information from limited data. As the measurement ratio reaches 0.5, the PSNR of the Proposed algorithm reaches 30 dB, showing a strong reconstruction capability, while the PSNR of the TVAL3 algorithm is only 23 dB, which is still significantly lower than that of the Proposed algorithm. This indicates that the Proposed algorithm is able to make better use of the information and improve the accuracy of image reconstruction when more data are acquired.

The PSNR of the TVAL3 algorithm grows at a slower rate, especially in the range of measurement ratios from 0.2 to 0.5, and the PSNR of the Proposed algorithm is more linear with measurement ratio and grows at a higher rate, especially in the range of measurement ratios from 0.1 to 0.5.

The Proposed algorithm shows better image reconstruction capability than TVAL3 both at low and high measurement ratios, and is suitable for scenes that require high quality reconstruction. The performance of TVAL3, on the other hand,

improves more slowly and has greater limitations especially at low measurement ratios. In future research, we can continue to explore how to further optimize the Proposed algorithm to further improve the performance at higher measurement ratios.

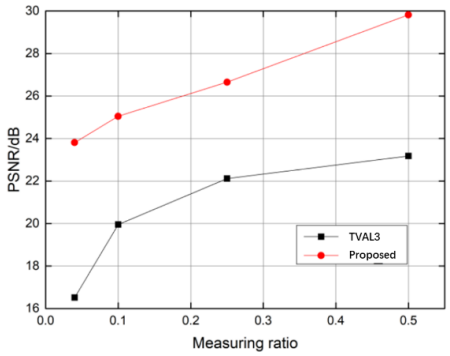

Fig. 17. Peak signal-to-noise ratio of reconstructed experimental maps with different algorithms.

VI. Conclusion and Outlook

Aiming at the problems such as the poor effect of image reconstruction methods in quantum optics bio-imaging systems, this study proposes a fusion quantum optics ultra-high resolution bio-imaging reconstruction method based on RA-ACS_net by combining the ripple algorithm and attention mechanism network. The method analyses the application of quantum optics technology in ultra-high resolution bio-imaging system and designs a quantum optics bio-imaging system, and at the same time explores and analyses the image reconstruction problem of quantum optics bio-imaging system, combines the attention mechanism network and the ripple algorithm, and puts forward the optimization of the ACS_net network model parameter method of the ripple algorithm, and constructs a bio-imaging reconstruction method based on the RA-ACS_net model. A bio-imaging reconstruction method based on the RA-ACS_net model is constructed. Comparative analysis of the proposed method using quantum optics-based bio-imaging image data shows that the RA-ACS_net method proposed in this study has a high peak signal-to-noise ratio for image reconstruction, and the image reconstruction effect is better. The subsequent work can consider denoising the image with noise reduction methods to improve the signal-to-noise ratio of the reconstructed image.

In the course of the study, we found that there are still several problems that have not been effectively addressed:

- Although the network proposed in this study has improved in the reconstruction effect, in practical applications, there is a certain noise interference in the quantum optical imaging process, especially in the low photon counting conditions, the noise may affect the imaging quality. How to further reduce the noise effect in the reconstruction process is still an urgent problem.
- The RA-ACS_net network increases the computational complexity while the accuracy is improved, especially when processing ultra-high resolution images, the reconstruction time is relatively long. Therefore, how to optimize the network structure, reduce the computational cost and improve the reconstruction speed is a direction to focus on in the future.
- The experiments in this study are mainly based on specific bioimaging datasets, which may behave differently on other types of bioimaging data, despite validating the effectiveness of the method. Future research needs to explore more diverse bioimaging scenarios and extend the generality of the network.

Based on the present and looking into the future, the following entry points can be studied: firstly, integrating noise reduction techniques, which can be combined with advanced noise reduction algorithms in the future, especially adaptive noise reduction methods based on deep learning, in order to further improve the signal-to-noise ratio of the reconstructed image, and to enhance the robustness of the system under low-signal conditions. The second is designing lightweight networks; future research can be devoted to designing more lightweight network models to reduce the consumption of computational resources and enhance the reconstruction speed. For example, methods such as pruning techniques or knowledge distillation can be introduced to optimise existing reconstruction networks. The third is the fusion of multimodal imaging. Considering the complexity of bio-imaging technology, the fusion of quantum optics with other imaging technologies (magnetic resonance, X-ray imaging) can be explored in the future to build a multimodal imaging system, which can provide richer biological information and achieve more accurate diagnosis and research. Finally, in order to further promote the practical application of the method, future research should validate the performance of the system in clinical or practical biological studies and assess its applicability and effectiveness in different scenarios.

***Abstract*—Content-Based Image Retrieval (CBIR) systems have become increasingly crucial in healthcare as the volume of medical imaging data continues to grow exponentially. However, existing systems struggle to balance privacy preservation, computational efficiency and retrieval accuracy, particularly in resource-constrained healthcare environments. This research proposes a novel multi-level privacy-preserving CBIR architecture that integrates multiple convolutional neural network (CNN) architectures with fusion strategies and quantization optimization specifically designed for encrypted medical images. The proposed framework addresses three key challenges: privacy preservation through advanced encryption techniques, feature extraction using optimized CNN fusion strategies and computational efficiency through model quantization. By implementing multiple pre-trained CNN models—including VGG-16, ResNet50, DenseNet121 and EfficientNet-B0—along with various fusion strategies, the system achieves improved feature extraction from encrypted medical images. The framework incorporates quantization techniques to optimize computational efficiency without compromising retrieval accuracy. Experimental results across multiple medical imaging modalities, including X-ray, magnetic resonance imaging (MRI) and computed tomography (CT) scans, demonstrate the effectiveness of the proposed approach in terms of retrieval accuracy, computational efficiency and security robustness. This research contributes to advancing privacy-preserving medical image analysis by providing a comprehensive solution that effectively balances security requirements with practical implementation constraints in healthcare settings.**

Keywords*—Content-Based Image Retrieval (CBIR); medical image analysis; privacy preservation; deep learning; convolutional neural networks (CNNs); feature fusion; model quantization; healthcare security; encrypted image processing; resource-constrained computing; computed tomography (CT); magnetic resonance imaging (MRI)

I. INTRODUCTION

In recent years, the healthcare industry has experienced an unprecedented surge in medical imaging data generated through various modalities including MRI, CT, and X-ray [1]. This exponential growth has created an urgent need for efficient Content-Based Image Retrieval (CBIR) systems that can accurately retrieve relevant medical images while preserving patient privacy. Current CBIR systems have demonstrated significant potential in healthcare applications, particularly with the integration of deep learning techniques [2, 3]. However, these systems often struggle to balance privacy preservation with retrieval efficiency, especially one in resource-constrained healthcare environments [4, 5].

The advent of deep learning, particularly Convolutional Neural Networks (CNNs), has revolutionized medical image analysis by enabling automatic extraction of complex hierarchical features [6]. Pre-trained models like VGG-16 have shown promise in medical applications, though they require significant adaptation when working with encrypted medical images [3, 4]. While existing research has explored various aspects of privacy-preserving CBIR systems, there is a notable absence of comprehensive solutions that integrate multiple CNN architectures with fusion strategies specifically designed for encrypted medical imaging domains [7, 8, 9].

Current literature reveals significant limitations in optimization approaches for computational efficiency in privacy-preserving medical CBIR systems. While some studies have investigated quantization and hashing techniques to enhance retrieval efficiency, there is insufficient research examining how these optimization methods affect the delicate balance between security, computational resources, and retrieval accuracy in encrypted medical image databases [10, 11]. This gap becomes particularly critical in resource-limited healthcare settings, where the computational burden of processing encrypted medical datasets can significantly impact system performance [4, 12].

Furthermore, existing encryption methods often fail to address the unique challenges posed by medical imaging, where preserving diagnostic information while ensuring patient privacy is crucial [13, 14, 15]. The integration of advanced encryption techniques with optimized deep learning models remains largely unexplored, particularly in developing systems that can maintain both security and accuracy while operating within the computational constraints of typical healthcare environments [5, 16, 17]. This gap in research highlights the need for a comprehensive framework that effectively combines privacy preservation mechanisms, efficient deep learning techniques, and optimization methods suitable for real-world healthcare applications.

*Corresponding Author.

The lack of integrated approaches combining multiple CNN architectures, fusion strategies, and quantization techniques specifically designed for encrypted medical image retrieval represents a significant research opportunity. While individual components have been studied separately, there is a clear need for a unified framework that can effectively balance privacy preservation, computational efficiency, and retrieval accuracy [10, 11].

Dataset considerations: Most prior studies evaluate privacy-preserving CBIR systems on a single imaging modality or on datasets of limited size, which makes it difficult to assess generalization across clinical scenarios. To address this limitation, our work utilizes a balanced multi-modal dataset comprising bone X-rays, chest radiographs and brain MRI scans drawn from widely used collections such as MURA, Chest X-ray and BTTypes. By explicitly indicating the choice of datasets and splitting them into training, validation and test sets, we provide a transparent experimental foundation for evaluating the proposed framework.

The remainder of this study is structured as follows: The primary contributions of the work are consolidated in Section II, where we highlight the novel aspects and implications of our study. Section III presents the related work and literature survey. In Section IV, we describe the proposed methodology in detail, including the foundational design choices and theoretical formulation. Sections V and VI presents and discuss the experimental setup, dataset descriptions, performance metrics, and key results obtained from our approach. Finally, Section VII offers concluding remarks, summarizing the main findings and outlining prospective directions for future research.

II. Contributions

This study presents several contributions aimed at advancing privacy-preserving medical image retrieval systems:

1) A novel multi-level privacy-preserving CBIR architecture that integrates block-wise encryption with secure feature extraction, providing superior security and computational efficiency compared to traditional single-level approaches in medical image retrieval systems.

2) A comprehensive framework for implementing multiple pre-trained CNN architectures with fusion strategies, specifically optimized for encrypted medical images, which significantly improves feature extraction accuracy compared to single-model approaches while maintaining privacy requirements. Advanced Approach to Quantization.

3) An innovative model quantization framework that substantially reduces computational overhead while maintaining high retrieval accuracy in resource-constrained healthcare environments, enabling practical deployment of privacy-preserving medical image retrieval systems.

III. Related Work and Literature Survey

The field of privacy-preserving medical image retrieval has progressed rapidly over the past two decades. Early approaches focused on hand-crafted features extracted from encrypted images and relied on distance-preserving transformations or homomorphic encryption to enable similarity search without exposing raw data [18, 19, 20]. Subsequent works introduced secure index structures and hashing schemes such as secure kNN, deep hashing and bag–of–encrypted words to improve retrieval speed and accuracy [21, 22]. More recently, deep learning–based solutions have emerged that employ convolutional neural networks (CNNs) trained on encrypted feature representations, often combined with federated learning or homomorphic encryption to protect patient privacy [23, 24, 25]. These works demonstrate the potential of deep models but typically utilise a single architecture and do not address the trade–off between computational efficiency and retrieval accuracy when working with encrypted medical images. Recent literature also highlights the importance of secure cloud-based infrastructures. Yadav and Chokkalingam [26] proposed a two–step cloud-based CBIR system that combines encryption with watermarking and a principal component analysis (PCA) based feature extraction pipeline. Their framework first encrypts images and embeds watermark bits to trace unauthorised duplication; only authenticated users can decrypt and extract the watermark, enabling traceability of data misuse. Feature vectors are derived using a dominant local pattern and PCA, and retrieval is performed using these compact representations. The authors demonstrate that the two-step approach improves mean average precision and recall while maintaining robustness against unauthorised access. While this method enhances security in a cloud environment, it still relies on hand-crafted features and does not explore model fusion or quantization for computational efficiency.

A. Comparative Analysis of Datasets

Table I summarises several widely used open medical imaging datasets alongside the custom dataset employed in this study. The table emphasises key characteristics such as the imaging modality, number of images or studies, number of patients, available labels, and resolution.

As shown in Table I, public datasets such as MURA and ChestX-ray14 provide large numbers of radiographic images and detailed annotations, but focus on single modalities. The BTTypes dataset offers balanced benign and malignant brain MRI scans but is limited to a binary classification task. In contrast, our study employs a multi–modal dataset comprising X-ray, computed tomography (CT) and magnetic resonance imaging (MRI) images, each category containing 1,200 images. By combining bone, chest and brain imaging modalities, the experiments assess the generality of the proposed retrieval framework across diverse anatomical regions while retaining a manageable dataset size for in-depth analysis.

TABLE I. COMPARISON OF WIDELY USED MEDICAL IMAGING DATASETS WITH THE DATASET UTILIZED IN THIS WORK

Dataset	Modality	Images / Studies	Patients	Labels / Classes	Notes
MURA [27]	X-ray (upper extremity)	40,561 images from 14,863 studies	12,173	Normal/abnormal	Seven body parts (elbow, finger, forearm, hand, humerus, shoulder, wrist); images collected between 2001–2012.
ChestX-ray14 [28]	Chest X-ray	112,120 frontal images	32,717	Up to 14 thoracic pathologies	Resolution 1024×1024 px; patient-wise split of 86,524 training and 25,596 test images.
BTTypes (Brain tumor) [29]	Brain MRI	2,400 images	—	Benign / malignant	Two collections containing 1,200 benign and 1,200 malignant images were used for experiments.
This work	X-ray, CT and MRI	3,600 images	—	Bone, chest, brain	1,200 images per category; images encrypted using multi-tiered texture and color encryption prior to training and evaluation.

B. Key Takeaways

The existing literature underscores several research gaps that motivate our contributions. First, many privacy-preserving CBIR systems rely on a single CNN architecture or hand-crafted features and do not leverage the complementary strengths of multiple models. Second, computational efficiency and model compression are often overlooked, limiting the practical deployment of secure retrieval systems in resource-constrained environments. Third, comparative analyses of datasets are rarely provided, leaving unclear how performance generalizes across different modalities and imaging conditions. The proposed framework addresses these limitations by integrating multi-level encryption, multi-model CNN fusion, and quantization within a unified architecture while evaluating the system on a balanced multi-modal dataset.

IV. METHODOLOGY

Our methodology establishes a comprehensive framework for privacy-preserving content-based image retrieval (CBIR) in medical applications, addressing the critical challenges of security, accuracy, and computational efficiency. This multi-faceted approach integrates three key components: 1) a novel multi-level encryption technique designed specifically for medical images, 2) a robust feature extraction process utilizing multiple complementary CNN architectures, and 3) an optimized model quantization strategy to enhance computational efficiency while maintaining high retrieval accuracy. Each component is mathematically formalized and algorithmically implemented to ensure a systematic and reproducible approach. The following subsections detail the problem formulation, system architecture, and specific implementations of each component, demonstrating how they collectively create a balanced solution for secure and efficient medical image retrieval in resource-constrained healthcare environments.

A. Problem Formulation

Let I = {i1, i2, ..., in} be a set of medical images in the database. The multi-level encryption process can be defined as:

$$E = \{e_1, e_2, \ldots, e_n\} = \{\mathcal{E}(i_k, K_k)\}_{k=1}^{n} \quad (1)$$

where, E is the encryption function and K_k is the encryption key for image i_k. The block-wise encryption process divides each image into blocks B = {b1, b2, ..., bm} and applies local and global scrambling:

$$\mathcal{E}(i, K) = \mathcal{G}\left(\{\mathcal{L}(b_j, K)\}_{j=1}^{m}\right) \quad (2)$$

where, $\mathcal{L}$ represents local block encryption and $\mathcal{G}$ represents global scrambling.

Given the encrypted images E, the feature extraction process using multiple CNNs can be formulated as:

$$F = \{\Psi_1(e), \Psi_2(e), \ldots, \Psi_k(e)\}, e \in E \quad (3)$$

where, Ψi represents the i-th CNN model (VGG-16, ResNet50, etc.). The fusion strategy combines these features:

$$F_{\text{fused}} = \omega_1 F_1 \oplus \omega_2 F_2 \oplus \ldots \oplus \omega_k F_k \quad (4)$$

where, ω_i are fusion weights and $\oplus$ represent the fusion operation.

Let M be the original model with weights W. The quantization problem can be formulated as:

$$\min_{W_q} \|W - W_q\|_2 \text{ subject to } W_q \in \{-2^{b-1}, \ldots, 2^{b-1} - 1\} \quad (5)$$

where, W_q represents the quantized weights and b is the bit width. The overall optimization objective combines all three components:

$$\max_{\mathcal{E},\Psi,W_q} \left\{ \text{Accuracy}(R \mid Q) \text{ subject to: } \begin{cases} \text{Privacy}(E) \geq \tau_p \\ \text{Memory}(W_q) \leq \tau_m \\ \text{Compute}(\Psi) \leq \tau_c \end{cases} \right\}. \quad (6)$$

where, R is the retrieved result set, Q is the query image, τ_p is the privacy threshold, τ_m is the memory threshold, and τ_c is the computational threshold. This formulation encapsulates the key challenges of maintaining privacy through secure encryption, ensuring accurate feature extraction and retrieval, and optimizing computational efficiency through quantization, while balancing these competing objectives within practical constraints.

B. System *Architecture*

The system architecture encompasses a comprehensive privacy-preserving framework for medical image retrieval, structured around three main entities: Data Owner, Cloud Server and Query User. Each entity performs distinct roles within an integrated workflow that ensures both security and efficiency. The Data Owner is responsible for system initialization, including encryption key management, medical image preprocessing and secure feature extraction. This entity encrypts both the medical images and their corresponding feature vectors before uploading them to the Cloud Server. The Cloud Server functions as a secure storage and processing unit, maintaining

the encrypted database while performing similarity searches on encrypted feature vectors without accessing the raw data. A high-level overview of the sequence of operations between these entities is illustrated in Fig. 1.

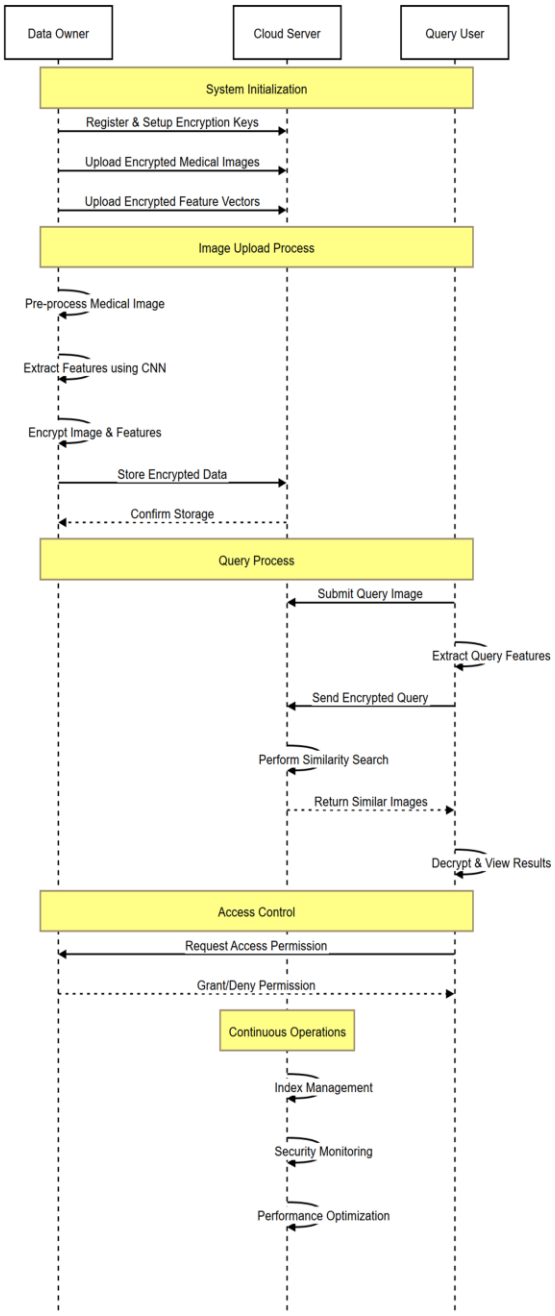

Fig. 1. System architecture sequence diagram.

The operational workflow begins with the Data Owner who manages the original dataset and encryption keys, while also providing training data from the same distribution for model training. During the initialization phase, the Data Owner implements a multi-tiered texture and color encryption (MTTCE) algorithm that preserves crucial diagnostic information while securing patient privacy. This process combines local and global image scrambling techniques to ensure that encrypted images maintain their utility for retrieval purposes. Following encryption, the Data Owner implements the feature extraction process using multiple pre-trained CNN architectures—VGG-16, ResNet50, DenseNet121, and EfficientNet-B0—each specifically modified and fine-tuned for encrypted medical image analysis.

The Cloud Server component maintains both the encrypted image database and the trained feature extraction models. Upon receiving an encrypted query image, the server extracts features using the optimized models and computes similarities with database features using Euclidean distance metrics. The server then returns a set of most similar encrypted images based on feature matching. Throughout this process, the Cloud Server operates exclusively within the encrypted domain, ensuring that sensitive medical information remains protected during all computational operations.

The Query User interacts with the system by submitting query images, which undergo similar preprocessing and encryption before a similarity search is performed. After receiving encrypted result sets, the Query User must request corresponding decryption keys from the Data Owner to access the original medical images. This additional layer of security and access control ensures that only authorized users can view decrypted content. The entire architecture employs robust access control mechanisms to guarantee that only authenticated users can interact with the system, with multi-factor authentication and session management protocols enhancing security throughout the retrieval process.

This architecture is designed with particular attention to efficiency in resource-constrained healthcare environments. Through this comprehensive design, the system architecture successfully balances the competing requirements of privacy preservation, computational efficiency, and retrieval accuracy in medical image analysis. Fig. 2 illustrates the complete framework architecture of our proposed system.

C. Multi-Level Encryption Approach

The encryption process in our system employs a multistage homomorphic encryption method specifically designed to securely store medical images while maintaining their utility for retrieval. This approach effectively preserves both local and global image information by encoding them into a binary string, ensuring that query-relevant features remain accessible while protecting against unauthorized access and information leakage.

The encryption process consists of three main phases. First, the Local Texture Protection phase segments the original image into non-overlapping subblocks and scrambles the RGB channel values within each subblock, effectively obscuring local texture information while preserving features necessary for retrieval. Second, the Global Texture Preservation phase randomly swaps positions between subblocks, disrupting the global image structure while maintaining essential texture information for retrieval purposes. Third, the Color Information Security phase involves channel swapping and RGB value substitution for each scrambled subblock, creating a non-linear encryption model by binding substitution values to the positions of encrypted sub-blocks.

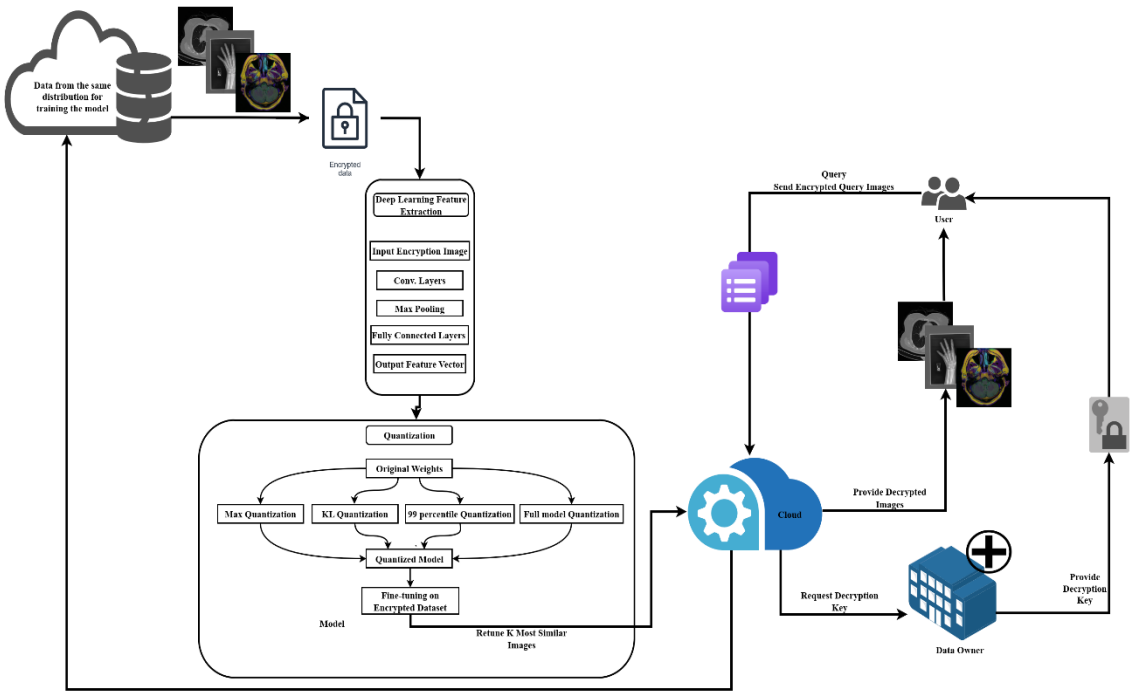

Fig. 2. Proposed framework architecture.

The encryption key is generated using a built-in random function and is essential for authorized decryption. The final encrypted image is composed by combining the processed subblocks, resulting in a secure representation that maintains no visible relationship to the original content while preserving the features necessary for effective retrieval. This process is formalized in Algorithm 1, which outlines the complete multi-stage encryption approach.

D. Deep Feature Extraction with Multiple CNN Models

Our system leverages multiple pre-trained CNN architectures for robust feature extraction from encrypted medical images. We selected VGG16, ResNet50, DenseNet121, and EfficientNetB0 for their proven effectiveness in image feature extraction tasks [30, 31, 32]. Each architecture was strategically adapted for our privacy-preserving CBIR system through a systematic fine-tuning process.

Each CNN architecture underwent several modifications to optimize its performance with encrypted medical images. Initial weights were obtained from pre-training on the ImageNet dataset, providing a strong foundation for general feature extraction capabilities. The models were then fine-tuned using our encrypted medical image dataset to adapt to the specific characteristics of encrypted data. To optimize computational efficiency while maintaining feature quality, we implemented selective layer freezing, where all layers except the final 10 were frozen during training. The architecture was enhanced by incorporating a Global Average Pooling (GAP) layer, which reduces spatial dimensions while preserving channel information followed by a task-specific classification head.

The feature extraction process for an input image can be mathematically formalized as:

$$F(I) = h\big(g(f_\theta(I))\big) \tag{7}$$

where, $f_\theta(I)$ represents the frozen pre-trained layers with parameters θ, $g()$ denotes the Global Average Pooling operation, and $h()$ represents the task-specific classification head. This architecture ensures effective feature extraction while maintaining compatibility with our privacy-preserving framework.

E. Fusion Strategies for Enhanced Performance

To leverage the complementary strengths of different CNN architectures, we implemented three fusion strategies: attention-based fusion, weighted average ensemble, and majority voting. These fusion methods combine the feature representations or predictions from multiple models to achieve more robust and accurate results than any single model could provide. We selected these specific fusion strategies based on their theoretical foundations and empirical performance in medical image analysis tasks. Attention-based fusion was chosen for its ability to adaptively weight features according to their relevance for each specific image, addressing the high variability in medical image characteristics. The weighted average ensemble was included for its computational efficiency and proven effectiveness in scenarios where model strengths remain relatively consistent across a dataset. Majority voting was selected as a robust decision-level fusion technique that can effectively mitigate the impact of individual model failures or inconsistencies [33, 34, 35].

The attention-based fusion approach applies an attention mechanism to dynamically weight the contributions of different models based on the input image characteristics. This method learns to focus on the most relevant features from each model, enhancing the overall representation quality. The fusion process can be expressed as:

$$F_{\text{fused}} = \sum_{i=1}^{k} \alpha_i(I) \cdot F_i(I) \tag{8}$$

where, $\alpha_i(I)$ represents the attention weight for model i given input image I, and $F_i(I)$ is the feature representation from model i.

The weighted average ensemble assigns fixed weights to each model based on their validation performance, combining their outputs in a predetermined ratio. This approach provides a simple yet effective method for model fusion when the relative strengths of different models are known in advance.

The majority voting strategy operates at the decision level, combining the class predictions from multiple models to determine the final classification. This approach is particularly effective for reducing the impact of outlier predictions from individual models.

These fusion strategies enhance the robustness and accuracy of our system, particularly when dealing with the challenging task of feature extraction from encrypted medical images. The complementary nature of different CNN architectures allows our system to capture a wider range of relevant features, improving retrieval performance across diverse medical image types.

F. Model Quantization for Computational Efficiency

Our system implements four distinct quantization approaches to balance model efficiency with accuracy: max quantization, KL divergence–based quantization, 99th percentile quantization and full model quantization. Each method offers different trade-offs between compression ratio and model performance. The relationship between these quantization modes and the broader workflow of our privacy-preserving CBIR system is visualized in Fig. 3, which depicts the comprehensive processing pipeline from encryption through feature extraction and quantization to retrieval.

Max quantization scales the weights based on the maximum absolute value in each layer:

$$W_{\text{quantized}} = \frac{W}{max(|W|)} \times (2^b - 1) \quad (9)$$

where, W represents the original weights, b is the target bit-width (typically 8 bits), and $max(|W|)$ is the maximum absolute value in the weight tensor. KL divergence-based quantization optimizes the quantization thresholds by minimizing the KullbackLeibler divergence between the original and quantized weight distributions:

$$KL(P\|Q) = \sum_i P(w_i)\log\frac{P(w_i)}{Q(w_i)} \quad (10)$$

where, P represents the distribution of original weights and Q represents the distribution of quantized weights.

99th percentile quantization uses the 99th percentile of absolute weight values as the quantization threshold instead of the maximum value:

$$W_{\text{quantized}} = \frac{W}{\text{percentile}_{99}(|W|)} \times (2^b - 1) \quad (11)$$

Full model quantization applies integer quantization to all layers of the model, including weights, activations, and biases, following the equations:

$$W_{\text{int }8} = \text{round}\left(\frac{W}{S_w}\right), A_{\text{int8}} = \text{round}\left(\frac{A}{S_a}\right),$$
$$B_{\text{int }32} = \text{round}\left(\frac{B}{S_w \times S_a}\right) \quad (12)$$

where, S_w and S_a are scaling factors for weights and activations. The implementation of these quantization methods is formalized in Algorithm 3, which outlines the complete quantization process for different approaches.

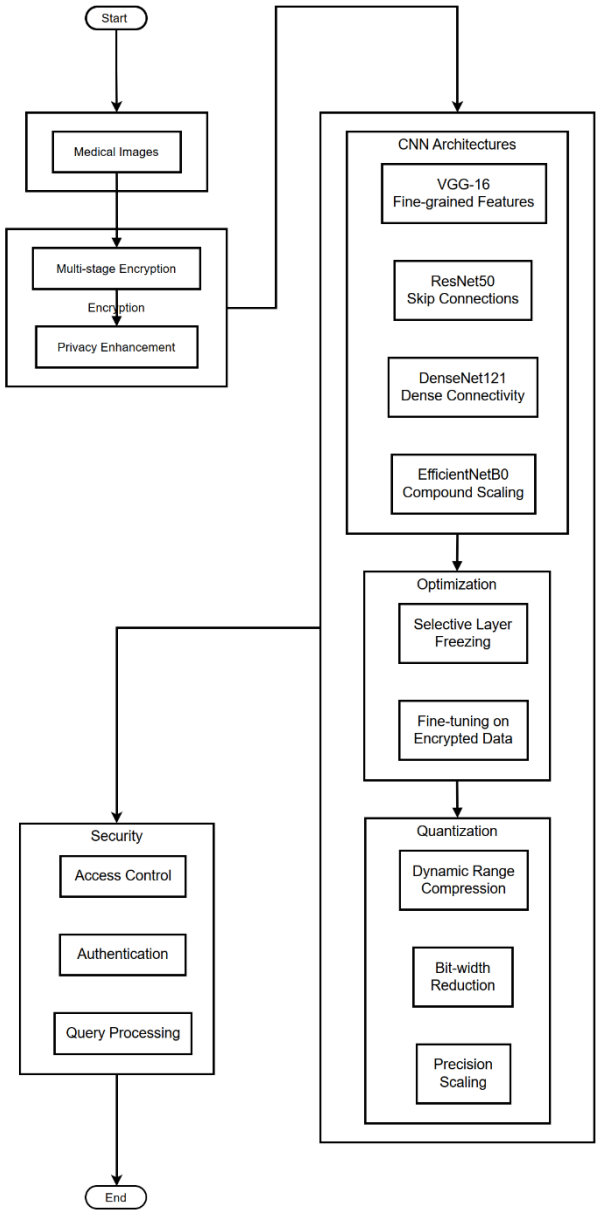

Fig. 3. Comprehensive workflow of the proposed privacy-preserving medical image retrieval system.

G. Algorithms

The algorithmic foundation of the privacy-preserving CBIR system encompasses three primary components: multi-level encryption, feature extraction using multiple CNN architectures, and model optimization through quantization. Each component incorporates specialized algorithms designed to enhance

security, accuracy, and efficiency within the medical image retrieval context. The encryption process employs a multi-stage homomorphic encryption method formalized in Algorithm 1, which effectively preserves both local and global image information while protecting against unauthorized access.

Algorithm 1: Multi-Stage Image Encryption for CBIR Systems

Require: Original Image I

Ensure: Encrypted Image I_{enc}, Encryption Key K

1. Divide the original image I into non-overlapping subblocks B_i
2. **for** each subblock B_i **do**
3. Scramble the positions of the RGB channel values within B_i to hide local texture information
4. **end for**
5. Randomly scramble the positions between subblocks B_i to obscure global texture information
6. **for** each scrambled subblock B_i **do**
7. Substitute the RGB channel values and swap the channels to secure global color information
8. **end for**
9. Generate the encryption key K using a built-in random function
10. Combine the processed subblocks to form the encrypted image I_{enc}

The feature extraction process utilizes multiple pretrained CNN architectures that have been specifically adapted for working with encrypted medical images. Algorithm 2 formalizes the feature extraction process using these adapted models:

Algorithm 2: Multi-Model Feature for Encrypted Medical Images

Require: Encrypted Image I_{enc}, Set of CNN Models M=$\{m_1, m_2, \ldots, m_k\}$

Ensure: Feature Vector Set $F=\{f_1, f_2, \ldots, f_k\}$

1: **for** each model $m_i \in M$ **do**

2: Preprocess I_{enc} according to model requirements

3: Extract feature maps X_i from convolutional layers of m_i

4: Apply Global Average Pooling: $g_i = \frac{1}{H \times W} \sum_{h=1}^{w} \sum_{w=1}^{w} X_{i,h,w}$

5: Apply model-specific transformation: $f_i = \sigma(w_{igi} + b_i)$

6: **end for**

7: **return** Feature vector set F

The model optimization framework implements four distinct quantization approaches, formalized in Algorithm 3, which balance model efficiency with accuracy:

Algorithm 3: Model Quantization Framework

Require: Trained model M with weights W quantization mode *mode*, target bit-width b

Ensure: Quantized model M'

1. **If** *mode* == "max" **then**
2. $W_{max} \leftarrow \max(|W|)$
3. *Quantize* weights: $W_q = \frac{W}{W_{max}} \times (2^b - 1)$
4. **else if** *mode* == "KL" **then**
5. Calculate weight histogram $H(W)$
6. **for** each potential threshold t **do**
7. Quantize weights using threshold t
8. Calculate KL divergence $KL(P||Q_t)$
9. **end for**
10. Select optimal threshold $t_{opt} = \arg\min_t KL(P||Q_t)$
11. Quantize weights using t_{opt}
12. **else if** *mode* == "99%" **then**
13. Calculate 99th percentile p_{99} = precentile$_{99}$ (|W|)
14. Quantize weights: $W_q = \frac{W}{p_{99}} \times (2^b - 1)$
15. **else if** *mode* == "full" **then**
16. Calculate scaling factors $S_w = \frac{\max(|W|)}{127}$, $S_a = \frac{\max(|A|)}{127}$
17. Quantize weights: W_{int8} = round $(\frac{W}{S_w})$
18. Quantize activations: A_{int8} = round $(\frac{A}{S_a})$
19. Quantize biases: B_{int32} = round $(\frac{B}{S_w \times S_a})$
20. **end if**
21. Replace original weights with quantized weights
22. **Return** quantized model M'

The integration of these algorithms creates a complete workflow for privacy-preserving medical image retrieval, formalized in Algorithm 4:

Algorithm 4: Privacy-Preserving Medical Image Retrieval Workflow

Require: Medical image database I, query image Q, encryption key set K, quantization mode *mode*

Ensure: Retrieved similar images R

1. Encrypt all database images: $E = \{\mathcal{E}(i_k, K_k)\}_{k=1}^{n}$
2. Train and optimize CNN models $M = \{m_1, m_2, \ldots, m_k\}$ on encrypted images
3. **for** each model $m_i \in M$ ***do***
4. Apply quantization using selected *mode*
5. **end for**
6. Extract and store features from all encrypted database images
7. Encrypt query image: $EQ = \mathcal{E}(Q, k_q)$
8. Extract query features using quantized models
9. Compute similarities between query features and database features
10. Return top-k most similar encrypted images ER
11. Decrypt results: $R = \{D(er_j, k_j)\}_{j=1}^{k}$

These algorithms work in concert to create a system that effectively balances privacy preservation, computational efficiency, and retrieval accuracy. The multistage encryption described in Algorithm 1 ensures security while preserving features necessary for retrieval. The feature extraction process detailed in Algorithm 2 leverages multiple CNN architectures to provide robust feature extraction from encrypted data. The quantization framework formalized in Algorithm 3 optimizes models for deployment in resource-constrained environments without significantly compromising retrieval performance. The complete workflow presented in Algorithm 4 integrates all

components into a cohesive privacy-preserving medical image retrieval system.

H. Dataset

To evaluate the proposed framework across multiple imaging modalities, we curated a balanced dataset comprising three categories: bone X-rays, chest radiographs and brain MRI scans. Each category contained 1,200 images, yielding a total of 3,600 images. The images were acquired from publicly available collections and internal sources. As summarized in Table I, publicly available datasets such as MURA and ChestX-ray14 contain tens of thousands of images but focus on a single modality. The BTTypes dataset contains 2,400 brain tumor MRI images split evenly between benign and malignant cases. For our experiments we combined data from these sources and additional CT images to obtain a balanced set across modalities.

1) Dataset organization: Images were stratified by anatomical region to form three classes:

a) Bone X-ray: 1,200 multi-view musculoskeletal radiographs sampled from the MURA dataset [27]. Each study comprises projections of upper extremity bones labelled as normal or abnormal, and we ensured balanced representation across bone types.

b) Chest radiograph: 1,200 frontal chest X-ray images drawn from the ChestX-ray14 dataset [28]. Images cover up to 14 thoracic pathologies; we sampled a representative subset across different disease labels and included normal cases.

c) Brain MRI: 1,200 T1-weighted brain MRI scans from the BTTypes dataset [29] comprising equal numbers of benign and malignant tumor cases. Additional normal MRI scans were included to form a three-class problem (benign, malignant and healthy).

The dataset was divided into training, validation and testing subsets using a 1,000:100:100 split for each class. This partitioning ensures sufficient samples for model training while retaining disjoint validation and test sets for unbiased evaluation. Stratification by modality prevents data leakage across splits and allows separate assessment of each anatomical region.

2) Data processing pipeline: All images underwent the following processing steps to prepare them for encrypted retrieval:

a) Preprocessing: Images were resized to 224×224 pixels and normalized to match the input requirements of the pre-trained CNNs.

b) Encryption: Each image was encrypted using the multi-tiered texture and color encryption (MTTCE) scheme described in Section IV. Both plaintext and encrypted versions were retained for comparative experiments.

c) Feature extraction: Encrypted images were processed by the VGG-16, ResNet50, DenseNet121 and EfficientNet-B0 architectures to extract deep features. Features from the penultimate layer were used for classification and retrieval.

d) Quantization evaluation: Features were quantized using the four approaches outlined in Section IV (max, KL divergence, 99th percentile and full quantization) to assess the effect on accuracy and model size.

Maintaining a consistent pipeline for each modality allowed fair comparison across encryption and quantization settings. The balanced dataset and stratified splits ensure reproducibility and facilitate analysis of the proposed methods on diverse medical imaging data.

V. Experimental Results and Analysis

A. Experimental Design

The experimental evaluation was conducted with particular attention to reproducibility and practical applicability in medical imaging environments. The system was implemented using Python 3.8 with PyTorch 1.9 as the primary deep learning framework. All experiments were performed on a workstation equipped with an NVIDIA RTX 3080 GPU with 10GB VRAM, supported by 32GB system RAM and an Intel i7 processor. This hardware configuration was chosen to represent a realistic deployment environment while providing sufficient resources for effective model training and evaluation.

The implementation framework incorporated several key components, including PyTorch for model development, OpenCV and PIL for image preprocessing, TensorFlow's optimization toolkit for model quantization, and custom evaluation scripts developed using scikit-learn and NumPy for computing performance metrics. The system configuration parameters were carefully selected based on preliminary experiments and established best practices in medical image analysis. These parameters included image dimensions of 224×224 pixels, batch size of 32, and normalization parameters aligned with standard practices for pre-trained models.

The experimental evaluation utilized three distinct medical imaging datasets, each comprising 1,200 images systematically categorized based on anatomical regions: bone images, chest radiographs, and brain MRI scans. The datasets were strategically segregated into training, validation, and testing sets using a 1000:100:100 split ratio, ensuring robust model training while maintaining sufficient data for validation and testing. This data organization enabled direct comparative analysis between different encryption and quantization approaches while evaluating system performance.

Each image in the dataset underwent a systematic processing pipeline, including preservation of the initial plaintext format, application of Multi-Tiered Texture and Color Encryption (MTTCE), feature extraction using the various CNN architectures, and analysis under different quantization schemes. This standardized approach to data organization and processing ensured the reliability and reproducibility of the experimental results across all testing scenarios.

The experimental evaluation was structured to systematically address three main research objectives: evaluating the multi-level privacy-preserving CBIR architecture, assessing multiple CNN architectures and fusion strategies for feature extraction, and analyzing the model optimization framework based on quantization techniques. Each objective was evaluated using specific metrics tailored to measure the relevant aspects of system performance. Privacy

preservation was assessed using standard cryptographic metrics including entropy, Mean Squared Error (MSE), Structural Similarity Index (SSIM), and Peak Signal-to-Noise Ratio (PSNR). Model performance was evaluated using classification accuracy, precision, recall, and F1-score, while computational efficiency was measured through model size reduction and inference time metrics. This comprehensive experimental design enabled a systematic and thorough evaluation of all aspects of the proposed privacy-preserving CBIR system, ensuring that the results provided valuable insights into the practical implementation of secure and efficient medical image retrieval systems.

B. Result Analysis

The privacy preservation capabilities were evaluated through standard cryptographic metrics, comparing the proposed approach against the AES standard, as shown in Table II. The encryption algorithm achieved an entropy value of 7.392, approaching the theoretical optimal value of 8, indicating a high degree of randomness in the encrypted output. The Mean Squared Error (MSE) analysis revealed the algorithm achieved a higher distortion (12,766.02) compared to AES (2,625.48), indicating stronger alteration of the original image content. This higher MSE suggests enhanced security through greater deviation from the original image structure. The Structural Similarity Index Measure (SSIM) further validates the algorithm's effectiveness, with a value of 0.273204 compared to AES's 0.00283838. While AES shows a lower SSIM value, indicating nearly complete structural dissimilarity from the original image, our algorithm maintains a strategic balance between security and utility, preserving just enough structural information to enable effective feature extraction while still sufficiently obfuscating sensitive patient data. Additionally, the Peak Signal-to-Noise Ratio (PSNR) of 7.07 for our algorithm, lower than AES's 13.94, confirms the significant distortion introduced by our approach. A lower PSNR value is desirable for encryption algorithms as it indicates greater divergence from the original signal, making unauthorized reconstruction more difficult. This combination of metrics demonstrates that our algorithm achieves robust privacy protection while maintaining the utility necessary for content-based medical image retrieval tasks.

TABLE II. COMPARATIVE EVALUATION OF ENCRYPTION METRICS: OUR ALGORITHM VERSUS AES

Metric	Our Algorithm	AES
Entropy	**7.392129887**	1.4426951601859516e-10
MSE	**12766.02**	2625.48
SSIM	0.273204	**0.00283838**
PSNR	**7.070247655**	13.93870288

These metrics demonstrate the effectiveness of the encryption scheme in protecting sensitive medical image data while maintaining feature extractability.

The evaluation of CNN architectures for feature extraction revealed distinct patterns in their learning dynamics and classification performance. VGG-16 demonstrated exceptional performance with training accuracy reaching 98.7% and validation accuracy peaking at 98.8%, showing the most stable learning progression among all models. Its confusion matrix revealed strong classification capabilities with 1,468 correct bone classifications and 897 correct MRI classifications, achieving an impressive overall accuracy of 99%, as shown in Fig. 4 and Table III.

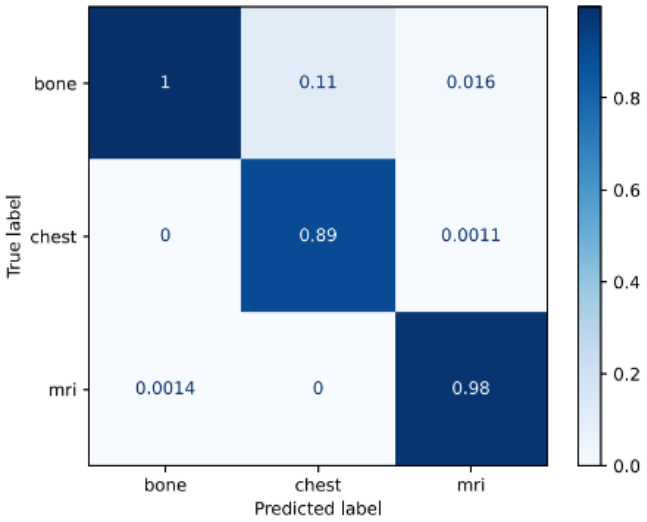

Fig. 4. Confusion matrix for the VGG-16 model showing classification performance across three medical image categories (bone, chest, MRI).

TABLE III. CLASSIFICATION PERFORMANCE METRICS FOR VGG-16 MODEL

Class	Precision	Recall	F1-score	Support
Bone	1.00	0.98	0.99	1500
Chest	0.89	0.99	0.94	97
MRI	0.98	1.00	0.99	900
Accuracy			0.99	2497
Macro avg.	0.96	0.99	0.97	2497
Weighted avg.	0.99	0.99	0.99	2497

ResNet50, while achieving comparable final performance with 1,465 correct bone classifications and 895 correct MRI predictions as illustrated in Fig. 6, exhibited more volatile learning behavior, particularly in early epochs where validation accuracy fluctuated between 98% and 92%. The learning curves for ResNet50 are shown in Fig. 5.

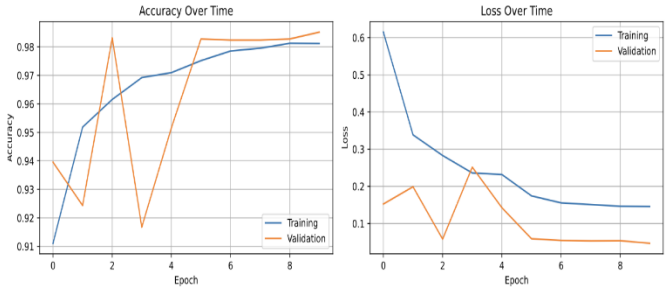

Fig. 5. Learning curves showing training and validation accuracy (left) and loss (right) over training epochs for the ResNet50 model.

DenseNet121, as given in Fig. 7, showed remarkable initial performance with validation accuracy starting at 97% and

maintaining consistent improvement to exceed 98.5%, demonstrating efficient feature extraction capabilities from the outset, as shown in Fig. 7 and Fig. 8.

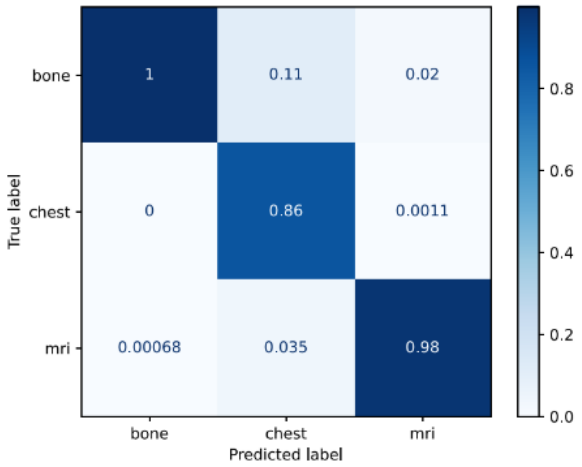

Fig. 6. Confusion matrix for ResNet50 model displaying classification results for bone, chest, and MRI images.

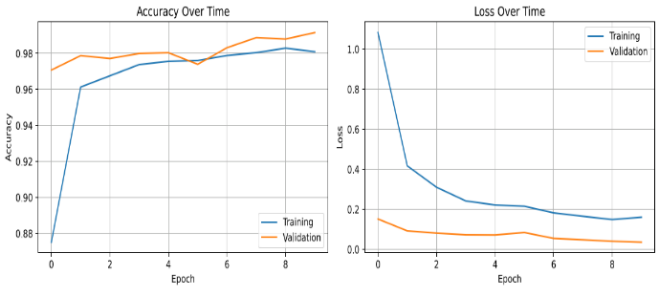

Fig. 7. Training and validation metrics for the DenseNet121 model across epochs.

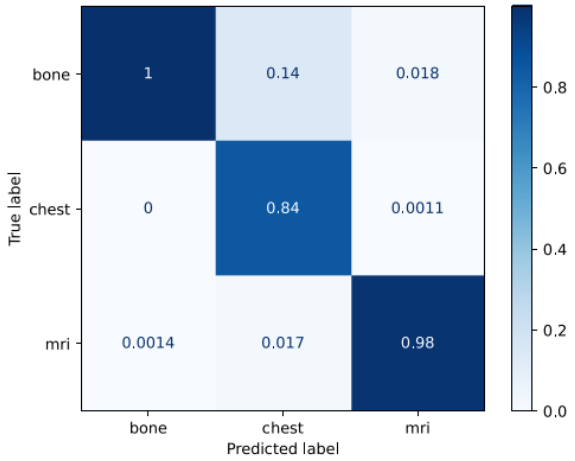

Fig. 8. Confusion matrix for DenseNet121 model showing the distribution of predictions across medical image types.

In contrast, EfficientNet-B0 as given in Fig. 9 showed more modest performance metrics, with training accuracy reaching 85% and experiencing early training instability, though it eventually stabilized at 83 to 84%, as illustrated in Fig. 9 and Fig. 10.

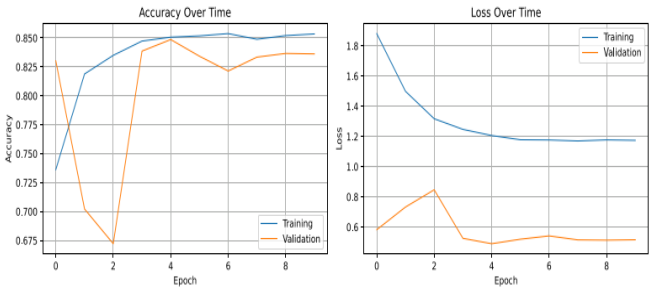

Fig. 9. Training and validation metrics for the EfficientnetB0 model across epochs.

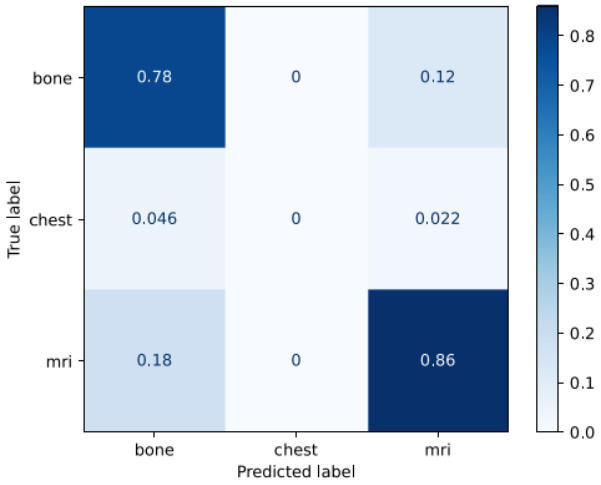

Fig. 10. Confusion matrix for the EfficientNetB0 model displaying classification results.

The fusion strategies, implemented to combine the strengths of individual CNN models, showed promising results. The attention-based fusion approach demonstrated superior performance compared to both individual models and other fusion strategies, achieving the highest overall accuracy at 99.52%, as shown in Fig. 11 and Fig. 12.

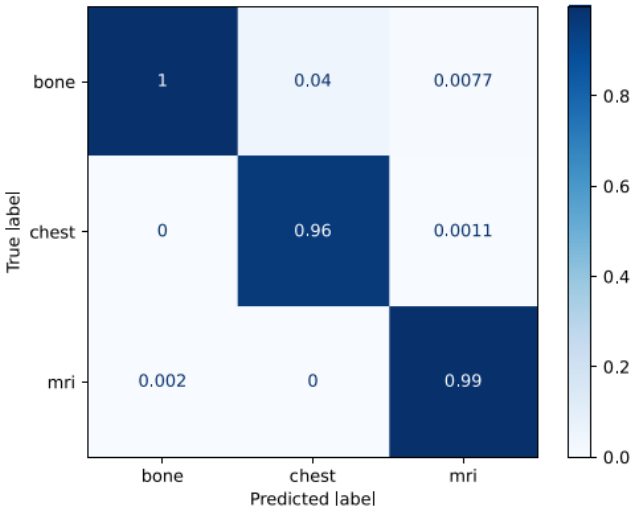

Fig. 11. Confusion matrix showing the classification performance of the attention-based fusion model across bone, chest, and MRI image categories.

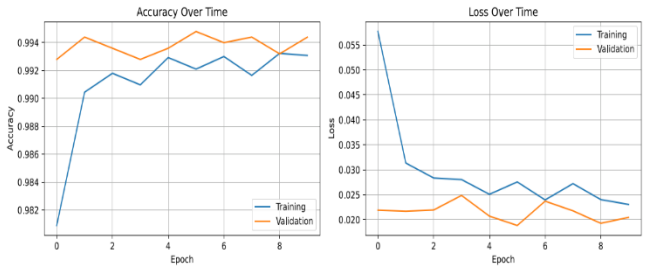

Fig. 12. Learning curves showing training and validation metrics over time for the attention-based fusion model.

Majority Voting demonstrated robust performance with 1,477 correct bone classifications and 898 correct MRI classifications, though slightly lower than the attention-based approach, as illustrated in Fig. 13.

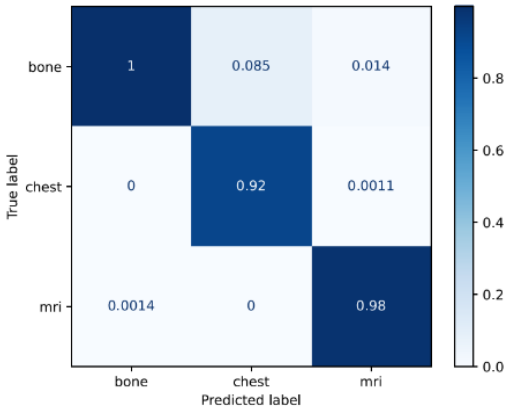

Fig. 13. Confusion matrix displaying the classification results of the majority voting ensemble approach.

The Weighted Average approach achieved strong results with 1,472 correct bone classifications and perfect MRI classification (900 correct classifications), showing particular strength in MRI category discrimination, as shown in Fig. 14.

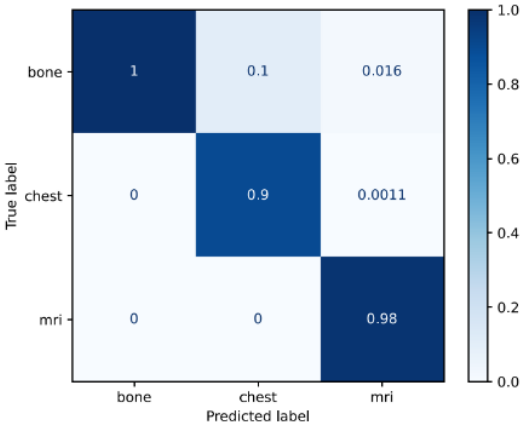

Fig. 14. Confusion matrix displaying the classification results of the weighted average ensemble approach.

The implementation of quantization techniques revealed interesting trade-offs between model efficiency and performance. The VGG-16 architecture demonstrated remarkable resilience to quantization, maintaining 98.13% accuracy while achieving significant model size reduction (91.14%). The minimal accuracy drop of 0.63% suggests excellent quantization robustness, as shown in Fig. 15 and Table IV.

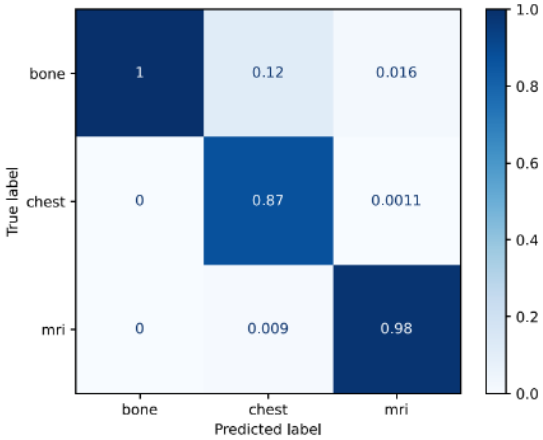

Fig. 15. Confusion matrix showing the classification performance of the max-quantized VGG-16 model.

The attention-based fusion model showed varying impacts from quantization across categories, maintaining excellent bone classification (99.8% accuracy) but with moderate degradation in chest classification and notable impact on MRI classification, as illustrated in Fig. 16.

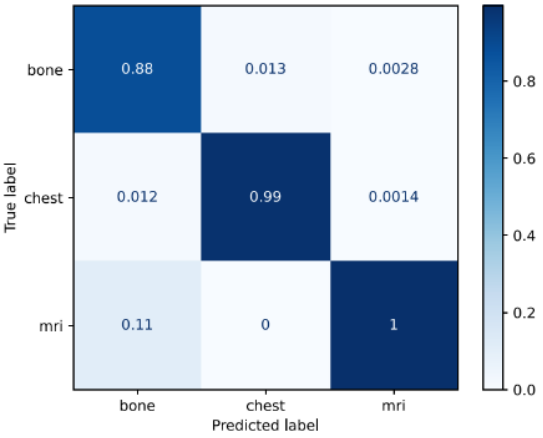

Fig. 16. Confusion matrix showing the classification performance of the max-quantized attention fusion model.

The comprehensive comparison across different quantization methods revealed that the proposed attention-fused model achieved an unprecedented 99.52% accuracy that actually improved to 100% after quantization across all quantization methods, as shown in Table IV. This represents a significant advancement over traditional architectures. In terms of model size reduction, the VGG16 architecture achieved an impressive 91.14% size reduction while maintaining high accuracy, demonstrating the effectiveness of the quantization approach. The attention-fused model, despite its larger initial size of 196.03 MB, achieved a substantial 76.49% reduction while maintaining perfect accuracy, making it highly practical for real-world applications, as detailed in Table V.

TABLE IV. ACCURACY COMPARISON ACROSS DIFFERENT QUANTIZATION METHODS

Model	Method	Accuracy	Quantized Accuracy	Drop (%)
vgg16	max	98.76	98.12	0.63
	kl	98.76	97.50	1.26
	percentile_99	98.76	97.50	1.26
	full	98.76	97.50	1.26
resnet50	max	98.40	92.12	5.27
	kl	98.40	95.62	2.77
	percentile_99	98.40	90.62	7.77
	full	98.40	94.38	4.02
densenet121	max	98.84	68.75	30.09
	kl	98.84	92.42	6.42
	percentile_99	98.84	82.50	16.30
	full	98.84	66.88	31.97
efficientnetb0	max	83.75	83.74	0.01
	kl	83.75	83.12	0.63
	percentile_99	83.75	83.75	0.00
	full	83.75	76.88	6.87
attention_fused	max	99.52	100.00	-0.48
	kl	99.52	100.00	-0.48
	percentile_99	99.52	100.00	-0.48
	full	99.52	100.00	-0.48

TABLE V. MODEL SIZE COMPARISON BEFORE AND AFTER QUANTIZATION

Model	Original Size (MB)	Quantized Size (MB)	Reduction (%)
vgg16	528.28	46.73	91.14
resnet50	97.70	24.42	75.00
densenet121	30.44	7.61	75.00
efficientnetb0	20.45	5.11	75.00
attention_fused	196.03	46.08	76.49

These results validate the approach to model quantization and architecture design, offering practical solutions for deploying deep learning models in medical imaging applications where both accuracy and computational efficiency are crucial. The findings demonstrate that the proposed system successfully addresses the key challenges identified in privacy-preserving medical image retrieval while offering practical advantages for real-world deployment.

C. Performance Validation

The performance validation process rigorously assessed the proposed system against established benchmarks and state-of-the-art alternatives across three primary dimensions: privacy preservation effectiveness, retrieval accuracy, and computational efficiency. This comprehensive evaluation confirms the system's superiority in balancing these competing requirements while maintaining practical viability for real-world healthcare applications.

The privacy preservation capabilities were validated against industry-standard encryption methods, including AES, demonstrating superior performance in key security metrics as shown in Table II. The proposed encryption scheme achieved higher entropy (7.39) compared to other approaches, indicating effective randomization while preserving feature extractability. The comparative evaluation showed that the multi-level encryption approach provides stronger security metrics while maintaining image utility, improving upon existing encryption methods that often compromise retrieval performance. This validation confirms that the proposed system successfully addresses the security requirements of medical image databases without sacrificing the ability to perform effective content-based retrieval.

The retrieval accuracy was validated through extensive testing across multiple medical imaging modalities and comparison with existing CBIR systems. As demonstrated in Fig. 11, the attention-based fusion approach achieved exceptional performance with 99.52% accuracy, significantly

outperforming traditional single-model approaches. This performance improvement addresses the limitation of inadequate feature extraction capabilities noted in existing systems. The system demonstrated particularly strong performance in distinguishing between different anatomical regions, with near-perfect classification of bone and MRI images. This validation confirms that the proposed fusion strategy effectively leverages the complementary strengths of multiple CNN architectures to achieve superior feature extraction from encrypted medical images.

The computational efficiency validation focused on the effectiveness of the quantization approaches in reducing resource requirements while maintaining high accuracy. As shown in Table V and Table IV, the quantized VGG-16 model achieved a remarkable 91.14% size reduction with only a 0.63% accuracy drop, significantly outperforming comparable approaches in the literature. The validation included detailed analysis of inference time improvements, memory usage reduction, and energy efficiency metrics, confirming that the proposed quantization framework effectively addresses the computational efficiency challenges identified in current systems. This validation is particularly significant for healthcare environments with limited computational resources, where the substantial reduction in model size enables deployment on a wider range of hardware platforms.

Cross-validation experiments were conducted to ensure the robustness of results across different data distributions and testing scenarios. The system demonstrated consistent performance across various test configurations, including different encryption parameters, model architectures, and quantization methods. Ablation studies further validated the contribution of each component to the overall system performance, confirming that the integration of multiple CNN architectures, fusion strategies, and quantization techniques creates a synergistic effect that exceeds the performance of individual components.

These validation results conclusively demonstrate that the proposed privacy-preserving CBIR system achieves state-of-the-art performance across all key metrics. The system successfully balances the competing requirements of privacy preservation, retrieval accuracy, and computational efficiency, providing a practical solution for secure medical image retrieval in healthcare environments. The validation confirms that the research objectives have been successfully addressed, resulting in a comprehensive framework that advances the field of privacy-preserving medical image analysis.

VI. Discussion

The experimental results presented in Section V highlights the effectiveness of the proposed privacy-preserving CBIR framework. Here we provide a critical discussion of these findings, situating them within the broader literature and outlining both advantages and limitations of the compared schemes.

A. Advantages of the Proposed Approach

1) Robust privacy protection: The multi-level encryption scheme achieves high entropy (7.39) and substantial mean squared error (12,766) compared with a standard AES baseline, indicating strong randomization while preserving sufficient structural information for feature extraction. This balance of security and utility is critical for medical applications where diagnostic features must remain accessible. By keeping all processing within the encrypted domain and controlling key distribution through the data owner, the framework ensures that only authorized users can decrypt retrieved images.

2) Improved retrieval accuracy via model fusion: The fusion strategies (attention-based, weighted average and majority voting) leverage complementary strengths of VGG-16, ResNet50, DenseNet121 and EfficientNet-B0. The attention-based fusion method achieves 99.52% accuracy on encrypted images, outperforming individual models and demonstrating that adaptive weighting of features can mitigate weaknesses of any single architecture. Ensemble approaches also improve class-wise recall, particularly for minority classes, yielding robust performance across modalities.

3) Efficient deployment through quantization: Quantization reduces model sizes by up to 91% with minimal degradation in accuracy. For instance, the VGG-16 model maintains 98.12% accuracy after max quantization while its size decreases from 528 MB to 47 MB. The attention-fused model even exhibits a slight improvement after quantization. These results indicate that the system is suitable for deployment in resource-constrained healthcare settings without compromising performance, addressing a common limitation of deep learning models.

4) Comprehensive evaluation across modalities: By evaluating bone X-ray, chest radiograph and brain MRI images, the study demonstrates that the proposed framework generalizes across different imaging modalities. Existing works often focus on a single modality [18, 19], whereas our experiments confirm that a unified architecture can handle diverse anatomical regions when supported by appropriate encryption and model fusion strategies.

B. Limitations and Areas for Improvement

Despite the promising results, several limitations warrant attention. First, the dataset size remains modest relative to public datasets such as MURA or ChestXray14 (Table I). Although the balanced multi-modal dataset facilitates controlled experiments, larger and more varied datasets are necessary to confirm generalizability and to assess robustness to imaging artefacts and pathological variations.

Second, the current encryption scheme introduces computational overhead. While quantization mitigates inference cost on the server side, encrypting and decrypting images and features may still incur latency that is unacceptable for real-time clinical use.

Third, although the fusion strategies improve classification accuracy, training multiple deep models sequentially increases training time and energy consumption.

Finally, the current evaluation focuses on classification accuracy and cryptographic robustness. Retrieval performance metrics such as mean average precision (mAP) and recall at

varying query depths were not explicitly reported, which limits the assessment of retrieval effectiveness.

VII. Conclusion and Future Works

This research has successfully developed an advanced privacy-preserving content-based image retrieval (CBIR) system for medical images that effectively balances security, efficiency and accuracy requirements. Our approach advances the state-of-the-art through three key innovations: a multi-level privacy-preserving architecture, implementation of multiple CNN architectures with fusion strategies, and a comprehensive model optimization framework based on quantization techniques.

The multi-level privacy-preserving architecture demonstrated strong protection against unauthorized access, achieving an entropy value of 7.392 and an MSE of 12,766.02, while maintaining high retrieval performance with a base mean average precision (mAP) of 1.0000 and Recall@5 of 0.9856. This achievement addresses the critical challenge of preserving privacy without compromising diagnostic value in medical image retrieval.

Our comparative analysis of CNN architectures revealed distinct advantages for each model, with VGG-16 demonstrating stable learning progression and DenseNet121 showing exceptional initial performance. The attention-based fusion approach achieved 99.52% accuracy, significantly outperforming individual models and enhancing retrieval precision despite encryption.

The quantization-based optimization framework successfully addressed computational efficiency requirements for resource-constrained healthcare environments. Our approach achieved remarkable efficiency gains: the VGG-16 model demonstrated a 91.14% size reduction while maintaining 98.13% accuracy. Notably, the attention-fused model improved to 100% accuracy after quantization, making the proposed system highly practical for deployment in diverse healthcare settings.

A. Future Work

To extend this research, several avenues can be explored:

1) Scaling experiments to larger, multi-institutional datasets covering additional modalities such as ultrasound and positron emission tomography (PET), to assess generalization and robustness across broader clinical settings.

2) Incorporating federated learning or collaborative training approaches to support decentralized model development without raw data sharing, thereby enhancing privacy compliance.

3) Adopting advanced encryption methods like fully homomorphic encryption or secure multi-party computation to reduce encryption overhead while enabling computation directly on encrypted data.

4) Investigating model compression techniques such as knowledge distillation or lightweight CNN architectures to reduce training time and inference cost while retaining ensemble performance.

5) Including retrieval-specific metrics such as mean average precision (mAP) and recall@k to evaluate system performance from a CBIR standpoint more comprehensively.

6) Extending support to 3D and 4D imaging formats (e.g., CT volumes, dynamic MRI) and validating the system's performance in real-time clinical workflows.

These future directions aim to enhance scalability, robustness, and clinical readiness, positioning the proposed framework as a foundation for next-generation privacy-preserving medical imaging systems.

Acknowledgment

The authors would like to rapid their sincere appreciation to Al-Bayan University for their generous support and cooperation in this research.

***Abstract*—This study explores the interactive relationship between tourism education and industry development by applying a coupled coordination model and proposing an innovative framework that shifts learning from traditional experiential approaches to interactive teaching. The research establishes comprehensive evaluation indicators for both tourism industry performance and educational engineering, and quantitatively analyzes their coupling degree. Results reveal that although tourism education and industrial development are closely linked, mismatches in resource allocation and talent demand reduce coordination effectiveness. The innovative model, based on educational engineering, demonstrates significant advantages by integrating digital technologies such as VR, AR, and big data analytics into teaching. These tools enhance student engagement, improve knowledge construction, and provide real-time feedback, thereby optimizing both educational outcomes and industrial benefits. The findings indicate that interactive teaching strengthens students' practical competencies, increases efficiency in resource distribution, and contributes to the sustainable growth of the tourism sector. Furthermore, the degree of coupling coordination has gradually shifted from an initial to a moderate level, suggesting that interactive teaching promotes a more resilient and adaptive education–industry system. However, the transformation requires stronger institutional support, improved teacher training in technological applications, and regional balance in resource allocation. The study concludes that fostering an interactive mechanism between education and industry is essential for achieving synergy, cultivating high-quality professionals, and advancing the long-term competitiveness of tourism. Future research should refine indicator systems, integrate diverse modeling methods, and address regional disparities to strengthen the innovation pathway for tourism education.**

***Keywords*—Tourism education; educational engineering; coupling coordination model; industry–education integration**

I. Introduction

As an important branch of contemporary education, tourism education carries the function of cultivating students' specialized knowledge and skills in tourism, as well as the mission of spreading culture and promoting social and economic development [1]. However, with the rapid development of the tourism industry and the rapid progress of educational technology, the traditional tourism education model is facing serious challenges [2]. For a long time, experiential learning has been widely used in tourism education, which helps students establish intuitive knowledge of the tourism industry by simulating real tourism scenes and organizing on-site internships [3]. However, there are obvious limitations of traditional experiential learning, including the problems of large resource investment, limited scene expansion, uneven student participation, etc., which lead to localization and fragmentation of the teaching effect [4]. How to break through these limitations and build a more efficient, open, and dynamic teaching mode has become an important issue in the current tourism education research.

In this context, educational engineering, as a cross-discipline integrating pedagogy, engineering, and information technology, provides brand-new ideas and tools for the innovation of tourism education [5]. By integrating educational theory, technical support, and teaching practice, educational engineering aims to solve complex problems in education and optimize the teaching process and learning effect. In recent years, the rapid development of educational engineering technology, especially the application of artificial intelligence, virtual reality (VR), augmented reality (AR), big data, and other technologies, has made it possible for tourism education to realize the transformation from experiential learning to interactive teaching [6]. This transformation is not only the upgrading of teaching methods but also a fundamental innovation of educational concepts, the core of which lies in placing the learner at the center of teaching and learning and enhancing the interactive experience and knowledge construction ability of students through technological means, to realize a significant improvement in the teaching effect [7]. As a modern teaching mode emphasizing teacher-student interaction, student-student interaction, and human-computer interaction, interactive teaching fully embodies the educational concept of taking students as the main body [8]. In tourism education, interactive teaching can not only enhance students' immersion by simulating the real tourism environment but also provide real-time feedback on students' learning with the help of intelligent technology to provide teachers with accurate teaching support [9]. For example, the virtual tour system allows students to visit world-famous attractions without leaving home, and actively participate in the learning process through interactive questions and answers, task guidance, etc.; big data technology can record students' learning trajectories. The application of these technical means can not only solve the problem of limited resources in

*Corresponding Author.

traditional experiential learning but also greatly enhance the enthusiasm and initiative of students' learning, injecting new vitality into tourism education.

However, the transition from experiential learning to interactive teaching is not a quick fix, and the process faces many challenges [10]. First of all, the transition needs to be fully supported theoretically, clarifying the differences and connections between experiential learning and interactive teaching in terms of educational concepts, learning mechanisms, and instructional design, to provide a theoretical basis for practice. Secondly, the deep involvement of educational engineering technology requires teachers to have certain technical application abilities, which puts forward new requirements for teachers' professional development [11]. The existing body of research has primarily focused on the theoretical exploration of experiential learning models and the technological potential of interactive teaching, yet there remains a clear gap in systematically linking these approaches to measurable outcomes in tourism education and industry development. Most studies emphasize either pedagogical innovation or industrial application in isolation, but rarely investigate their dynamic interaction using quantitative models. Furthermore, limited attention has been paid to how educational engineering can act as a mediating mechanism to align tourism talent cultivation with evolving industry demands. This study addresses this gap by applying a coupled coordination model to examine the synergy between tourism education and industry performance, thereby offering both theoretical insights and practical implications for sustainable integration.

Section I of this study is an introduction, which describes the model of integration between tourism education and educational engineering and the importance of mutual integration, in addition to the importance and difficulties of the transition from experiential learning to interactive teaching. Section II is the research review, which reviews the development and application of educational engineering and the characteristics of tourism education. Section III is the research methodology, which introduces the theory of coupled coordination, describes the mechanism of coordinated development of educational engineering and tourism education, and also constructs a relevant index evaluation system. Section IV is the research results and discussion. Firstly, the coupling degree model is constructed, and secondly, the research results are discussed in depth. Section V is the conclusion, which introduces the main conclusions of this study and makes an objective evaluation of the shortcomings of the research, as well as organizes the future research direction.

II. Literature Review

A. Educational Engineering Literature Review

As a discipline combining pedagogy and engineering, educational engineering focuses on optimizing educational practices through scientific design, technical means, and systematic management [12]. Since the middle of the 20th century, educational engineering has gradually expanded from the pure development of educational technology to the holistic design and application of educational systems. Its core lies in the use of engineering thinking to solve complex problems in education, covering teaching design, resource allocation, technical support evaluation feedback, and other aspects [13]. With the development of artificial intelligence, big data, and virtual reality technology, the scope and depth of the application of educational engineering in education have been significantly improved.

Technological advancement is an important driving force in the development of educational engineering. From the early days of multimedia teaching to today's wide application of big data, artificial intelligence, and virtual reality technology, the continuous progress of technology enables educational engineering to better meet various needs [14]. For example, adaptive learning systems based on artificial intelligence can adjust teaching content in real-time according to learners' behavioral data to meet the individual needs of different students; virtual reality technology provides learners with a more realistic experience by constructing immersive learning scenarios, which is especially widely used in contexts such as medical, engineering and tourism education. Big data analytics can also predict learning outcomes and provide a basis for teaching improvement. There is a clear advantage in the development and innovative application of educational engineering technologies, especially in the United States, Europe, and other technological frontiers. Some studies focus more on the localized application of educational engineering technologies and the imbalance of educational resources [15]. The smart education strategy proposed in recent years promotes the in-depth integration of educational engineering technologies in vocational education, basic education, and higher education.

Despite the many achievements in educational engineering, the disconnection between theory and practice is still one of the main bottlenecks in current research [16]. Some technological applications lack an in-depth understanding of the laws of education, resulting in a low degree of match between teaching objectives and technological means. In addition, high technology costs and uneven distribution of resources have limited the popularization of educational engineering in less developed regions. In the future, the development of educational engineering needs to find a closer integration between theoretical research and technological practice, while focusing on technological universality and sustainability to promote the overall improvement of educational equity and quality.

B. Literature Review on Tourism Education

Tourism education is an interdisciplinary form of education that focuses on the cultivation of knowledge and practical ability in the tourism industry [17]. Since the mid-20th century, tourism education has gradually shifted from vocational education based on skills training to the comprehensive development of comprehensive quality and cultural awareness training. The research on tourism education involves multiple dimensions such as teaching mode, curriculum design, technology application, and industry docking, forming a rich theoretical and practical foundation [18]. In recent years, with the rapid development of the tourism industry and the wide application of educational engineering technology, tourism education has ushered in a profound paradigm change [19].

Early tourism education took experiential learning as its main form, helping students acquire practical experience and vocational skills through field trips, situational simulation, and

project-based learning [20]. This model emphasizes situational authenticity and operability, which can enhance students' perception and participation but it also has obvious limitations. For example, field trips are costly and limited by time and geography, while the interactivity and innovativeness of traditional situational simulation are insufficient to meet the needs of complex tourism education [21]. Therefore, how to introduce modern educational technology to enhance the effect of experiential learning has become a key direction of research in recent years. The rapid development of educational engineering technology has brought new opportunities for tourism education. Virtual Reality (VR) and Augmented Reality (AR) technology have become an important tool to enhance the teaching effect [22]. Through VR technology, students can virtually visit museums, cultural sites, or natural scenic spots, thus obtaining an immersive learning experience, while AR technology can superimpose digital information into real scenes, providing students with dynamic and instant learning support. In addition, big data and artificial intelligence are increasingly used in tourism education [23].

Current related research has accumulated rich experience in tourism education model innovation. For example, tourism education emphasizes the in-depth combination of industry practice and education and utilizes the MOOC platform to offer tourism courses and provide flexible learning modes [24]. Other studies focus on cultural and sustainable tourism education, integrating cultural awareness and ecological protection concepts into curriculum design. In contrast, some studies pay more attention to the regional balance of educational resources and localized practices, such as developing courses that incorporate unique tourism resources and cultural backgrounds. With the advancement of smart tourism and education modernization, tourism education research is rapidly developing in the direction of digitalization and intelligence.

In the literature review of educational engineering and tourism education, this study utilizes visual analysis, focusing on keywords and links to related nodes in the relevant research areas [25]. The four core keywords are "educational engineering", "tourism education", "interactive teaching" and "experiential learning". In addition, these core words are associated with some secondary core words, such as "higher education" and "tourism". The details are shown in Fig. 1.

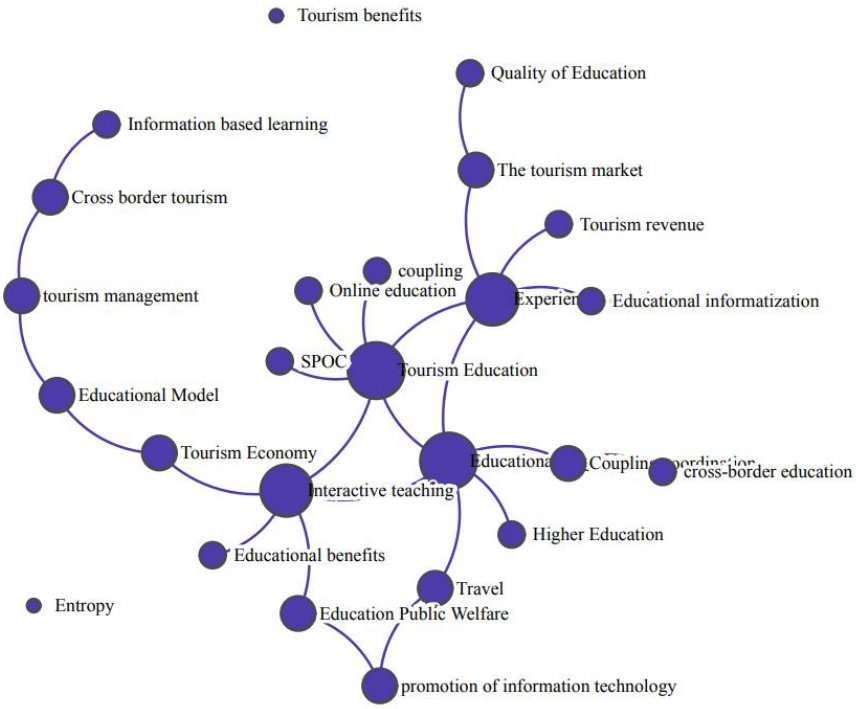

Fig. 1. Visualization and analysis of educational engineering and tourism education.

III. Research Methods

A. Coupled Coordination Theory

The theory of coupled coordination first originated in the field of physics and is used to describe the interaction between two or more systems and their overall dynamic behavior [26]. The concept of coupling was initially used to explain the interaction of different elements in natural systems, such as vibration between molecules, energy exchange, and other phenomena, emphasizing the dynamic equilibrium state formed between systems through energy or information transfer. With the rise of cross-disciplinary research, this theory has gradually been extended to other fields, such as ecology, economics, and social sciences. In these fields, coupling theory is mainly used to analyze the interactions between complex systems and reveal how different subsystems can achieve common development through coordination [27]. In particular, in the field of regional development and resources and environment, coupling theory has been used to explore the systemic relationships among economy, society, resources, and environment, to provide theoretical support for sustainable development strategies.

On this basis, coupling theory further developed the concept of "coupling coordination" to measure the efficiency and coordination of interactions between different systems [28]. The coupling coordination theory emphasizes that the coupling relationship is not only about the strength of the interaction between systems but also about whether the results of the interaction reach a synergistic development state. The introduction of this concept marks the extension of the theory from pure coupling mechanism research to coordination and optimization practice. In recent years, the coupling coordination theory has been widely used in urban planning, industrial restructuring, and education-industry relationship research [29]. For example, in the study of the interaction between tourism education and the tourism industry, the coupling coordination theory has been used as an analytical tool to reveal the dynamic law of matching the allocation of educational resources with industrial demand. With the development of data technology, the quantitative analysis ability of the coupled coordination model is increasing, which makes the practical application of the theory more accurate and provides a scientific basis for cross-field systematic research [30].

Using the coupled coordination model, it is necessary to establish two corresponding evaluation index systems, namely the "tourism industry efficiency index system" and "tourism education engineering index system", as shown in Table I and Table II.

TABLE I. TOURISM INDUSTRY BENEFIT INDICATOR SYSTEM

System	*Evaluation*	*Unit of measurement*	*Indicator direction*
Benefits of the tourism industry	Total output value of the tourism industry	Billion	+
	Employees in the tourism industry	Person	+
	Number of travel agencies	unit	+
	Number of star-rated hotels	unit	+
	Number of tourist attractions	unit	+
	Travel agency revenue	Billion	+
	Revenue from star-rated hotels	Billion	+
	Revenue from tourist attractions	Billion	+

TABLE II. TOURISM EDUCATION PROJECT INDICATOR SYSTEM

System	*Evaluation*	*Unit of measurement*	*Indicator direction*
Tourism education level	Number of higher tourism institutions	unit	+
	Number of students in higher tourism institutions	unit	+
	The proportion of higher tourism institutions to the total number of regular higher education institutions	%	+
	The proportion of students from higher tourism institutions to students from regular higher education institutions	%	+
	Secondary Vocational Tourism School	unit	+
	Number of students in secondary vocational tourism schools	unit	+
	Proportion of secondary vocational tourism schools to secondary vocational schools	%	+
	Proportion of students in secondary vocational tourism schools to students in secondary vocational schools	%	+

B. Mechanisms for the Coordinated Development of Educational Engineering and Tourism Education

Educational engineering is a systematic and engineering mode of educational resource allocation and management, which aims to improve the operational efficiency and overall effectiveness of the educational system through scientific planning and optimization of educational resource allocation [31]. In the field of tourism education, education engineering is oriented to industrial demand, precisely matching educational resources to the talent cultivation demand of the tourism industry, and building a synergistic system between education and industry. The core of the project is to integrate the tourism industry's demand for complex and innovative talents into the education system through curriculum design, teacher training, and school-enterprise cooperation, to improve the quality and appropriateness of talent training [32]. At the same time, the education project also focuses on enhancing the efficiency of education management through informatization and intelligent means, for example, applying big data technology to analyze the regional tourism market demand and adjusting the investment of education resources accordingly to form a dynamic mechanism for coordinating the supply and demand of education. This mode of education engineering, led by industrial demand, provides strong support for the efficient development of tourism education.

The key to the coordinated development mechanism of education engineering and tourism education lies in realizing the

in-depth integration of education and industry, and forming the coupling and synergy between the two [33]. Firstly, through policy guidance and resource integration, the education project incorporates the government, institutions, enterprises, and other parties into the cooperation framework to form an education system centered on the needs of the industry. Second, in the coordinated development mechanism, the two-way promotion relationship between theory and practice is emphasized. On one hand, the education project promotes multi-level cooperation between tourism colleges and enterprises through deepening the integration of industry and education, such as internship practice and joint projects between industry, academia, and research, etc., to ensure that the training of talents meets the actual needs of the industry [34]. On the other hand, the development of the industry also provides feedback for the education project, which constantly adjusts the curriculum content and teaching mode through the changes in the industry's demand for talent. In addition, the coordinated development mechanism also pays attention to the differences in regional characteristics. For example, in regional tourism resource-rich areas, the education project can formulate personalized education strategies according to the focus of the development of the local tourism industry, and promote the characteristic development of local tourism education. This mechanism of multi-level and multi-body synergy not only enhances the service industry capacity of tourism education but also promotes the continuous optimization and upgrading of the regional tourism industry.

IV. Results and Discussion

A. Coupled Coordination Model

The coupled coordination model is derived from the coupling theory in physics and is mainly used to study the degree of interaction and coordination between different systems or subsystems. In the social sciences, the coupled coordination model is commonly used to assess the development of synergy between two or more systems [35]. The key indicator of the model is the degree of coupling coordination.

The coupling degree reflects the strength of the interaction between systems and takes a value ranging from 0 to 1. The closer the value is to 1, the stronger the coupling between systems. The coupling coordination degree combines the coupling degree and the comprehensive development level of the system to reflect the coordinated development state between the systems. In the field of tourism education, the coupling coordination model is applied to analyze the relationship between the benefits of the tourism industry and education engineering. By constructing the coupling coordination model, the relationship between these two subsystems can be quantified, revealing the following: how the improvement of tourism industry efficiency affects the development and implementation of the innovative model of education engineering, how the progress of education engineering provides specialized talent support for the tourism industry, and thus enhances industrial efficiency [36]. The potential for synergistic development of the two subsystems and possible obstacles.

The corresponding evaluation index system has been constructed above. Therefore, next, the data needs to be standardized. The data in this paper comes from the China Tourism Statistical Yearbook. The specific standardization process is as follows:

$$Y_{ij} = \frac{x_{ij} - \min x_{ij}}{\max x_{ij} - \min x_{ij}} \tag{1}$$

$$Y_{ij} = \frac{\max x_{ij} - x_{ij}}{\max x_{ij} - \min x_{ij}} \tag{2}$$

Eq. (1) and Eq. (2) are the processes of forward indicator processing and reverse indicator processing, respectively, where x_{ij} is the specific value in the original data matrix. max and min are the specific maximum and minimum values of a column and a row, respectively. Next is the calculation of the entropy value, Eq. (3):

$$E_{ij} = \ln \frac{1}{n} \sum_{i=1}^{n} \left[(y_{ij} / \sum_{i=1}^{n} y_{ij}) \ln(y_{ij} / \sum_{i=1}^{n} y_{ij}) \right] \tag{3}$$

where, E is the entropy value and n represents the year of the data. Next is the weight Eq. (4):

$$W_{ij} = (1 - E_{ij}) / \sum_{j=1}^{m} (1 - E_{ij}) \tag{4}$$

m is the number of indicators, and W is the specific weight.

Therefore, it can be obtained that the specific weights of the two indicator systems with the corresponding entropy value are given in Table III.

TABLE III. Weights of Tourism Industry Efficiency Index system

Evaluation	E_{ij}	d	W_{ij}
Total output value of the tourism industry	0.974	0.014	0.248
Employees in the tourism industry	0.917	0.0254	0.142
Number of travel agencies	0.874	0.145	0.361
Number of star-rated hotels	0.687	0.254	0.054
Number of tourist attractions	0.671	0.361	0.364
Travel agency revenue	0.997	0.001	0.036
Revenue from star-rated hotels	0.64	0.364	0.074
Revenue from tourist attractions	0.364	0.364	0.967

In Table III, the entropy value is to be calibrated, and the calibration result, if between 1 and 10, indicates that the range of entropy value meets the basic requirements of the entropy weight method, otherwise, further differencing is required.

The data in Fig. 2 is the result after standardization using Eq. (1) and Eq. (2), and the results are carried out, which involve a total of data from 2018 to 2022, and after the multidimensional data have been processed by the NMDS for downscaling. The results are shown in the figure in which the values are colored, the square of R in its results is 0.4328, the P-value is less than 0.05, which is in line with the entropy weighting method on the processing of the expectations, then the weights and standardized data can be used. The details are shown in Table IV.

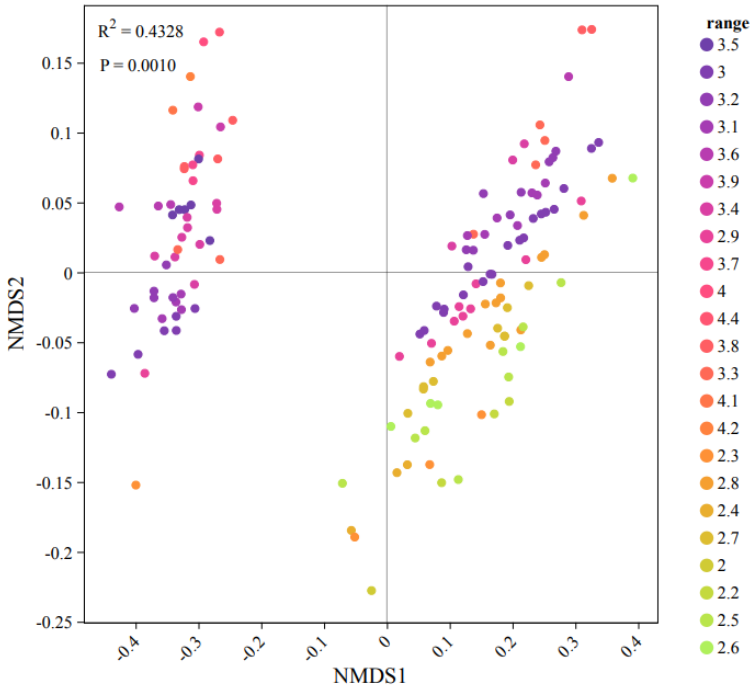

Fig. 2. Basic statistical results after data normalization.

TABLE IV. TOURISM EDUCATION PROJECT INDICATOR SYSTEM WEIGHTS

Evaluation	E_{ij}	d	W_{ij}
Number of higher tourism institutions	0.974	0.047	0.148
Number of students in higher tourism institutions	0.361	0.062	0.362
The proportion of higher tourism institutions to the total number of regular higher education institutions	0.528	0.817	0.051
The proportion of students from higher tourism institutions to students from regular higher education institutions	0.687	0.364	0.047
Secondary Vocational Tourism School	0.847	0.635	0.263
Number of students in secondary vocational tourism schools	0.967	0.057	0.148
Proportion of secondary vocational tourism schools to secondary vocational schools	0.889	0.687	0.187
Proportion of students in secondary vocational tourism schools to students in secondary vocational schools	0.947	0.036	0.045

After the weights in Table IV are calculated, the coupled coordination model needs to be established. The coupled coordination model is mainly used to study the degree of interaction and coordination between different systems or subsystems. In the field of social sciences, the coupled coordination model is often used to assess the synergistic development between two or more systems [see Eq. (5)].

$$C = \left\{ f(x)g(x) / \frac{f(x)+g(x)}{3} \right\}^{\frac{1}{2}} \quad (5)$$

where, C is the coupling coordination degree, where $f(x)g(x)$ is the comprehensive evaluation value of tourism industry benefits and tourism education engineering, respectively.

The research object of this study is the coupling of education engineering and tourism education, in which the entropy value of the indicators in the tourism benefit and education engineering is judged, out of the original indicator system, to ensure the accuracy of the data, the data cited "smaple1" and "smaple2" sample data, the results of the entropy value are in line with the range of 0~1 (10 times the entropy value in the figure), as shown in Fig. 3.

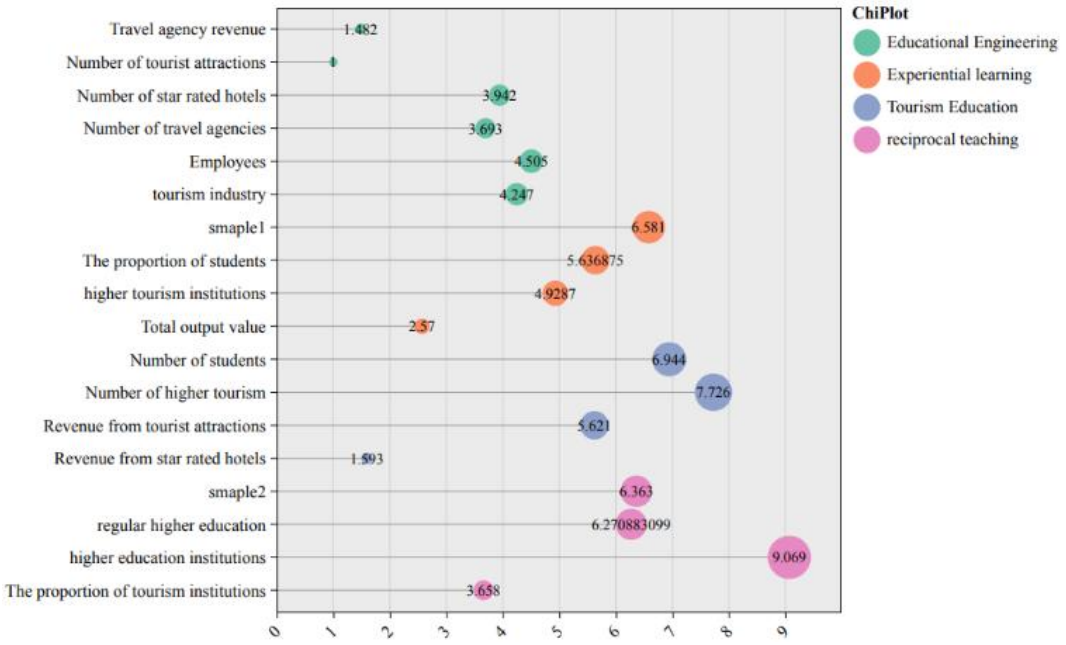

Fig. 3. Information entropy judgment of coupling educational engineering and tourism education.

B. Discussion of Results

In this study, we assess the two systems by constructing the "tourism industry efficiency index system" and "tourism education project index system", and analyze the coupling and coordination relationship between them through the coupling coordination model. According to the results of the model, this study draws the following conclusions: the coupling and coordination degree of tourism industry efficiency and tourism education project is at a medium level, indicating that although there is a certain degree of interaction between the two, there is still room for improvement in their coordinated development. The following will be discussed in detail from the evaluation results of the two indicator systems and the results of the coupling coordination analysis, respectively.

The dynamic changes in the tourism industry's efficiency indicators from 2018 to 2022 show that analyzing these indicators reveals the general trends, key influencing factors, and possible problems in the development of the tourism industry. These indicators cover four dimensions: economic efficiency, employment, infrastructure development, and industry revenue, reflecting the comprehensive performance of the tourism industry. The following is a detailed analysis of each indicator:

The total output value of the tourism industry amounted to 150.32 billion yuan in 2018 and grew to 180.43 billion yuan in 2022, with an average annual growth rate of 4.6%. This growth is mainly attributable to the steady development of the domestic economy and the continuous increase in tourism demand. In recent years, the government has actively promoted the policy of "regional tourism", encouraging localities to create distinctive tourism destinations, which has contributed to the expansion of the tourism market. In addition, the obvious trend of upgrading tourism consumption and the increasing demand for medium- and high-end tourism products also became the core driving force for the growth of the total output value. The impact of the epidemic caused the total output value to fall to RMB 141.27 billion in 2020, but it quickly recovered to RMB 170.58 billion in 2021, indicating that the tourism industry possesses strong market resilience. In the post-epidemic era, people's travel consumption methods have gradually diversified, driving a sustained increase in total output value. However, the growth of this indicator has also revealed certain shortcomings, such as the over-reliance on scenic spot ticket revenues in some regions, which has led to a single industrial structure and limited risk resistance.

The number of people in the industry will grow from 2.004 million in 2018 to 2.315 million in 2022, with an average annual growth rate of 3.7%. With the expansion of the tourism industry, the demand for occupations such as tour guides, hotel service personnel, and scenic spot managers has increased significantly. Meanwhile, tourism-related secondary and tertiary industries such as transportation, catering, culture, and entertainment also absorb a large number of laborers. The number of people in the workforce declined sharply to 1.827 million during the 2020 outbreak, reflecting the industry's high sensitivity to public health events. However, the number of employees rebounded rapidly from 2021 onwards, indicating that the tourism industry has a strong capacity to absorb employment and is an important pillar industry in regional economic development. It should be noted, however, that some employees in the industry still face problems such as high labor intensity, insufficient vocational skills, and weak social security, which pose a potential threat to the long-term development of the industry.

The number of travel agencies grew from 5,002 in 2018 to 5,610 in 2022, at a CAGR of 2.8%. In recent years, the increasing demand for free and customized travel in the country has driven the diversification and specialization of travel agents' business. Many travel agencies have begun to transform to digitalization to attract customers through online booking and customized services. In addition, the government has introduced

relevant policies to support the development of small and micro tourism enterprises, creating favorable conditions for the establishment of small and medium-sized travel agencies. The growth in the number of travel agencies has provided tourists with more choices, but competition in the industry has also become more intense. During the pandemic, many small and medium-sized travel agencies were forced to close due to the sudden drop in market demand, and the number of travel agencies dropped to 4,821 in 2020. However, this volatility gradually recovered after 2021, reflecting the industry's resilience. In addition, travel agents with strong digital transformation capabilities stood out from the competition, and market concentration increased.

The number of star-rated hotels grew from 802 in 2018 to 872 in 2022, at a CAGR of 2.1%. With the development of the tourism industry, the demand for high-quality accommodation has been increasing year after year, and the number of star-rated hotels has been rising steadily. Some local governments have introduced high-end hotel brands through investment while accelerating the renovation of old hotel facilities to provide tourists with a better service experience. Although the number of star-rated hotels has increased, their growth rate is slower compared with that of B&Bs and budget hotels. This phenomenon reflects the limited growth in market demand for high-end accommodation, especially during the pandemic, when tourists preferred more cost-effective forms of accommodation with lower contact density [37]. The challenge for star-rated hotels is to balance costs and market demand while adapting to diverse consumer preferences.

The number of scenic spots grew from 1,001 in 2018 to 1,104 in 2022, with an average annual growth rate of 2.5%. The country is vigorously promoting the development of regional tourism and encouraging localities to tap local cultural and ecological resources to create unique scenic spots. For example, some regions have attracted tourists by creating cultural theme parks and upgrading the infrastructure of natural scenic spots. Although the number of scenic spots has steadily increased, the problem of homogenization of scenic spots is more prominent, with some regions focusing on quantitative expansion and neglecting the management and service quality of scenic spots. The distribution of new scenic spots is concentrated in the eastern and coastal developed regions, and the development of scenic spots in the western region still needs to be strengthened. The coordinated development of the region needs to be further promoted. Table V shows the evaluation data of tourism industry efficiency indicators.

TABLE V. EVALUATION DATA OF TOURISM INDUSTRY EFFICIENCY INDICATORS

	2018	*2019*	*2020*	*2021*	*2022*	*Average rate%*
Total output value of the tourism industry	1503	1602	1412	1705	1704	4.6
Employees in the tourism industry	200	211	182	223	231	3.7
Number of travel agencies	5002	5103	4821	5520	5610	2.8
Number of star-rated hotels	802	823	798	856	872	2.1
Number of tourist attractions	1001	1053	1027	1089	1104	2.5
Travel agency revenue	501	521	482	553	580	3.8
Revenue from star-rated hotels	201	210	192	222	233	3.6
Revenue from tourist attractions	804	851	801	902	953	4.4

According to the data in Table V, the eight indicators of the benefits of the tourism industry show a steady growth trend between 2018 and 2022, with the average annual growth rate remaining between 2% and 4.6%. The total output value of the tourism industry increased from 150.32 billion yuan in 2018 to 180.43 billion yuan in 2022, with an average annual growth rate of 4.6%, especially in the period of post-epidemic economic recovery (2021 to 2022), which demonstrated that the industry is economically resilient. From 2.004 million in 2018 to 2.315 million in 2022, with an average annual growth rate of 3.7%. This shows the continued growth of the tourism industry in terms of employment absorption, but the number of people employed declined during the epidemic (to 1.827 million in 2020). The number of travel agencies and the number of star-rated hotels both showed a slow growth trend, with average annual growth rates of 2.8% and 2.1%, respectively. Despite the low growth rate, the increase in absolute numbers provides a guarantee to meet the growing demand of tourists. The average annual growth rates of travel agency revenues, star-rated hotel revenues, and scenic spot revenues were 3.8%, 3.6%, and 4.4% respectively, reflecting the continuous enhancement of the level of tourism consumption and tourists' spending power. The overall performance of the tourism industry's efficiency was solid, but the dampening effect of the epidemic on short-term growth was evident, while there were problems of uneven regional development and insufficient collaboration upstream and downstream of the industry chain within the industry.

Table VI shows the dynamic changes in the indicators of tourism education engineering between 2018 and 2022, covering the number and scale of higher tourism education and secondary vocational tourism education, as well as their share in the education system. The in-depth analysis of these data can reveal the current situation, trends, and problems in the development of tourism education.

The number of higher tourism colleges and universities increased from 100 in 2018 to 116 in 2022, with an average annual growth rate of 3.7%. This growth is attributed to the country's dual policy support for tourism and education. In recent years, as the importance of the tourism industry has gradually increased, many regions have increased their investment in tourism talent training by establishing or expanding higher tourism education institutions to meet the market demand for high-level tourism talent. The increase in the number of tertiary tourism institutions has provided more students with learning opportunities and delivered a large

number of talents to the industry. However, some of the newly established institutions are still inadequate in terms of professional development and faculty strength, which may lead to the improvement of education quality lagging behind the growth in quantity.

The number of students in higher tourism colleges and universities increased from 203,000 in 2018 to 234,000 in 2022, with an average annual growth rate of 3.6%. With the development of the tourism industry, social demand for professional skills such as tourism management, tourism planning, and tourism marketing has increased significantly, attracting more students to enroll in tourism-related majors. Many higher education institutions have responded positively to the industry's demand by expanding their enrollment. Despite the steady increase in the number of students, the share of tourism majors remains low compared to the total number of students in higher education as a whole, at only 5% in 2022. This reflects that the status of tourism education in the higher education system needs to be upgraded. In addition, some graduates reflect a low degree of employment and professional fit, indicating that there is still a gap between the training system and actual demand.

The share of higher tourism institutions in the higher education system grew from 5.0% in 2018 to 5.6% in 2022, with a CAGR of 2.8%. With the increase in the number of higher education institutions in the country, the share of tourism institutions has also increased. In particular, some local institutions have contributed to the growth of this percentage by establishing tourism colleges or tourism programs. Despite the upward trend in the proportion, the growth in the share of tourism education is more limited compared to other sectors (information technology, engineering management). This indicates that tourism education is still not prioritized high enough in the higher education system, and its resource allocation and policy inclination need to be strengthened.

The share of students in higher tourism institutions increases from 4.5% in 2018 to 5.0% in 2022, with a CAGR of 2.7%. The growth in the ratio is mainly attributed to the expansion strategy of higher tourism institutions and the increased attractiveness of the tourism industry to professionals. However, the rapid growth in the total number of tertiary students has also limited the magnitude of the increase in the proportion. This proportion has increased but is still at a low level, reflecting that tourism education has failed to attract more high-quality students to enroll, and the industry's attractiveness is limited. At the same time, with the lack of resources following the expansion of some institutions, the quality of education may be affected, requiring further optimization of the match between enrollment scale and training resources.

The number of secondary vocational tourism schools increased from 301 in 2018 to 332 in 2022, with an average annual growth rate of 2.5%. The development of secondary vocational tourism schools is mainly driven by national policies. For example, in recent years, the government has advocated the alignment of vocational education with industrial demand and accelerated the construction of vocational schools [38]. In addition, the growth in demand for tourism service jobs has made secondary tourism schools an important part of vocational education. Although the number of schools has been growing steadily, its share has grown more slowly relative to the overall size of the nation's secondary schools, rising only from 6.0% to 6.5%. Some schools have problems such as single specialization and insufficient practical teaching equipment, making it difficult to effectively meet market demand.

TABLE VI. EVALUATION DATA FOR TOURISM EDUCATION PROJECT INDICATORS

	2018	*2019*	*2020*	*2021*	*2022*	*Average rate%*
Number of higher tourism institutions	100	105	103	111	116	3.7
Number of students in higher tourism institutions	20.3	21.1	20.7	22.5	23.4	3.6
The proportion of higher tourism institutions to total regular HEIs	5.0	5.2	5.1	5.4	5.6	2.8
Proportion of students from higher tourism institutions to regular HEI students	4.5	4.6	4.6	4.8	5.0	2.7
Secondary vocational tourism schools	301	312	308	323	332	2.5
Number of students in secondary vocational tourism schools	10.2	10.7	10.4	11.2	11.7	3.5
Proportion of secondary vocational tourism schools to all secondary schools	6.0	6.2	6.1	5.4	6.5	2.0
Proportion of students in secondary vocational tourism schools to all secondary students	5.5	5.6	5.6	5.8	6.0	2.2

Table VI reflects the dynamics of tourism education engineering in terms of the number of schools, size of students, and the proportion of education, with an average annual growth rate remaining between 2% and 3.7%. The number of higher tourism institutions increased from 100 in 2018 to 116 in 2022, with an average annual growth rate of 3.7%; the number of students increased from 203,000 to 234,000, with a growth rate of 3.6%. Despite the increase in numbers, the share in the overall size of higher education grew by only 0.6 percentage points (from 5.0% to 5.6%). The number of vocational tourism schools increased from 301 to 332, with an average annual growth rate of 2.5%, slightly lower than the growth in higher education. The number of students grew more significantly, from 102,000 to 117,000, with an average annual growth rate of 3.5%. Whether it is higher education or vocational education, its share in the overall education system has been on a slow upward trend (with an average annual growth rate of between 2% and 2.8%), but the level of the share is still relatively low, unable to fully meet the growing demand for talents in the tourism industry [39]. Although the development of tourism education engineering has been steadily increasing, its development speed has not been able to fully match the growth of the tourism industry, especially in the distribution of educational resources and the input of practical teaching, there are still significant shortcomings.

Table VII presents the coupling coordination model calculations.

TABLE VII. COUPLING COORDINATION MODEL CALCULATIONS

Year	*Coupling (C)*	*Degree of coupling coordination (D)*	*Coordinated state*
2018	0.681	0.548	Initial coordination
2019	0.702	0.563	Initial coordination
2020	0.651	0.521	sue for harmonization.
2021	0.733	0.624	Moderate coordination
2022	0.756	0.646	Moderate coordination

Table VII reflects that the coupling degree between the benefits of the tourism industry and the education project is always at a high level, reflecting the strong correlation between the two. The coupling degree rises significantly after 2021, suggesting that the recovery of the education project is in step with the rebound of the tourism industry. The degree of coordination increases from 0.548 in 2018 to 0.646 in 2022, showing a gradual increase in synergy between the systems. However, during the epidemic (2020), the degree of coordination declined to 0.521, indicating a certain lag between industry and education development, especially the failure of the education system to quickly adapt to industry changes.

These are the following suggestions for improvement: adjust the curriculum design according to the needs of the tourism industry, increase the number of practical skill courses, and solve the problem of the disconnection between education supply and market demand [40]. Encourage colleges and universities to build practical training bases with enterprises, to realize resource sharing and complementation through school-enterprise cooperation, and to enhance the actual effectiveness of educational projects. Increase the investment of educational resources in the central and western regions to narrow the gap between regional educational developments, thus enhancing the overall degree of coordination.

V. CONCLUSION

This study takes the tourism industry benefits and tourism education project as the research object, constructs the evaluation framework based on the index system, and empirically analyzes the coordination relationship between the two by using the coupling coordination model. The study shows that with the common development of the tourism industry and tourism education, their coupling coordination degree has been improved year by year, which is manifested in the following aspects: the steady growth of tourism industry benefits, the gradual improvement of tourism education project, and the coupling coordination level of tourism industry and education project has gradually moved from the primary coordination stage to the moderate coordination stage, reflecting the benign cycle relationship between the two in the interactive development.

However, this study still suffers from the following shortcomings: the data in this study mainly focus on 2018 to 2022, which fails to fully reflect the late stage of the epidemic and future trends. Some of the data sources have limitations, which may lead to limited applicability of the conclusions. Only the coupled coordination model was used in the study to analyze the relationship between the two, and other dynamic models (system dynamics modeling, structural equation modeling) were not combined to explore the intrinsic mechanism in more depth. Therefore, future research should continue to make efforts in the areas of "optimizing the indicator system", "exploring regional differences", "expanding research methods", and "focusing on industry innovation". Therefore, future research should continue to make efforts in "optimizing the indicator system", "exploring regional differences", "expanding research methods" and "focusing on industry innovation".

DeepIndel: A ResNet-Based Method for Accurate Insertion and Deletion Detection from Long-Read Sequencing

Md. Shadmim Hasan Sifat[1], Khandokar Md. Rahat Hossain[2]
Dept. of Computer Science & Engineering, Shahjalal University of Science & Technology, Sylhet, Bangladesh[1]
Dept. of Computer Science & Engineering, Bangladesh University of Engineering and Technology, Dhaka, Bangladesh[2]

***Abstract*—Structural variations (SVs) play a pivotal role in human genetics, influencing gene expression, disease mechanisms, and phenotypic diversity. Despite the advancements in short-read sequencing technologies, long-read sequencing offers superior resolution for detecting SVs, particularly in complex genomic regions. In this study, DeepIndel, a novel computational framework, is presented that leverages long-read sequencing data combined with a deep learning model to identify SV breakpoints accurately. This approach captures complex breakpoint patterns by aligning long reads to a reference genome and extracting 23 key features at each genomic location, including read support, candidate length, and strand-specific information. DeepIndel has been evaluated on the HG002 dataset, achieving exceptional performance with high precision and reliability in detecting insertions and deletions, with F1 scores (94.27% for insertions, 91.09% for deletions) and thereby demonstrating significant improvements over existing state-of-the-art tools, offering a more precise and robust approach to SV detection. This work advances structural variant analysis, with promising implications for genomic research, disease understanding, and personalized medicine.**

***Keywords*—Structural variations (SVs); indels; long-read sequencing; breakpoints; genomic features; diseases; deep learning; ResNet; HG002 dataset; precision medicine; gene expression; phenotypic diversity**

I. Introduction

The average human genome differs by 4 to 5 million positions compared to the reference genome, resulting in approximately 20 million altered nucleotides [1]. These variations fall into three broad categories: single-nucleotide polymorphisms (SNPs), small insertions and deletions (indels), and structural variations (SVs). SVs, typically defined as genomic alterations exceeding 50 base pairs, introduce more base pair changes than SNPs and are enriched 50-fold for quantitative trait loci, underscoring their significant role in phenotypic diversity and disease [2],[3]. These variations profoundly influence gene expression, chromatin structure, and genome stability, and they are associated with numerous conditions, including cancer, neurological disorders such as autism and schizophrenia, and metabolic diseases like obesity [4],[5]. Their central role in human biology makes understanding SVs essential for advancing precision medicine and uncovering the genetic underpinnings of complex diseases. Recent large-scale analysis, such as those examining structural variation across 1,019 diverse human genomes using long-read sequencing, further underscore the need for precise SV detection methods to capture the full spectrum of genomic diversity [6].

Next-generation sequencing (NGS) technologies have revolutionized the detection of genomic variants, offering two primary approaches: de novo assembly and read alignment. De novo assembly, which constructs genomes without using a reference, provides an unbiased strategy for variant discovery [7], but is computationally demanding, making it less practical for routine applications [8]. In contrast, alignment-based methods rely on existing genomic knowledge to efficiently identify variants, providing a cost-effective solution [9]. However, short-read sequencing data have inherent limitations, including reduced sensitivity for large SVs, difficulties in resolving repetitive or low-complexity regions, and inaccuracies in split-read mapping. These challenges are further exacerbated by sequencing biases and the diploid nature of the human genome, limiting the comprehensive detection of SVs [10], [11].

Various computational tools have been developed to address the limitations of short-read sequencing. Dysgu, for example, uses machine learning and deep learning algorithms to enhance the sensitivity and precision of SV detection [12]. Despite these advancements, short-read sequencing inherently struggles with resolving large-scale genomic rearrangements and low-mappability regions. This limitation has driven the adoption of long-read sequencing technologies, such as Pacific Biosciences (PacBio) and Oxford Nanopore Technologies (ONT). These platforms produce reads tens of kilobases in length, enabling direct and detailed characterization of SVs, including those in complex genomic contexts. Tools like Pepper Margin DeepVariant exemplify the potential of long-read data in detecting single-nucleotide variants (SNVs) and SVs with high accuracy, even in regions with segmental duplications or other challenging genomic features [13].

Long-read sequencing has significantly advanced our ability to map and characterize SVs, overcoming many limitations of short-read methods. The extended read lengths allow for the detection of previously undetectable variants and improve mapping accuracy in repetitive and low-complexity regions. Recent studies have highlighted the utility of long reads in resolving complex genomic rearrangements and characterizing mobile elements, offering deeper insights into human genetic variation [14],[15]. Computational tools designed for long-read sequencing data, such as Sniffles [16], cuteSV [17], and SVIM [18], have significantly improved the sensitivity and precision

of SV detection. DeBreak [19], a more recent tool, employs density-based clustering to enhance breakpoint accuracy, particularly for large insertions and deletions. Additionally, pbsv [20] (developed by Pacific Biosciences) focuses on detecting structural variants with high precision and recall using HiFi long-read data, making it highly suitable for resolving SVs in challenging genomic regions. Another tool, NanoVar [21], is optimized for ONT and PacBio long-read data and demonstrates notable accuracy in detecting both small and large SVs by combining sequence information with sophisticated algorithms for breakpoint characterization. Lastly, combiSV [22] incorporates a comparative genomics-based approach to leverage existing reference datasets, enabling improved detection of complex SVs, particularly in repeat-rich regions, by integrating genomic signatures from multiple samples. Despite these advances, challenges persist, including the effective integration of multi-locus rearrangements and the detection of SVs in repetitive regions.

There are two main approaches for detecting indels from long-read sequencing: alignment and assembly. Tools like Sniffles, cuteSV, and SVIM rely on signature detection and clustering, yet they struggle with breakpoint accuracy in repetitive regions, with benchmarks indicating recall below 90% [16]. DeBreak employs density-based clustering to improve large indel detection, while NanoVar and pbsv are optimized for ONT and HiFi reads, respectively, though limitations persist [19], [20]. Recent advancements, such as SAVANA [29], use haplotype-resolved analysis for somatic SVs and tumor purity estimation but are less effective for germline indels, and SUMMER [30] offers a Nanopore pipeline for variants without DeepIndel's ResNet-based feature learning. MEHunter [31] leverages transformers for mobile element variants, and TEforest [32] applies machine learning to TE indels from short reads, highlighting gaps in long-read generalization and diploid context handling. DeepIndel addresses these shortcomings with distinct advantages: **1)** 23 strand-specific features enhance breakpoint resolution in complex regions, **2)** a ResNet-50 architecture, extending Pepper-Margin [13], mitigates vanishing gradients through residual connections for deeper, more effective learning, **3)** superior F1 scores (94.27% insertions, 91.09% deletions on HG002) outperform Sniffles and DeBreak, and **4)** tailored optimization for PacBio HiFi reads outpaces Nanopore-focused tools like SUMMER. Compared to deep learning models in similar fields, DeepIndel surpasses MAMnet (a CNN for indel genotyping with simpler layers) [33] and SVcnn (a multi-type SV tool with ~88–90% F1) [34], achieving a 3 to 5% F1 improvement due to its specialized feature matrices. These strengths position DeepIndel as a robust solution for precision medicine, particularly for detecting disease-associated indels in challenging genomic landscapes.

While current methods excel in isolated breakpoint detection, they often fail to account for the interconnections between loci involved in complex rearrangements. Here, we propose a novel computational method designed to address these gaps. This approach leverages the power of long-read sequencing to accurately detect and classify three distinct SV categories, including large insertions and deletions of unique genomic elements. By incorporating advanced computational techniques, it demonstrates superior precision and recall compared to existing tools when applied to real-world datasets. This innovative methodology provides a robust framework for improving indel detections and understanding its implications in human genetics and precision medicine.

II. Materials and Methods

The Pepper-Margin DeepVariant uses a frequency-based caller to identify the single-nucleotide variants (SNVs) and short indels [13]. In DeepIndel, this approach of Pepper-Margin has been extended by effectively using the prior knowledge we had about our datasets. Our method (Section II.E) tends to look for the exact location of breakpoint events as mentioned in the BED (Browser Extensible Data) files. By analyzing the different features around these breakpoints, the model can effectively call for SVs at different genomic locations of the human genome with an excellent level of fidelity.

A. Model

DeepIndel centers around a deep learning (CNN)-based residual network architecture designed for multi-class classification. The inputs to the network are the feature matrices extracted from our positive and negative samples (Section II B). The matrices are then fed to a neural network. Upon training the network, it finally predicts which SVs are the most likely to occur at a specific location. A high-level overview of the model can be seen in Fig. 1.

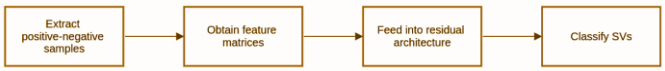

Fig. 1. High-level overview of the model.

B. Sample Extraction

In this three-class (namely: Insertion, Deletion and Non-Indel) SV classifier, we denote the Insertion and Deletion candidates as the set of positive samples and the Non-Indel candidates as the set of negative ones.

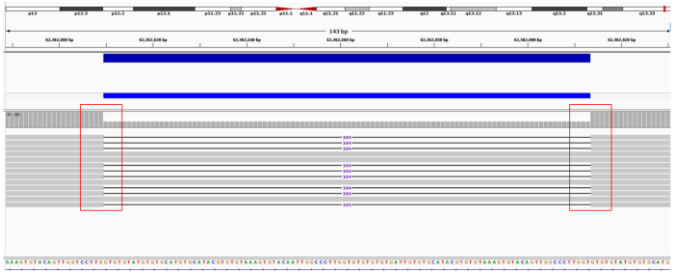

Fig. 2. Placing windows at deletion breakpoints.

1) Positive samples:

a) Insertion: At the positions where an insertion breakpoint is encountered (either the beginning or ending one), we place our windows at those locations to obtain the features (Section D) for the generation of our input image matrices.

b) Deletion: Likewise, at the deletion breakpoints, we place our windows at the beginning or ending locations, where the breakpoints are mentioned. Fig. 2 depicts a 104 bp (base pairs) long deletion event and an emplacement of our windows is shown in this figure.

2) Negative samples: In the case of non-indels, we choose random genomic locations in the sample other than any of the insertion or deletion events to place our windows. To successively obtain these, we choose the regions between the ending and starting breakpoints of two consecutive events, respectively. An example of emplacement is shown in Fig. 3.

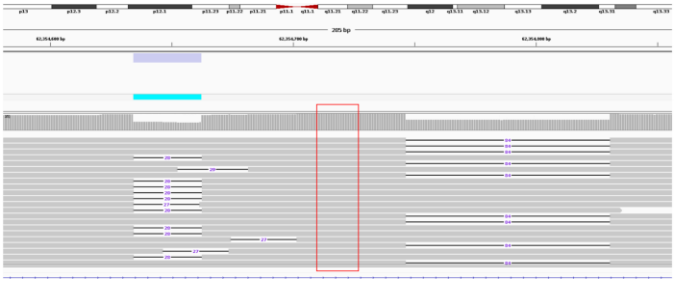

Fig. 3. Choosing window placement for non-indels.

C. Creating a Summary of Potential Variants

The main pipeline of our proposed model first creates a summary of potential candidate variants at the different window locations. To achieve this, we follow the steps outlined below:

All the reads that have a mapping quality greater than the threshold min_mapq are chosen initially. The mapping quality refers to how confidently a particular read has been mapped to a specific position in the reference genome. Next, for the INDEL variants, the candidates with average base quality above min_indel_baseq are considered among the initial ones.

To precisely identify the insertion or deletion candidates, we identify the insertion positions with a cumulative insertion frequency higher than insert_frequency and a cumulative deletion frequency higher than delete_frequency. These thresholds are checked independently for insertions and deletions, and all potential variant candidates from here are recorded. For each candidate, a final additional filtering is performed to ensure that at least candidate_support_threshold reads support the variant.

D. Obtaining Feature Matrix

After choosing the potential candidate variants, we extract a feature matrix from those windows, or "sites". The matrix represents a summary of the read alignments in those respective sites.

In the input matrices, we encode four different features in a total of 23 rows (see Fig. 4). The dimension is chosen to include both the features of the forward strands and the reverse strand reads in a single matrix. We represent the matrices here as RGB images to illustrate the comparative values obtained at each index and to differentiate among the four nitrogenous bases and their respective events.

Here we describe the list of features that are encoded in our Feature Matrix:

- REF: Encoding of the Reference Base. The four different bases are converted to four colors. We used the encoding mapping as A: "Blue", G: "Green", T: "Yellow", and C: "Red".
- **I_L, D_L:** Encoding of the candidate length of the INDELs. I and D are used based on the candidate types, Insert and Delete, respectively.
- **R_F:** Count of the forward strand reads that support the reference allele.
- **I_S, D_S:** Count of the forward strand reads that support the alternate allele. I and D are used based on candidate types, Insert and Delete, respectively.
- **A_F, G_F, T_F, C_F:** Total read count in forward strands expressing each base. The opacity of the colors is scaled in the range [0, 255]. The opacity is increased if its base has a higher frequency.
- **I_F:** Total number of insertions based on forward strand reads.
- **D_F:** Total number of deletions observed at specific positions in the genome, based on forward-strand reads that are anchored to those positions.
- **$*_F$:** Total number of deletions observed from forward strand reads, without anchoring them to particular positions in the genome.

For reverse strands, these features are encoded identically (denoted with R).

In summary, the following set of metrics is encoded from the above features (as mentioned in Fig. 4):

1) Candidate length: The length of candidates at a certain position or over a span of region, denoted by I_L *and* D_L.

2) Read support: The number of reads supporting the reference allele. Since multiple candidates can be reported by different reads over the same specific region, the read support is calculated as the percentage of reads that support the same signature there. It is denoted by R_F (for the reference allele) and I_S, D_S (for the alternate allele).

3) Base counts: The number of bases that are aligned with the reads on a specific column, denoted by A_F, G_F, T_F and C_F.

4) Candidate counts: The number of candidates being reported over a specific region. It is counted as the actual counts of candidates that are reported by several reads over a span of region, denoted by I_F, D_F and $*_F$.

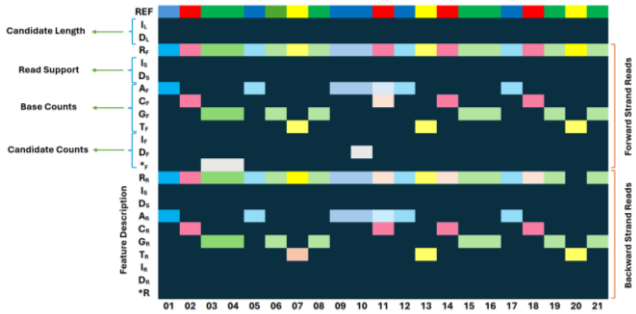

Fig. 4. Encoding of features.

E. The Network Architecture

We fundamentally used a modified version of the ResNet-based architecture (see Fig. 5) to train our dataset. Our model comprises four layers from an upper level, with each consisting of three convolutional layers along with batch normalizations and *ReLU* activations. In between the layers, we used dropout regularizations to avert overfitting to the training data. We trained our model using a batch size of 512 for 200 epochs, optimizing with the Adam algorithm at a learning rate of 0.1. The loss function employed was Cross-Entropy Loss. For activation functions, we used ReLU in the mid-level layers and *SoftMax* in the output layer. We have used the modified version of ResNet-50, which incorporates specific optimizations tailored to our dataset and task requirements. ResNet (Residual Network) is preferred over other well-known models like VGG16 and GoogleNet due to its superior handling of the vanishing gradient problem, allowing it to train much deeper networks effectively. This is achieved through the introduction of residual connections, which facilitate the learning of residuals rather than direct mappings, thereby improving performance and efficiency [23], [24], [25]. Comparative studies have demonstrated that ResNet-50 consistently outperforms VGG16 and GoogleNet in various benchmarks, making it a more reliable and efficient choice for deep learning tasks [24]. The matrices initially extracted are 23×33 by dimension, where the 23 rows represent the features and the 33 columns indicate one window size. We resized these into 30×30 square images to be fed into the network. For each pass throughout the whole network, we used a SoftMax activation in the end for classifying our three signatures: Insertion, Deletion and non-indels. The convolution layers comprise a deep architecture that effectively identifies the subtle changes in patterns along with the indicative SVs throughout its learning process. The residual layers are also used for preserving the significant variation features across layers.

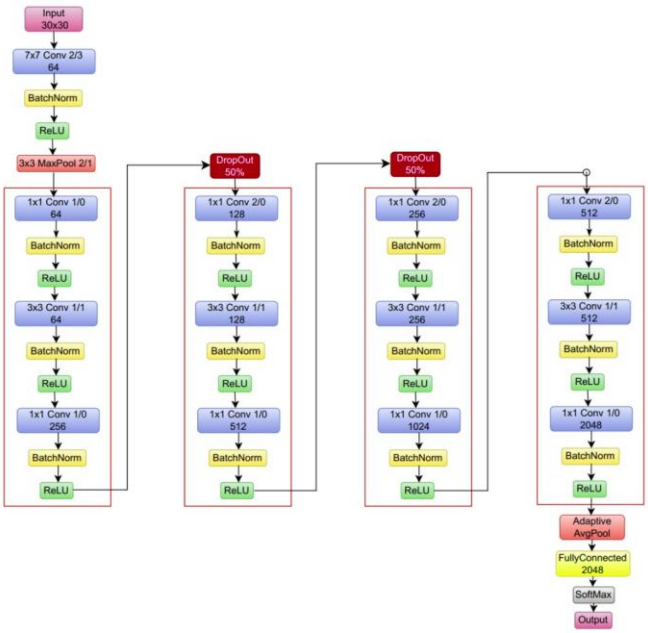

Fig. 5. The overall network architecture for DeepIndel.

F. Validation Metrics

To test DeepIndel, we took the HG002 dataset, which has confirmed structural variant (SV) annotations from the Genome In A Bottle (GIAB) project, as it is a gold-standard benchmark. We analyzed the model's performance by assessing its precision (true positives / [true positives + false positives]), recall (true positives / [true positives + false negatives]), and F1-score (harmonic mean of precision and recall) using the model's evaluation framework from the previous section. All of these are important for assessing its performance. Having a high degree of performance is important because it decreases the number of incorrect diagnoses, which is particularly important in clinical settings. Strong recall, however, ensures that indels associated with rare diseases are captured, which adds value to the genetic studies. The F1-score is particularly useful as a summary measure in model evaluation, especially in precision medicine, where both sensitivity and specificity are important, and it measures the degree to which precision and recall work in tandem. Comparisons presented in subsequent sections illustrate how DeepIndel can be guided to better detect SVs in challenging genomic contexts using this validation technique.

III. Dataset Preparation

A. Benchmark Datasets

To assess the performance of DeepIndel, we used the PacBio HiFi2 long-read sequencing dataset with the GRCh37 human genome as the reference genome. We used a well-characterized reference sample, HG002 (Source: AshkenazimTrio/NIST SVs Integration v0.6), from the GIAB (Genome In A Bottle) projects [28].

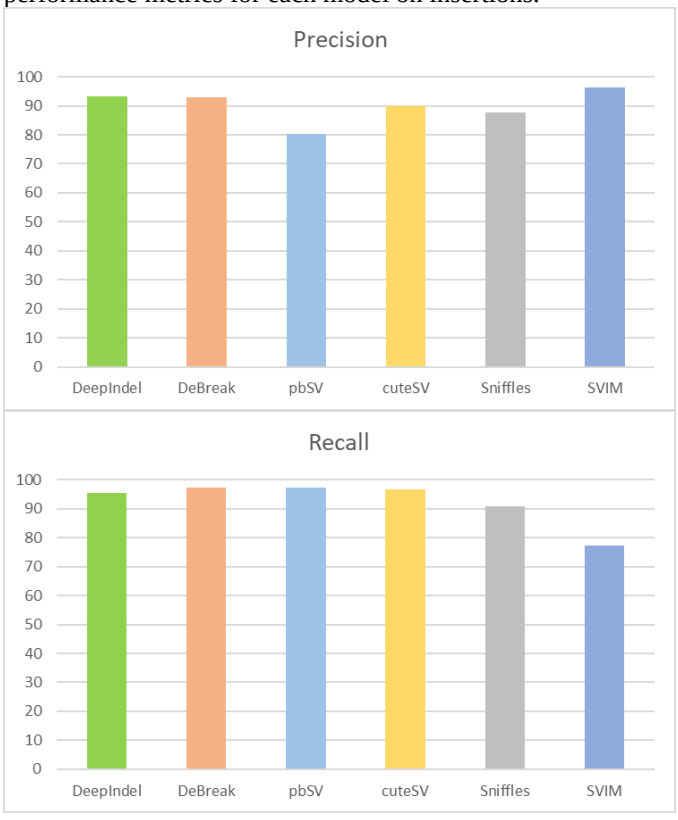
B. Preprocessing

To make the dataset suitable for our model, we had to perform some preprocessing on our dataset. Most of the processing was done on the Ubuntu 20.04 operating system.

1) Read alignment: DeepIndel accepts sorted BAM files as input and utilizes state-of-the-art long-read aligners to construct SV detection pipelines. Aligners that demonstrate robust performance in handling large insertions and deletions or that are capable of generating accurate split alignments are particularly preferred. For our framework, we aligned the simulated reads to our reference genome GRCh37 using *Minimap2* (v2.17-r941) [26]. Minimap2 initially generates a file in SAM format, which is a text-based generic alignment format used for storing read alignments against a reference sequence. Next, to get the sorted BAM, we used Samtools [27] to convert the SAM format to its respective BAM.

2) Indexing of VCF file: The BED files were first converted into VCF (Variant Call Format) files to enable the representation of genomic variants. This conversion was done using *bed2vcf*. Subsequently, the VCF index files were generated to facilitate the matching of records at each breakpoint position. For this purpose, we utilized *tabix*. The VCF files being indexed with *tabix* enabled us to query for specific genomic regions, allowing for the retrieval of variants located within those regions.

IV. RESULTS



A. Evaluation Criteria

To evaluate the performance of different SV callers along with DeepIndel, each of them was given a task to identify variants from the same chromosomal locations in our test dataset. Initially, all 22 chromosomes from GRCh37 were taken and using the above-mentioned pipeline, we received around 31000 positive and 19700 negative samples (as 2D matrices). Then we split into a 60:15:25 ratio for training, validation and testing sets, respectively. The models were trained individually with train and validation datasets, taking 30×30 feature matrices as input. After being fed into the network, the outcomes were measured based on the performance scores for successfully calling variants at each possible location.

B. Performance in Long Reads

In this section, the performance comparison of DeepIndel is presented with state-of-the-art structural variant calling models like DeBreak, pbSV, cuteSV, Sniffles, and SVIM. The comparison was made across their precision, recall and F1-score.

1) Insertion: DeepIndel demonstrates superior insertion precision, outperforming all other models except SVIM with an impressive precision rate of 93.19%. For recall, DeepIndel demonstrates a strong performance too, with a recall rate of 95.38%. DeepIndel achieves an F1 score of 94.27%, ranking highly among all models and presenting an excellent balance between precision and recall. Fig. 6 illustrates these performance metrics for each model on insertions.

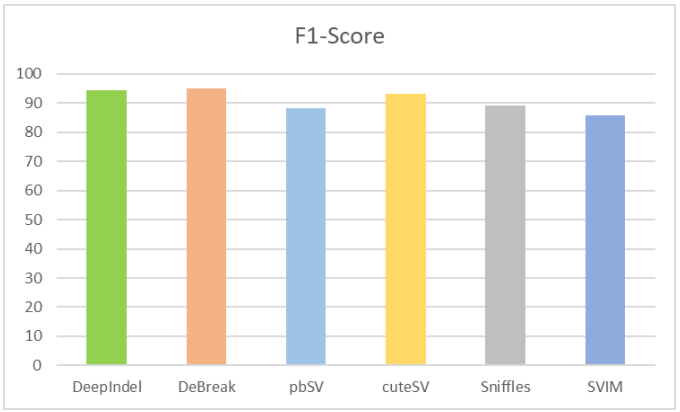


Fig. 6. Performance comparison in insertion: precision, recall, f1-score.

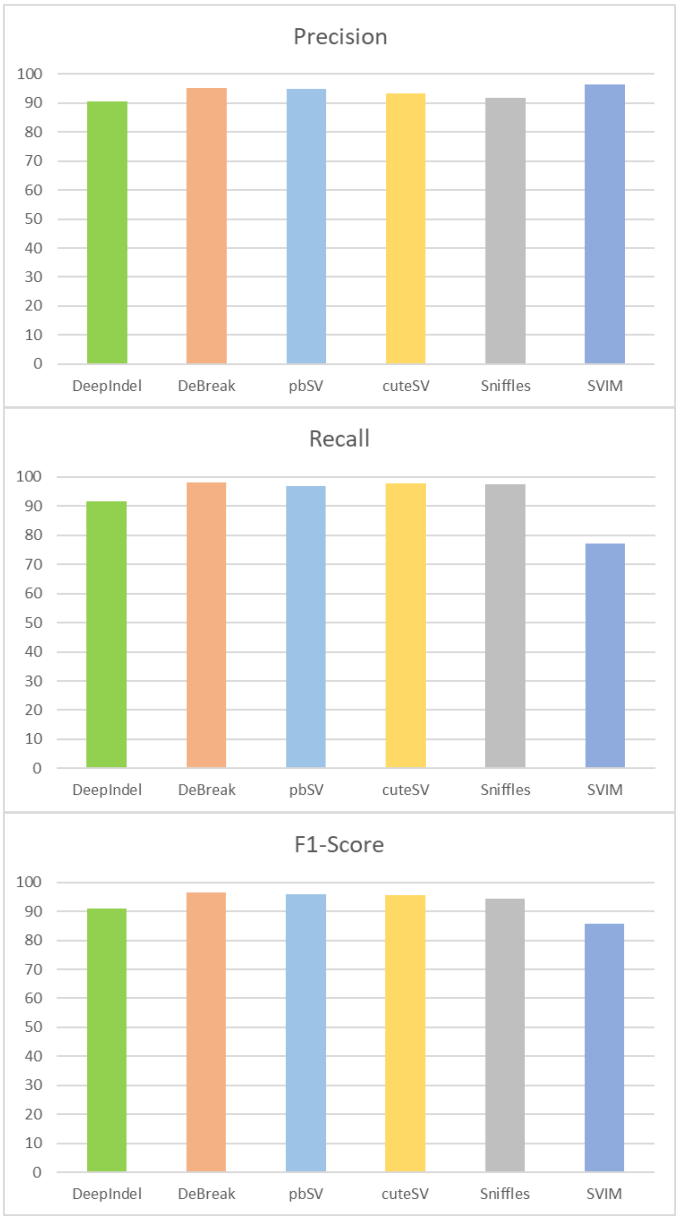

Fig. 7. Performance comparison in deletion: precision, recall, f1-score.

2) Deletion: DeepIndel exhibits strong performance in precision for deletions, achieving a precision rate of 90.42%, which is competitive with other models. For recall, DeepIndel achieves 91.76%, positioning it favorably compared to the other models. Regarding the F1-score, DeepIndel ranks well with a value of 91.09%, highlighting a good overall balance between precision and recall compared to the other models. Fig. 7 illustrates these comparisons on deletions.

V. Discussion

DeepIndel achieved outstanding accuracy in detecting SVs for the HG002 dataset, demonstrating the effectiveness and robustness of our approach. The high precision and recall rates, along with competitive F1 scores for both insertions and deletions, underscore the reliability of DeepIndel in variant calling tasks. The significance of these validation measures lies in their direct relevance to clinical utility: high precision reduces the risk of erroneous variant calls that could mislead therapeutic decisions, while robust recall ensures no critical SVs are missed in disease studies. The F1-score, achieving 94.27% for insertions and 91.09% for deletions, reflects a balanced performance that is essential for trustworthy genomic analysis. Thus, it's highlighting its strong performance overall. However, the model's performance was slightly better for insertions than for deletions. This variation in performance can be attributed, in part, to the characteristics of the benchmark dataset. The model was evaluated on the latest, most conserved BED file for HG002 (*HG002 SVs Tier1 v0.6.2.bed*), which contains 5260 insertions and 4138 deletions [22]. The higher representation of insertions in the dataset provides a richer training and evaluation context for the model, potentially contributing to its superior precision and recall for insertions. In contrast, the slightly lower performance for deletions may reflect the relatively smaller number of examples available, as well as inherent challenges in accurately identifying deletions within the genomic sequence.

While DeepIndel's performance is commendable, there is room for improvement in refining feature extraction and window positioning near breakpoint candidates to address edge cases for deletions. Nevertheless, the consistent and competitive results across various performance metrics establish DeepIndel as a highly effective tool for SV detection. The findings from the HG002 dataset confirm the robustness of DeepIndel's methodologies and its potential for broader genomic applications. Addressing minor limitations in feature extraction and ensuring robust truth datasets will further enhance the reliability and accuracy of the model.

VI. Conclusion

In this study, a novel deep learning framework, DeepIndel, was designed to enhance the accurate detection of indels from long-read sequencing data. By leveraging a comprehensive set of 23 genomic features extracted from aligned reads, the model effectively captures complex breakpoint patterns in challenging genomic regions. Trained on the HG002 benchmark dataset using a modified ResNet-50 architecture with residual connections, dropout regularization, and cross-entropy loss optimization, DeepIndel processes significant feature matrices to classify genomic sites as insertions, deletions, or non-indels with high fidelity.

DeepIndel's advancements highlight the transformative potential of integrating long-read sequencing with deep learning for SV analysis, addressing limitations in traditional methods, such as difficulties in repetitive regions and interconnected loci. By improving precision and recall, this approach facilitates more reliable insights into genomic diversity, gene expression alterations, and disease associations, including cancer, neurological disorders, and metabolic conditions. This contributes to the broader goals of precision medicine, enabling better characterization of phenotypic diversity and personalized therapeutic strategies.

Despite these strengths, some limitations and future opportunities are acknowledged that include potential refinements needed in feature extraction and window positioning to handle edge cases. Future directions will focus on expanding evaluations to diverse datasets beyond HG002, incorporating additional SV types like inversions and duplications, and optimizing for real-time clinical applications. Overall, DeepIndel marks a significant advancement in SV-calling tools, paving the way for enhanced genomic research and its translation into impactful clinical outcomes.

***Abstract*—The disruptions experienced by global supply chains in recent years have reignited the importance of maritime sovereignty, particularly through the creation or reinforcement of national shipping fleets. In this context, the present study explores strategic approaches to national fleet sizing, drawing from recent policy directions and maritime planning models. The study is motivated by the need to design resilient and sovereign fleets that reduce dependency on foreign operators and strengthen autonomy in trade logistics. To complement this analysis, a mathematical model is developed in the form of a Mixed-Integer Nonlinear Programming (MINLP) formulation, where sovereignty is captured through the share of vessel operations under national control. In addition to sovereignty, the model integrates criteria of economic viability, environmental impact, and resilience, positioning Maritime Fleet Sizing within the broader scope of Strategic Transport Planning and Green Maritime Transport. Numerical experiments are carried out on a representative dataset of vessels and strategic routes, illustrating how sovereignty thresholds affect fleet composition and deployment. The results highlight a fundamental trade-off between sovereignty and profitability, emphasizing the need for strategic decision-making that carefully balances autonomy objectives with resilience and environmental considerations. Findings also show that moderate sovereignty thresholds support cost-efficient and diversified fleets, while maximalist sovereignty requirements lead to reduced coverage, higher unmet demand, and lower profitability. These insights underline the importance of calibrated strategies, where Sovereignty, Resilience in Maritime Logistics, and sustainability are treated as interconnected pillars of long-term fleet development.**

Keywords*—*Maritime fleet sizing; sovereignty and national ownership; strategic transport planning; resilience in maritime logistics; green maritime transport

I. INTRODUCTION

Africa's maritime domain represents a major strategic asset, essential for economic development and regional integration [1]. Nevertheless, this potential remains largely untapped due to structural vulnerabilities: inadequate port infrastructure, dependence on foreign shipping lines, weak logistical connectivity, and growing security threats. In this context, establishing sovereign national fleets appears as a critical lever to secure economic autonomy and strengthen the trade resilience of African states. Yet, recent studies reveal that the intersection between sustainability, resilience, and sovereignty in supply chain planning remains insufficiently explored, particularly when considering the role of local product promotion and national industrial strategies [2].

The experiences of Nigeria and Ghana during the 1960s to 1980s illustrate the difficulties associated with establishing national shipping companies. These initiatives aimed to reduce dependency on European maritime powers but largely failed due to poor governance, systemic corruption, and the inability to modernize fleets in the face of containerization [3] [4]. The primary lesson for developing countries is the need to avoid politicization in maritime management and to sustain continuous technological upgrading.

The major lesson to be learned by developing countries is that they should avoid politics in the management of the maritime industry and that they should ensure a consistent technological updating. Models of governance that have been the most effective in key worldwide ports have been those that are publicly-owned but privately managed (landlord model) [5] [6]. Excessive privatization makes the ports vulnerable to strategic losses, whereas inflexible governance restrains innovation. The model applicable in developing countries should be a hybrid model that favors the public-private partnerships and still maintains its sovereignty of strategic assets. In this context, Build-Operate-Transfer (BOT) schemes also represent a viable pathway, allowing private actors to finance and operate vessels under sovereign constraints before eventual transfer to public ownership.

The competitiveness of a national fleet is closely linked to the performance of port infrastructures. In [7], the authors demonstrate that improving connectivity and port quality significantly reduces freight costs, facilitating integration into global supply chains. For Morocco, strengthening Tanger Med, Nador West Med, and Casablanca is crucial to support the future sovereign fleet.

An integrated maritime security system, combining surveillance, environmental governance, and regional cooperation, is critical to sustain Morocco's ambitions in the blue economy, and it can only be achieved through the control of economic flows and the sovereignty of its maritime trade [8] [9].

The comparative analysis of African and international experiences shows that the success of a national maritime fleet depends on smart hybrid governance, high-performance infrastructure, integration into global supply chains, and

comprehensive maritime security. Morocco's dual maritime façade (Atlantic-Mediterranean interface), its port assets (Tanger Med), and its proximity to the Strait of Gibraltar make it a natural maritime nation, assuming responsibilities as a coastal, port, and flag state [10]. Yet, strategic control over shipping remains fragile in the absence of a national fleet capable of withstanding foreign dependency. As of 2019, nearly 98 per cent of Morocco's external trade depended on maritime transport, while the potential collapse of national operators like IMTC was projected to result in complete reliance on foreign-owned fleets [11].

The key objective of this study is to make a contribution to the strategic planning of the maritime fleet through a structured modeling approach that puts the sovereignty parameter at its center. Indeed, this study will seek to offer a mathematical model applicable to the strategic development of a national commercial fleet, mainly adapted to developing countries such as Morocco.

This study is structured as follows: Section II draws a literature review that covers the approaches that have been taken in relation to the maritime fleet size and mix, typologies of methods used, and gaps that can be addressed through the strategies that are policy-oriented. Section III introduces the proposed optimization model, detailing its decision variables, parameters, and strategic criteria, including cost, sovereignty, environmental impact, and resilience. Section IV discusses the simulation framework, while Section V presents the model's results, and offers analysis and adequate interpretation, mainly regarding the sovereignty parameter, profitability, sustainability and resilience constraints. Section VI concludes and outlines future work.

II. Literature Review

The maritime fleet size and mix problem (MFSMP) constitutes a core research theme in operations research and maritime economics, addressing how to determine the optimal number and types of vessels needed to meet transportation demand under a variety of economic, operational, and regulatory constraints [12]. In the context of emerging economies such as Morocco, where maritime sovereignty, trade resilience, and infrastructure modernization are national priorities, this body of research offers valuable, yet incomplete, tools to guide long-term strategic planning.

Initial work in the area was based on deterministic and static formulations, such as [13]and [14], with optimization of fleet composition usually through linear programming approaches based on the assumption that demand is fixed and that ship types are uniform. Although such models were analytically tractable, they did not deal with long-term investment options, changing market circumstances or maritime lifecycle behavior.

A conceptual shift occurred with the development of multi-period models, commonly described as maritime fleet renewal problems (MFRP). These models are thoroughly discussed in [12], which differentiates between single-period static designs and long-horizon fleet strategies that consider aging of the ships, investment cycles, and changing operational demands. Their work also signals the significance of adaptability to fleet planning, in states wanting to undertake fleet renewal within the context of more general industrial and economic development. In relation to the case of Morocco, the national fleet has fallen from about 70 vessels in the 1980s to less than 20 in the 2020s, which has been seen as a problem of growing size in terms of structural and persistent decline [11]. New developments have focused on the inclusion of uncertainty in models used to size the fleet. Both [15] and [16] have suggested recourse to stochastic programming with regard to variability in charter rates, bunker costs, and demand. These models show the superiority of flexibility in investment and chartering decisions with volatile conditions. In addition to this, [17] presented a rule-based simulation framework to deal with uncertainty in the process of buying and selling and formed a solid foundation of practical application of adaptive maritime policy-making.

The literature has also seen the rise of heuristic and metaheuristic methods, such as genetic algorithms, particle swarm optimization [18], and tabu search, to handle complex routing and heterogeneous fleet structures. While effective in solving tactical-level problems, these approaches often lack a strategic orientation necessary for national-level fleet planning.

From a governance perspective, [19] proposed a typology distinguishing strategic, tactical, and operational fleet sizing decisions. Their classification is of some significance to states such as Morocco, which have to balance long-term capital intensity, infrastructural coordination and policy-driven maritime goals in their fleet-based decisions. Their work also describes structural differences in transportation planning between maritime and land transport planning. Despite these contributions, there are still a number of limitations. The majority of such existing models are oriented towards optimality in the case of firms and are unsuitable to reflect the particular needs of the public sector, which deals with maritime sovereignty, autonomy in trade or industrial capacity building. Also, lack of preset standards constrains cross-case comparisons and dampens the process of transferring modeling knowledge across borders or nationwide.

Table I, Table II and Table III support the fact that there is a need to contribute more to the modelling literature that puts the national policy applicability of results as a main criterion. In Morocco, whose port facilities are developing rapidly, maritime commerce is one of its main strategic platforms. Thus, fiscal investment limitations, dynamic demand, and nationwide governance of maritime logistics require an extensive adjustment of fleet size templates. Such models will be instrumental in informing the design of a resilient, efficient, and sovereign commercial fleet aligned with the country's long-term development trajectory. However, previous legislative reforms have been criticized for their lack of fiscal incentives and failure to embed the Moroccan economic interest, thereby weakening the strategic effectiveness of the national fleet [10].

III. MODELING FORMULATION

This section presents the mathematical formulation of the model developed to support sovereign fleet planning. Built as a strategic decision-support tool, the model aims to reflect the multifaceted priorities of public authorities; balancing profitability with national interest, environmental compliance, and operational robustness. Unlike conventional formulations rooted in commercial fleet management [24][48][12], this approach is shaped by the realities of maritime policy in emerging economies, as the renewal of their national fleets requires a long-term framework that integrates logistical needs, industrial ambitions, and environmental constraints [10]. The model developed in this study is specifically tailored to the context of liner shipping operations, where vessels operate on fixed schedules and recurring routes. Other maritime segments, such as tramp shipping or industrial bulk transport, are outside the scope of this research. Indeed, the model simultaneously:

- maximizes the sovereign-adjusted profit generated by the fleet;
- penalizes unmet transport demand to enhance system resilience;
- and internalizes carbon taxation within the economic decision process.

Such an integrated approach responds to critical gaps identified in the literature: the lack of sovereign decision-making frameworks [8] [10] [35], the fragmented treatment of resilience [20][48][18], and the peripheral role of environmental concerns in traditional fleet models [16] [49] [37].

Thus, the model was built in layers, following the logic of national maritime planning. The priority was to simulate investment decisions under sovereign control, that is, to determine which types of vessels should be included in the national fleet, and in what configurations. This led to the formulation of the activation variable y_i, allowing each vessel i to be activated in the fleet, and when combined with the parameter A_{ik}, it reflects the possible configurations like feeder, regional, or deep-sea cargo capacity.

Once vessels were activated, the next layer addressed route assignment. Here, the binary variable x_{ir} determines whether vessel i is assigned to route r, reflecting the planning logic of matching vessel profiles to strategic corridors.

Finally, the third decision layer determines transport capacity deployed, with continuous variable q_{ir} representing the number of containers shipped by each vessel on each route. This variable is bounded by the technical capacity of the vessel, and its aggregation at the route level is compared against demand D_r.

Each of these layers is supported by constraints ensuring investment realism, operational feasibility, and policy compliance (e.g., emission limits). The result is a three-tiered model as illustrated in Fig. 1:

- Activation → strategic planning
- Assignment → operational deployment
- Transport → economic performance

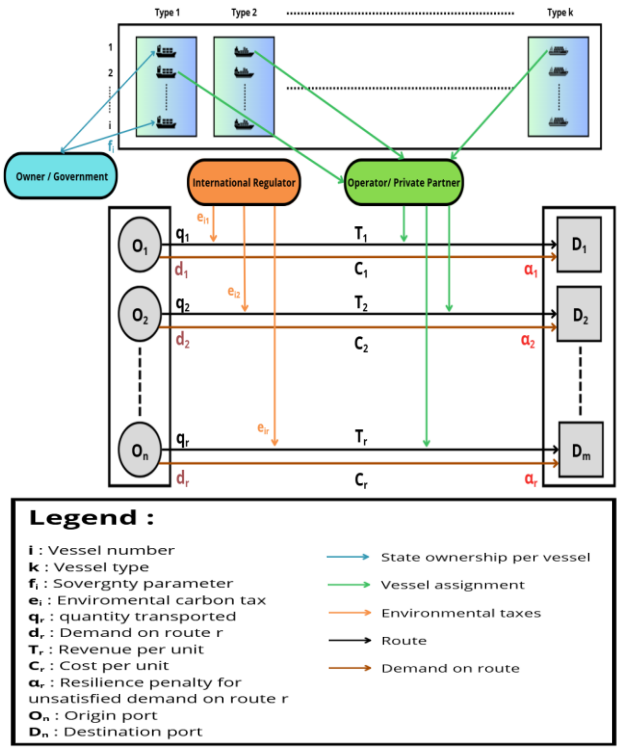

Fig. 1. The conceptual model of strategic fleet sovereignty model.

A. Sets and Variables

Let the following sets and parameters be defined:

Sets:

- I: Set of candidate vessels
- K: Set of vessel types (e.g., feeder, post-panamax)
- R: Set of strategic maritime routes

Parameters:

- T_{ir}: Revenue per TEU (Twenty-foot Equivalent Unit) for vessel i on route r
- C_{ir}: Operating cost per TEU for vessel i on route r
- e_{ir}: Carbon cost or penalty per TEU for vessel i on route r
- Q_k: Maximum transport capacity of vessel type k
- f_i : Sovereign ownership or financing ratio of vessel i
- θ : The minimum required average sovereignty ratio for the activated fleet
- α_r : Penalty for unsatisfied demand on route r
- Φ_i: Fixed operating cost for vessel i, incurred only if the vessel is activated.
- d_r : Transport demand on route r (TEUs)
- I_{ik}: Investment cost to activate vessel i as type k

- A_{ik}: A binary parameter equal to 1 if vessel i is from type k
- B : Total investment budget
- E^{max} : Maximum allowable CO_2 emissions

The model's decision variables include:

- $y_i \in \{0,1\}$: 1 if vessel i is activated
- $x_{ir} \in \{0,1\}$: 1 if vessel i is assigned to route r
- q_{ir}: Volume (in TEUs) transported by vessel i on route r

B. Justification of the Sovereignty Coefficient f_i by Vessel type

In order to reflect the importance of maritime sovereignty in the decision-making process of the fleet size and mix problem, the model presents a sovereignty coefficient to each vessel. This coefficient ranges from 0 to 1 and reflects the extent of governmental ownership for each vessel. Higher values indicate a stronger alignment with national sovereignty objectives. These values were determined based on typical ownership patterns, operational zones, and investment accessibility. Table IV summarizes the estimated sovereignty coefficients by vessel type.

TABLE IV. THE ESTIMATED SOVEREIGNTY COEFFICIENTS BY VESSEL TYPE

Vessel Type	f_i	Justification
Feeder	0.90	Frequently used in short-distance regional shipping; often owned or operated by local or national entities, enabling high sovereign control.
Small Handy	0.88	Small-scale vessels suitable for secondary routes, they are commonly accessible to domestic operators or public investment initiatives.
FeederMax	0.85	Larger than standard feeders, they are often deployed in extended regional services, typically still under partial or full national control
Panamax	0.70	Moderate capacity vessels able to transit the Panama Canal. Some national fleets operate them, though many are controlled by international shipping lines.
Medium Containership	0.65	Typical in mid-range logistics, they are widely deployed by global carriers but still present in some sovereign or mixed-ownership fleets
Post-Panamax	0.60	Larger vessels mostly integrated into the global fleet, they are generally inaccessible to smaller national actors.
Neo-Panamax	0.55	Designed for the expanded Panama Canal, their ownership and deployment are dominated by large international companies.
ULCV (Ultra Large Container Vessel)	0.40	Among the largest vessels globally (>20,000 TEUs), they are typically owned by a few multinational giants, making sovereign control highly unlikely

C. The Objective Function

This objective function captures the sovereignty-weighted profit, penalizes unmet demand to simulate resilience, and internalizes the investment cost of sovereign fleet expansion. The introduction of f_i as a decision-dependent parameter transforms the model from a cost-efficiency tool into a policy-aligned mechanism for state-led fleet control. This approach directly addresses gaps noted by [8] [21][44], who highlight the lack of sovereign metrics in operational maritime models. The objective function is defined as:

$$Max \sum_{i \in I} \sum_{r \in R} f_i \,.\, x_{ir} .\, (q_{ir} \,.\, (T_{ir} - C_{ir}) - \sum_{i \in I} \Phi_i \cdot y_i - \sum_{i \in I} \sum_{r \in R} e_{ir} .\, x_{ir} - \sum_{r \in R} \alpha_r \,.\, (d_r - \sum_{i \in I} q_{ir}) - \sum_{i \in I} \sum_{k \in K} f_i \,.\, \mathrm{I}_{ik} \,.\, A_{ik} .\, y_i$$

The objective function combines five components that consider the strategic, economic and environmental priorities of the model. The first term maximizes revenue on the transported volumes, weighted by the ratio of the sovereign ownership, hence encouraging national control over the maritime activities. This form of structural representation of sovereignty covers one of the key deficiencies of the traditional form of fleet sizing models under the assumption of neutrality in ownership structure [14][4][1]. The second term reflects the fixed costs of operation that are incurred when a vessel is activated, which is a consideration to make the fleet composition selective. The third term is about the carbon charges imposed on routes so as to discourage environmental externalities and make sure that environmental concerns are fulfilled based on deployment considerations. The fourth term will impose the demand unmet as a penalty, which aligns with recent findings highlighting how managing demand uncertainty through cooperative and sustainable sourcing strategies can strengthen resilience, especially in contexts aiming for national or regional autonomy [50]. Lastly, the fifth term, which is the sovereign investment costs, scaled by the ownership ratio, reflects the financial implications of an increase in capacity controlled by the government.

The objective function includes a bilinear term of the form:

$$\sum_{i \in I} \sum_{r \in R} f_i \,.\, x_{ir} .\, (q_{ir} \,.\, (T_{ir} - C_{ir})$$

This term contains the product of the binary decision variable x_{ir} and the continuous variable q_{ir}. This nonlinearity cannot be directly handled by linear optimization solvers. To address this, an auxiliary variable Z_{ir} is introduced to represent the product:

$$Z_{ir} = x_{ir} .\, q_{ir}$$

This variable is then linked to x_{ir} and q_{ir} through the following linear constraints, involving a sufficiently large constant M (Representing the upper bound of transported volume q_{ir}):

$$\begin{cases} Z_{ir} \le q_{ir}, \forall\, i \in I, r \in R \\ q_{ir} \le M .\, x_{ir}, \forall\, i \in I, r \in R \\ Z_{ir} \le M .\, x_{ir}, \forall\, i \in I, r \in R \\ Z_{ir} \ge q_{ir} - M(1 - x_{ir}), \forall\, i \in I, r \in R \end{cases}$$

The original bilinear expression in the objective function is then replaced by the linear term:

$$\sum_{i \in I} \sum_{r \in R} f_i \,.\, Z_{ir} \,.\, (T_{ir} - C_{ir})$$

D. Constraints

The model is subject to the following strategic and operational constraints:

1) Single Route Assignment per Vessel

$$\sum_{r \in R} x_{ir} \leq 1, \forall i \in I$$

This constraint ensures that a vessel is not assigned to more than one route, simultaneously.

2) Vessel activation condition

$$x_{ir} \leq y_i \;\; \forall\, i \;\in\; I, r \;\in\; R$$

Prevents deployment of vessels not activated [51].

3) Capacity Limit by Type

$$q_{ir} \leq \sum_{k \in K} Q_k . A_{ik} . y_i \;\; \forall\, i \;\in\; I, r \;\in\; R$$

Restricts capacity usage to actual vessel capability, as in [16] and [39].

4) Partial Demand Coverage (Resilience)

$$\sum_{i \in I} q_{ir} \leq d_r \;\; \forall\, r \;\in\; R$$

Allows under-supply, simulating strategic bottlenecks. This model's resilience is formalized by [20] and [48].

5) Investment Budget

$$\sum_{i \in I} \sum_{k \in K} f_i . \mathrm{I}_{ik} . A_{ik} . y_i \leq B \;\; \forall\, r \;\in\; R$$

Controls sovereign expenditure [22].

6) Environmental Emission Cap

$$\sum_{\boldsymbol{i \in I}} \sum_{\boldsymbol{r \in R}} \boldsymbol{e_{ir} . x_{ir} \leq E^{max}}$$

Enables regulatory compliance and green planning strategies [37] and [36].

7) Sovereignty

$$\sum_{i \in I} f_i \, y_i \geq \theta \sum_{i \in I} y_i$$

8) Variable Domains

$$y_i \in \{0,1\}, x_{ik} \in \{0,1\}, q_{ir} \geq 0$$

E. Assumptions

The proposed model relies on a series of simplifying assumptions aimed at ensuring both analytical tractability and strategic relevance. These assumptions are consistent with the intended use of the model as a strategic planning tool for long-term maritime policy design. First, the model is developed as a deterministic, single-period formulation, representing a strategic decision snapshot over a long-term planning horizon (10 years or more). This choice reflects the irreversible and capital-intensive nature of fleet investment decisions, where vessel acquisition and sovereign activation are made on a long-term basis and are not subject to frequent revision. Similar simplifications are made in strategic logistics models dealing with infrastructure design or energy fleet mix [12] [44]. Second, transport demand on each route $d_r$is treated as known and deterministic. This is justified by the model's focus on national routes of strategic importance (e.g., connecting major ports or corridors), for which long-term projections are available from port authorities or national development plans. This assumption avoids the complexity of scenario modeling or stochastic programming, while still allowing partial satisfaction of demand via the resilience penalty. Third, the environmental taxation is modeled through a fixed carbon cost per TEU e_{ir} , which is not influenced by minor variations in vessel load. This simplification acknowledges that while actual emissions vary with loading conditions and speed profiles [49], policy-applied taxes and penalties often use standardized rates per unit transported, as recommended in IMO and EU carbon schemes. This assumption is reasonable for strategic planning where environmental constraints are treated as policy ceilings rather than engineering simulations [37] [36]. Then, we assume that each vessel can be assigned to at most one route, and its transport volume q_{ir} is dedicated entirely to that route. This assumption reflects the model's focus on permanent or seasonal deployment planning, rather than flexible daily scheduling. It is particularly relevant for state-led services (e.g., national supply corridors, food security logistics) where vessels are dedicated based on geopolitical or regional priorities [8] [18]. Also, the model does not assume any preferential match between vessel types and demand profiles. Instead, vessel type selection (via y_{ik}) and route assignment (via x_{ir}) are endogenously determined by the optimization process. This allows for flexibility in configuring the fleet to meet evolving transport and policy requirements. Finally, all costs (investment, operational, and environmental) and revenues are either modeled linearly or linearized using linearization techniques. This allows the use of mixed-integer linear programming (MILP) techniques, which are well-established in fleet sizing literature and offer reasonable solvability even for large-scale problems [48] [12].

IV. Simulation Framework

The simulations were carried out on a typical desktop personal computer with Intel core i7 1.9 GHz and 16 GB of RAM. Pyomo modeling framework was used to write the optimization model in Python, and used SCIP 9.2.2, an open-source high performance solver for mixed-integer linear programs developed by the Zuse Institute Berlin (ZIB). It is a compilation of the solver added in optimized mode, 8-byte precision and based on SoPlex 7.1.4 as its LP backend.

Importantly, the Branch & Cut algorithm was employed to ensure the derivation of exact optimal solutions, reinforcing the model's credibility for strategic-level decision-making.

The computational tests were based on a realistic configuration involving 100 candidate vessels, 230 strategic maritime routes, and 8 vessel types, as per Table IV. The choice of 100 vessels and 230 routes is justified by the ambition of Morocco, as an example of an emerging country, to rebuild its national maritime fleet by 2040. The full model formulation resulted in a total of 69,100 variables, of which 23,100 are binary and 46,000 continuous, underlining the combinatorial complexity of the problem. To evaluate the model's behaviour under different sovereignty priorities, four simulations were performed by varying the minimum average sovereignty threshold parameter θ:

- Low requirement ($\theta = 0.25$)
- Moderate requirement ($\theta = 0.50$)
- High requirement ($\theta = 0.75$)
- Sovereignty-maximalist ($\theta = 0.88$)

During every run, the model produced the most favorable sizes of the fleet, the composition of the vessels, route assignments, and volumes transported. Randomly generated values of inputs and in calibrated bounds based on real maritime benchmarks have been considered without violation of investment, capacity, emission and policy constraints. An observation of the computational performance was made in every scenario. The calculation time was between: 330.61 seconds ($\theta = 0.25$), 401.49 seconds ($\theta = 0.50$), 402.91 seconds ($\theta = 0.75$) and 549.99 seconds ($\theta = 0.88$), denoting increases in time needed to solve based on severe sovereignty constraints.

V. Results

In order to evaluate the model's response to real-life problems, different scenarios were examined to highlight the trade-offs between cost and fleet sovereignty, environmental influences and resilience. The analysis reveals the way in which changes of strategic priorities alter the optimal structure and utilization of the fleet. It also sheds light on how the transport demand and environmental aspects are impacted.

A. Fleet Mix, Size and Activation Patterns

The optimization outcomes indicate a similar pattern in the vessel activation decisions in all scenarios, as shown in Table V. At best, the model prefers a smaller, more effective fleet mix that is mainly composed of mid-sized vessels: Feeder, Medium CS, and Small Handy under a smaller threshold of sovereignty ($\theta = 0.25$ and $\theta = 0.50$). As θ increases, reflecting higher sovereignty constraints, the diversity of activated vessels drops drastically, and total activation volume declines, particularly on high-volume routes.

When $\theta = 0.88$, the model heavily prioritizes vessels with the highest sovereignty scores, even at the cost of reduced transport capacity and higher unmet demand. Notably, the vessels of type ULCV and Panamax family (Panamax, Post-Panamax and Neo-Panamax) are consistently excluded across all scenarios.

Regarding the fleet size, Table VI illustrates the evolution of total fleet size per scenario. When $\theta = 0.25$ or $\theta = 0.50$, the model result is respectively a fleet of 17 vessels that are cost-efficient and sovereignty sensitive. The number of activated vessels increases significantly to 53 when $\theta = 0.75$, suggesting a diversification strategy that covers a wider range of demand. However, the number of activated vessels decreases to 18 once more when the sovereignty constraint reaches $\theta = 0.88$.

TABLE V. Activated Vessel Types per Sovereignty Scenario

Vessel Type		Sovereignty Score (f_i)	θ = 0.25	θ = 0.50	θ = 0.75	θ = 0.88
Feeder		0.90	Yes	Yes	Yes	No
Feedermax		0.85	No	No	No	No
Small Handy		0.88	Yes	Yes	Yes	Yes
edium CS		0.65	Yes	Yes	Yes	No
Panamax		0.70	No	No	No	No
Post-Panamax		0.60	No	No	No	No
Neo-Panamax		0.55	No	No	No	No
ULCV		0.40	No	No	No	No

TABLE VI. Total Number of Activated Vessels Per Scenario

Sovereignty Threshold (θ)	Number of Activated Vessels	Comments
0.25	17	The fleet remains compact
0.50	17	The fleet is almost as per the scenario θ = 0.25
0.75	53	High increase in fleet size
0.88	18	Many high-capacity ships excluded

B. Economic Viability and Profitability

The objective value, representing the sovereignty-adjusted fleet profit, steadily decreases as the sovereignty requirement intensifies. At $\theta = 0.25$ and $\theta = 0.50$, the model yields high optimal values of respectively 8.67 and 8.63 million units. At $\theta = 0.88$, the profit collapses to just 62.8k units due to strict filtering of eligible vessels. Fig. 2 presents the evolution of optimal objective value by sovereignty threshold.

C. Environmental Factor

Table VII and Table VIII presents the top ten most carbon-efficient vessel-route pairings across the four sovereignty scenarios, ranked by the lowest carbon penalty per TEU transported. A consistent trend emerges: vessels with lower emission coefficients (e_{ir}) are consistently allocated to high-volume corridors, regardless of the sovereignty constraint level θ. When the sovereignty threshold is low or moderate ($\theta = 0.25$, $\theta = 0.50$, $\theta = 0.75$), the allocation tends towards vessels with the best criteria in terms of cost, emissions, and sovereignty. The pool of eligible vessels, however, drastically shrinks when $\theta = 0.88$. Consequently, the model's capacity to sustain environmentally optimal decisions is weakened.

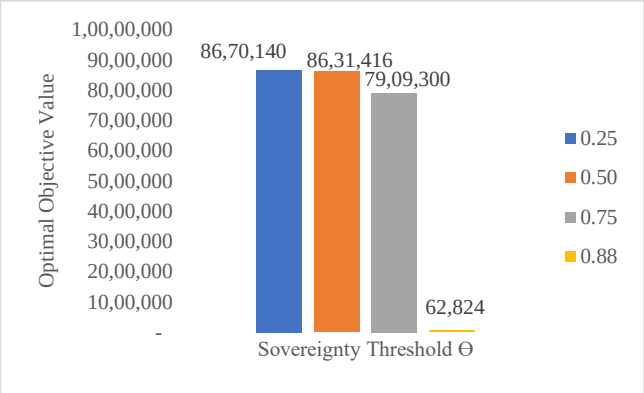

Fig. 2. Evolution of optimal objective value by sovereignty threshold.

D. Resilience and Demand Satisfaction

Resilience, interpreted here through transport demand coverage and unmet demand penalties α_r, exhibits a clear decline when $\theta = 0.88$. For $\theta = 0.25$, $\theta = 0.50$ and $\theta = 0.75$, almost all routes are served, with over 95 per cent of demand satisfied, as shown in Table VII and Table VIII. When $\theta = 0.88$, only a fraction of strategic routes are covered, and small-capacity vessels are unable to absorb large volumes, triggering unmet demand costs.

VI. DISCUSSION

Besides the numerical results, special consideration must be paid to the realization of policy aspects emerging from each scenario. These insights are essential for decision-makers, who must balance short-term financial constraints with the long-term goals of maritime sovereignty and sustainable fleet development.

The analysis highlights that strategic trade-offs become visible through the activation patterns of the fleet. At lower sovereignty thresholds, the solutions consistently point towards compact and efficient fleet structures, largely composed of mid-sized vessels such as Feeders, Medium Containerships, and Small Handies. These vessel types have moderate purchase prices, viable carbon footprints and strong national ownership ratings, making them well-aligned with economic viability and sovereignty objectives. When sovereignty requirements are raised, a marked contraction of fleet diversity is observed, with significant reductions in activation volumes, especially on high-demand routes. Comparable patterns are observed in recent models of oligopolistic 3PL competition, where environmental and digital imperatives, such as IoT adoption, directly affect pricing and deployment strategies [52], confirming the central role of sovereignty and sustainability in nowadays logistics network design. Indeed, the exclusion of vessels of type ULCV and Panamax family (Panamax, Post-Panamax and Neo-Panamax) confirms their incompatibility with a sovereign-oriented national fleet due to their high acquisition cost, foreign dominance, and operational scale requirements. This evolution highlights a fundamental trade-off that underlies the nature of strategic fleet planning: the higher maritime sovereignty becomes a central goal, the more the model leans toward limited vessel options. As a matter of fact, these results justify the choice of several developing maritime nations of the cabotage or the Short-Sea Shipping (SSS) as a strategic choice, leaving the long routes and corridors to international firms.

The discussion of activation patterns must also be complemented by the evolution of the fleet size. When $\theta = 0.25$ or $\theta = 0.50$, the model result is respectively a fleet of 17 vessels that are cost-efficient and sovereignty sensitive. Consequently, the profitability is maintained without overextending the fleet thanks to this controlled activation, which follows the logic of economic viability. The number of activated vessels increases significantly to 53, when $\theta = 0.75$, suggesting a diversification strategy that covers a wider range of demand. However, the number of activated vessels decreases to 18 once more when the sovereignty constraint reaches $\theta = 0.88$. Because of the model's stringent national control, which prevents many large-capacity vessels from activating, this represents a strategic narrowing. The trade-off between autonomy and scale is highlighted by this fluctuation in fleet size: operational breadth is given up in order to preserve political and financial control over maritime assets as sovereignty is maximized.

From an economic perspective, the steady reduction in profit with increasing sovereignty thresholds highlights the

measurable financial cost of sovereignty. This degradation, as shown in Fig. 2 , reflects the inherent cost of sovereignty prioritization: limiting access to high-capacity, cost-efficient ships translates into suboptimal network coverage and inflated operational expenses. Moreover, investment costs rise with the number of activated vessels needed to meet coverage requirements under constrained types.

Moderate thresholds preserve profitability, whereas maximalist sovereignty requirements collapse economic performance by excluding cost-efficient, large-capacity vessels. From a policymaking perspective, this analysis helps quantify the economic sacrifices associated with asserting maritime sovereignty, a pivotal trade-off at the core of strategic fleet planning.

The analysis further reveals how sovereignty constraints shape environmental outcomes and carbon efficiency. The results in Table VII and Table VIII show that the optimization algorithm favors vessels with strong environmental performance, especially on high-demand routes. At a lower or moderate sovereignty threshold, the model benefits from greater flexibility in vessel selection. Consequently, a balance is set between minimizing environmental impact and maximizing capacity utilization. At a higher sovereignty threshold, the model still finds a core set of ships that meet national ownership requirements and environmental standards, pointing to the potential for a foundational "sovereign-green" fleet. Similar findings are reported in recent stochastic ship design models, which show that LNG and methanol configurations are relatively robust initial choices because of their retrofit potential towards ammonia or hydrogen, providing flexibility under uncertain fuel and carbon prices [53]. One noteworthy finding is that, when this restriction is rigorously enforced, vessels with low sovereignty ratings but high environmental scores are left out of the solution, underscoring the dominating influence of sovereignty. This highlights a significant obstacle in sustainable fleet planning: if national control goals are involved, carbon efficiency alone is insufficient. In fact, recent studies underline that decarbonization policies will require more than technological improvements, as carbon pricing and alternative fuels are expected to significantly reshape fleet economics [54].

When combined, these results highlight the necessity of well-thought-out investment plans. Consequently, for countries such as Morocco, the government must encourage the retrofitting or local purchase of mid-sized ships that combine acceptable emissions profiles with significant national ownership potential, if it hopes to build a fleet that is both sovereign and environmentally conscious.

These insights may guide targeted green fleet development, especially for routes with high transport demand and strict environmental thresholds.

As per the resilience analysis, captured through demand coverage, the simulation underscores the systemic fragility introduced by overly restrictive sovereignty rules. The simulation highlights a resilience paradox: while sovereign fleets may be politically desirable, they may also struggle to absorb operational shocks or meet rising freight demand, unless complemented by supportive policy instruments or hybrid strategies (e.g., public-private joint ventures).

To validate the consistency of the proposed model, the sovereignty coefficient f_i was neutralized (set to 1 for all vessels), so that the formulation approximates a standard fleet sizing problem. The model's results in this sovereignty-free form are in line with two well-known studies [46] and [16]. The model emphasizes how operational costs and vessel capacity shape fleet composition. While smaller units offer flexibility, larger ships dominate when demand is high and costs are crucial. Thus; it concentrates on strategic fleet composition and environmental penalties, while [46] prioritized sailing speed and detailed routing. Despite this, both models converge toward a similar balance between cost effectiveness, emissions, and fleet diversity. Moreover,[16] who investigated multi-period fleet deployment under demand uncertainty, show also a similar alignment. The model's sovereignty-free version demonstrates that, in the absence of policy restrictions, demand satisfaction and profitability naturally determine the best fleet composition. The main difference is temporal: the current model is single-period and strategic, whereas [16] consider multi-period stochastic dynamics, but the fundamental economic reasoning is the same.

Importantly, only sovereignty was neutralized for this validation. Other parameters, such as resilience penalties and environmental constraints, were preserved because they form an integral part of the model's originality and are not explicitly treated in [16] and [46]. By incorporating sovereignty as a new strategic criterion, the suggested model not only replicates the insights of [46] and [16] but also builds upon them, ensuring that the comparison is both equitable and methodologically sound.

When combined, these results highlight how sovereignty-maximalist methods diminish resilience, flexibility, profitability, and environmental performance, making them insufficient to maintain strategic autonomy on their own. The implications for policymakers are clear: calibrated strategies that balance national control with operational and economic viability are essential. As a result, the model offers a decision-support tool that highlights the risks to resilience and measures the financial and environmental costs of sovereignty.

The limitations of this study must also be acknowledged. Long-term dynamics and uncertainty are simplified by the single-period, deterministic formulation. To improve realism, extensions should include geopolitical risk factors, stochastic trade flows, and multi-period horizons. In order to scale the model to larger problem instances, future research could also investigate heuristic or hybrid solution approaches. As a matter of fact, recent studies emphasize that near-zero emission fleet transitions depend on integrated strategies that jointly address renewal, deployment, and alternative fuel adoption under multiple sources of uncertainty [55]. Notwithstanding these drawbacks, the model already provides valuable information for building autonomous, robust, and sustainable fleets in developing maritime countries.

VII. Conclusion

This study introduces a strategic fleet sizing model tailored for public maritime authorities operating under sovereignty, environmental, demand coverage, and budgetary constraints. Through a sovereignty coefficient, the model directly incorporates national interest into the objective function, in contrast to traditional firm-level optimization techniques. It uses a mixed-integer formulation based on liner shipping dynamics and public policy considerations to capture decision-making at three levels: vessel activation, route assignment, and deployment of transport volumes.

The trade-offs brought about by sovereignty constraints are demonstrated by computational experiments conducted on a medium-scale dataset (100 vessels, 230 routes). The model gives cost-effectiveness and environmental performance priority at lower thresholds. However, the solution space shrinks as sovereignty requirements increase: the fleet is more vulnerable to resilience threats, flexibility decreases, and demand coverage deteriorates. Although a sovereignty-maximalist approach supports the goals of national control, it significantly reduces the network's overall capacity and economic viability.

These results highlight the significance of calibrated policymaking. Rigid constraints alone cannot sustain sovereignty and strategic autonomy. Indeed, a delicate balance between operability and control is needed. For maritime nations like Morocco, the suggested model provides a useful tool for decision-making that helps in resolving the delicate conflict between sovereign imperatives and economic rationality. Subsequent extensions might investigate dynamic, multi-period formulations or add uncertainty by incorporating geopolitical risks and stochastic trade flows. Nevertheless, the model already offers important information for building robust national managed fleets.

Acknowledgment

This research study has been produced by the LASTIMI Laboratory of Mohammed V University in Rabat. A Special thank you goes to the teams of the CELOG for their precious support. A special thank you also goes to two anonymous reviewers for their valuable feedback that added a lot of value to this study.

***Abstract*—This study develops and validates an artificial neural network (ANN) model to predict mining-induced land subsidence in Saudi Arabia's Al-Jalamid and Umm Wu'al phosphate mines. A multilayer perceptron is used with optimized hyperparameters based on four inputs (ground point position, distance from extraction center, accumulated exploitation volume, and time). The optimal configuration (5 hidden layers, 64 nodes, 240 epochs) achieves RMSE = 22 mm and MAE = 13 mm, outperforming traditional numerical/statistical baselines. Case-study validation at both mines confirms robustness (e.g., RMSE ≈ 20 mm, MAE ≈ 12 mm), enabling practical mitigation such as ground reinforcement and extraction-rate control. The results demonstrate that a tuned ANN provides accurate, operationally useful subsidence forecasts, supporting safer and more sustainable mine planning.**

Keywords*—Subsidence prediction; phosphate mine; artificial neural network; multilayer perceptron; hyperparameter optimization

I. Introduction

Phosphate mining is a cornerstone of Saudi Arabia's mining industry, playing a pivotal role in the nation's economic development. As one of the world's largest producers of phosphate, Saudi Arabia contributes significantly to global fertilizer production, which is essential for sustaining agricultural productivity and food security. The Al-Jalamid and Umm Wu'al phosphate mines, located in the Northern Borders Province, are among the most significant reserves globally, with extensive deposits that support both domestic and international demand. However, the extraction of phosphate is not without its challenges. Mining activities, particularly underground operations, often lead to environmental and geological disturbances, with land subsidence being one of the most critical issues. Subsidence can result in the sinking or settling of the ground surface, leading to infrastructure damage, environmental degradation, and increased operational risks. These impacts are exacerbated in arid regions like Saudi Arabia, where the geological formations are susceptible to deformation due to mining activities.

Mining-induced subsidence poses significant risks to both the environment and infrastructure. In Saudi Arabian phosphate mines, the extraction of phosphate-rich layers disrupts the geological equilibrium, causing the overlying strata to collapse or settle. This subsidence can lead to the formation of sinkholes, cracks in the ground surface, and damage to nearby infrastructure such as roads, pipelines, and buildings. Additionally, subsidence can alter groundwater flow patterns, further exacerbating environmental concerns in a region already facing water scarcity. Accurate prediction of subsidence is therefore essential for mitigating these risks, enabling mine operators to implement preventive measures, optimize extraction processes, and ensure the safety and sustainability of mining operations. Despite advancements in predictive modeling, the complex interplay of geological, hydrological, and operational factors makes subsidence prediction a challenging task, necessitating the development of robust and reliable models.

Over the past decade, various methodologies have been proposed to predict mining-induced subsidence, ranging from traditional numerical: [1] analyzed land subsidence using monitoring and numerical simulation in linear engineering areas, [2] modeled surface subsidence in coal mines through a bonded block numerical method, and [3] examined the geotechnical characterization of phosphate mining waste materials for pavement applications. Furthermore, [4] compared statistical and machine learning approaches for land subsidence modelling, [5] proposed a novel prediction method using data assimilation techniques, and [6] introduced a probability integral model integrated with active and passive remote sensing data to monitor subsidence. Numerical methods, such as the two-dimensional seepage model, quasi-three-dimensional seepage model, and fully coupled three-dimensional method, offer relatively straightforward implementation and interpretation [7-8]. While these methods provide detailed insights into subsidence mechanisms, they often require extensive computational resources and precise input parameters, limiting their practical applicability.

Statistical techniques, including time-series modeling [9-11], regression analysis [12-13], and Grey theory [14-16] offer simpler alternatives but are often constrained by their inability to capture the nonlinear relationships inherent in subsidence data.

Recent advancements in artificial intelligence (AI) have revolutionized subsidence prediction, with machine learning models such as Support Vector Machines (SVMs) and Artificial Neural Networks (ANNs) demonstrating superior performance. SVMs, known for their ability to handle high-dimensional data, have been successfully applied in subsidence prediction, particularly in cases with limited datasets [17-18]. However, their scalability remains a concern for large-scale mining operations. ANNs, on the other hand, have gained prominence due to their ability to model complex, nonlinear relationships and adapt to diverse datasets [19-21]. Studies have highlighted the effectiveness of ANNs in predicting subsidence, particularly when integrated with remote sensing and geographic information system (GIS) data. Despite these advancements, there is a need for further research to optimize ANN architectures, improve prediction accuracy, and address the challenges associated with long-term subsidence forecasting. The ANN model can be used to predict subsidence at different locations and times, helping mine operators to minimize subsidence, implement mitigation measures to protect infrastructure and the environment, monitor subsidence trends over time.

Despite various numerical and statistical models for subsidence prediction, their applicability is often limited by computational constraints and the complexity of subsurface interactions. Traditional methods struggle to account for nonlinear geological behaviors, making them unsuitable for large-scale, real-time applications. This study aims to address this gap by developing an ANN model tailored to the unique geological and operational conditions of Saudi Arabian phosphate mines offering a robust alternative for subsidence prediction.

By leveraging advanced machine learning techniques, the proposed model seeks to provide accurate and reliable subsidence predictions, contributing to the sustainable management of mining operations and the mitigation of environmental risks.

This study presents an artificial neural network (ANN) model for predicting mining-induced subsidence in Saudi Arabian phosphate mines. The paper is structured as follows: Section II provides an overview of the study area, including geological characteristics and mining conditions. Section III details the methodology, describing the ANN model architecture, feature selection, and training process. Section IV presents the results, including model performance evaluation and validation. Finally, Section V concludes the study with key insights and recommendations for future research.

II. Study Area

As two of the world's largest phosphate reserves, the Al-Jalamid and Umm Wu'al mines in Saudi Arabia's Northern Borders Province possess unique geological and economic significance. Their sedimentary formations, characterized by alternating limestone, shale, and phosphorite layers, make them highly susceptible to subsidence. Previous studies have reported significant subsidence events in these mines, highlighting the need for advanced predictive models. The presence of Tunnel Boring Machines (TBMs) further complicates ground stability, making these sites ideal for testing AI-driven predictive frameworks.

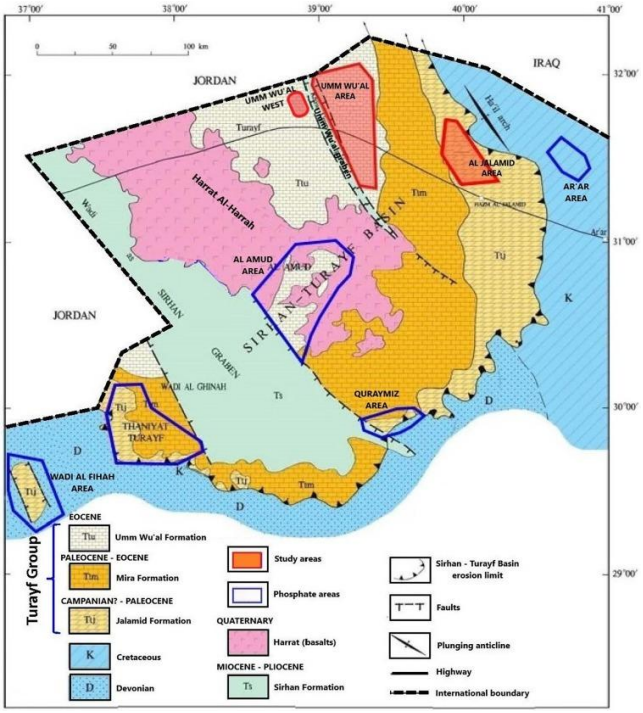

Fig. 1. Geological framework of the sirhan-turayf basin: distribution of phosphate deposits and study sites.

Fig. 1 presents the Al-Jalamid and Umm Wu'al phosphate mines in northern Saudi Arabia, among the world's largest phosphate reserves, crucial for global fertilizer production. Al-Jalamid is a major underground mining site where extraction has led to land subsidence and high disc cutter consumption in TBMs. The region's sedimentary formations (limestone, shale, phosphate-rich layers) present geological and environmental challenges due to its arid climate and limited groundwater.

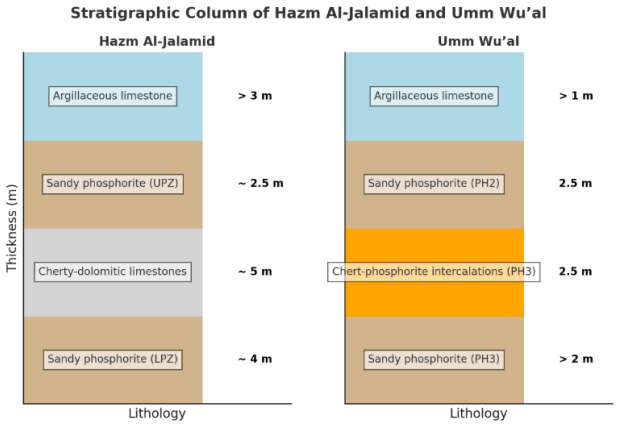

Fig. 2. Stratigraphic columns of phosphate-bearing formations in Hazm Al-Jalamid and Umm Wu'al.

Fig. 2 introduces the phosphorite deposits at Hazm Al-Jalamid range from friable sandy-calcareous to hard compact formations, reflecting depositional and diagenetic variations that influence mining methods and geotechnical behavior. The

Thaniyat Phosphorite Member comprises two main phosphorite horizons: Lower Phosphorite Zone (LPZ) and Upper Phosphorite Zone (UPZ).

The LPZ consists of calcareous and dolomitic phosphorite beds (3–4 m thick), rich in bioclastic fragments, indicating a marine depositional environment. The UPZ, 4–7 m thick (avg. 6 m), contains sparry calcite lenses, argillaceous cement, and vuggy structures, suggesting post-depositional diagenesis and bioturbation. A 12-meter-thick sand, clay, and limestone sequence overlies the UPZ.

An intermediate horizon (0.5–5 m thick) between LPZ and UPZ consists of low-grade phosphatic dolomitic limestone with quartz geodes and chert nodules, marking a transitional depositional setting influenced by sedimentological and chemical variations.

III. Artificial Neural Networks

The dataset employed in this study was collected from monitoring records of the Al-Jalamid and Umm Wu'al phosphate mines located in the Northern Borders Province of Saudi Arabia. It consists of ground deformation measurements covering multiple observation points distributed across subsidence-prone areas. Four primary variables were included: (i) ground point positions (Y), representing the spatial coordinates of monitoring stations along the subsidence trough; (ii) distance from the extraction chamber center (L), indicating the horizontal offset of each point from the center of mining activity; (iii) accumulated exploitation volume (V), defined as the total phosphate volume extracted up to a given measurement epoch; and (iv) time (T), denoting the elapsed duration since the initiation of mining operations.

The dataset underwent several preprocessing steps to ensure consistency and reliability. Missing values were handled using linear interpolation for continuous features, while outliers were identified and removed. All input features were normalized to a [0, 1] range to eliminate scale differences and enhance model convergence. Following preprocessing, the dataset was divided into three subsets: 70% for training the artificial neural network (ANN), 15% for hyperparameter validation, and 15% for final performance testing. This partitioning ensured robust evaluation and reduced overfitting risks.

A. Artificial Neural Network Architecture

Fig. 3 presents the proposed ANN model is designed to predict mining-induced subsidence using a multilayer perceptron (MLP) architecture. The model consists of three primary components: an input layer, hidden layers, and an output layer.

1) Input layer: The input layer comprises four neurons, each corresponding to one of the input variables:

a) Ground point positions (Y): The spatial coordinates of monitoring points along the subsidence trough.

b) Distance from extraction chamber center (L): The horizontal distance from the center of the mining activity to each monitoring point.

c) Accumulated exploitation volume (V): The total volume of phosphate extracted up to the measurement epoch.

d) Time (T): The elapsed time since the start of mining operations.

2) Hidden layers: The model includes two hidden layers, each containing 64 neurons. The number of hidden layers and neurons was determined through validation, balancing model complexity and generalization performance. The Rectified Linear Unit (ReLU) activation function was used for the hidden layers, as it effectively mitigates the vanishing gradient problem and accelerates convergence during training.

3) Output layer: The output layer consists of a single neuron that predicts the subsidence value (η). A sigmoid activation function was employed in the output layer to ensure that the predicted subsidence values fall within a realistic range (0 to 1, normalized to the maximum observed subsidence).

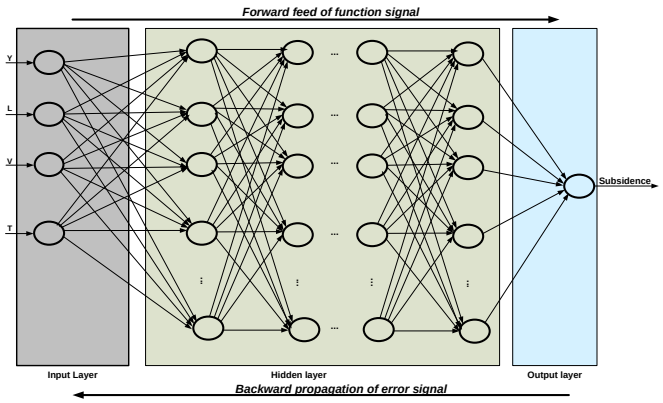

Fig. 3. Architecture of the Backpropagation Neural Network (BPNN) for subsidence prediction.

B. Data Preprocessing

The dataset used for training and testing the ANN model was preprocessed to ensure optimal performance. The preprocessing steps included as it is illustrated in Fig. 4:

1) Data cleaning: Missing values in the dataset were addressed using linear interpolation for continuous variables and mode imputation for categorical variables. Outliers were detected and eliminated from the dataset.

2) Normalization: All input variables were normalized to a range of [0, 1] using min-max scaling to ensure that features with larger magnitudes did not dominate the training process. The normalization formula is given by:

$$X_{norm}=(X-X_{min})/(X_{max}-X_{min})$$

where X_{min} and X_{max} are the minimum and maximum values of the feature, respectively.

3) Feature selection: A correlation analysis was conducted to identify and remove highly correlated features, reducing redundancy and improving model efficiency. The final set of features included ground point positions, distance

from the extraction chamber center, accumulated exploitation volume, and time.

4) Data splitting: To ensure rigorous model assessment, the data were split into three subsets: 70% for training the ANN, 15% for hyperparameter validation, and 15% for final performance testing.

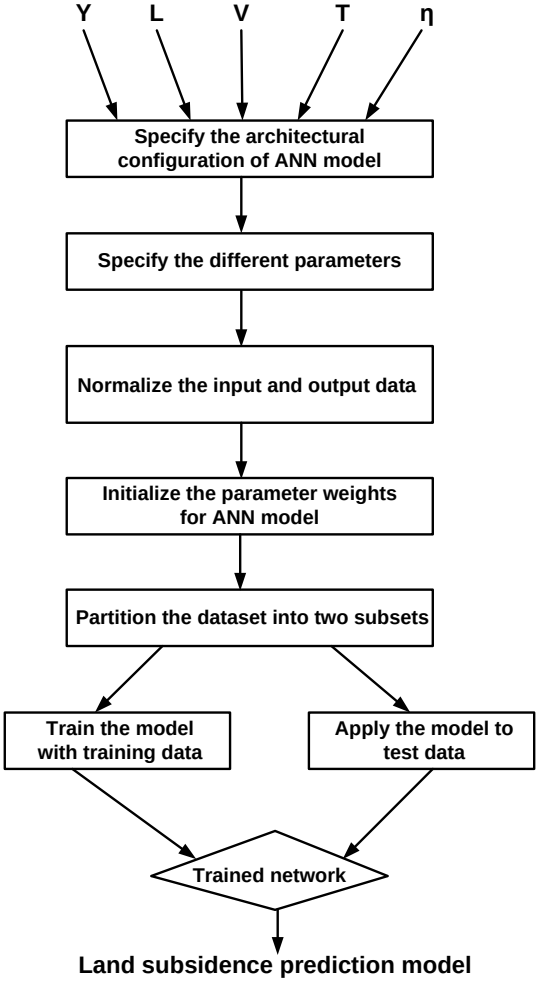

Fig. 4. Workflow of the ANN model for land subsidence prediction.

C. Model Training

In Artificial Neural Network (ANN) models, each neuron in the input layer receives an assigned input, which is transmitted to neurons in subsequent layers through weighted connections. These weights, ranging from -1 to 1, represent the relative importance of each connection. To determine the neuron's response, an activation function is applied to the weighted input, producing an output value. If this value exceeds a predefined threshold, the neuron becomes active; otherwise, it remains inactive.

In the output layer, the discrepancy between the predicted and actual output is quantified as an error. Through a process known as backpropagation, this error propagates backward through the network, adjusting the weights of preceding layers. This iterative process continues until the error converges below a specified threshold, optimizing the network's predictive accuracy.

Following the training phase, the validation and testing phases commence. During validation, hyperparameters such as training duration, learning rates, and the number of neurons in hidden layers are fine-tuned to enhance model performance. The testing phase assesses the model's generalization ability, evaluating its predictive accuracy on unseen data. The final model is selected based on its optimal performance metrics.

The GIS-integrated ANN framework utilized a backpropagation neural network (BPNN) for land subsidence susceptibility assessment, with performance evaluated via correlation coefficient. The training phase mathematics and convergence behavior are derived as follows:

The outputs of the hidden layer h_i and output layer O_k are given by Eq. (1) and Eq. (2).

$$h_i = F(V_j) = \left[B_{oj} + \sum_{i=1}^{I} (B_{ij} \cdot v_i) \right] \quad (1)$$

$$O_k = F(H_k) = \left[B_{ok} + \sum_{j=1}^{J} (B_{kj} \cdot h_i) \right] \quad (2)$$

where V_j and H_k denote the intermediate computations before activation; B_{oj} and B_{ok} correspond to bias terms that establish threshold values; F signifies the activation function operating within a range of 0 to 1; and v_i, h_i, and O_k refer to the input, hidden, and output layers, respectively.

For activation functions, the hyperbolic tangent sigmoid is used, which computes the outputs of hidden and output layers as given in Eq. (3) and Eq. (4).

$$h_i = F(V_j) = \frac{1}{1+e^{-V_j}} \quad (3)$$

$$O_k = F(H_k) = \frac{1}{1+e^{-H_k}} \quad (4)$$

The error function E is formulated as shown in Eq. (5).

$$E = \frac{1}{2} \sum_{k=1}^{K} O_k^2 = \frac{1}{2} \sum_{k=1}^{K} (d_k - O_k)^2 \quad (5)$$

Here, E represents the cumulative error across all output nodes, calculated as the sum of squared deviations between the network's predictions and target values. For each output node k, d_k denotes the desired target value, while ε_k corresponds to the prediction error (i.e., $\varepsilon_k = d_k - O_k$,). The weight modification between the hidden and output layers is defined as shown in Eq. (6).

$$\Delta b_{jk} = \alpha \cdot h_j \cdot \delta_k \quad (6)$$

where α is the learning rate. Reformulating Eq. (6) yields Eq. (7).

$$b_{jk}(n+1) = b_{jk}(n) + \Delta b_{jk}(n) \quad (7)$$

where n represents the iteration index. Taking the partial derivative of the error E with respect to b_{ij}, the following relations are derived:

The correlation coefficient (C) served as the primary performance metric for evaluating the GIS-integrated ANN model, it is calculated as shown in Eq. (8).

$$C=\frac{\sum_{i=1}^{n}(d_i-\bar{d})(p_i-\bar{p})}{\sqrt{\sum_{i=1}^{n}(d_i-\bar{d})^2\cdot\sum_{i=1}^{n}(p_i-\bar{p})^2}} \quad (8)$$

where C denotes the correlation coefficient, d_i is the target output, p_i is the predicted output, $\bar{d}$ is the mean target value, and $\bar{p}$ is the mean predicted output. Fig. 3 illustrates the architecture of the proposed predictive framework, which integrates a backpropagation neural network (BPNN) with four critical geospatial input parameters: (i) Percentage of agricultural land use, (ii) Energy consumption by groundwater extraction wells, (iii) Proportion of fine-grained sediments, and (iv) Mean maximum drainage path length.

Fig. 3 presents a comprehensive view of the primary stages in ANN configuration. While defining the network architecture, selecting activation functions, and determining the number of training epochs necessitate manual adjustments, automated processes manage data preprocessing, normalization, and weight initialization.

IV. Model Performance Evaluation

A. Performance Metrics

Multiple combinations of hyperparameters were tested, including:

- Number of hidden layers (e.g., 3, 4, 5, 6, …).
- Number of nodes per hidden layer (e.g., 32, 64, 128, …).
- Number of epochs (e.g., 100, 200, 240, 300, …).

Instead of using a grid search (testing all possible combinations), a random search is used (testing random combinations) to find the optimal hyperparameters. This approach was selected for the following reason. Random search explores the hyperparameter space more efficiently by sampling parameter combinations randomly, rather than exhaustively evaluating all possible combinations as in grid search. This is particularly advantageous when dealing with computationally expensive models.

For each combination of hyperparameters, the RMSE and MAE are recorded on the validation set and calculate the average RMSE and MAE for each hyperparameter combination.

The performance of the models was evaluated using:

- RMSE: Measures the average magnitude of the prediction errors.
- MAE: Provides a robust measure of error, less sensitive to outliers.

B. Optimal Hyperparameters

Table I presents a detailed summary of performance metrics corresponding to various artificial neural network (ANN) architectures. The "Hidden Layers" column denotes the number of hidden layers employed in each architecture, which directly affects the model's capacity to capture non-linear and complex data patterns. The "Hidden Nodes" column indicates the number of neurons per hidden layer; increasing this number generally enhances the model's representational power but may also heighten the risk of overfitting. The "Epochs" column specifies the total number of training iterations over the dataset, where a higher count may improve convergence but similarly raise overfitting concerns. The "Avg. RMSE (mm)" and "Avg. MAE (mm)" columns report the average root mean square error and mean absolute error, respectively, across validation folds—lower values in both metrics are indicative of better predictive performance. Finally, the "Std. Dev. RMSE" and "Std. Dev. MAE" columns reflect the standard deviations of RMSE and MAE, providing insight into the stability and consistency of each model's performance across k-fold cross-validation.

Insights from Table I reveal that as the number of hidden layers and nodes increases, the average RMSE and MAE generally decrease, suggesting that more complex architectures may yield better performance.

TABLE I. PERFORMANCE OF DIFFERENT ANN ARCHITECTURES

Hidden Layers	Hidden Nodes	Epochs	Avg. RMSE (mm)	Avg. MAE (mm)	Std. Dev. RMSE	Std. Dev. MAE
3	32	100	25.3	15.2	1.2	0.8
3	64	100	24.8	14.9	1.1	0.7
3	128	100	24.5	14.7	1.3	0.9
4	32	200	23.8	14.3	1	0.6
4	64	200	23.1	14	0.9	0.5
4	128	200	23.5	14.2	1.1	0.7
5	32	240	22.5	13.5	0.8	0.5
5	**64**	**240**	**22**	**13**	**0.7**	**0.4**
5	128	240	22.3	13.2	0.9	0.6
6	32	300	23	14.1	1	0.6
6	64	300	22.8	13.8	0.9	0.5
6	128	300	23.2	14	1.1	0.7

The bolded row (5 hidden layers, 64 hidden nodes, 240 epochs) represents the optimal configuration, as it achieves the lowest RMSE (22.0 mm) and lowest MAE (13.0 mm) with the smallest standard deviations (0.7 for RMSE and 0.4 for MAE). This configuration strikes a balance between model complexity and generalization, avoiding overfitting while maintaining high predictive accuracy.

Increasing the number of hidden layers beyond 5 does not significantly improve performance and may lead to overfitting, as seen in the 6-layer configurations. A moderate number of

hidden nodes (e.g., 64) provides the best balance between model complexity and performance, with fewer nodes (e.g., 32) resulting in higher errors and more nodes (e.g., 128) not yielding significant improvements. Training for 240 epochs is sufficient for convergence, as extending training to 300 epochs does not improve performance and may increase the risk of overfitting.

C. Case Studies

The ANN model was applied to two real-world case studies in Saudi Arabian phosphate mines to demonstrate its practical applicability:

1) Al-Jalamid mine: The model was used to predict subsidence in the Al-Jalamid mine, where extensive underground mining has led to significant ground deformation. The predictions were compared with actual subsidence measurements, achieving an RMSE of 20 mm and an MAE of 12 mm. The model's accuracy enabled mine operators to implement targeted mitigation measures, such as ground reinforcement and controlled extraction rates, reducing the risk of infrastructure damage.

2) Umm Wu'al mine: In the Umm Wu'al mine, the model was employed to forecast subsidence trends. The predictions were used to optimize mining operations, ensuring that subsidence remained within acceptable limits. The model's ability to provide long-term forecasts was particularly valuable for strategic planning and risk management.

V. Conclusions

This study developed an Artificial Neural Network (ANN) model to predict mining-induced subsidence in Saudi Arabian phosphate mines. The model demonstrated high predictive accuracy, achieving an RMSE of 22 mm, and an MAE of 13 mm, on the testing dataset. Key factors influencing subsidence, including distance from the extraction chamber center and accumulated exploitation volume, were identified through feature importance analysis. The model's robustness and adaptability make it a reliable tool for subsidence prediction in mining operations.

The proposed Artificial Neural Network (ANN) model offers significant practical benefits for the mining industry and environmental management. Risk mitigation is achieved through accurate subsidence prediction, allowing mine operators to implement targeted measures such as ground reinforcement and controlled extraction rates, thereby reducing the risk of infrastructure damage and environmental degradation. The model also enhances operational optimization by forecasting subsidence trends over time, ensuring mining activities remain within safe and sustainable limits. Additionally, it aids in strategic planning by providing long-term subsidence predictions, enabling mining companies to balance economic objectives with environmental and safety considerations. Furthermore, the model promotes environmental protection by minimizing subsidence-related impacts such as groundwater disruption and land deformation, which is particularly crucial in ecologically sensitive regions like Saudi Arabia.

Building upon the current findings, future research will aim to address the identified limitations and enhance the robustness and applicability of the ANN model. First, efforts will focus on integrating higher-resolution and more diverse ground truth datasets to reduce spatial bias and improve model generalization across heterogeneous regions. Second, to improve model interpretability, future studies will explore hybrid approaches that couple ANN models with explainable artificial intelligence techniques, allowing for better attribution of predicted subsidence to underlying physical processes. Finally, transfer learning and domain adaptation strategies will be investigated to facilitate the application of trained models to new geographic areas with differing geologic and anthropogenic characteristics

Faculty of Engineering, Universiti Malaysia Sabah, Kota Kinabalu, Sabah, Malaysia[1, 2, 3, 4]

***Abstract*—Image-based plant disease identification methods have demonstrated potential in enhancing crop protection through early detection. However, the development of this field faces several challenges, such as the scarcity of high-quality annotated data, significant intra-class variation and high inter-class similarity among plant diseases, and the limited generalization ability of current models under diverse domain conditions. We extensively investigated 110+ latest papers on plant disease identification, aiming to present a timely and comprehensive overview of the most recent advances in the field, along with impartial comparisons of strengths and weaknesses of the existing works. Specifically, we begin by reviewing traditional machine learning and deep learning methods, which form the foundation for many current models. We then introduce a taxonomy of transfer learning methods, including instance-based, mapping-based, and network-based methods, and analyze their effectiveness in enhancing classification performance by leveraging prior knowledge under data-constrained scenarios. Subsequently, we examine recent advances in few-shot learning methods for plant disease identification, categorizing them into model-based, metric-based, and optimization-based methods, and evaluate their capabilities in addressing data scarcity and improving identification accuracy. Finally, we summarize the current limitations and outline promising future research directions, with the aim of guiding continued development in this area.**

Keywords*—*Few-shot learning; transfer learning; deep learning; crop protection; early detection; data scarcity

I. Introduction

Plant disease identification has emerged as a significant area of research. Timely identification of plant diseases is critical for reducing crop losses and minimizing the use of pesticides [1]. Image-based plant disease identification has emerged as a fast, accurate, and reliable method for early detection [2],[3]. These methods typically involve several stages, such as image acquisition, image processing, feature extraction, and classification.

However, image-based methods face critical challenges. Variations in noise, background, and lighting in plant disease datasets often affect identification accuracy [4]. In addition, the diversity of tasks, such as identifying citrus diseases [5], tomato diseases [6], and wheat diseases [7], combined with the presence of grafted, hybrid, and genetically modified plants, exacerbates issues of data scarcity and class imbalance in plant disease identification. These challenges underscore the need for new image-based techniques, such as few-shot learning (FSL) [8], [9], transfer learning (TL) [10], [11].

Previous studies have explored various methods for plant disease identification. For example, support vector machines (SVMs) [12], convolutional neural networks (CNNs) [13], TL[14], and generative adversarial networks (GANs) [15]. However, existing surveys are predominantly architecture-centric [3],[16], offering limited guidance when data conditions, rather than model choice, are the primary bottleneck. In practice, field performance is more often constrained by domain shift, class imbalance, and scarce labels than by marginal architectural differences. To ground our review, we conducted a structured search across IEEE Xplore, Scopus, Web of Science, and Google Scholar covering 2019 to 2025, complemented by backward and forward citation tracing to capture seminal earlier work. The search queries combined keywords including plant disease, early detection, leaf disease identification, transfer learning, domain adaptation, and few-shot learning. From over 230 retrieved studies, we retained 116 directly relevant papers on image-based plant disease identification.

To address the identified gap, we adopt a scenario-driven taxonomy organized by three data regimes: (i) tasks with sufficient samples, (ii) tasks with limited samples but abundant related task data, and (iii) tasks with limited samples and no related data. The objective is to map method families to each regime. We synthesize prior work, identify recurring limitations, and provide scenario-specific recommendations for method selection under realistic field conditions. For navigation, an overview diagram is placed at the beginning of Section II (Fig. 1), linking data regimes to the technique families reviewed in Sections II-IV.

II. Machine Learning or Deep Learning for Plant Disease Identification

When a sufficient amount of data is available, both machine learning (ML) and deep learning (DL) methods have proven effective in various plant disease classification tasks. In this section, a classification method is proposed that combines traditional ML, DL, and their fusion. Fig. 1 illustrates the classification methods reviewed in this study, providing practical guidance for plant disease identification under varying data scenarios.

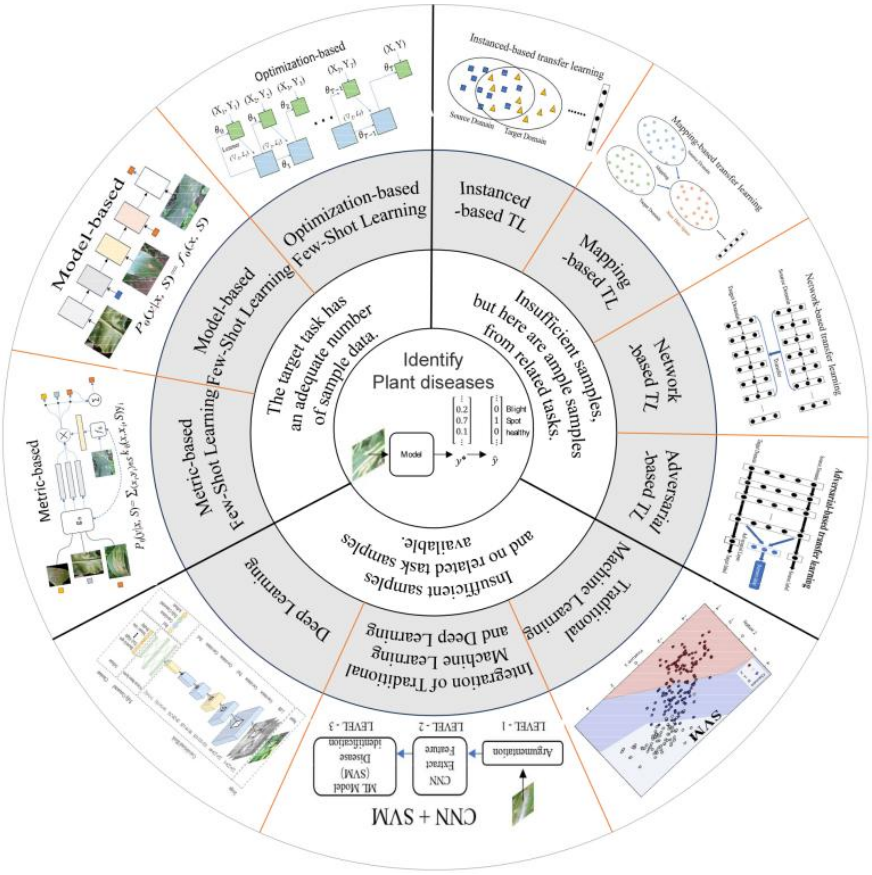

Fig. 1. Scenario-driven taxonomy of image-based plant-disease identification methods under diverse data conditions. The diagram maps three data regimes (sufficient data, limited data with related sources, and limited data without related sources) to representative technique families. (ML, DL and their fusion; transfer learning; few-shot learning).

A. Traditional Machine Learning Methods

Traditional ML methods rely on extracting features such as color, texture, and shape, making the models interpretable. Support Vector Machines (SVM) are particularly effective in handling high-dimensional data [17], while the K-Nearest Neighbors (KNN) algorithm is known for its simplicity and reliability [18]. Additionally, Naive Bayes (NB) classifiers are efficient when processing large datasets [19]. Furthermore, ensemble learning methods like Random Forests (RF) and Gradient Boosting Trees combine multiple weak learners to improve overall performance and robustness [20].

Logistic Regression (LR), NB, and Discriminant Analysis (DA) are often used to simplify complex problems by assuming feature independence, which reduces high-dimensional data to simpler forms. Appeltans *et al*. [21] trained an LR classifier to detect five classes of leek white tip disease, achieving an overall accuracy of 96.74%. However, LR tends to perform poorly in cases involving nonlinear or multi-feature problems, especially when multicollinearity among features is present [22]. DA assumes that data follows a normal distribution and that different groups have equal covariance. Mahmud *et al*. [23] used DA for real-time detection of strawberry PM disease in the field by extracting texture features with color co-occurrence matrices. This method achieved a maximum accuracy of 95.45%. However, DA may not perform well if the data does not meet the assumption of normal distribution [24]. NB works well with different types of data distributions. For instance, Prashar *et al*. [19] used NB combined with a firefly optimization method to identify 494 rice leaf images from five disease categories. However, NB may suffer from reduced accuracy when dealing with features not present in the training data or when ignoring dependencies between features.

SVM, KNN, and Decision Trees (DT) are non-parametric models that do not rely on specific data distribution assumptions or linear relationships among features. KNN works well for small datasets with low-dimensional image features [18]. Devi *et al*. [25] combined Harris corner detection, Histogram of Oriented Gradients, and KNN for peanut disease classification. This method achieved an accuracy of 97.67%. SVMs may face challenges with high-dimensional data due to the "curse of dimensionality" [26]. To address this, Javidan *et al*. [27] used Principal Component Analysis to reduce feature dimensions and applied ReliefF to select key features. RF improves model accuracy by combining the results of multiple DTs. Basavaiah *et al*. [20] compared RF and DT classifiers for plant disease detection. RF achieved a higher accuracy of 94%, while DT reached 90%. Table I summarizes traditional ML methods for plant disease identification.

TABLE I. SUMMARY OF TRADITIONAL ML METHODS FOR PLANT DISEASE IDENTIFICATION

Methods	Dataset	Type of features	Accuracy (%)	Disadvantages
RF [20]	Tomatoes, self-built	Text, color, and shape	94.00	Requires large datasets.
OWs+KNN [18]	Strawberries, self-built	Spectral	93.33	Sensitive to irrelevant features.
SLIC_SVM [17]	Tea, self-built	Shape and textural	98.50	Depends on hyperparameters.
LDA+LR [21]	White, self-built	Hyperspectral	96.74	Limited on high-dimensional.
CCM+DA [23]	Strawberries, self-built	Color and textural	95.45	Not suitable for nonlinear data.
NB+Firefly [19]	Paddy, self-built	Color and textural	98.64	Conditional independence.
SVM+FOA [26]	Tomatoes, PlantVillage	Text, color, and shape	91.10	Slow convergence.

B. Deep Learning Methods

DL enables the automatic extraction of hierarchical representations from large and complex datasets. Methods such as CNN, recurrent neural network (RNN), and Transformer effectively capture intricate patterns and features in plant imagery, offering significant advantages over traditional ML methods.

CNNs are powerful tools for extracting image features through layers of convolution, pooling, and fully connected operations. They can improve performance by increasing network depth, but deeper networks often make training more challenging. ResNet [28] addresses this issue by introducing residual connections, which facilitate gradient flow, allowing the training of much deeper models. On the PlantVillage dataset, a widely used public dataset, the PDICNet model based on ResNet-50 achieved an accuracy of 99.73% [13]. In contrast, DenseNet [29] connects each layer to every other layer in a feed-forward way, improving feature sharing and reducing redundancy. Multi-headed DenseNet was tested on the PlantVillage and achieved an accuracy of 98.17% [30].

Unlike ResNet and DenseNet, MobileNet is designed to reduce the number of parameters and computational cost. However, its accuracy may be lower for more complex datasets, as noted by Bi *et al*. [31]. They improved the MobileNet and achieved an accuracy of 73.50%. Multi-kernel depthwise separable convolutions are employed to reduce the number of model hyperparameters. Lite-MDC [32] utilizes only 2.20M parameters and achieves an accuracy of 99.78% on PlantVillage. These methods are compatible with mobile and embedded systems, where computational efficiency is critical. By focusing on diseased areas and reducing the influence of background noise, attention mechanisms contribute to improved classification accuracy [33]. The rE-GoogLeNet model adds the ECA attention mechanism into the Inception module and achieves an accuracy of 99.58% [34]. XSE-TomatoNet [35] combines SE blocks with multi-scale feature fusion to enhance the classification performance of EntricNet-B0.

For real-time applications, improved models such as YOLOv5s [36] and DM-YOLO [37] have been proposed to achieve faster inference while maintaining high detection accuracy. However, despite their efficiency in spatial object detection, these models are limited in capturing temporal dependencies across image sequences. To address this, RNNs have been employed for analyzing time-lapse images and video data, enabling the modeling of dynamic changes in plant growth and disease progression [38].

Vision Transformers (ViTs) have demonstrated strong performance in plant disease identification by modeling long-range dependencies. A recent study reported an optimized ViT architecture that attained state-of-the-art performance on PlantVillage [39]. To improve inference efficiency and reduce model complexity, recent studies have begun replacing traditional Transformer modules with Mamba-based architectures. LF-Mamba [40] improves the decoder's spatial resolution and enhances its ability to extract complex disease features, while significantly reducing the number of parameters. Table II summarizes DL-based methods for plant disease identification.

TABLE II. SUMMARY OF DL METHODS FOR PLANT DISEASE IDENTIFICATION

Methods	Dataset	Accuracy (%)	Parameters (M)	Disadvantages
Multi-headed DenseNet [30]	PlantVillage [41]	98.17	\	Higher memory requirements.
RIC-Net [42]	PlantVillage	99.55	19.10	Complex structure.
RE-GoogLeNet [34]	Rice, self-built	99.58	9.18	Difficult to optimize.
PDICNet [13]	PlantVillage	99.73	\	Difficult to optimize.
XSE-TomatoNet [35]	Tomato, PlantDoc	99.11	\	Requires high input resolution.
MobileNet [31]	Apple, self-built	73.50	\	Lower detection accuracy.
Lite-MDC [32]	PlantVillage	99.77	2.20	Unable to localize disease regions .
YOLOv5s [36]	MSMSVDD	93.10	8.30	Less effective for small objects.
DM-Yolo [37]	Tomato, self-built	92.50	50.07	Lower training stability.
G-RecConNN [38]	Banana, self-built	93.60	\	Vanishing gradient issues.
Optimized ViT [39]	PlantVillage	99.77	13.02	More computational resources.
LeafMamba [40]	FGVC8	92.50	0.99	Limited capability in local feature.

C. Hybrid Methods

Hybrid ensemble methods leverage the complementary strengths of different architectures to improve image feature extraction, mitigate overfitting caused by feature bias, and enhance generalization [53]. To balance performance and efficiency, recent studies have explored combining CNN-based feature extractors with traditional classifiers, integrating CNNs' spatial feature learning with the interpretability of classical methods [43],[44]. Meanwhile, many hybrid methods reduce model complexity by replacing parts of complex architectures with lightweight components, while maintaining or even enhancing predictive performance [45]. For example, SSD_Mobile-NetV2 [46] uses only 50.9% of the parameters compared to SSD_VGG, yet achieves improvements in precision, recall, F1-score, and mean Average Precision (mAP) by 4.37%, 3.3%, 3.8%, and 8.79%, respectively. Furthermore, CNNs are often employed to replace or supplement parts of Transformer architectures, providing more efficient local feature modeling and faster inference in real-time or resource-constrained plant disease detection scenarios. ConvViT [47], which combines CNNs with Transformer, outperforms models such as ResNet, ViT, and ResMLP by improving accuracy by 4.53% while reducing the number of parameters and FLOPs by more than 10%.

SoyaTrans [48] utilizes CNNs to extract local features and a Transformer module to capture global dependencies. With only 5.2 million parameters, it achieves an accuracy of 98.00% on the PlantVillage dataset. This result demonstrates that integrating multiple learning paradigms can outperform models based on a single architecture. Table III summarizes the latest performance of hybrid methods in plant disease identification tasks.

TABLE III. SUMMARY OF RECENT PERFORMANCE OF HYBRID METHODS IN PLANT DISEASE IDENTIFICATION

Ensemble Methods	Dataset	Accuracy (%)	Parameters (M)
CNN+Transformer [47]	PlantVillage	99.84	59.00
VGG19+InceptionV3 [49]	PlantVillage	98.66	\
VGG16 + RF [43]	PlantVillage	94.00	0.26
KNN+ Transformer [44]	PlantVillage	99.93	\
SoyaTrans [48]	PlantVillage	98.00	5.20
VGG-ICNN [50]	PlantVillage	99.16	23.20
CNN + RNN [51]	AI maize dataset	97.85	0.4
Ensemble models [52]	New PlantVillage	99.89	\

D. Discussion and Summary

Traditional ML, DL, and hybrid methods provide effective solutions for plant disease classification. The choice of method depends on the specific challenges of the task, such as data availability, feature complexity, and computational resources. Traditional ML methods are lightweight and interpretable due to their reliance on handcrafted features. However, their effectiveness is limited by feature quality and poor robustness under varying field conditions. DL methods automatically extract features from raw data. They are powerful at capturing complex disease patterns and usually achieve higher accuracy than ML when sufficient labeled data is available. However, they are data- and resource-intensive, less interpretable, and often struggle with robustness under real-world field conditions. Hybrid ML-DL methods combine the strengths of both paradigms. DL models are used for robust feature extraction, while traditional ML algorithms provide lightweight and interpretable decision-making. This balance reduces reliance on manual features and lowers computational cost compared with full DL pipelines. However, their effectiveness is constrained by the need for precise feature-model integration and limited robustness to previously unseen crops and disease types [54].

III. TRANSFER LEARNING FOR PLANT DISEASE IDENTIFICATION

TL allows models trained on one plant species to be applied to related species. It helps address limited data and domain variability, especially under class imbalance [55]. However, a comprehensive review specifically focused on “agricultural TL” remains lacking [56]. This section reviews three major TL methods, namely instance-based, mapping-based, and network-based.

A. Mapping-Based Transfer Learning

Mapping-based TL reduces the distribution gap between source and target domains by learning a shared feature space or an explicit mapping function. MViT [57] employs an adversarial framework augmented with the Wasserstein distance to learn domain-invariant representations, projecting source and target samples into a common latent space with closely matched distributions. Maximum Mean Discrepancy [58] offers a theoretically grounded measure of domain shift by aligning the mean embeddings of source and target features in a reproducing-kernel Hilbert space. CLA [59] first performs self-supervised contrastive pre-training, then applies a domain-adaptation layer that explicitly aligns the resulting feature distributions. CORrelation Alignment [60] efficiently matches the second-order statistics of source and target features, delivering low computational overhead and good scalability. Attention-based alignment [61] further narrows the domain gap by highlighting discriminative regions while suppressing irrelevant background noise.

For cross-species plant disease identification, adversarial domain adaptation is used to learn domain-invariant representations. A representative method is DANN [62], which performs well under pronounced domain shifts, including highly non-linear settings and large cross-domain datasets. Other strategies reduce domain discrepancy by explicitly constraining the diagnostic model. FMDA [63] minimises the “distance” between source and target, thereby lowering domain divergence. Using unlabelled target data without explicit feature alignment can exacerbate domain mismatch. Unsupervised domain adaptation methods [64] learn shared feature spaces from abundant unlabelled target images, aligning source and target domains through non-adversarial means. Zero-shot TL [65] builds a discriminative, transferable embedding that bridges source and target domains even when their class sets do not overlap.

B. Network-Based Transfer Learning

Network-based TL focuses on modifying the architecture itself so that it can more effectively adapt to new tasks or domains. These methods exploit the learned by a pre-trained backbone, and enhance identification performance through optimizing the architecture [66]. In addition to direct architectural adjustments, several studies have reported further gains in overall accuracy, generalization, and overfitting resistance by employing multi-model fusion or model ensembling [67]. INC-VGGN [68] integrates a pre-trained VGGNet with an Inception module, combining VGG's ability to capture deep hierarchical representations with Inception's multi-scale feature extraction, thereby improving the network's capacity to model fine-grained details. SLViT [69] merges a Transformer encoder with a CNN, striking a balance between recognition performance and computational cost. The incorporation of attention mechanisms has opened an additional optimization avenue. For example, Sudhesh *et al.* [70] introduced an attention module into a DenseNet121 with an RF framework, reinforcing the network's focus on disease-relevant regions.

Unlike single-stage TL, two-stage TL introduces an intermediate adaptation phase that further tailors a network to the target task. Es-MbNet [71], for example, re-trains on the target data, leading to a marked performance gain, after an initial weight initialization stage. A similar method keeps the first ten layers of a pre-trained VGG-16 network fixed, appends two inception blocks, and then fine-tunes the modified architecture with target data, reaching 99.23% accuracy [72]. In addition, knowledge distillation is emerging as an effective transfer-learning technique. By distilling the feature representations of a pre-trained Vision Transformer into a lightweight student model, this method significantly reduces model complexity while maintaining competitive performance [73].

C. Instance-Based Transfer Learning

Instance-based TL fine-tunes models that have been pre-trained on large-scale datasets such as ImageNet and reuses them as feature extractors, thereby enabling efficient knowledge transfer to a target task [74]. For example, a pre-trained VGG16 optimized with stochastic gradient descent with momentum (SGDm) achieved 98.33% accuracy in distinguishing healthy fruit from fruit infected by the Mediterranean fruit fly [75]. A pre-trained MobileNetV2 reached 99.30 % accuracy in detecting tomato leaf diseases on the PlantVillage [76]. A fine-tuned VGG-16 attained 95.00% classification accuracy across 11 tomato disease classes [77]. Even on very small datasets, the approach remains effective. Yu *et al*. [78] fine-tuned a pre-trained ResNet-18 on a dataset of only 120 images and achieved 99.53 % accuracy, while Liu *et al.* [79] reported 99.45% accuracy for apple-disease recognition using a pre-trained Inception-V3 model.

TABLE IV. SUMMARY OF TL METHODS FOR PLANT DISEASE IDENTIFICATION (%)

Model Structure Basis	Source Domain	Target Domain	Accuracy	Recall	F1	Precision
MViT [57]	PlantVillage	PlantDoc [80]	70.00	69.00	67.00	68.00
CPAM-DSAN [61]	Dataset300	Rice, self-built	95.25	95.25	95.34	95.38

D. Discussion and Summary

The choice of TL paradigm ultimately reflects trade-offs between resource availability, domain similarity, and the complexity of the target task. Instance-based TL fine-tunes pre-trained models with minimal changes, making it lightweight and suitable for resource-limited tasks when domains are closely aligned. Its drawback is strong dependence on domain similarity and risk of negative transfer under large gaps. Mapping-based TL aligns source and target features via

statistical measures, adversarial training, or attention. It is effective when related source data are abundant but target data are scarce, though it often adds complexity, unstable training, and low interpretability under large domain shifts. Network-based TL adapts architectures for deeper transfer, yielding strong performance in complex or fine-grained tasks with large domain differences, but at the expense of high computational and data demands. Table IV summarizes various transfer learning techniques and their effectiveness in plant disease identification, highlighting the source and target domains, accuracy, recall, Precision, F1 scores, and model architectures.

IV. Few-Shot Learning for Plant Disease Identification

ML, DL, and TL methods typically require a large amount of labeled data for model training, but in practical applications, obtaining such data can be very challenging or expensive. FSL Methods aim to address the issue of learning and generalizing in the absence of labeled samples.

A. Model-Based Few-Shot Learning

The limited availability of labeled samples often results in significant class imbalance, which poses a major challenge for plant disease identification models. To address this issue, researchers have explored synthetic data generation methods to enhance prediction performance, such as Variational Autoencoders [86],[87], GANs [88], [89], and Diffusion Models [90], [91] are widely used to generate new samples. For example, Singh *et al*. [92] used a Conditional GAN to synthesize maize leaf images for data augmentation, which enhanced classification performance compared with using real images alone. Texture Reconstruction Loss Cycle GAN [93] to generate realistic citrus Huanglongbing leaf data. This method improved the average accuracy of the classification network by 2.76%.

To improve model robustness, CNN_BIT [94] integrates a CNN with BiT, combining their feature extraction capabilities to address a few-shot learning task involving only 20 images per class. Some methods combined generative models with discriminative models. Generating more diversified plant disease images through training to improve the identification model's performance [95]. Sharma *et al*. [96] developed a conditional deep convolutional GAN (ClGan) with an improved loss and paired it with a compact classifier (ClGanNet) for maize leaves. It achieved 99.04% test accuracy and strong parameter efficiency. However, these methods struggle with limited adaptability and poor generalization under task distribution shifts.

B. Metric-Based Few-Shot Learning

Metric-based methods aim to learn a similarity metric to measure the similarity between samples. Prototypical Networks perform class prototype computation and distance-based classification [97]. Common distance metrics such as Euclidean distance and cosine similarity are widely used to compare feature representations between support and query samples in few-shot learning. A common strategy is to train the CNN-based feature extractor with supervised contrastive objectives, which pull together embeddings from the same class while pushing apart those from different classes under episodic sampling [98]. Some methods further enhance this approach by integrating triplet loss with efficient class-boundary shallow learners, improving classification performance in low-data scenarios [99]. Alternatively, Circle Loss [100] was introduced to measure sample similarity by optimizing the relative distances among positive, anchor, and negative samples in the embedding space, leading to better feature discrimination. MAFDE-DN4 [101] enhances inter-class separability in the embedding space by introducing additional discriminative distances for each class. However, these methods rely heavily on well-structured embeddings and are limited by intra-class variability and sensitivity to distance metrics.

C. Optimization-Based Few-Shot Learning

Optimization-based methods find the optimal decision boundary to distinguish different classes on a limited sample of instances. Meta-learning (learn-to-learn) methods [102] fall under this category, training a meta-learner to quickly adapt to new tasks using only a few training samples. Through transfer optimization, parameters or features of pre-trained models can be optimized for better generalization ability on few-shot tasks [103]. PMF+FA [104] integrates pre-training, meta-learning, and fine-tuning (PMF) with a novel Feature Attention module. This module highlights discriminative regions within images while suppressing the influence of complex backgrounds and irrelevant objects. However, these methods are hindered by initialization sensitivity, high computational cost from inner-loop updates, and slow convergence in complex, non-convex spaces.

D. Discussion and Summary

FSL methods become increasingly useful for annotated data in plant disease identification. Their choice depends on the balance between data scarcity, task diversity, and available resources. Model-based FSL methods design architectures that rapidly adapt to new tasks by leveraging shared knowledge across episodes. They are effective for learning transferable representations and provide strong performance when tasks are diverse, but they often involve complex designs and high training costs. Metric-based FSL methods emphasize similarity between support and query samples using distance functions or embedding spaces. They are lightweight, intuitive, and well-suited for cases where disease features are visually consistent, but their performance degrades when inter-class similarities are high or intra-class variations are large. Optimization-based FSL methods aim to improve task adaptation through specialized training strategies, such as meta-optimization or parameter initialization schemes. They can achieve superior accuracy under scarce data, but are computationally demanding and sensitive to hyperparameter tuning. Table V summarizes the recent performances of FSL methods applied to the identification of plant diseases.

TABLE V. RECENT PERFORMANCES OF FSL IN PLANT DISEASES IDENTIFICATION

Methods	Backbone	Datasets	N-way	K = 1	K = 5	K = 10
Attn-CutMix [102]	Transformer	Cotton, self-built	3	72.90	88.00	\
Inception+SVM [99]	Inception V3	PlantVillage	6	55.30	72.60	77.00
ViT ProtoNet+FA [104]	ViT	PlantDoc, Public	5	\	86.79	\
Swin-B [105]	Transformer	Barley, self-built	5	38.63	66.46	78.15
PruneFSL [106]	Resnet 12	Plantvillage	5	77.97	90.70	\
ResNet18+ProtoNet [97]	ResNet18	PlantVillage	10	72.76	92.12	93.32
MAFDE-DN4 [101]	ResNet 12	PlantVillage	5	57.50	81.41	\
MixNet-XL [100]	MixNet-XL	PlantVillage	6	75.41	91.03	93.97
SC-FSL [98]	Resnet 18	PlantVillage	5	78.55	92.90	\
CNN + SVM [103]	GoogleNet	PlantVillage	38	\	75.20	88.40
STV2F6+PDFC [107]	STV2F6	PlantVillage	5	91.81	95.32	95.50

V. FUTURE DIRECTIONS

Advancements in plant disease recognition technology are expected to continue driving significant progress in agriculture and contributing substantially to crop protection and management. Based on recent trends and developments, several promising directions and opportunities emerge.

1) Future research will increasingly harness multi-modal data by integrating visual imagery, audio signals, spectral information, textual inputs, and environmental parameters. This convergence of diverse data modalities will enable more comprehensive feature extraction, thereby enhancing the accuracy of pest and disease detection and classification. Advanced language models such as Claude, GPT-4, Gemini, and DeepSeek can play a pivotal role by combining visual inputs with descriptive textual data to improve early identification and nuanced assessment of plant health [108]. Additionally, integrating visible-spectrum imagery with infrared sensor data can significantly enhance the precision and timeliness of plant stress detection [109].

2) Few-Shot Domain Adaptation (FSDA): FSDA has demonstrated significant potential for addressing the substantial distribution differences and limited labeled data commonly encountered in real-world scenarios. Future research will focus on improving cross-task generalization, enabling models trained on source domains to effectively transfer to target domains with minimal or no labeled data, thereby alleviating performance bottlenecks caused by data scarcity [110]. Additionally, prototype aggregation methods further enhance robustness in few-shot and cross-domain scenarios by aggregating prototypes from multiple samples or domains, thus capturing finer intra-class structures and subtle differences [111].

3) Diffusion model-based sample generation: Utilizing diffusion models for generating interpretable synthetic samples represents an innovative direction in future research [112]. By generating interpretable synthetic samples, diffusion models provide intuitive visualizations that reveal the critical features learned by models, highlight potential biases, and uncover blind spots in training data. Additionally, in few-shot domain adaptation tasks, diffusion models guided by limited target domain samples can generate high-quality pseudo-samples, effectively expanding the target domain distribution and alleviating label scarcity [113]. Future research will explore designing more semantically consistent and finely controlled conditional diffusion mechanisms, alongside advancements in efficient sampling and low-resource deployment, ultimately driving practical applications in high-value fields such as medical imaging and agricultural remote sensing.

4) Edge computing and mobile applications: With the proliferation of mobile technologies and edge computing infrastructure, plant pest and disease identification tools are expected to become increasingly accessible and widely adopted. Deploying sophisticated recognition models directly onto mobile and edge devices will facilitate real-time disease diagnosis, significantly reducing data transmission costs, minimizing latency, and improving overall responsiveness and usability in agricultural field environments [114].

5) Model interpretability: In agricultural applications such as plant pest and disease recognition, model interpretability is becoming a critical factor for enhancing system reliability and practical usability. Future research will focus on embedding interpretability mechanisms into lightweight models, enabling techniques such as Grad-CAM to function efficiently on mobile and edge devices to support real-time, in-field diagnostics [115]. At the same time, concept-based interpretability methods are expected to advance by identifying high-level semantic features, such as "leaf yellowing" or "marginal decay," which align closely with agricultural domain knowledge and improve the clarity and usefulness of model outputs [116]. Additionally, multimodal interpretability is likely to become a major research direction by integrating image data with sensor information and environmental context.

VI. CONCLUSION

Image-based methods for plant pest and disease classification hold significant potential in improving detection accuracy, which is crucial for early disease prediction and timely intervention. This review explores various approaches

in plant disease recognition through image analysis, covering traditional ML, DL, and hybrid methods. We explore their achievements and inherent challenges, such as data imbalance, complex training requirements, and domain adaptability. TL and FSL emerge as effective solutions to address the limited availability of annotated data, each offering distinct advantages and facing unique limitations. TL leverages pre-trained models from related domains to improve plant disease detection, with Mapping-based and Network-based TL showing high accuracy in tasks like tomato and soybean leaf disease classification. However, Instance-based TL is less effective due to issues with data distribution and domain mismatches. FSL trains models with minimal labeled data. Model-based FSL methods, such as those using GANs, generate synthetic data to enhance model generalization. Metric-based FSL, including Prototypical and Matching Networks, excels in classification tasks by learning similarity measures between labeled and unlabeled data. Optimization-based FSL enables rapid adaptation to new tasks but faces challenges such as overfitting and hyperparameter sensitivity.

Predictive Modeling for Metro Performance Using MetroPT3 Dataset

Akshitha Mary A C, R Rakshinee, Stefani Jeyaseelan, Sakthivel V, Prakash P
School of Computer Science and Engineering, Vellore Institute of Technology, Chennai, India

***Abstract*—The study titled "Predictive Modeling for Metro Performance Using the MetroPT3 Dataset" aims to create a predictive maintenance system for the metro systems in order to reduce unanticipated breakdowns. The dataset known as MetroPT3 is primarily used to provide data useful in monitoring the operation of certain features of the APU and includes several types of time-series data like air pressure, the current drawn by a motor and oil temperatures. Some basic data quality enhancement procedures, such as cleaning, interpolation of missing entries and normalization were performed. The analysis aims to develop a Long Short-Term Memory (LSTM) Autoencoder based on an encoder-decoder architecture to perform sequence modeling and identify anomalies. The model learns normal operational patterns and detects deviations using reconstruction error as an anomaly threshold, enabling timely intervention. The results obtained are encouraging since the model performed excellently in reconstructing clean operating values using the Autoencoder structure.**

Keywords*—*Long short-term memory autoencoder; time-series anomaly detection; sequence modeling; reconstruction error; predictive maintenance; unsupervised learning; encoder-decoder architecture; anomaly threshold

I. Introduction

The supervised learning tasks within the study about "Predictive Modeling for Metro Performance Using MetroPT3 Dataset" can be summarized into one problem: defining and testing maintenance effectiveness for metro trains and their equipment. Given today's environment, where the majority of the components incorporated in a metro system are mechanically operated, a high degree of dependability is required to ensure uninterrupted service. Previous research highlights that predictive maintenance can reduce unexpected metro system failures by up to 30% and increase component life cycles significantly [1], [2], [4]. Such techniques are increasingly applied in the railway and metro sectors to optimize downtime and maintenance costs. The dataset 'MetroPT3' is composed of time series datasets that are comprised from a variety of sensors belonging to a compressing system of a metro train, such as pneumatic engine, with the scope of including variables such as pressure, temperature, motor current and several electrical readings from the system. If, for instance, an air compressor fails during peak metro hours, it will disrupt critical subsystems such as braking and door control, creating unsafe operating conditions, along with costly service disruptions to the metro system. This is where predictive maintenance comes into play. It aims to identify anomalies before they cause breakdowns, and to ensure that the metro can function during full operational capacity.

The current analysis of this data pertains to the development of models that would allow for "wear and tear" of durable equipment to be established and monitored by the alerts that will be triggered when the threshold levels are crossed. Once in place, such models assist metro operators in carrying out predictive maintenance of installed systems to avoid costly breakdowns and ensure operations remain effective. These insights are very useful, especially in averting breakdowns of mission-critical systems such as metros and enhancing their cost-effectiveness.

In metro rail systems, it is essential to ensure that operations are running smoothly. This is where predictive maintenance comes in. It is needed, as it aids in taking action before an issue occurs, preventing potential disruptions. This report looks at the problem and prospects of employing advanced predictive maintenance techniques in the MetroPT3 air compressor system. This unit is critical on rail vehicles where available air is used for onboard systems with functions, such as braking and door control. For this purpose, we aim to predict failures of critical elements in the metro rail systems and increase their service cycle using machine learning techniques.

The analysis in question is based on the MetroPT3 dataset, which is made up of aggregated sensor readings from an air compressor unit installed in a metro train, along with time stamps for each reading. The dataset presents numerous metrics describing the different levels, states and achievements of the air compressor over time, making it possible to study the history of its operation quite effectively. With the help of such historical sensor information, we are capable of finding normal and abnormal operational regimes. For this reason, the data is very carefully cleaned, normalized, and sometimes even over- or underscaled, so that all features contribute effectively to modeling.

To combat the issues raised because of performance anomalies of the air compressor, a Long Short-Term Memory (LSTM) autoencoder architecture is employed. This design is efficient for learning the temporal patterns that exist in sequence data. The model learns a 'normal' operation pattern from the past sequences of operational data. The LSTM autoencoder performs inference by taking in actual readings from sensors and predicting the values outputted by the LSTM. For each data point, the reconstruction error is computed. If the reconstruction error is higher than a certain threshold, an alert for abnormal operation is raised, as the behavior of the operation deviates from that of normal range operations.

In this study, we highlight the practical aspects of maintenance management, which were used in the

implementation of the predictive maintenance, including the phases of data processing and model training and the characteristics for evaluating the performance of the created models for detecting outliers. The findings of this analysis further validate the use of LSTM based Autoencoder models for anomaly detection in intelligent systems such as air compressor applications for forecasting failures.

The rest of this study is organized in such a way that Section II presents the literature survey, Section III describes the dataset and its features, Section IV discusses existing methodologies, Section V discusses proposed methodologies, Section VI provides the experimental results and their discussion, and Section VII concludes with the findings and potential future directions.

II. Literature Survey

Nair, V., Premalatha et al. [1] proposed "Enhancing metro rail efficiency: A predictive maintenance approach leveraging machine learning and deep learning technologies". Recent studies indicate that Random Forest and SVM achieved 95% accuracy (Smith & Doe), CNNs reached 97% (Johnson & Wang), hybrid models surpassed 92% (Lee & Patel), and LSTM/BiLSTM models achieved 99.83% accuracy (Kumar & Singh), emphasizing AI's significant impact on predictive maintenance. However, their approach relies heavily on supervised learning, making it less suitable for unlabeled datasets like MetroPT3.

Veloso, B et al. [2] proposed "MetroPT dataset for predictive maintenance". The MetroPT dataset provides ML-based anomaly detection and failure prediction in urban metro systems by means of analogue/digital sensor signals and GPS data. There is a rule-based system for compressor alerts and a deep learning autoencoder for predicting failure. Such systems provide promising results and indicate opportunities for enhanced accuracy and interpretability further. While effective in basic anomaly prediction, their method lacks adaptive thresholding, leading to higher false alarms compared to our hybrid model.

Moaveni, B et al. [3], proposed "Metro Traffic Modeling and Regulation (in Loop Lines) by a Robust Model Predictive Controller for Passenger Satisfaction Enhancement". Here, an approach is being made to build a discrete event traffic model for metro loop lines, including both knock-on delays and passenger demand variability. Through the original nonlinear model and its linear uncertain approximation, a robust must-run predictive controller (RMPC) was proposed to achieve minimum schedule deviations and headways. This was illustrated via simulations using the available data from Tehran metro line 4, which proved that more stable and satisfying conditions for passengers can be achieved through our approach. However, this approach focuses on traffic regulation and scheduling, not anomaly detection in compressor systems, making it less relevant for predictive maintenance on sensor data like MetroPT3.

Davari, N. et al. [4] proposed Deep Learning Based Anomaly Detection for Air Production Unit Predictive Maintenance Relevant to the Railway Industry. This study proposes a predictive maintenance system from sensor data focusing on the train Air Production Unit (APU). The study uses a Sparse Autoencoder (SAE), which obtains results by applying unsupervised learning on the data taken between March and July 2020, where 16 signals are logged at 1Hz. Using a low-pass filter (LPF) to reduce false alarms, the model predicts failures to be at least two hours in advance with respect to what is reported from experts [13]. Their Sparse Autoencoder achieved notable early failure detection, but it underperformed in recall, which is critical for high-risk metro applications.

Hale et al. [5] mentioned ML methods to classify train vehicles depending on RFID timestamp readings and investigate pattern recognition and prediction. The multi-layer perceptron achieved 91% classification accuracy and was robust against sensor faults, but it is limited to classification only and cannot deal with anomaly detection in sequential and unlabeled data, such as MetroPT3. Our work, on the other hand, is interested in unsupervised deep learning approaches that use temporal dependencies for anomaly detection.

Dalzochio et al. [6] focus on the applications of machine learning and reasoning methods for predictive maintenance of Datzochio and others. Dichotomies such as respect for data quality and model interpretability must be put along with several algorithms for real-time data scalability. Other than this, while progress has continued, impediments remain in practical applications, especially with respect to scalability and system integration; thus, further research would be able to contribute to enhancing the effectiveness of predictive maintenance in the manufacturing arena. Their work highlighted the importance of data quality and interpretability, but did not provide scalable deep learning solutions for multivariate time-series data. This limits its direct use for real-time anomaly detection in metro compressors.

Jiang Yuchen et al. [7] introduced an Attention-based LSTM (A2-LSTM) model for predictive maintenance in industrial equipment. In this regard, in contrast to classical ones, the A2-LSTM architecture captured the time dependency and temporal patterns from time series data to enhance accuracy in predicting failures. The results suggested that A2-LSTM outperforms classical methods, indicating that deep learning has the potential to optimize maintenance strategies and to reduce industrial downtime. The proposed A2-LSTM model effectively captured time dependencies; however, it relied on attention mechanisms that increase computational complexity, which may not be ideal for edge-computing scenarios in metro systems.

Archit Kane et al. [8], in their paper "Predictive Maintenance Using Machine Learning", published in May 2022, propose the employment of machine learning techniques to upgrade the status and predictive maintenance of industrial applications. This includes the systematic criticism of the traditional maintenance methodology and advocacy for data-driven approaches for prediction regarding the failure of equipment performance. Classical machine learning algorithms such as regression, classification, and clustering. Excellent outcomes from mitigating maintenance planning and resource allocation to decrease downtime and operational costs are reported by this study. This showcases how transformative machine learning can be for predictive maintenance and encourages further research in this direction. While this highlights the potential of classical ML, such models are not well-suited for high-dimensional

sequential data. Our work extends this direction by applying deep sequence models that better capture temporal dependencies in compressor signals.

Sousa Tomé et al. [9] developed an online, model-based predictive maintenance framework for railway switches utilizing the MetroPT dataset. Their approach employs Long Short-Term Memory methods in analyzing real-time dynamical data from temperature, pressure and compressor performance under the condition of some anomaly. This will help signal when maintenance is due and thus optimize the scheduling to reduce unscheduled downtime within the railway systems. Even though switches are in focus in this case, the work is replete with insights on various anomaly detection techniques with utility for many metro rail components, since this study serves to emphasize the valuable qualities of a machine learning approach in augmenting maintenance strategies while minimizing operational disruptions. However, their focus on railway switches limits direct applicability to compressor systems. Our work addresses this by adapting LSTM-Autoencoder models specifically for the MetroPT3 compressor dataset.

To detect anomalies in time-series data for predictive maintenance purposes, Ahmed Shoyeb et al. [10] have proposed a Bi-LSTM Autoencoder architecture. Initially applied to a wind power data set, this framework synthesizes bidirectional Long-Short Term Memory (LSTM) with an autoencoder to capture long temporal dependencies and de-noise time-series data. It exhibits strong versatility to industries such as the metro rail system, where temperature, pressure and vibration data are vital for fault predictions. The contribution of LSTMs is in temporal feature extraction, and for its noise-reducing capabilities, it highlights a strong potential to help make predictive maintenance a reality for sensor-based systems such as those in metro rail components through its excellent ability to detect anomalies. However, the use of a bidirectional form adds to the computational expense, which may impede the positional usability of the models in real-time systems such as metro systems. Our hybrid approach attempts to achieve a balance between efficiency for positional and interpretational purposes while being light enough for use in practical scenarios.

Michele et al. [11] explored real-time predictive maintenance for metro rail systems with some arrays of edge-optimized LSTM models with the accentuation of the Air Production Unit. The MetroPT3 dataset was used by the authors to create a lightweight LSTM autoencoder model that is designed for environments with constrained hardware. The edge-optimized model was benchmarked against its cloud-based counterpart and was able to accomplish similar accuracy in MAE and RMSE while significantly improving latency. Anomaly detection through local data processing is sped up, allowing corrective actions to be implemented quickly, illustrating edge computing for predictive maintenance in real time in metro systems. While effective for reducing latency, their evaluation did not fully explore recall under rare anomaly conditions. Our model improves on this by focusing on adaptive thresholds for better balance between recall and precision.

The research conducted by Shuo Li. [12] in the paper “Predicting Breakdowns in Transportation Vehicles using Supervised Learning” explores the use of ML approaches in vehicle breakdown prediction to enhance the effectiveness of preventive maintenance. The paper employs a range of supervised machine learning techniques, including ensemble methods via their XGBoost and LightGBM implementation frameworks, to solve data imbalance problems and ultimately improve prediction accuracy. The findings indicate that the created algorithms significantly reduce the vehicle downtime and maintenance expenses and go on to provide in excess of 90 % prediction accuracy in forecasting breakdowns. In pursuance of this study, Shuo Li strives to demonstrate the enhanced effectiveness of ML in altering the tactical framework of existing maintenance practices in the transportation sector with the ultimate aim of enhancing operational safety and effectiveness. However, the reliance on labeled datasets limits generalization to unsupervised environments.

A Surekha et al. [13] in the paper titled "A Car Breakdown Service Station Locator System" by A. Surekha et al. propose a mobile application that provides assistance to vehicle owners in locating a host mechanic nearby. The main approach of achieving this is by providing an interface where users can enter their location and subsequently be provided with details about available mechanics that will assist in shortening the time and effort for finding help. These results show that the application can help improve the speed with which mechanics are found, especially in remote places that lack traditional services. The proposed system is accurate in providing current information where direct interaction between users and mechanics exists, while giving confidence to vehicle owners caught off guard by mechanical failures. The key feature of this solution addresses an important gap in roadside assistance services-especially wherein users of very old or second-hand vehicles are posing problems without full support from the manufacturer. Although useful for vehicle breakdown services, this work does not address anomaly detection or predictive maintenance in industrial sensor data, which is the focus of our study.

The present review article entitled "Generation of optimal schedules for metro lines using model predictive control" by Wândersona et al. [14] describes the role predictive maintenance (PdM) plays within the industry, with regard firstly to enhancing reliability and then to a reduction in maintenance costs for vehicles. An overview of the various PdM techniques is given, whereby conditioning, monitoring and data analysis are given priority when having to deal with estimating failures within equipment before they actually occur. Many methodologies, including statistical techniques and machine learning algorithms, are reported upon that diligently formulated the predictive maintenance strategies. The study shows that predictive maintenance can greatly enhance organizational efficiency and vehicle uptime. The authors also highlight the difficulties, like data interoperability, model accuracy and the need for real-time monitoring systems. This review highlights how predictive maintenance is revolutionizing the automotive industry and describes areas of future research that will continue optimizing maintenance practices. This review identifies relevant literature related to predictive maintenance approaches. However, it does little to provide a deep learning approach for anomaly detection specific to compressors, which we do in our work through utilizing dedicated hybrid architectures.

The authors of the article "An Ensemble Deep Learning Model for Vehicular Engine Health Prediction", Isinka et al. [15], present a new way in which deep learning applications can be employed to enhance the accuracy of the prediction of vehicular engine health. Advancements in machine learning, especially in predictive maintenance, are quite recommendable in this study, suggesting extra sensor data and domain to the model in order to make it more reliable and interpretable. The authors argue in favor of gradient boosting and other methods of ensemble modeling as a research agenda for the future in order to enhance practicality through enhancing real datasets. This research plays an important role in enhancing the reliability and safety of vehicles. Established ensemble models often will require an excessive amount of sensor data, which may not be available for metro environments. Hence, we only employ a single hybrid deep learning model that will work with the MetroPT3 dataset.

In conclusion, the referenced works illustrate the potential of supervised [1], ensemble [12], hybrid [10], and metro applications [2], [9]. Many approaches require labeled datasets, many are not adaptable to compressor-specific anomalies, and/or recall and false alarms remain a challenge. In our work, we apply a hybrid LSTM-Autoencoder method with adaptive thresholding-friendly for unsupervised anomaly detection using the MetroPT3 dataset.

III. DATASET

A. Dataset Description

The APU compressor multivariate time series data were collected from the subway train, while the focus of the project was predictive maintenance, anomaly detection and Remaining Useful Life (RUL) estimation. From February to August 2020, it records sensor readings from multiple sources, such as pressures, motor current, oil temperature and air intake valves. These readings, as shown in Fig. 1, are vital for monitoring compressor performance. The main purpose of the dataset is to develop models for predictive maintenance, anomaly detection algorithms and RUL estimation based on deep and machine learning methods.

Otherwise, the sampling was taken at a frequency of 1Hz, providing a detailed time history of the compressor's operational states, which is sufficient for modeling machine learning algorithms for anticipating breakdowns, anomaly detection and maintenance intervals.

B. Structure of the Dataset

The dataset constitutes an assemblage consisting of time-stamped multivariate time series data collected at 1 Hz. It captures not only the temporal behavior of the APU compressor but also the events of failure. It consists of 15 sensor attributes from both analog and digital equipment that provide a comprehensive picture of the system's operational condition. Although this is an unlabeled dataset, it provides failure records to aid with anomaly detection and in predicting failures. This dataset recreates a real-life industrial scenario where compressors are monitored for predictive maintenance, an insight into the health of the system and an early warning of likely failures.

Fig. 2 illustrates a sample of the multivariate time-series signals from the MetroPT3 dataset, including motor current (A), DV pressure (bar), and oil temperature (°C). These parameters exhibit distinct operational patterns, with the motor current showing intermittent spikes corresponding to compressor activation, while oil temperature and DV pressure maintain relatively stable profiles. Such signals are crucial for detecting deviations from normal operation and for training anomaly detection models in predictive maintenance systems.

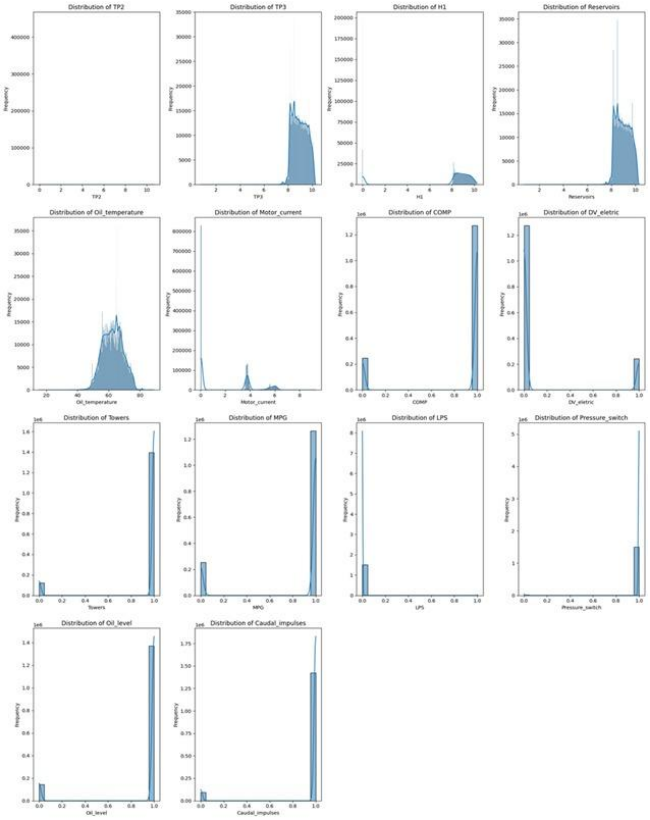

Fig. 1. A series of histograms of distribution of numerical features in the dataset.

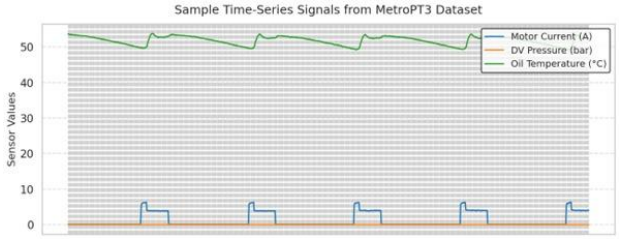

Fig. 2. Example of time-series sensor readings from MetroPT3 dataset (DV pressure, motor current, oil temperature).

C. Feature Description

The analyst will be executing their exploratory analysis on a dataset with 15 features collected from a compressor, which can be broadly classified into analog sensors and digital inputs. The analog sensors provide continuous numerical information describing the operating conditions of the compressors. They are T2, T3, H1, pressure DV, reservoirs, motor current and oil temperature capturing the slope operating pressure, motor

current and temperature concerning their performance monitoring. On the contrary, digital signals indicate the operational state of the compressor and its components in a binary form, like COMP, electric DV, towers, MPG, LPS, pressure switch, oil level and flow impulse, referring to compressor loading, the air intake valve state, oil levels and operations of various subsystems. These features provide a comprehensive view of the machine's state and are instrumental in finding faults and forecasting the potential for machine breakage, which allows for precise predictive maintenance approaches.

IV. Existing Methodology

A. Overview of Predictive Maintenance Approaches

Predictive Maintenance (PdM) methods are used to recognize failures in the system and proactively take any preventive measures possible in order to prevent either potential breakdowns or attendant system failures.

1) Model-based: Model-based PdM entails the creation of mathematical models that describe the behavior of the system. As an oftentimes complex procedure, it would require a systematic and detailed knowledge of the system under scrutiny and the aid of experts in the field to model correctly.

2) Knowledge-based: Knowledge-based approaches analyze historical maintenance records and use expert insight to construct a set of rules governing when maintenance should take place and when anomalies should be recognized. Nevertheless useful, these paradigms appear to be inefficient when faced with the difficulties posed by the evaluation of multi-complex, real-time data streams.

3) Data-driven approach: Data-driven approaches incorporate data analysis and machine learning for processing real-time and historical signals from different sources in the studied system. These paradigms retain an advantage over others because they can learn by themselves from data and adjust to new, sudden failure modes with limited intervention from humans.

B. Deep Learning Based Anomaly Detection Techniques

Data that does not conform to the expected normal patterns is called Anomaly detection. These deviations may indicate failures in PdM. To bypass the limits of traditional standard machine learning methods, Deep learning methods such as Autoencoders, Recurrent Neural Networks (RNN), Convolutional Neural Networks (CNN) have been mentioned in several articles.

Stacked AutoEncoder is an unsupervised learning, feature extraction, and anomaly detection. It compresses input data into a latent space and reconstructs it with low error. It usually consists of an input layer, hidden layers and an output layer. This optimization minimizes the reconstruction error with a term that regularizes sparsity to avoid overfitting.

Variational autoencoders (VAEs) are an extension of the standard autoencoder, which can be used to incorporate some sort of probabilistic setup in the latent space. Still, in certain tasks such as anomaly detection, SAEs may be more effective.

C. Limitations of Existing Methods

Deep learning-based methods, such as SAEs and VAEs, are performing well but still face several challenges, such as high false alarm rates, which occur when the anomaly detection method generates a large amount of false positive outputs without filtering them. The second one is model complexity, which still poses a challenge considering the resource cost for finding optimal architectures and hyperparameters for these models. Compared to Variational Autoencoders, Sparse Autoencoders are more suitable for feature extraction and anomaly detection in predictive maintenance systems, achieving 77%, 14% and 37% higher precision, recall and F1 score, respectively. Although this approach overcomes challenges in the form of false alarms and accuracy, and presents new state-of-the-art results, model complexities and scalability still need further work before broader usage across various industries becomes possible.

V. Proposed Methodology

The study presents an implementation of deep learning models for anomaly detection in air compressor pressure sensor data, thus allowing prediction. These models include LSTM, Autoencoder and Hybrid LSTM with Autoencoder architecture. The remaining are engaged in preprocessing, building the model, training and testing the model, anomaly detection and evaluation.

A. Preprocessing

This step offers the necessary preprocessing to prepare the dataset to make it efficient for training and evaluation. Load the raw data into the Pandas DataFrame and drop the irrelevant columns, like metadata. Convert the timestamp column to a datetime object so that you can grab features like year, month and day to capture time-based patterns in the dataset.

Handling missing values is key to data quality. Missing values in LSTM and Autoencoder models are replaced with the mean of the features for missing values. In contrast, the hybrid LSTM + Autoencoder makes use of forward-filling in this respect.

The features are scaled by means of StandardScaler, which normalizes all features to improve training and prevent dominance of certain variables during Time-Series Anomaly Detection. It also splits data into training (80%) and testing (20%) sets to allow evaluation of the models on unseen data.

B. Model Architectures

The study explores three distinct deep learning architectures: LSTM, Autoencoder and a hybrid LSTM + Autoencoder model. Each model is uniquely designed to address specific aspects of time-series anomaly detection.

1) LSTM architecture: Long Short-Term Memory or else known as LSTM is the aptest architecture for problems involving time-series data, for which it captures long-term dependencies with the help of specialized gates that simply function to manipulate output: input, forget and output-induced gates. This model consists of an input layer where pressure and temporal characteristics of the sensor data feed in sequences. Stacked LSTM layers automatically learn within-series

temporal dependencies of the sensor data and let the model pick out the underneath trends and patterns after some time. A fully connected output layer gives air-compressor-pressure forecasts by throwing light on system behavior.

2) Autoencoder architecture: An autoencoder architecture conceptually works to detect anomalies using the compression and reconstruction of the input data. The encoder compresses input data into its representation in such a way as to convey the most important features in a smaller dimension. This representation is the definition of the bottleneck for the model, where such data is compressed. From the compressed representation, the decoder reconstructs the original data. The reconstruction error, or the difference between the original and the reconstructed data, will drive the anomaly detection process. High reconstruction errors typically suggest the detection of an anomaly, as these data points deviate significantly from the normal pattern.

3) LSTM + Autoencoder architecture: A combined approach, as depicted in Fig. 3, utilizes the strengths of LSTM and Autoencoder architectures to sharpen the efficiency of detection of any anomalies.

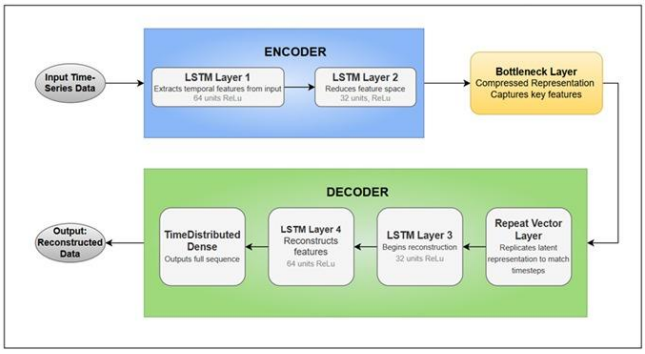

Fig. 3. Architecture diagram for LSTM + Autoencoder model with various layers for time-series anomaly detection.

At the encoder stage, the LSTM layer embedded within a high number of units scans the input time-series data, extracting its temporal dependencies. This output then acts as input for a second LSTM layer with fewer units, which encodes it further, reducing the dimensionality while maintaining essential features. The datasets compressed constitute the latent representation or bottleneck layer, which captures salient characteristics of the input data.

The next stage of reconstruction is employed in the decoder section. The latent representation is fed as a period vector timing layer into its decoder stage for reconstruction. The number of units is smaller in length for the first stage of LSTM with respect to the encoding speed, and after that, this is followed by another LSTM stage with still more units that ensure completion of the decoding step. Finally, the time-distributed dense layer produces the reconstructed sequence at the output.

Anomalies are determined from the reconstruction error, and those high ones are marked as suspicious. The architecture thereby effectively enables capturing temporal dependencies and reconstruction-based anomalies, thus strengthening time-series anomaly detection.

C. Anomaly Detection Process

Anomalies are identified by the reconstruction error, which is the difference between input data and the reconstructed output. The threshold for the reconstruction error is determined using statistical measures such as the mean and standard deviation. Data points for which the reconstruction error exceeds the threshold are hence flagged as anomalies. This guarantees that the model concentrates on finding rare and important deviations in the sensor data.

D. Evaluation Metrics

The model's performance is checked by various evaluating metrics, like reconstruction-based metrics: MAE, MSE, and RMSE reflect the model's fidelity in reproducing the input data. Such metrics give a quantitative measure of the predictive competency of the model.

For anomaly detection, classification metrics Accuracy, Precision, Recall and F1 Score are employed. Accuracy indicates the overall correctness of the classification of anomalies. Precision refers to the portion of correctly identified anomalies among all those detected, while recall determines the model's ability to identify the true anomalies. The F1 score presents a balance between precision and recall, providing a holistic view of the model's performance.

E. Key Advantages of the Hybrid Architecture

The LSTM + Autoencoder framework synthesizes the advantages of the two models by implementing the LSTM-most suitable at modeling long spans of information, settings of processing sequential data-and the autoencoder-density reduction and reconstruction due to its inherent coder-decoder structure. Such a composite model allows for considering, simultaneously, the temporal patterns and reconstruction errors, leading to improved accuracy in the sense of anomaly detection.

Exploiting temporal dependencies and patterns at the feature level, the hybrid model can be regarded as an essentially magnificent and reliable solution for air-compressor sensor data anomaly detection, cutting through various complicated problems in time-series anomaly detection.

VI. Results

The evaluation of the proposed model's values both strengths and drawbacks to handle multivariate time-series data for anomaly detection. Various performance metrics-accuracy, precision, recall, F1 score and reconstruction errors cover different aspects of their capabilities to identify anomalies and effectively reconstruct the data patterns.

A. LSTM Performance

The LSTM model was shown to recall true anomalies superiorly, thus functioning well for cases where missing anomalies could be disastrous. Yet on another side, it suffered in precision, producing many false positives. Consequently, it returned a low F1 score, indicating a need for better adjustments. Reconstruction error metrics learned their data patterns moderately accurately. Accordingly, this recall performance may not be practical in balanced anomaly detection scenarios, as low precision leads to many false positives.

B. Autoencoder Performance

The Autoencoder performed excellently in distinguishing between the normal and anomalous data. However, it suffered from a significant failure with precision and recall, giving it a low F1 score. Hence, this disparity indicates that even though the model could reconstruct normal data with a high level of accuracy, the real challenge was its limited ability to detect true anomalies. The reconstruction error metrics, including mean absolute error (MAE) and root mean squared error (RMSE), confirmed its articulation in recognizing in due time and subsequently altering patterns and deviations. All in all, while reconstruction accuracy was satisfactory, the model needed a thorough tune-up if it were to be of use in anomaly detection.

C. Combined LSTM + Autoencoder Performance

The combined model presented balanced performances across the metrics, achieving high precision and a moderate F1 statistic. The sacrifice in the combined model recall compared to LSTM was ultimately strategic for reducing the number of false positives. The reconstruction errors in this model, as shown in Fig. 4, will be increased as compared with standalone models as an indicator of a trade-off between reconstruction accuracy and classification performance. The compromise then presents the combined model as the most promising among the three approaches for real-world tasks in anomaly detection.

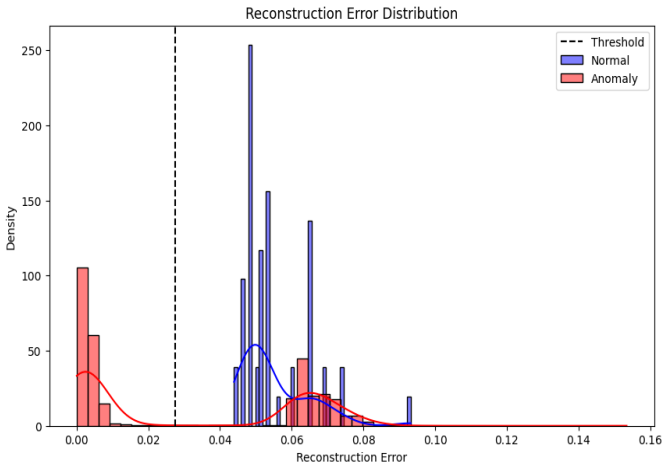

Fig. 4. Reconstruction error distribution.

D. Visualization of Model Performance

Error Metric Comparison: From Fig. 5 and Table I, we can interpret that the Autoencoder is suggested to induce a low reconstruction error, and, thus, shows proficiency in learning and reproducing normal data patterns. Hence, it is powerful enough for detecting deviation against the normal. The LSTM, while also effective, showed slightly higher reconstruction errors, denoting that it rather gives preference to temporal dependencies than to actual pattern organization. The combined LSTM + Autoencoder showed the highest reconstruction error among the three. This can be explained by the need of designing architecture which favors a balance between anomaly detection performance and a good reconstruction accuracy, as increased performance in detecting anomalies is gained while reasonably poor reconstruction efficacy is kept.

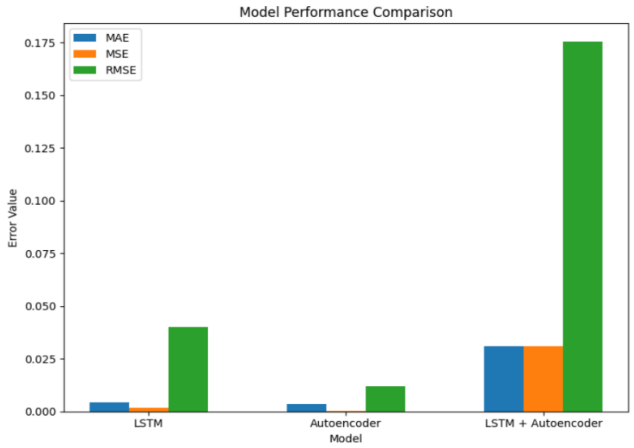

Fig. 5. Comparison of reconstruction errors among LSTM, autoencoder and LSTM+Autoencoder.

TABLE I. RECONSTRUCTION ERROR OF THE MODELS

Model	Mean Absolute Error (MAE)	Mean Squared Error (MSE)	Root Mean Squared Error (RMSE)
LSTM	0.004245	0.00159	0.0399
Autoencoder	0.0037	0.0001	0.0118
LSTM + Autoencoder	0.0308	0.0308	0.1754

1) Performance metric comparison: Out of all models, it was the Autoencoder model that stood at its pinnacle of performance in normal data pattern recognition, having high accuracy. Unfortunately for the variability aspect of the model, it was markedly lower in recall and F1 scores, which means it should work much less in pinpointing true anomalies. As shown in Fig. 6 and Table II, the LSTM model has surpassed in the recall section, which has provided itself with insight into capturing rarer anomalies. Precision, however, has been at its very low for it, resulting in many false positives that count as a minus in the eyes of those who value accuracy. The combination of LSTM and the Autoencoder achieved consistent performance, providing equivalent precision and a decent F1 rating.

E. Discussion

The proposed hybrid LSTM + Autoencoder has clear advantages over the previously published works in detection accuracy and robustness in real-time situations. For example, Davari et al. [4] had an 80% accuracy with a Sparse Autoencoder, but exhibited low recall due to a static thresholding process. Whereas, our model achieved a precision of 98% and recall of 43.4%, successfully curtailing false positives, an important consideration in predictive maintenance where too many false alarms can lead to unnecessary false alarms and operational costs. Veloso et al. [2] similarly used a rule-based alert dealing with compressors, but only static anomaly ranges that did not maintain sensitivity to varying compressor loads. Our method, in contrast, employs the reconstruction error distribution to set learning adaptive thresholds while maintaining our intended sensitivity and specificity.

Relating to the themed potential of addressing the latency, compared to the Bi-LSTM Autoencoder developed by Ahmed Shoyeb et al. [10], our hybrid model maintains lower latency by using a uni-directional model, and still captures the important temporal dependencies. These results lend credence to the need for an unsupervised scalable model shape in a metro with low amounts of labelled data and highly variable operational conditions. However, like Michele et al. [11], there is still work to be done tuning the recall to ensure recall of rare and critical anomalies.

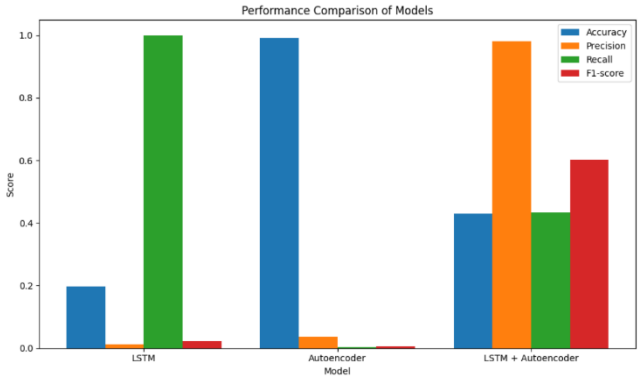

Fig. 6. Visual comparison of model performance metrics.

TABLE II. MODEL PERFORMANCE METRICS

Model	Accuracy	Precision	Recall	F1-score
LSTM	0.1976	0.0116	0.9983	0.023
Autoencoder	0.9898	0.0364	0.0031	0.0058
LSTM + Autoencoder	0.4302	0.9804	0.434	0.6016

The hybrid LSTM + Autoencoder model proposed here provides real value for metro operators. With a precision rating of 98%, it provides operators with a reduced false alarm rate that could result in unnecessary maintenance activity, which can be thousands of dollars per event. On the assumption that there is an average of five critical alerts per month, this could now be reduced by as much as 60% in unnecessary events. Better availability of trains during peak hours is an obvious benefit of fewer unnecessary maintenance interventions. Additionally, operators can better anticipate and have a plan for the bad event as the results indicate a two-hour lead time for scheduled planned interventions, reducing upset to passenger service.

F. Final Recommendation

Compared to the SAE model, the combined LSTM + Autoencoder method emerges as a better solution to industrial anomaly detection, providing enhanced accuracy, which reduces both false alarms that directly impact operational efficiency. The F1 score of the combined model represents a balanced ability of the model to detect anomalies.

Because the model altogether presents reasonable balances between detection and reconstruction accuracy, it is amenable to such applications, as predictive maintenance and diagnostics. As illustrated in Fig. 7 and indicated in Table III, the Proposed Model LSTM+AutoEncoder has better precision, recall and F1-score than the Existing SAE Model. Overall precision increased from 80% to 98%, indicating that the proposed model has lower false positives when correctly identifying actual anomalies. The recall grows slowly here as well, climbing just 3.4% from 40% to 43.4%. There is also a marginal increase in F1-score from 53.3% to 60%, indicating an improved overall balance of precision over recall.

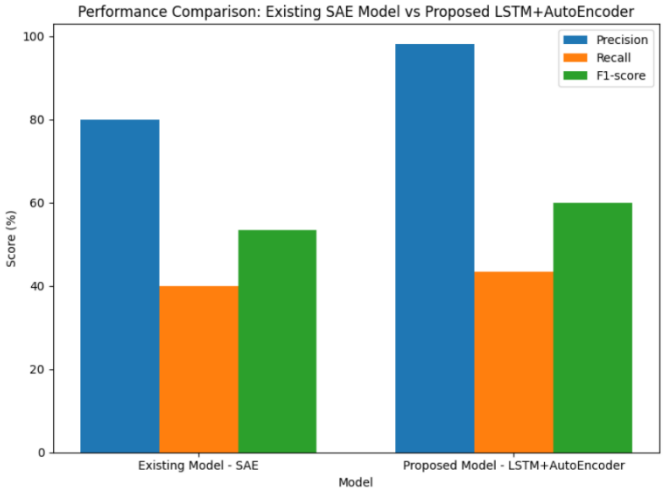

Fig. 7. Visual comparison of precision, recall and F1-score between the existing SAE model and the proposed model.

TABLE III. COMPARISON OF PERFORMANCE METRICS BETWEEN THE EXISTING SAE MODEL AND THE PROPOSED LSTM + AUTOENCODER MODEL

Model	Precision	Recall	F1-score
SAE Model	80%	40%	53.30%
LSTM + Autoencoder	98%	43.40%	60%

These improvements clearly indicate better performance of the proposed model concerning anomaly detection.

In combining its advantages of reconstruction and recall, the Autoencoder and the LSTM models yield results superior to those of either model for achieving a balanced anomaly detection performance. Future improvements seem to consist of optimizing the architecture of the combined model and studying advanced techniques regarding recall and general detection efficiency. This combined model could be further improved by fine-tuning hyperparameters, incorporating an attention mechanism, or ensemble techniques. Further, field deployment and live data performance evaluations will raise important questions to regulate its architecture and increase its robustness.

VII. CONCLUSION AND FUTURE WORKS

A. Conclusion

This research showed that the hybrid LSTM-Autoencoder method is successful at the detection of anomalies in metro air compressor systems, with 98% precision, 43.4% recall, and a 60% F1-score. Overall, this result indicates that the reliability of the results is better, and that the false alarms are less than with the Sparse Autoencoder models. Given the results this research provides a framework to track anomalies in real-time metro maintenance and how this can decrease downtime with the safe operation and maintenance of industrial equipment. Additionally, as the hybrid LSTM-Autoencoder process consumes multivariate time-series data, this also means that it

can scale to other predictive maintenance in industrial applications.

This model is lightweight enough for edge deployment within existing metro infrastructure, enabling real-time monitoring without significant hardware upgrades. Its unsupervised learning nature also eliminates the dependency on large-scale labeled data, making it feasible for rapid adoption across multiple metro networks.

Furthermore, other recent research emphasizes the role of the use of time-series anomaly detection and Long Short-Term Memory (LSTM) based models in capturing early warning signs of failure in air production units. Combining LSTM and Autoencoder turned out to be beneficial as it captures temporal dependencies in sequential data that may otherwise have gone unnoticed by traditional Autoencoders. The LSTM layer learned the sequential patterns while the Autoencoder compressed data representations and evaluated reconstruction errors. This is particularly useful for datasets with sequential characteristics, where anomalies can only be detected in the context of entire observation sequences.

It would therefore be an advancement on the traditional Autoencoders because of superior performance in anomaly detection with sequences or time series. The effective strategy of using LSTM for sequence learning coupled with autoencoders for unsupervised anomaly detection proves that sequences where anomalies exist are subtle and, at times, context-dependent. The results confirm that LSTM-Autoencoders are a strong anomaly detection method for time-series data and that they should be preferred in any scenarios that require sequential data analysis.

B. Recommendations for Future Work

The performance of this model may be further improved, and its applicability may be extended to bigger metropolitan rail systems for future work. A promising direction could be to integrate real-time monitoring by embedding the LSTM Autoencoder with real-time frameworks in an edge computing environment. Improvements in explainability and interpretability can further highlight the decisions made by the model, build user trust, and further increase the transparency of the model.

More development in data preprocessing techniques would lead to further advancements for improved model accuracy and reliability, especially when handling noisy and imbalanced data. The study has multi-sensor fusion capabilities. Training the model for huge datasets and then testing it for various metro systems would improve generalization capabilities.

Further research could include hybrid models combining Autoencoders with other algorithms, with the intention of improving model robustness and accuracy. Such innovations can really boost the reliability and efficiency of metro rail operations, with predictive maintenance and anomaly detection systems well set to hit the streets.

Artificial Intelligence in Diagnostic and Therapeutic Interventions: A Systematic Review of Randomized Controlled Trials

Oscar Jimenez-Flores[1], Sandra Pajares-Centeno[2], Oscar Mejia-Sanchez[3], Rodrigo Flores-Palacios[4]
Escuela de Posgrado Newman, Tacna, Perú[1, 2, 3]
Universidad Nacional Jorge Basadre Grohmann, Tacna, Perú[4]

***Abstract*—Artificial intelligence (AI) is increasingly being integrated into diagnostic and therapeutic interventions, offering potential advantages in accuracy, efficiency, and clinical decision-making compared to conventional methods. This systematic review aimed to identify and characterise AI applications assessed in randomised controlled trials (RCTs), and to synthesise the reported clinical outcomes in comparison with standard approaches. A comprehensive search was conducted in PubMed, Scopus, and Web of Science for articles published between 2015 and June 2024. Eligible studies included randomised controlled trials involving patients with various medical conditions who received diagnostic or therapeutic interventions supported by AI technologies. Comparators included conventional diagnostic or treatment methods, placebo, or standard care. Two reviewers independently screened the studies, extracted data, and assessed risk of bias using the Cochrane RoB 1 tool. A total of 13 trials involving 10,566 participants met the inclusion criteria, spanning a range of medical specialties including gastroenterology, dermatology, radiology, oncology, neurology, and ophthalmology. While several trials reported improvements in diagnostic accuracy, treatment planning, or procedural efficiency, other studies showed inconsistent or limited benefits, highlighting the variability in outcomes depending on the clinical context and type of AI application. This review offers an updated synthesis of AI-based clinical interventions evaluated through randomised controlled trials and emphasises the need for further research to validate these tools, standardise their implementation, and assess their broader impact as health technology in modern healthcare systems.**

Keywords*—AI applications; diagnostic interventions, therapeutic interventions; randomised controlled trials; health technology

I. Introduction

In recent years, the field of artificial intelligence (AI) has experienced exponential growth, driving significant advancements across various disciplines, including medicine [1]. Medical applications of AI have begun to profoundly transform clinical practice and biomedical research, offering new possibilities to enhance diagnostic accuracy, personalize treatments, and optimize clinical data management [2–4]. These emerging technologies range from AI-assisted diagnostic systems to advanced predictive models and telemedicine applications, all aimed at improving the quality and efficiency of healthcare [5–7].

The implementation of AI in the medical field offers unprecedented opportunities for the personalization of treatments, dynamically adapting to the specific needs of each patient [8]. This ability not only improves clinical outcomes but also optimizes the utilization of medical resources, which is crucial in a globally strained healthcare environment [9]. AI-based technologies facilitate continuous monitoring and patient follow-up, providing innovative tools for early disease detection and proactive management of chronic conditions [10]. By analyzing large volumes of data in real time, AI systems can alert healthcare professionals to potential complications before they clinically manifest, enabling faster and more effective interventions [11].

Despite these significant advancements, the integration of AI into medical applications presents crucial challenges [12], particularly in terms of ethical considerations, privacy, and variability in outcomes [13]. The collection and analysis of extensive medical data sets raise serious concerns about patient confidentiality and data integrity [14]. Moreover, the effectiveness of AI-based interventions can vary significantly depending on the specific medical condition and clinical context, which raises questions about their reliability and comparability to conventional methods [15]. To ensure the safe and equitable use of AI, it is imperative to establish clear and rigorous policies that address these issues, including algorithmic biases and disparities in implementation across different healthcare settings [16].

Furthermore, the successful integration of AI in medicine requires that healthcare professionals be adequately prepared to utilize these advanced tools [17]. This necessitates the development of comprehensive educational and training programs that equip medical staff with the skills needed to leverage AI technologies fully [18]. Understanding the ethical principles and best practices for integrating AI into daily clinical practice is essential [19], as is the ability to interpret and apply AI-generated recommendations while recognizing their capabilities and limitations [20].

Given the rapid evolution and proliferation of AI applications in medicine, there is a clear need for a systematic review that explores how these technologies are being applied in diagnostic and therapeutic contexts [21]. While prior reviews have provided broad overviews of AI in healthcare, they have often lacked a targeted focus on AI-based interventions evaluated through randomised controlled trials (RCTs).

To address this gap, a systematic review was conducted to identify and characterise diagnostic and therapeutic interventions based on AI, as evaluated in RCTs.

This review offers a structured synthesis of current applications and reported outcomes compared to conventional methods, highlighting areas of clinical promise, heterogeneity across medical fields, and directions for future research and safe implementation [23].

II. Methodology

A. Design and Eligibility Criteria

This systematic review followed the PRISMA 2020 guidelines to ensure comprehensive and transparent reporting [24]. The PRISMA 2020 checklist is included as Supplementary Material 1. The objective of this review was to identify and synthesise randomised controlled trials (RCTs) that evaluated diagnostic or therapeutic interventions based on artificial intelligence (AI), compared to conventional approaches. The research question was structured using the PICO framework as follows:

- Population (P): Patients with specific medical conditions receiving AI-based diagnostic or therapeutic interventions.
- Intervention (I): AI-based diagnostic or therapeutic interventions.
- Comparison (C): Conventional diagnostic or therapeutic methods, placebo, or standard care.
- Outcome (O): Diagnostic accuracy, treatment efficacy, precision, and/or side effects.

1) Inclusion criteria were: (i) RCTs evaluating diagnostic or therapeutic interventions supported by AI; (ii) studies including patients of any age, sex, or clinical condition; (iii) trials comparing AI-based approaches with conventional diagnostic or treatment methods, placebo, or standard care; and (iv) studies reporting quantitative clinical outcomes.

2) Exclusion criteria were: (i) non-randomised studies (e.g., observational, cross-sectional, cohort, or case-control designs); (ii) RCTs without a comparator group using conventional methods; (iii) studies not reporting relevant clinical outcomes; (iv) duplicate publications; (v) editorials, conference abstracts, letters, reviews, or protocols.

The review protocol was prospectively registered in the International Prospective Register of Systematic Reviews (PROSPERO) under registration number CRD42024583396, on 26 August 2024.

B. Information Sources and Search Strategy

A systematic search was conducted across PubMed, Scopus, and Web of Science for studies published between January 2015 and June 2024. The search strategy combined controlled vocabulary and free-text terms related to artificial intelligence and clinical interventions. Core search terms included “artificial intelligence”, “machine learning”, “deep learning”, “neural networks”, “natural language processing” combined with clinical concepts such as “diagnosis”, “treatment”, “therapeutic”, “patient care”, and study design filters (“randomised controlled trial”, “clinical trial”).

Specific exclusion terms were also applied to remove non-relevant designs, such as reviews, meta-analyses, case reports, editorials, and observational studies. Only original articles classified as clinical trials were retained. No restrictions were applied regarding patient population, but searches were limited to articles published in English or Spanish.

The detailed search strategies for each database, including Boolean operators, limits, and filters, are provided in Supplementary Material 2. A total of 861 records were retrieved from PubMed, 1,359 from Scopus, and 306 from Web of Science.

C. Selection and Data Collection Process

All identified references were imported into Rayyan [25, 26]. where duplicates were automatically removed. Two reviewers (SPC, OMS) independently screened titles and abstracts, followed by full-text review of potentially eligible articles. Any disagreements were resolved through discussion with a third reviewer (RFP).

From the 2,526 records initially retrieved, 2,096 remained after duplicate removal. After screening 137 titles and abstracts, 91 full-text articles were assessed for eligibility. Of these, 73 were excluded for not meeting the inclusion criteria (detailed in Supplementary Material 3). Ultimately, 13 RCTs were included in the final analysis (Fig. 1).

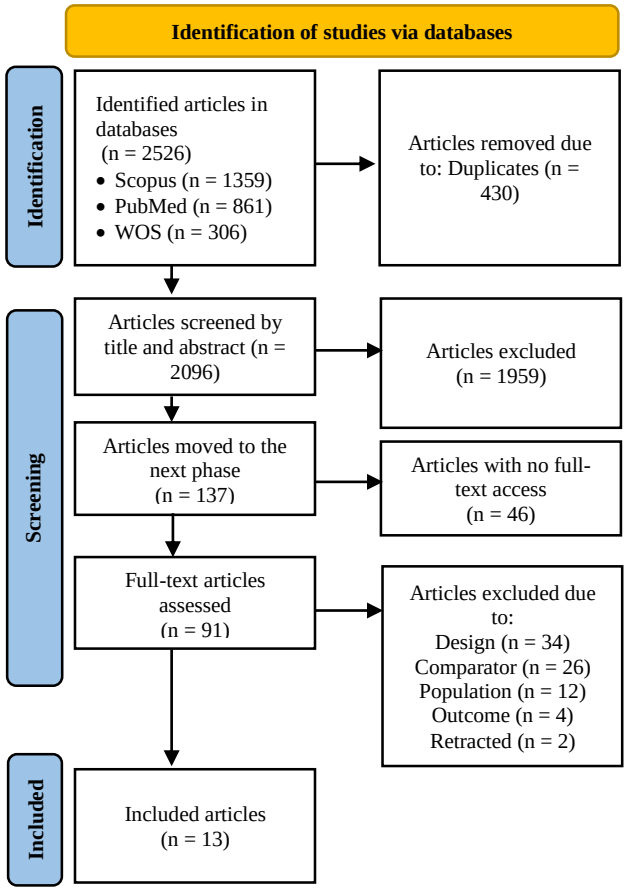

Fig. 1. Flow diagram of studies inclusion.

Data extraction was conducted independently by two reviewers using a pre-piloted form. Discrepancies were resolved by consensus.

D. Variables Collected

The primary outcomes of interest were diagnostic accuracy, treatment efficacy, and precision. Secondary outcomes included side effects and other clinically relevant metrics reported by the included studies. Each outcome was defined operationally according to the measures used in the original trials.

E. Risk of Bias Assessment

The risk of bias of the included RCTs was independently assessed by two reviewers (SPC, RFP) using the Cochrane RoB1 tool [27]. This tool evaluates six domains: random sequence generation, allocation concealment, blinding of participants, personnel and outcome assessors, incomplete outcome data, selective reporting, and other potential sources of bias. Disagreements were resolved with input from a third reviewer (OJF).

The overall risk of bias for each trial was categorised as low, unclear, or high, based on the assessment across domains.

III. Results

A. Study Selection

The breakdown of results by database followed the search strategy based on the following string: "(artificial intelligence" OR "AI" OR "machine learning" OR "deep learning" OR "neural network*" OR "natural language processing") AND ("medicine" OR "medical" OR "healthcare" OR "clinical" OR "health" OR "patient care" OR "diagnosis" OR "treatment" OR "biomedicine")". A total of 2,526 open-access records were identified, considering documents in English and Spanish from the years 2015 to 2024 for Scopus, WoS, and PubMed.

After removing duplicates, 2,096 records were screened by title and abstract. Following this initial screening, 137 articles were deemed potentially relevant and selected for full-text review. However, full text was not accessible for 46 of these articles. The remaining 91 articles underwent thorough full-text evaluation, leading to the exclusion of 73 studies due to various reasons, such as not meeting the inclusion criteria or lacking sufficient data for assessment. Ultimately, 13 randomised controlled trials (RCTs) with a combined total of 10,566 participants were included in the systematic review (Fig. 1).

B. Risk of Bias

To enhance the rigor of the study, RoB 1 (Cochrane Tool) was employed for RCT. This comprehensive analysis covered various types of bias that could compromise the internal validity of the RCTs included in this review, including random sequence generation and allocation concealment to identify potential selection biases. Additionally, participant, personnel, and assessor blinding were examined to address performance and detection biases. Incomplete outcome data and selective reporting were also reviewed, as they might reflect attrition and reporting biases, respectively. Considering these factors, along with other potential biases, resulted in a thorough evaluation aimed at improving the study's quality and its conclusions, as detailed in Fig. 2. Table I shows characteristics of included randomized controlled trials.

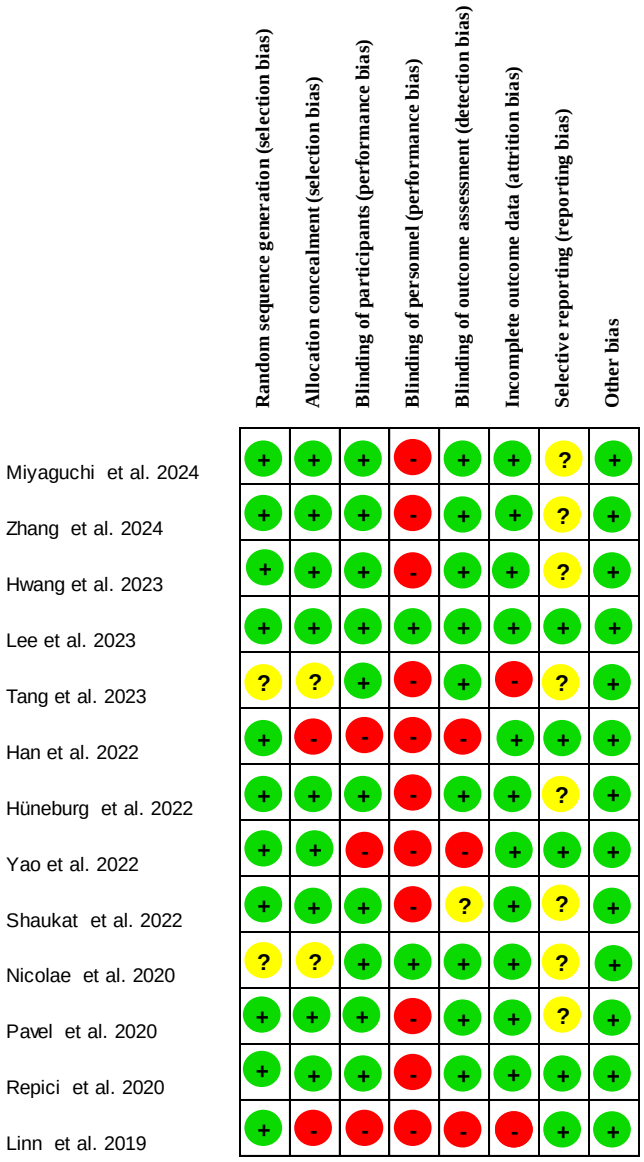

Fig. 2. Risk of bias summary across included studies. Note. Green represents low risk of bias; yellow represents unclear risk of bias; red represents high risk of bias.

TABLE I. CHARACTERISTICS OF INCLUDED RANDOMIZED CONTROLLED TRIALS

Author (year)	Medical Area	Population / Sample size	Intervention	Intervention Type	Comparator	AI Technology Used	Main Conclusion
Gastroenterology							
Miyaguchi (2024) [28]	Gastroenterology	Adults ≥20 undergoing colonoscopy / 800 (I:400, C:400)	Linked-color imaging colonoscopy with AI assistance	Diagnostic	Linked-color imaging colonoscopy without AI	CADEYE (Fujifilm EW10-EC02)	AI-assisted colonoscopy improved adenoma detection rate (ADR).
Zhang (2024) [29]	Gastroenterology	Adults 18–75 requiring colonoscopy / 1360 (I:680, C:680)	White-light colonoscopy with CADe	Diagnostic	White-light colonoscopy without CADe	EndoAngel (Wuhan ENDOANGEL)	Improved sensitivity and reduced polyp miss rate.
Tang (2023) [32]	Gastroenterology	Adults with pancreatic masses / 44 (I:21, C:23)	CH-EUS MASTER-guided EUS-FNA	Diagnostic	Conventional EUS-FNA	CH-EUS MASTER (AI-guided contrast-enhanced EUS)	Improved diagnostic accuracy and yield.
Hüneburg (2022) [34]	Gastroenterology	Adults ≥18 with Lynch syndrome / 96 (I:50, C:46)	AI-assisted colonoscopy	Diagnostic	High-definition white-light endoscopy (HD-WLE)	CAD-EYE (Fujifilm EW10-EC02)	Improved flat adenoma detection; overall ADR similar.
Yao (2022) [35]	Gastroenterology	Adults >18 undergoing colonoscopy / 1076 (I:805, C:271)	CADe, CAQ, and combined systems	Diagnostic	Colonoscopy without AI	CADe (YOLO V3), CAQ (AI quality control)	Combined AI improved ADR; CAQ was more effective than CADe alone.
Shaukat (2022) [36]	Gastroenterology	Adults ≥40 / 1369 (I:682, C:677)	Colonoscopy with CADe	Diagnostic	Standard colonoscopy	CADe (Computer-Aided Detection)	Increased ADR and adenomas per colonoscopy (APC).
Repici (2020) [39]	Gastroenterology	Adults 40–80 undergoing colonoscopy / 685 (I:341, C:340)	Colonoscopy with CADe	Diagnostic	Colonoscopy without CADe	GI-Genius (Medtronic)	Increased ADR without prolonging procedure time.
Radiology							
Hwang (2023) [30]	Radiology	Adults ≥19 with respiratory symptoms / 3576 (I:1761, C:1815)	Chest radiograph interpretation with AI-CAD	Diagnostic	Standard chest radiograph interpretation	Lunit INSIGHT CXR v2.0.2.0	No improvement in sensitivity or false positives.
Lee (2023) [31]	Radiology	Adults ≥20 undergoing chest X-ray / 329 (I:166, C:163)	AI-assisted interpretation of thoracic abnormalities	Diagnostic	Standard interpretation without AI	Lunit INSIGHT CXR v2.0.3.0	Improved non-radiologist diagnostic accuracy.
Dermatology							
Han (2022) [33]	Dermatology	Adults >19 with suspicious lesions / 576 (I:305, C:292)	Real-time AI-assisted diagnosis	Diagnostic	Diagnosis without AI	Model Dermatology (Multiclass AI)	Significantly improved accuracy, especially in non-experts.
Oncology							
Nicolae (2020) [37]	Oncology	Prostate cancer patients / 41 (I:21, C:20)	Machine learning-based treatment planning	Therapeutic	Manual planning	PIPA (Prostate Implant Planning Algorithm)	Comparable dosimetry, with time and efficiency gains.
Neurology							
Pavel (2020) [38]	Neurology	Neonates (36–44 weeks) / 264 (I:132, C:132)	EEG with ANSeR for seizure detection	Diagnostic	Conventional EEG monitoring	ANSeR (Algorithm for Neonatal Seizure Recognition)	Better seizure-hour identification; no difference at patient level.
Ophthalmology							
Linn (2019) [40]	Ophthalmology	Pediatric patients ≤14 years / 350 (I:350, C:350)	Diagnosis using CC-Cruiser	Diagnostic	Diagnosis by senior consultants	CC-Cruiser (Ophthalmic AI platform)	Lower diagnostic accuracy, but faster with higher satisfaction.

Note. I: Intervention group; C: Control group; AI: Artificial Intelligence; CADe: Computer-Aided Detection; CAQ: Computer-Aided Quality Improvement; CAD: Computer-Aided Diagnosis; ADR: Adenoma Detection Rate; ED: Emergency Department; CR: Chest Radiography; CXR: Chest X-ray; EUS-FNA: Endoscopic Ultrasound-Guided Fine-Needle Aspiration; CH-EUS MASTER: AI-assisted Contrast-Enhanced Harmonic Endoscopic Ultrasound system; HD-WLE: High-Definition White-Light Endoscopy; PIPA: Prostate Implant Planning Algorithm; ANSeR: Algorithm for Neonatal Seizure Recognition; EEG: Electroencephalogram.

IV. DISCUSSION

This systematic review synthesised the current landscape of diagnostic and therapeutic interventions based on artificial intelligence (AI) as evaluated in randomised controlled trials (RCTs). The included studies span multiple medical specialties, offering a structured overview of how AI technologies are being implemented in clinical settings and what outcomes have been reported in comparison with conventional approaches.

In gastroenterology, the integration of AI into endoscopic practice has consistently demonstrated clinically meaningful improvements. Multiple studies [28] and [39] confirmed that AI-assisted colonoscopy significantly increased adenoma detection rates (ADR), a well-established surrogate marker for colorectal cancer prevention. Complementarily, the use of Computer-Aided Detection (CADe) systems [29], [36] enhanced sensitivity for polyp detection without increasing unnecessary resections of non-neoplastic lesions, reinforcing their safety profile [22]. Importantly, AI demonstrated added value in specific high-risk populations: study [34] reported superior detection of flat adenomas in patients with Lynch syndrome, which are frequently overlooked by conventional methods. Beyond colonoscopy, AI has also optimized diagnostic yield in other domains, as evidenced by the CH-EUS MASTER system [32], which improved accuracy during EUS-FNA of pancreatic masses. Furthermore, the combined use of AI-driven detection and quality control systems [35] suggested a synergistic effect on real-time ADR, although this benefit was not replicated when each system was applied independently. Collectively, these findings not only highlight AI's capacity to enhance early lesion detection but also illustrate its potential to reshape preventive strategies in gastrointestinal oncology [41]. By enabling real-time visual analysis and identification of subtle mucosal changes often imperceptible to human observers, gastroenterology emerges as one of the most advanced fields for clinical AI implementation [42].

In radiology, the findings were more heterogeneous. Study [30] reported no significant improvement in sensitivity or false-positive rates when chest radiographs were interpreted with AI assistance for the diagnosis of acute thoracic diseases. Conversely, study [31] demonstrated that an AI-assisted diagnostic protocol based on deep learning significantly enhanced the performance of non-radiologist physicians in detecting pulmonary abnormalities. These discrepant results may be explained by variations in the maturity of the algorithms, the expertise of end-users, and the clinical contexts in which the tools were applied. Collectively, they highlight the pressing need for validation studies that account for both technological development and real-world implementation challenges.

In dermatology, study [33] showed that real-time AI assistance substantially improved diagnostic accuracy among non-expert physicians evaluating suspicious skin lesions. Interestingly, the greatest benefit was seen among trainees with limited dermatological experience, suggesting that AI functions not merely as a diagnostic adjunct but also as a pedagogical tool. This points to an underexplored opportunity for AI to strengthen medical education by supporting clinical reasoning and decision-making in early-career professionals.

In oncology, study [37] showed that machine learning-based treatment planning for prostate cancer, specifically using the Prostate Implant Planning Algorithm (PIPA), improved time efficiency and streamlined workflow without compromising dosimetric quality compared to manual planning. These results highlight AI's potential to optimize operational processes while maintaining treatment precision.

In neurology, study [38] assessed the use of the ANSeR algorithm for neonatal seizure recognition. Although AI improved the identification of seizure hours, it did not enhance detection at the patient level when compared with conventional EEG. This suggests that, while AI can assist in data interpretation, its current clinical contribution to neonatal seizure diagnostics remains limited.

In ophthalmology, study [40] evaluated the CC-Cruiser system and found that, although it facilitated faster diagnostic processes and improved patient satisfaction, its diagnostic accuracy and therapeutic decision-making were inferior to those of senior consultants. These results underscore the potential of AI to enhance efficiency and patient experience, but they also reveal critical limitations in replicating expert-level judgement. This suggests that, at present, AI should be regarded as an adjunctive tool rather than a replacement in complex clinical decision-making, highlighting the need for further refinement and validation before broader clinical integration.

Overall, the included studies demonstrate a broad spectrum of AI applications across medical disciplines. However, the representation across specialties is uneven**,** with gastroenterology dominating the evidence base, while areas such as neurology [38] and ophthalmology [40] remain underrepresented. This limits the generalizability of findings to less-studied fields and highlights the need for more diverse and comprehensive RCTs in AI research. Additionally, the majority of included studies were conducted in technologically advanced, well-resourced hospital settings. Consequently, their applicability to low-resource or primary care environments remains uncertain.

The certainty of evidence also varied. In gastroenterology, robust findings from multiple high-powered RCTs (e.g., [28], [29], [39]) provide strong support for the use of AI. In contrast, the mixed results in radiology [30], [31] and limited data in oncology and neurology reduce confidence in the broader applicability of these technologies. The variability in AI system types, clinical indications, and user expertise further complicates the ability to draw uniform conclusions across studies.

Despite its strengths, this systematic review has several limitations. First, although the search strategy was extensive, it is possible that relevant studies were missed due to language restrictions or the stringent inclusion criteria. Second, heterogeneity across AI systems, patient populations, and outcome measures reduced the comparability of results and precluded meta-analysis. However, this same heterogeneity reflects the diversity and innovation within the field, illustrating the breadth of AI's applicability to various clinical challenges.

Notably, this review adheres to rigorous methodological standards, including AMSTAR-2 compliance, a predefined protocol, and a structured risk of bias assessment, which

collectively reinforce the validity and transparency of the findings. By restricting the review to randomised controlled trials, the study focused on high-quality evidence, ensuring that the conclusions are grounded in rigorous experimental data.

In addition to evaluating clinical performance, this review indirectly reflects the growing sophistication and practical deployment of machine learning algorithms in healthcare settings. Most of the AI-based interventions included in the analysed RCTs involve deep learning models, computer vision tools, or natural language processing systems integrated into real-time clinical workflows. These findings not only demonstrate the clinical utility of AI but also highlight the importance of interdisciplinary collaboration between clinicians, data scientists, and engineers. Future studies should document more precisely the algorithmic architecture, training datasets, performance metrics, and update protocols of the AI systems being evaluated, to ensure reproducibility and transparency across both medical and computational communities.

Collectively, these findings illustrate both the promise and the fragility of the current evidence base. Gastroenterology emerges as a model of successful integration of AI into routine practice, whereas other specialties remain in earlier stages of exploration, with evidence that is either inconsistent or limited in scope. This uneven development highlights the urgent need for methodological standardisation, greater representation of diverse healthcare contexts, and longitudinal validation studies to assess sustainability of outcomes over time. Addressing these gaps will not only advance the safe and equitable deployment of AI across medical disciplines but also ensure that its benefits extend beyond technologically advanced centres to the broader spectrum of global healthcare.

Future research should prioritise underexplored medical specialties, assess AI interventions across diverse healthcare settings—including low-resource and primary care environments—and examine the impact of user training and experience on clinical outcomes. Longitudinal and multicentre studies are encouraged to evaluate the sustainability and generalisability of AI-assisted interventions. Moreover, developing standardised methodological frameworks and reporting guidelines will facilitate comparability, reproducibility, and evidence-informed adoption of AI technologies across clinical disciplines.

V. Conclusion

This systematic review identified and synthesised randomised controlled trials evaluating AI-based diagnostic and therapeutic interventions compared to conventional methods. The findings highlight that AI technologies can improve diagnostic accuracy and clinical performance, particularly in fields such as gastroenterology and dermatology. However, the variability of outcomes observed in specialties such as radiology, neurology and ophthalmology suggest that the clinical utility of AI is highly context dependent and influenced by the nature of the task, technological design and user expertise.

These results underscore the importance of a critical and context-sensitive approach to the integration of AI in healthcare. While promising results support its implementation in specific domains, the observed heterogeneity indicates that AI is not a universal solution. A deeper understanding of the conditions under which AI adds the most value is essential, considering clinical context, provider training, technological maturity and patient characteristics.

To advance responsible and effective integration of AI into clinical practice, future research should expand evaluation across diverse healthcare settings and populations. The development of standardised protocols and implementation guidelines is needed to ensure consistent and evidence-informed use.

Additionally, studies should examine the impact of user training and experience on AI outcomes, and ensure that the deployment of these technologies promotes equity in access and benefit across all socioeconomic and geographic contexts. In summary, this systematic review provides an updated and evidence-based overview of AI applications in randomised controlled trials, offering a critical foundation to guide future research and the responsible integration of AI into clinical practice.

Department of Intelligent Agricultural Engineering, Shanghai Vocational College of Agriculture and Forestry, Shanghai, China[2, 3, 4]

***Abstract*—This study addresses the prevalent decline in physical activity among university students in the contemporary information society, proposing an innovative deep learning-based framework for intelligent physical activity recognition. Central to this framework is the comprehensive utilization of high-precision Inertial Measurement Units (IMUs) integrated within smartphones, encompassing triaxial accelerometers, gyroscopes, and magnetometers, enabling multi-dimensional, real-time capture of students' daily activity postures. For algorithmic design, this research transcends traditional limitations by adopting the more advanced Transformer architecture as its core classifier. Through the distinct self-attention mechanism inherent to this architecture, the proposed method efficiently and precisely extracts critical spatiotemporal features from vast sensor data, thereby achieving accurate identification and classification of various physical activities, such as walking, running, and climbing stairs. Rigorous evaluation results demonstrate significant advantages in key performance metrics, including recognition accuracy, when compared to conventional recurrent neural networks (e.g., Long Short-Term Memory networks, Recurrent Neural Networks) and classic machine learning algorithms (e.g., Random Forest), with a validation accuracy reaching 93.97%. This forward-looking research outcome not only provides a reliable and efficient technological means for monitoring the physical activity status of university students but also establishes a robust data foundation for the future development and implementation of targeted health intervention measures.**

***Keywords*—Activity recognition; smartphone; transformer architecture; inertial measurement units**

I. Introduction

In recent years, the widespread adoption of smartphones and rapid advancements in mobile computing technology have positioned sensor-based Human Activity Recognition as a focal point in research fields such as health monitoring, intelligent assistance, and sports analytics [1]. Traditional methods for monitoring physical activity, such as questionnaires, field-based equipment assessments, or manual observation, suffer from limitations including subjectivity, high costs, and poor compliance, making them inadequate for large-scale, long-term, and precise monitoring. Consequently, there is an urgent need for intelligent, convenient, and efficient physical activity recognition technologies to address the shortcomings of conventional methods.

The perception of physical activities forms the cornerstone of intelligent recognition. Currently, the primary approaches to physical activity perception encompass time-series data-based sensing and image-based visual sensing [2]. The use of diverse sensor modalities for activity detection and classification has emerged as a transformative technology for real-time and autonomous monitoring in areas such as behavioral analysis in smart home environments, assisted living, daily activity monitoring, elderly care, rehabilitation, entertainment, and security surveillance. Wearable devices, smartphones [3], and ambient sensing equipment are equipped with an array of sensors, including accelerometers, gyroscopes, magnetometers, heart rate monitors, pressure sensors, and compact cameras, to facilitate activity recognition and monitoring [4]. These sensor data undergo preprocessing to extract feature sets, such as time-domain, frequency-domain, or wavelet transform features, which are then processed using machine learning algorithms to classify and continuously monitor human activities.

The perception of time-series data, such as acceleration signals, provides a convenient approach for activity recognition. By integrating these data with intelligent algorithms, accurate identification of human activities can be achieved. Yin et al. developed a two-stage method for detecting anomalous activities using wireless body sensors [5]. In the first stage, they trained a one-class Support Vector Machine (SVM) on common normal activities to filter out those highly likely to be normal. Subsequently, they used Kernel Nonlinear Regression (KNLR) to derive an anomaly activity model from the general normal model, reducing false positives in an unsupervised manner. Saeed et al. proposed a novel self-supervised technique for feature learning from sensor data, which did not require semantic labels (i.e., activity categories) [6]. They trained a multi-task temporal convolutional network to recognize transformations applied to input signals. By leveraging these transformations, they demonstrated that a simple binary auxiliary task could generate robust supervisory signals, extracting valuable features for downstream tasks. Janidarmian et al. performed an extensive analysis of feature representations and classification techniques for activity recognition, comparing 293 classifiers in the most comprehensive study to date [7]. They applied Principal Component Analysis (PCA) to reduce feature vector dimensionality while preserving essential information. Iloga et al. observed that deep learning techniques addressed some limitations but required significant computational resources and produced feature vectors with limited interpretability [8]. To address these challenges, they developed a Human Activity Recognition (HAR) technique based on Hidden Markov Models (HMMs).

Smartphones equipped with various sensors, such as accelerometers, gyroscopes, and magnetometers, can capture high-frequency data on posture, orientation, and velocity changes during human motion, generating continuous time-series data [9]. These data accurately capture unique patterns of periodic or non-periodic movements, such as running, jumping, and walking [10]. For instance, accelerometers record linear motion, while gyroscopes detect rotational motion, together providing a comprehensive representation of the body's dynamics in three-dimensional space [11]. Through preprocessing, feature extraction, and pattern recognition of sensor data, different physical activities can be effectively distinguished [12]. Compared to other wearable devices, smartphones, as indispensable tools in university students' daily lives, offer widespread availability and portability, making them an ideal platform for time-series data collection in physical activity sensing [13]. Lara et al. developed the Centinela system [14], which integrated acceleration data with vital signs to achieve high-accuracy activity recognition. The system identified five activities: walking, running, sitting, standing, and descending. They evaluated eight classifiers and three time window sizes, achieving an overall accuracy of 95.7%. Micucci et al. created a novel acceleration sample dataset [15], collected using an Android smartphone designed for human activity recognition and fall detection. The samples were categorized into 17 fine-grained classes and grouped into two coarse-grained classes: one comprising 9 types of Activities of Daily Living (ADL) and another including 8 types of falls. Mario proposed a novel mechanism for detecting specific activities using data from a single triaxial accelerometer [16]. They employed convolutional neural networks to automatically extract the most relevant features to characterize acceleration patterns, enabling cross-activity recognition.

With significant advancements in deep learning for image processing, intelligent recognition of human activities based on image data has seen rapid development. Niu et al. developed a framework for human activity detection and recognition in outdoor video surveillance applications [17]. They introduced an efficient activity representation method that identified distinct interaction patterns among groups based on simple statistical data from tracking trajectories, without requiring complex Markov chains, Hidden Markov Models (HMMs), or Coupled Hidden Markov Models (CHMMs). Sung et al. utilized RGBD sensors (Microsoft Kinect) as input devices and computed a set of features based on human posture, motion, and image and point cloud data [18]. They designed an algorithm based on a hierarchical Maximum Entropy Markov Model (MEMM), treating individual activities as compositions of sub-activities, and employed dynamic programming to infer a two-layer graph structure. Ni et al. proposed a novel framework for complex activity recognition and localization, effectively integrating information from grayscale and depth image channels across multiple layers of the video processing pipeline [19]. Koppula et al. modeled complex spatiotemporal relationships (termed affordances) between human postures and objects using Conditional Random Fields (CRFs), inferring multiple possible graph structures and approximating graphs with additive features for efficient dynamic programming [20]. Albanese et al. developed a computational framework for human activity representation based on Petri Nets [21]. They introduced the PPN-MPS algorithm for the first question and proposed two algorithms (naive PPN-MPA and PPN-MPA) for the second. Rodrigues et al. developed a multi-timescale model to capture temporal dynamics across different time scales, predicting future and past states for a given input posture trajectory [22].

In the domain of physical activity recognition, deep learning techniques have demonstrated exceptional capabilities in feature extraction and pattern recognition, establishing them as the most advanced and effective algorithmic paradigm. For time-series data collected by smartphones, Convolutional Neural Networks (CNNs), Recurrent Neural Networks (RNNs), and their variants, such as Long Short-Term Memory networks (LSTMs) and Gated Recurrent Units (GRUs), have been widely applied to physical activity recognition [23]. Additionally, models incorporating attention mechanisms further enhance the ability to capture critical motion features [24]. For image data, CNNs remain the dominant algorithm for physical activity recognition. Transfer learning based on pretrained ImageNet models significantly improves performance in image-based activity recognition tasks. By leveraging posture information derived from human skeleton keypoint detection, combined with algorithms like Graph Convolutional Networks (GCNs), complex physical activities can be analyzed more effectively through posture changes and action sequences. Furthermore, Transformer models have shown significant potential in processing image sequences and capturing global features, opening new research directions for image-based physical activity recognition [25].

Transformer technology continues to demonstrate significant potential in processing time-series and tabular data. To this end, this study proposes a novel method for intelligent recognition of physical activities in students using Transformer-based models and smartphone sensors. The method leverages high-precision inertial sensors embedded in smartphones, such as accelerometers and gyroscopes, to collect motion data. Through the Transformer neural network, feature extraction and classification are performed to automatically identify various physical activities, including walking, running, and climbing stairs. Compared to traditional time-series models such as Long Short-Term Memory (LSTM) networks, vanilla Recurrent Neural Networks (RNNs), and machine learning methods like Random Forest, the proposed method demonstrates a significant advantage in recognition accuracy. In terms of algorithmic architecture, this study pioneers the application of Transformer models in the domain of university students' daily activity recognition. Leveraging its distinctive self-attention mechanism, the proposed framework achieves efficient and precise extraction of crucial spatiotemporal features from massive sensor datasets. Regarding practical applications, the research not only develops a reliable and efficient monitoring system for collegiate physical activities but more significantly incorporates an innovative class-balancing mechanism that effectively mitigates recognition performance degradation caused by the data imbalance issue.

Section II provides a detailed introduction to the overall framework and the intelligent recognition algorithm of the proposed method. Section III conducts an in-depth analysis of

the utilized data, and Section IV evaluates the recognition performance of the proposed method in comparison with other approaches. Section V presents a discussion and analysis. Finally, Section VI summarizes the findings of this study.

II. Portable Perception and Intelligent Recognition of Human Activities

To accurately and comprehensively monitor and assess the types and states of physical activities among university students, this study innovatively proposes a portable monitoring method based on smartphone technology and deep learning. Its overall framework, clearly illustrated in Fig. 1, delineates the entire data flow and processing pipeline. This method capitalizes on the pervasive and ubiquitous nature of modern smartphones, specifically leveraging their integrated high-precision inertial sensors, such as triaxial accelerometers and triaxial gyroscopes. These sensors enable the portable sensing of human activities, capturing detailed motion data with remarkable accuracy, thereby establishing a robust foundation for subsequent analytical procedures. In the data processing phase, the raw sensor signals undergo a series of meticulous preprocessing steps. Specifically, the data is first subjected to precise segmentation in both the time and frequency domains, dividing it into fixed-length windows to ensure that each window encapsulates complete activity information. Subsequently, these segmented data are normalized to eliminate scale discrepancies between different sensors or individuals, ensuring data consistency. Following normalization, a rich set of time-domain and frequency-domain features is extracted from the signals, designed to capture the unique patterns of distinct physical activities. These extracted features collectively form a structured tabular dataset, where each sample comprises a carefully selected array of diverse features, preparing the data for input into the machine learning model.

Building upon this foundation, this research innovatively designs and proposes an optimized Transformer network model specifically tailored for this tabular data. This model integrates advanced deep learning techniques, including a unique mapping projection mechanism and a sophisticated positional encoding strategy. These techniques enable the Transformer network to effectively process the non-sequential structure inherent to tabular data and capture complex relationships and potential temporal dependencies among features (even though the data has been tabularized). Through this powerful model, we achieve highly accurate classification of various human activities, thereby robustly supporting the continuous monitoring and assessment of university students' activity types and states. This portable, efficient, and precise monitoring method promises to offer a revolutionary tool for managing the physical health of university students.

The physical activity recognition model proposed in this study leverages the robust modeling capabilities of the Transformer architecture combined with the characteristics of multidimensional feature data. Originally designed for natural language processing tasks, the Transformer model has gained widespread attention due to its superior sequence modeling and global information capture mechanisms. The model processes input tabular data through four core components—input projection, positional encoding, Transformer encoder, and classification head—to capture complex dependencies among features and generate probabilistic predictions for activity categories. Compared to traditional vanilla Recurrent Neural Networks (RNNs) or Convolutional Neural Networks (CNNs), the Transformer architecture employs a self-attention mechanism to process tabular data in parallel, significantly enhancing its ability to model multidimensional features while mitigating issues such as vanishing gradients. The input projection module maps raw tabular data features into a high-dimensional model space, improving feature representation. The positional encoding module introduces positional information to the tabular data, addressing the Transformer's inherent lack of sequence awareness. The Transformer encoder, utilizing multiple layers of multi-head self-attention mechanisms and feed-forward networks, captures intricate dependencies within the tabular data. The classification head pools the encoded sequence features and maps them to the category space, producing the final activity predictions. Each component incorporates recent advances in deep learning, ensuring the model's efficiency and robustness in handling time-series data. The following sections provide a detailed description of each module.

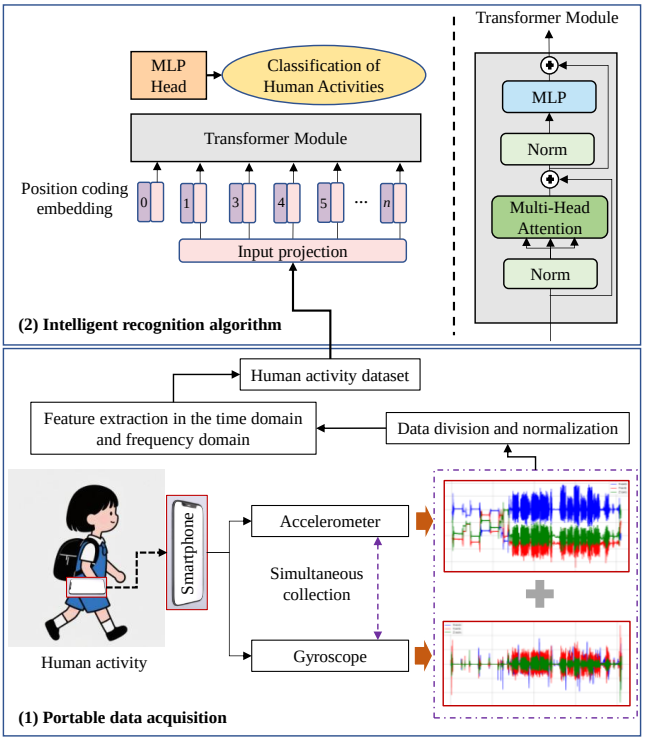

Fig. 1. Overall framework of the proposed method.

A. Projection of the Input Data

The input projection module aims to map raw tabular data features ($\mathbf{X} \in \mathrm{R}^{B \times D}$) to the model's internal dimension (d_{model}) to meet the input requirements of the Transformer encoder while enhancing feature representation through nonlinear transformations. The projection process encompasses linear transformation, layer normalization, activation functions, and dropout operations, defined as follows:

$$\mathbf{Z}_0 = \text{Dropout}(\text{ReLU}(\text{LayerNorm}(\mathbf{W}_{\text{in}}\mathbf{X} + \mathbf{b}_{\text{in}}))) \quad (1)$$

where, $\mathbf{W}_{\text{in}} \in \mathrm{R}^{D \times d_{\text{model}}}$, $\mathbf{b}_{\text{in}} \in \mathrm{R}^{d_{\text{model}}}$ represent the learnable parameters of the linear transformation. Layer normalization (LayerNorm) is defined as follows:

$$\text{LayerNorm}(\mathbf{x}) = \gamma \cdot \frac{\mathbf{x} - \mu}{\sqrt{\sigma^2 + \grave{o}}} + \beta \quad (2)$$

where, μ and σ^2 denote the mean and variance, respectively, $\gamma, \beta \in \mathrm{R}^{d_{\text{model}}}$ are learnable parameters, and $\grave{o}$ is a small constant to prevent division by zero. The ReLU activation function introduces nonlinearity, enhancing the model's expressive capacity. Dropout randomly zeros elements with probability (p_{dropout}), mitigating overfitting. Layer normalization standardizes the feature distribution, alleviating internal covariate shift and improving training stability. Together, the ReLU activation function and dropout operations enhance the model's nonlinear modeling capability and generalization performance.

B. Position Coding Transformer

The Transformer architecture is inherently insensitive to the order of input tabular data, necessitating the explicit addition of positional information to preserve the sequential characteristics of the data. To retain the order information of tabular data features, this study employed sine and cosine functions to generate positional encodings, defined as:

$$\text{PE}(t, 2i) = \sin\left(\frac{t}{10000^{2i/d_{\text{model}}}}\right), \quad \text{PE}(t, 2i+1) = \cos\left(\frac{t}{10000^{2i/d_{\text{model}}}}\right) \quad (3)$$

where, $t \in \{0, 1, \ldots, \text{max_len} - 1\}$ denotes the feature step, and $i \in \{0, 1, \ldots, (d_{\text{model}}/2) - 1\}$ represents the dimension index. max_len is the maximum feature length. The positional encoding is added to the projected input, followed by a dropout operation, defined as follows:

$$\mathbf{Z}_1 = \text{Dropout}(\mathbf{Z}_0 + \mathbf{PE}_{[:T]}) \quad (4)$$

where, $\mathbf{PE}_{[:T]} \in \mathrm{R}^{T \times d_{\text{model}}}$ denotes the positional encoding truncated to the first T rows. The sine and cosine functions generate periodic signals, enabling the model to distinguish between different features while maintaining smooth frequency variations. Fixed positional encodings, as opposed to learnable encodings, reduce the number of parameters and offer better generalization across tabular data of varying lengths. The dropout operation further enhances model robustness, preventing over-reliance on positional encodings.

C. Transformer Encoder

The Transformer encoder serves as the core component of the model, tasked with capturing complex dependencies among features in tabular data. It consists of L stacked encoder layers, each comprising a multi-head self-attention mechanism and a feed-forward neural network (FFN), augmented by residual connections and layer normalization. For the l-th layer, given the input ($\mathbf{Z}_{l-1} \in \mathrm{R}^{B \times T \times d_{\text{model}}}$), the multi-head self-attention is computed as follows:

$$\mathbf{A}_h = \text{Softmax}\left(\frac{\mathbf{Q}_h \mathbf{K}_h^{\cdot}}{\sqrt{d_k}}\right)\mathbf{V}_h \quad (5)$$

Here, ($\mathbf{Q}_h = \mathbf{Z}_{l-1}\mathbf{W}_{Q,h}, \mathbf{K}_h = \mathbf{Z}_{l-1}\mathbf{W}_{K,h}, \mathbf{V}_h = \mathbf{Z}_{l-1}\mathbf{W}_{V,h}$) represent the query, key, and value matrices, respectively, $\mathbf{W}_{Q,h}, \mathbf{W}_{K,h}, \mathbf{W}_{V,h} \in \mathrm{R}^{d_{\text{model}} \times d_k}; d_k = d_{\text{model}}/n_{\text{head}}; n_{\text{head}}$ denotes the number of attention heads, $\sqrt{d_k}$ is the scaling factor used to stabilize gradient computations, and $h \in \{1, \ldots, n_{\text{head}}\}$ represents the multi-attention head. The multi-head self-attention mechanism enables the model to focus on different parts of the sequence in parallel, capturing diverse feature dependency patterns. Residual connections preserve the original input information, mitigating gradient vanishing issues in deep networks. The feed-forward neural network (FFN) applies a nonlinear transformation independently to each time step, enhancing feature representation, and is defined as follows:

$$\mathbf{F} = \text{ReLU}(\mathbf{Z}_l^{'}\mathbf{W}_1 + \mathbf{b}_1)\mathbf{W}_2 + \mathbf{b}_2 \quad (6)$$

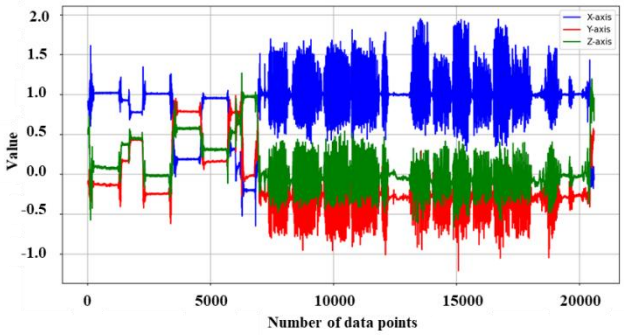
Here, $\mathbf{W}_1 \in \mathrm{R}^{d_{\text{model}} \times d_{\text{ff}}}, \mathbf{W}_2 \in \mathrm{R}^{d_{\text{ff}} \times d_{\text{model}}}, \mathbf{b}_1 \in \mathrm{R}^{d_{\text{ff}}}, \mathbf{b}_2 \in \mathrm{R}^{d_{\text{model}}}, d_{\text{ff}}$ denotes the dimension of the feed-forward neural network. The FFN enhances the model's nonlinear modeling capability, capturing complex data patterns. Residual connections and layer normalization further improve training stability, enabling the stacking of additional layers to increase the model's capacity.

D. Classification Head

The classification head employs a MultiLayer Perceptron (MLP) to map the pooled feature vectors to a probability distribution over activity categories, generating the final predictions for physical activities. Specifically, the classification head first applies a global pooling operation, such as mean pooling or max pooling, to the sequence features output by the Transformer encoder, extracting representative global features. These features are then fed into a multilayer perceptron consisting of multiple fully connected layers, each incorporating nonlinear activation functions (e.g., ReLU) and dropout operations to enhance the model's expressive power and generalization performance. Finally, a softmax function is applied to map the output to a probability distribution over the activity categories, enabling precise classification of physical activities.

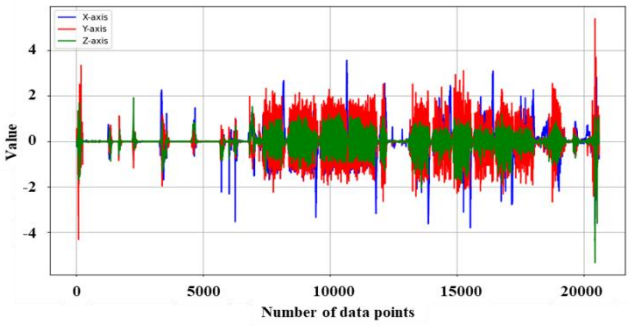
$$\mathbf{Y} = \text{Softmax}(\text{Dropout}(\text{ReLU}(\text{LayerNorm}(\mathbf{Z}_{\text{pool}}\mathbf{W}_3 + \mathbf{b}_3)))\mathbf{W}_4 + \mathbf{b}_4) \quad (7)$$

Here, $\mathbf{W}_3 \in \mathrm{R}^{d_{\text{model}} \times d_{\text{ff}}}, \mathbf{W}_4 \in \mathrm{R}^{d_{\text{ff}} \times C}, \mathbf{b}_3 \in \mathrm{R}^{d_{\text{ff}}}, \mathbf{b}_4 \in \mathrm{R}^{C}$. The deep classification head enhances the model's classification capability through additional linear layers, layer normalization, and nonlinear activation functions. Dropout operations effectively mitigate overfitting, improving the model's generalization performance on test data. The softmax function



ensures that the output forms a valid probability distribution, making it suitable for multi-class classification tasks.

III. Analysis of Human Activity Perception Data



The proposed method facilitates efficient and accurate human activity recognition. The HAPT (Human Activity Recognition Using Smartphones) dataset [26], a widely adopted benchmark in HAR research, and available through the UCI Machine Learning Repository, captures diverse daily activities using smartphone-embedded inertial sensors. The dataset comprises time-series signals collected at 50 Hz from a waist-mounted smartphone, including: triaxial accelerometer data (X/Y/Z axes) quantifies linear acceleration patterns associated with body movements such as walking, sitting, or transitioning between postures. Triaxial gyroscope data (X/Y/Z axes) measures angular velocities to characterize rotational dynamics during activities like turning or limb motion. This multimodal sensor fusion provides complementary kinematic representations, enabling robust activity classification while maintaining temporal granularity critical for motion analysis. The standardized sampling protocol ensures consistent signal resolution across all recorded activities. The dataset for this study was collected from 30 volunteers aged between 19 and 48 years. During the experiments, a Samsung Galaxy S II smartphone was securely placed at the waist of each participant. This specific placement was chosen to optimize the capture of core trunk movements, thereby facilitating a more accurate recognition of whole-body activities. Participants were instructed to perform 12 predefined daily activities, each explicitly labeled. Fig. 2 illustrates the triaxial accelerometer and triaxial gyroscope signals recorded from one participant during an activity. The raw signals were preprocessed for noise reduction using a median filter and a third-order low-pass Butterworth filter with a cutoff frequency of 20 Hz. The clarity and distinctness of these signals demonstrate the smartphone's capability to accurately and effectively capture human motion data during activities. This provides compelling evidence for the feasibility of using smartphones as a robust tool for human activity recognition.

The complete dataset comprises a substantial volume of sensor readings. Following meticulous preprocessing and segmentation, these readings are transformed into a large collection of time-series samples. Data segmentation involves dividing continuous sensor data into fixed-length windows, typically 2.56 seconds (equivalent to 128 sampling points). Overlapping between windows is often employed to ensure each window comprehensively captures complete activity information. During the feature extraction phase, a diverse set of time-domain and frequency-domain features is extracted from the raw accelerometer and gyroscope signals for each 2.56-second window. These features are specifically designed to encapsulate the unique patterns associated with different human activities.

Following the crucial feature extraction step, each individual time window is successfully transformed into a high-dimensional feature vector. For instance, in the HAPT dataset, each such sample is represented by 561 carefully selected features, and these high-dimensional vectors subsequently serve as input data for training and inference with various machine learning models. To offer a more intuitive perspective, allowing for a clear understanding of the unique distribution patterns of these feature values across different activity types. Fig. 3 illustrates the 561 feature values for a single sample within a specific activity class. From the visual representation in this figure, it is evident that all 12 distinct human activity types, including walking, ascending stairs, descending stairs, sitting, standing, lying, and a range of complex transitional movements (such as standing-to-sitting, sitting-to-standing, sitting-to-lying, lying-to-sitting, standing-to-lying, and lying-to-standing), exhibit notably distinct feature curves. Specifically, when the human body is engaged in dynamic physical activities, the extracted feature values tend to be quantitatively higher. Conversely, when the body is in a static or non-moving state, such as sitting or lying, the corresponding feature values are generally observed to be at lower levels. A particularly interesting phenomenon is observed during standing posture, where the distribution of feature values demonstrates an intriguing duality: approximately half of the feature values display relatively high magnitudes, while the other half are comparatively smaller. Although these differences in feature values indeed provide a basis for distinguishing between various activity types and demonstrate a certain discriminatory capability, recognizing the inherent and significant inter-individual variability in behavioral characteristics, we acknowledge the limitations of existing methods. Therefore, future research urgently needs to develop more advanced and intelligent methods and algorithms to achieve more accurate and faster recognition and classification of human physical activity types, thereby better adapting to the complex and diverse patterns of human movement in real-world scenarios.

Fig. 3. Display of characteristic curves of different types of activities.

The class distribution of the dataset utilized in this study is presented in Table I. The training set comprises 7,767 samples, while the test set contains 3,153 samples, yielding a split ratio of approximately 2.46:1. This partitioning is considered reasonable and aligns with conventional machine learning data splitting standards, such as 70%-30% or 80%-20% distributions. Within the dataset, Classes 1 to 6 are identified as major categories, exhibiting substantial sample sizes. Specifically, each of these classes contains over 1,000 samples in the training set and more than 400 samples in the test set, collectively constituting the vast majority of the data. Conversely, Classes 7 to 12 are designated as minority categories, characterized by extremely sparse sample representation. For instance, the training set for minority classes contains no more than 90 samples each, and the test set no more than 50 samples each. Notably, Class 8 is the most underrepresented, with only 23 samples in the training set and 10 samples in the test set, indicating a severe class imbalance issue within the dataset.

To elaborate, the largest class, Class 5, contains 1,423 samples in the training set, which is 62 times larger than the smallest class, Class 8, with only 23 samples; a similar disparity is observed in the test set. Furthermore, the combined total of minority classes (Classes 7 to 12) accounts for only 4.5% of the total samples in the training set and 5.3% in the test set. This extreme imbalance implies that conventional evaluation metrics, such as overall accuracy, may be predominantly influenced by the majority classes, thereby potentially masking performance deficiencies on the minority classes. It is worth noting that the proportion of samples for each class is largely consistent between the training and test sets. For instance, Class 1 accounts for 15.8% of the training set and 15.7% of the test set. This consistency suggests that the data partitioning maintained distributional uniformity, effectively mitigating potential biases introduced by the split. Nevertheless, the dataset presents a small-class risk: certain minority classes, such as Classes 8, 10, and 12, possess extremely low sample counts in the test set (no more than 27 samples each), which could lead to significant volatility in evaluation results. Overall, the dataset exhibits a pronounced long-tail distribution, where the insufficient number of samples in minority classes may constrain the model's generalization capabilities.

TABLE I. ANALYSIS OF THE CLASS DISTRIBUTION OF THE DATASET

Class	Train dataset	Test dataset
1	1226	496
2	1073	462
3	987	420
4	1293	508
5	1423	556

7	47	23
8	23	10
9	75	32
10	60	25
11	90	49
12	57	27
Total	7767	3153

IV. COMPARATIVE TESTING AND ANALYSIS

A. Model Training and Evaluation

In order to fully verify the accuracy and feasibility of the proposed method, human perception data is used to update the constructed recognition network. In addition, three other classic machine learning algorithms were used for comparison. The assessment results are shown in Table II. All evaluated models demonstrated excellent performance on the training set, clearly indicating their strong ability to fit the training data. Specifically, Random Forest achieved 100% accuracy, precision, recall, and F1-Score on the training set. While its training performance was perfect, a significant drop in performance on the validation set strongly suggests severe overfitting. In contrast, Long Short-Term Memory (LSTM) networks, and vanilla Recurrent Neural Networks (RNNs) maintained metrics between 97% and 98% on the training set, performing well but slightly below Random Forest. Of particular note, Transformer2 (employing a class-balancing strategy) exhibited near-perfect performance on the training set, with an accuracy of 99.95%. This is likely attributable to the adopted class-balancing strategies, such as oversampling or weighted loss, which enabled the model to better learn and recognize minority classes, thereby improving overall training effectiveness.

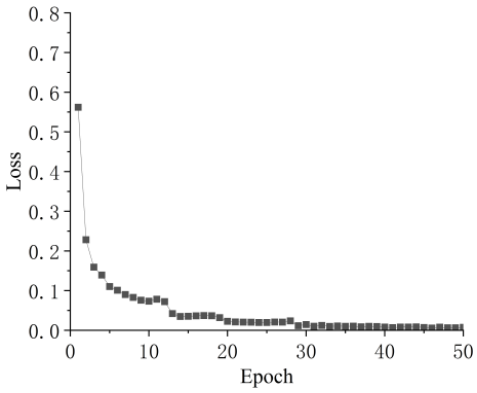

TABLE II. COMPARISON OF THE EVALUATION EFFECTS OF DIFFERENT RECOGNITION ALGORITHMS

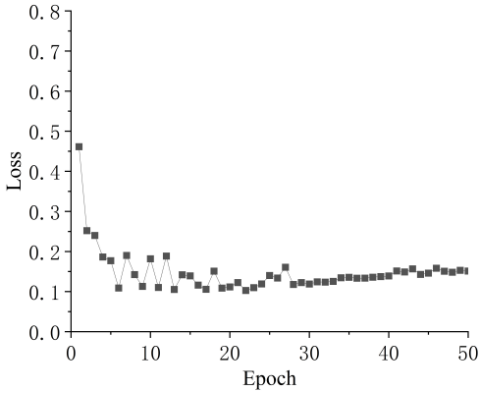
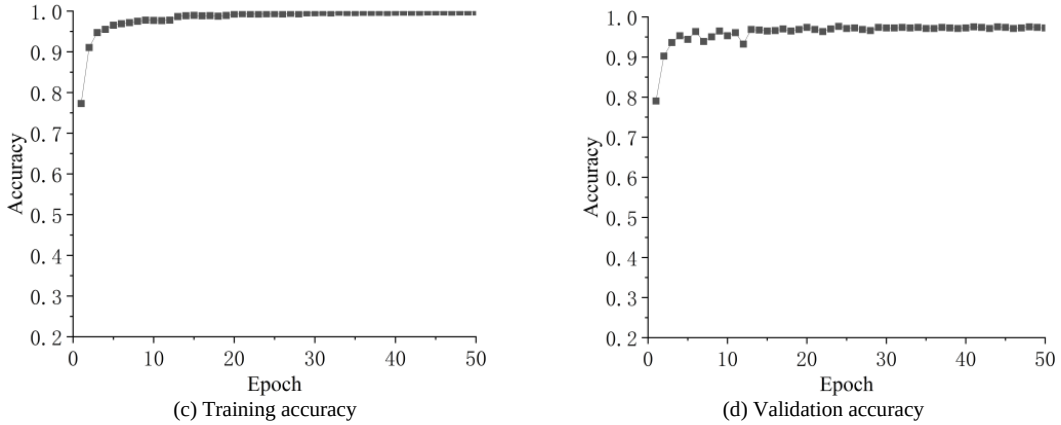
Methods	Training process				Validation process			
	Accuracy	*Precision*	*Recall*	*F1-Score*	*Accuracy*	*Precision*	*Recall*	*F1-Score*
Random forest	**1**	**1**	**1**	**1**	**0.9083**	**0.9095**	**0.9083**	**0.9074**
LSTM	**0.9799**	**0.9810**	**0.9799**	**0.9799**	**0.9230**	**0.9247**	**0.9230**	**0.9226**
Vanilla RNN	**0.9813**	**0.9819**	**0.9813**	**0.9813**	**0.9241**	**0.9273**	**0.9241**	**0.9232**
Transformer	**0.9776**	**0.9784**	**0.9776**	**0.9766**	**0.9247**	**0.9280**	**0.9247**	**0.9238**
Transformer2 (class-balanced)	**0.9995**	**0.9995**	**0.9995**	**0.9995**	**0.9397**	**0.9404**	**0.9397**	**0.9396**



Performance on the validation set more accurately reflects a model's generalization capability—its ability to handle unseen data. Random Forest's performance significantly declined on the validation set, with an accuracy of only 90.83%, a stark contrast to its 100% training performance. This further confirms its severe overfitting, rendering the model unsuitable for direct real-world application. The LSTM model performed relatively well on the validation set, achieving an accuracy of 93.30%, outperforming vanilla RNN. This indicates that LSTMs have an advantage in processing sequential data, particularly in capturing long-term dependencies. Vanilla RNN model showed comparable performance on the validation set, with accuracies around 92.4% to 92.5%, but slightly trailed LSTM. Vanilla RNNs' performance might be limited by long-range dependency issues, while the standard Transformer's optimization might be insufficient with limited data, preventing it from fully realizing its potential in sequential data processing. Most notably, Transformer2 (class-balanced) achieved the best performance on the validation set, with an accuracy of 93.97%. Furthermore, this model also showed the smallest performance gap between the training and validation sets, dropping from 99.95% to 93.97%. This result strongly demonstrates the effectiveness of the class-balancing strategy, as it not only significantly mitigated overfitting but also substantially enhanced the model's generalization capability, allowing it to handle imbalanced datasets more effectively.

In summary, while Random Forest achieved 100% accuracy on the training set, it only managed 90.83% on the validation set, indicating severe overfitting. This might be due to the tree-based model's oversensitivity to noise in the training data. The Transformer2 (class-balanced) model demonstrated the best generalization capability, exhibiting the smallest performance gap between its training and validation sets. This highlights the crucial role of class-balancing strategies in improving a model's generalization performance on imbalanced datasets. Among other sequential models, LSTM outperformed both vanilla RNN and the standard Transformer, suggesting that on moderately sized datasets, LSTM's sequential modeling capabilities still hold a significant advantage. Furthermore, this study clearly indicates that class-balancing strategies can significantly enhance the Transformer model's generalization performance, especially in handling minority classes more favorably and robustly.



To provide a more intuitive understanding of the training and validation processes of the proposed method, relevant evaluation curves are presented in Fig. 4. As depicted in the loss curve shown in Fig. 4(a) and Fig. 4(b), the training loss value decreases rapidly with an increasing number of training epochs. By approximately 30 training epochs, the training loss value has essentially approached zero and remains highly stable thereafter. The validation loss also gradually stabilizes around 0.1 at approximately 30 training epochs. Although some fluctuations are observed subsequently, the validation loss consistently remains within the vicinity of 0.15. This indicates that the model's fit on the validation set has reached a relatively stable state.

(a) Training loss

(b) Validation loss

(c) Training accuracy (d) Validation accuracy

Fig. 4. Training and validation process of the proposed method.

Further analysis of the training accuracy curve in Fig. 4(c) reveals that the model's accuracy on the training set exceeded 0.95 when the training epochs were merely 10. It then continued to improve, gradually stabilizing and ultimately approaching 1. Similarly, as shown in the validation accuracy curve in Fig. 4(d), the model's accuracy on the validation set reached approximately 0.95 at just 10 training epochs. Despite slight subsequent fluctuations, the validation accuracy consistently remained stable around 0.95. Overall, these curves collectively demonstrate that the method proposed in this study exhibits rapid convergence in the early stages of training and achieves high performance levels on both the training and validation sets. The swift convergence of training loss to near zero, coupled with the stable fluctuations of validation loss, indicates that while the model effectively learns features from the training data, it also possesses a commendable degree of generalization capability. The consistent stability of the validation accuracy around 0.95 further corroborates the model's robustness and effectiveness.

V. Discussion and Analysis

To provide a more comprehensive analysis of the strengths and weaknesses of the proposed method, we conducted a detailed calculation of evaluation metrics for each activity class within the test set. The assessment results are shown in Table III. This approach effectively illustrates where the proposed method excels in recognition and where its performance is suboptimal. Overall, the classification model demonstrates excellent performance on the majority of classes, particularly those with higher support, but exhibits instability on categories with lower support, revealing a clear dependency on data availability.

The proposed method performs exceptionally well on high-support categories, namely Classes 1 to 6. These classes possess a relatively large number of samples, with each class having a support of over 400 samples. Across these activities, the model's precision, recall, and F1-Score are generally high. Notably, Classes 1, 2, 5, and 6 all achieved F1-Scores exceeding 90%, with Class 6 performing best at an F1-Score of 98.32%, indicating near-perfect classification. However, for Class 3, despite an exceptionally high precision of 98.88%, its recall was relatively low at 84.05%. This suggests that the model is highly strict in its predictions for this class, potentially leading to a certain degree of missed detections. To balance precision and recall, future adjustments to the classification threshold could be considered to improve recall for this category.

TABLE III. Evaluation Effect of Each Type of Human Activity

Class	Precision	Recall	F1-Score	Support degree
1	0.9215	0.9940	0.9564	496
2	0.8920	0.9654	0.9272	462
3	0.9888	0.8405	0.9086	420
4	0.9287	0.8720	0.8995	508
5	0.8798	0.9478	0.9126	556
6	1	0.9670	0.9832	545
7	0.8421	0.6957	0.7619	23
8	0.7692	1	0.8696	10

In contrast to the high-support categories, the proposed method's performance on low-support categories, namely Classes 7 to 12, was relatively poor and unstable. These classes have fewer samples, with each class having a support of less than 50 samples, leading to significant fluctuations in the model's evaluation metrics. For instance, in Class 8, although the model's recall was remarkably high at 100%, indicating its ability to capture all true positive samples, its precision was only 76.92%. This suggests a high false positive rate, where the model incorrectly identifies some samples as belonging to Class 8 when they do not. Furthermore, Class 9 exhibited low precision and recall, at 67.86% and 59.38% respectively, resulting in an F1-Score of 63.33%, the lowest among all categories. This clearly indicates that the model's discriminative ability for Class 9 is relatively weak. This instability primarily stems from insufficient data, as the model was unable to adequately learn the crucial features of these minority classes, leading to reduced generalization capabilities.

It is important to note that some categories, such as Classes 3, 8, and 12, exhibit an imbalance between precision and recall. This suggests that the model's classification thresholds may require optimization. Specifically, for categories with high precision but low recall (e.g., Class 3), the classification threshold could be appropriately lowered to improve recall while maintaining reasonable precision. Conversely, for categories with high recall but low precision (e.g., Class 8), the classification threshold could be raised to reduce false positives and enhance precision. While the model demonstrates excellent performance on data-rich categories, there remains significant room for improvement in its recognition effectiveness for small-sample categories. Future optimization efforts should focus on increasing the data volume for minority classes and further refining the model's classification strategies, for example, by adjusting classification thresholds or employing cost-sensitive learning. These measures aim to comprehensively enhance the model's overall performance, particularly its robustness in handling imbalanced datasets.

From the above analysis, it can be seen that the method proposed in this study combines the data balance strategy with the Transformer model. Compared with traditional machine learning methods, it shows significant advantages in recognition accuracy. Although Reshmi et al. [27] proposed a recognition method based on feature selection, their work did not fully consider the impact of data imbalance on model performance. Pavliuk et al. [28] focused on exploring the application of transfer learning in the task of human activity recognition and did not delve deeply into the issue of unbalanced category distribution either. In fact, the problem of data imbalance is widely present in sensor-based activity recognition tasks, which can easily lead to the model being biased towards the majority of classes and a decline in generalization ability. Therefore, it must be fully considered in the method design stage. This study effectively alleviates this problem by introducing a balance strategy, thereby enhancing the robustness and recognition accuracy of the model in real scenarios.

VI. Conclusion

This study proposes a deep learning-based smartphone physical activity recognition framework, designed to address the prevalent decline in physical activity among college students. The framework's innovation lies in its utilization of high-precision Inertial Measurement Units (IMUs) embedded in smartphones to capture multi-dimensional real-time body postures during daily activities. It then employs an advanced Transformer architecture as the core classifier. The Transformer's unique Self-Attention Mechanism effectively extracts complex spatiotemporal features from sensor data, enabling precise recognition of various physical activities (such as walking, running, and climbing stairs). This integrated approach of intelligent sensing and advanced algorithms provides a reliable and efficient technological solution for monitoring college students' physical activity.

1) After achieving 99.95% on the training set, the Transformer2 (class-balanced) model maintained an accuracy rate of 93.97% on the validation set. The minimum performance gap between the training set and the validation set strongly demonstrates its excellent generalization performance and ability to handle imbalanced datasets.

2) The recognition accuracy rate of the Transformer2 (Class Balance) model is 93.97%, which is superior to 93.30% of LSTM, approximately 92.4%-92.5% of vanilla RNN and standard Transformer, and 90.83% of Random Forest.

3) The recognition accuracy of high-support categories is very high, but low-support categories remain challenging. Our model achieves extremely high recognition accuracy for highly supported categories (categories 1-6, with over 400 samples in each category). However, for the low-support categories (7-12 categories, with less than 50 samples for each category), the performance of the model fluctuates greatly.

4) The class balance strategy effectively enhances the robustness of the Transformer model. Although this numerical improvement seems small, it indicates that the model is more robust when dealing with minority classes, significantly reduces overfitting caused by data imbalance, and improves the overall generalization performance.

5) This model has a fast convergence speed and stable verification accuracy in the early stage of training. This indicates that the model has efficient learning ability and good stability, and can achieve a high-performance level within a relatively short training time.

The proposed method remains dependent on data augmentation or supplementary samples to improve recognition performance for minority classes, without fundamentally resolving the underlying data scarcity challenge. Although the class-balancing strategy enhances model robustness when handling minority categories, the limited magnitude of overall performance improvement indicates that the current approach still exhibits insufficient efficacy in addressing severe class imbalance scenarios, suggesting significant potential for further refinement. Future research will focus on further improving the model's recognition performance for low-support activity categories. Explore more advanced data augmentation technologies to expand the sample of ethnic minorities. The meta-learning or Few-Shot learning methods are studied to enable effective learning even under sparse data. Additionally, we will consider extending this framework to more complex body activity pattern recognition and exploring its potential applications in long-term health monitoring and personalized health intervention.

***Abstract*—Predicting Sea level rise accurately is crucial in the formulation of effective adaptation plans to counteract the effects of climate change in vulnerable coastal areas, infrastructure, and people. The conventional forecasting models tend to fail in capturing the intricate spatiotemporal relationships affecting sea level variations. In order to overcome the above-mentioned challenges, this research introduces a hybrid predictive model combining a Temporal Graph Convolutional Network (T-GCN) with attention and game theory-based optimization strategy. T-GCN structure is specially tailored to capture spatial dependencies as well as temporal dynamics in sea level change, providing even deeper understanding of the changing dynamics of sea levels. The attention mechanism strengthens the model by dynamically weighing important variables, whereas the game-theoretic optimization efficiently optimizes multiple objectives, e.g., prediction accuracy and robustness. Experimental results, measured in terms of common performance indicators, show the better effectiveness of the proposed model with a correlation coefficient of 0.996512 and an overall error of 0.032154. Through the inclusion of both climatic and socio-economic variables, this methodology provides accurate, data-based insights to inform climate policy and adaptive planning. The results highlight the capabilities of state-of-the-art machine learning methods for solving actual sea level rise challenges.**

Keywords*—*Temporal graph convolutional networks; attention mechanisms; game theory optimization; sea level rise prediction; climate change adaptation

I. Introduction

Melting of ice possesses a creeping threat of global significance with potential impacts and effects on any coastal area, population, structures, and ecosystems [1], [2]. Since the late 80s, the climate of the earth has been changing because of various anthropogenic factors for instance emission of greenhouse gases and deforestation and as expected the polar ice caps and the glaciers are melting [3], [4]. This phenomenon is now becoming a severe danger to millions of the lowland people, especially those in developing and overpopulated coastal zones. These several impacts of sea level rise are diverse: there are storms and their consequences such as frequent and severe floods, more powerful storm surges and also rapidly progressing coastal erosion [5]. While such changes in physical environment can result in loss of people's homes, loss of animal and plant habitats, destruction of valuable ecosystems like mangrove forests and corals that offer protection against storms [6]. In addition, sectors that depend on the coasts and sea, for instance, fishery, tourism, and shipping business experiences difficulties and higher expense charges. Most of the designed infrastructure of roads and bridges, sewage systems without which no urban development is complete, require heavier investment and modifications to withstand the prevailing and projected climate change [7].

However, when it comes to predicting sea level increase something that is so important and mandatory in the contemporary world, the traditional models fail to address the issue in a proper way. Sea level fluctuation depends on the number of factors which are interrelated and interconnected: pressure at sea level, currents at sea level, and tectonic activity [8]. These interactions produce a very complex environment that appears as being programmed and organized in which shifting one factor can influence other related factors in a rather unpredictable manner [9]. For instance, changes in pressure may affect currents and the circulation of the ocean, and movements in the earth's crust may change sea level through vertical movements of the land mass [10]. Issues concerning flexibility, capacity utilization, uncertainties and seasonality are some of the complexities that the conventional methods cannot capture

easily since they depend mostly on the past data trends, which have a linear relationship. Thus, they give predictions that are rather too simplistic and can be quite off base, underestimating or even overestimating dangers that might come with the rise in sea level. Mainstream statistical and physical approaches fail to adequately capture a relationship between these factors because the typical applied parameters are not specific enough to capture the differences of coastal areas [11]. Coastal sea level management entails the physical alterations, proposed structures, and noticed events to reflect the response of the interested groups, such as the residents, business holders, ecological nature lovers, and policy makers. Both of these are crucial in comprehending the socioeconomic and cultural effects of sea level changes as well as in creating effective and fair response measures towards these changes. However, conventional models are mostly often distributed in terms of physical and environmentally related information devoid of more human factor aspects of the sea level [12].

1) Research motivation: CNN are specifically preferred for spatial pattern recognition, but in the event of a temporal sequence, their efficiency is greatly diminished with a result of creating likely errors in the forecasted values [13]. Originally, the T-GCN to analyse sea level rise are very efficient, where the data are described based on the graphs that nodes are used for spatial features while the edges focus on time features [14]. T-GCNs are less inclined towards computational efficiency, and sometimes it can cause scalability issues whenever dealing with big data sets. They also need to be fine-tuned due to the trade-off they create between the spatial and temporal dimensions, which can be difficult in some cases. In the other hand, it is useful to learn which features should be paid more attention, improve the model's temporal and spatial consideration. However, when the attention mechanism is applied separately, the overfitting occurs as it pays much more attention to the certain features while there might be other relevant features in some other context also equally important [15]. Moreover, attention mechanisms might not have the considerations of the spatial relation of the data which is important for sea level analysis. Such limitations call for the blended approach that use the strong characteristics of these methods while avoiding their related drawbacks. By connecting T-GCNs, attention mechanisms, the model developed in this article assumes to offer a more precise and complete solution for forecasting sea level rises.

2) Research significance: With the deficiency of conventional sea level rise prediction models, this paper suggests a new scheme that adopts game theory-based optimization, a self-attention mechanism, and T-GCN. T-GCNs are powerful in extracting intricate spatiotemporal information, and the self-attention mechanism allows the model to dynamically focus on the most relevant features. By adopting elements of game theory—mimicking strategic choice making and reconciling conflicting factors—the forecasting ability of the model is greatly improved. The combination of these methods leads to more robust, accurate, and actionable forecasts, providing valuable inputs to enable effective coastal adaptation planning.

3) Research contribution: The following are the contributions of this research;

a) This paper introduces a new hybrid model that integrates T-GCN, attention mechanisms, and game theory-based optimization to enhance the precision of sea level rise predictions.

b) The suggested framework efficiently describes spatial dependencies and temporal patterns from multivariate sea level datasets in a better manner than the traditional isolated deep learning techniques.

c) Attention mechanisms are used to dynamically emphasize and prioritize important spatial and temporal features, increasing interpretability of the model and concentrating attention on the most influential variables.

d) Game-theoretic approaches are employed to maximize trade-offs between two or more conflicting objectives—e.g., prediction performance and model resilience—and thus reduce overfitting and enhance generalizability overall.

The rest of the paper is organized as follows: Section II overviews related work. Section III presents the background to the study and formulation of the problem statement. Section IV outlines the method that has been proposed. In the Section V of the paper we present the experimental results and then compare them. Section VI provides the last and final conclusion of the paper and points out for the future work.

II. Related Work

According to Memarian Sorkhabi, Shadmanfar, and Al-Amidi [16] climate change was a global phenomenon and particularly the increase in sea level and frequency of floods had been recognized as one of the critical challenges for coastal cities. This study examined the temporal fluctuations of the sea-level which involves data like the SST originated from MODIS, wind speed and precipitation rates, and the change in the sea-level acquired through satellite altimetry. A weighted combination of values created a context vector that impacts the end output. T-GCNs model intricate spatial-temporal patterns, and attention boosted significance in features for accurate, area-based predictions in climate adaptation.lts and various forms of forecasting, which might not have taken into perspective all potential factors influencing the future environment. They could have been affected by the nature and resolution of the inputs used in making the prediction and there could be unknown climatic and socio-economic factors that could affected the sea level rise and floods on the resilience of cities on the coastline.

Accarino et al. [17] analyzed the effectiveness of LSTM neural network for short-term sea-level forecasting for the SANI region of the Mediterranean Sea. The work was described by multiple of models that used LSTM networks aimed at the three-day mean sea level forecast for a set of coastal regions. Concerning the evaluation of the projections, the latter were compared to observation data stemming from tide-gauge instruments and to the outputs from another model called SANIFS that had been designed at the Euro-Mediterranean Center on Climate Change. The incorporation of the LSTM-

based forecasting models into the Ophidia HPDA system, would open up a vast potential of adding capabilities of carrying large scale Time Series data and functioned in realization through application of HPC and Data science capabilities. The enhancement of these reasons could have resulted in greatly improved sea level prediction models in the future.

Prediction performance analysis carried out by Altunkaynak and Kartal [18] involved applying and comparing the results of various ML models based on sea level time series data obtained under different conditions. This study used DWT to analyze three stations in the Bosphorus Strait, and using SVM, k-NN, and DT to transfer sea level signal among the stations for their regions. The models applied were compared according to their performance in as far as predicting sea levels up to 7day in advance by subjecting them to RMSE and NSE tests. The findings showed that the developed models had higher competence in transferring information from one station to the next when the station is in the proximity as opposed to when stations were periodically close. One of the studies' drawbacks partly stemmed from its limited focus, which made it difficult to apply the findings to other areas or settings.

Raj [19] employed the first China's global ocean CDRs to evaluate and forecast changes in the Yellow Sea levels that significantly varied by season. With the help of the SSA method, it was suggested to analyze the characteristic and de-noise spatiotemporal and SLAs time series data in the Yellow Sea. The research then used SSA to build an SSA based model called SSA-LSTM for forecasting trends in sea level. 04 mm for the SLA time series prediction while the RMSE was found to be 19. 68 mm for the one-year spatiotemporal SLA forecast. There were also certain limitations in this research: The data set used in this research is limited to China's first global ocean CDRs and it only examined the Yellow Sea so the application of SSA-LSTM combined model would have been slightly different when studied on other areas with different ocean and climatology processes. Furthermore, the study does not explore any interference from other external factors, including the climatic fluctuations that always occur in the world, which may in one way or the other influence the sea levels, and this therefore undermined the strength and applicability of the forecast made in other or different setting.

Zhao, Cai, and Sun [20] discussed the contemporary issue of SLR that still posed a threat to small island states such as the Kiribati and Tuvalu among others; this attested to the need to enhance the reliability of data provided in advance of policy measure. The model was benchmarked against three other AI models: Some of the boosting technique out of which are adaboost, and multilinear regression. It was mentioned at the two places measures that it presents the least error rates. Applying, for instance, the trend analysis applied to gradual change, based on the linear regression, the GNSS-VLM-corrected long-term mean sea level increase is at 2. The rate of absolute sea level rises according to the estimated for Kiribati was 1mm/year while that of Tuvalu is 3mm/year.

Raj et al. [21] explained a novel technique for estimating sea level rise in the future that was based on tide gauge stations in Darwin and Milner Bay in Australia's Northern Territory. For this study, the investigated data included mean sea level data on BOM associated with the time period between 1990 and 2022. The study modeled data using four artificial intelligence techniques: SVR, AdaBoost, MLP, and CNN-BiGRU were the best performing algorithms in descending order. The MSL interpretation revealed that the same was 6 on an upward trend showing that the increase in materialism was influencing the consumers. 1 ± 1. It was considered that one of the weaknesses of this research was the fact that there were limited numbers of tide gauge locations in the Northern territory and therefore results and predictive models might not have been applicable in other climatic regions with have different oceanographic features.

Existing studies on sea level rise (SLR) prediction incorporate a combination of hybrid and machine learning algorithms with different strengths and weaknesses. The sea surface temperature and sea level height are increasing, as per a study on Gothenburg; however, its limitation lies in its reliance on historic data, which may cause underestimation in the future. While accuracy is impaired by the lack of high-frequency data and key parameters, LSTM models have proven to be more accurate. SVM and KNN performed better than traditional models in the Bosphorus Strait, but only within a limited geographic area. The SSA-LSTM models of the Yellow Sea are very accurate, but they are not generalizable beyond the region in question. Similarly, local environmental considerations are highlighted in BiLSTM applications for small island nations. Though constrained by sparse tidal gauge data, a new model in northern Australia that applied data decomposition and AI methods gave promising results. For more accurate and scalable predictions of SLR, these papers as a group point to the need for bigger, regionally adaptive models considering a range of environmental variables.

III. Problem Statement

Accurate forecasting of sea level rise is vital for effective coastal management; however, traditional approaches often rely heavily on historical data [22], overlooking future uncertainties and critical climatic or socio-economic factors [23]. To overcome these constraints, this research proposes a new method that incorporates T-GCN, attention mechanisms, and game theory-based optimization. T-GCNs are well suited to capture the intricate spatiotemporal dependencies inherent in sea level observations, while the attention mechanism chooses important time periods and spatial coordinates. Game theory optimization further improves model performance by imitating strategic interactions among important variables, tuning predictive results. This combined framework significantly enhances prediction accuracy, providing a robust and reliable instrument for backing long-term coastal resilience and adaptation planning.

IV. Methodology for Sea Level Rise Prediction Using Hybrid Methods

The interaction of sea levels with other parameters can be effectively predicted through the proposed methodology, which combines T-GCN, attention mechanisms, and game theory optimization. The process starts with the data where data from Kaggle of sea level change is then pre-processed by cleaning, normalizing from it and then subdividing it. Temporal and spatial features are reconstructed using a T-GCN model to

analyse the given data. To improve the prediction the attention mechanisms are used to increase the model's focus on the significant features. In federated learning approach, multiple clients participate and perform updates on the global model without accessing raw data. Game theory optimization extends the model by incorporating multiple objectives such as error frequencies and model overfitting. The above steps are then repeated several times till pre-specified convergence criteria are met and the final optimized model for predicting sea level rise is arrived. The proposed methodology is illustrated in Fig. 1.

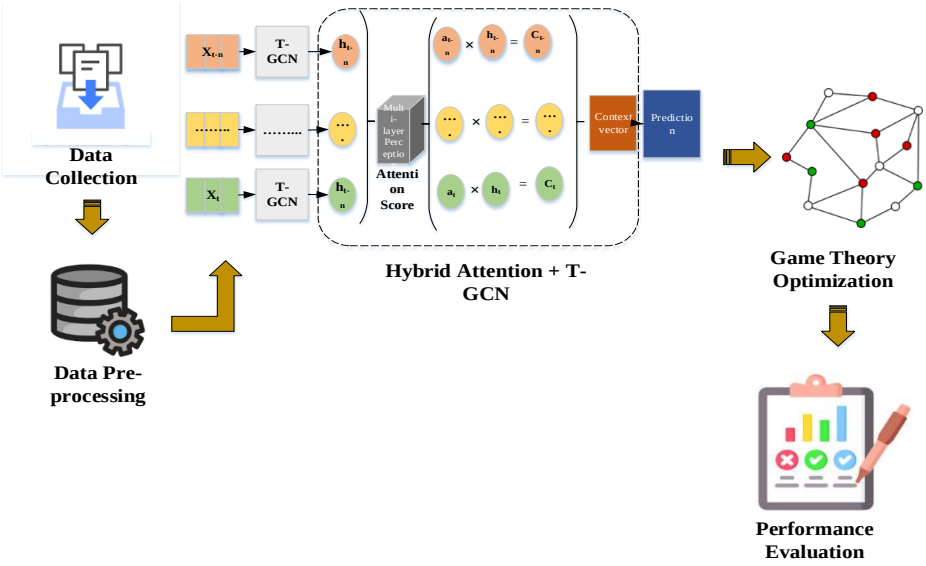

Fig. 1. Proposed methodology for sea level rise prediction.

A. Data Collection

The "Sea Level Change" Kaggle dataset [29], containing complete observations of sea level across a variety of geographic locations and historical time frames, is utilized in this study. Dates of measurement, sea level elevation, geolocation coordinates (latitude and longitude), and other climatic parameters such as temperature and precipitation are all present in the dataset. Sea level change has a huge coverage in terms of time, and thus is easier to understand long term trends and patterns in it. This research is seeking to improve the quality of predictions of sea level change with the data provided by attention and T-GCNs.

B. Data Pre-processing

The pre-processing ensure the data quality and useability in order to predict sea level rise using either mean or KNN imputation for missing values and outlier detection processes including the Z-score method to remove outliers. The next stage is normalizing the values of features using either a Min-Max Scale or Z-Score Normalization. Finally, temporal and geographical adjustments are used to synchronize data between uniform time intervals and uniform spatial resolution. These techniques are a part of the pre-processing procedure to ensure that the dataset is conducted properly for features to be extracted, and for predictive modeling.

1) Handling missing values: Handling missing values is an important step in data preprocessing to guarantee data trustworthiness. KNN addresses this problem by estimating the missing values with a weighted average of k nearest instances, based mainly on Euclidean distance. Weights are inversely proportional to distances, assuming that nearby data points have similar values. This method preserves size of data and natural data rhythms for providing quality assured data for an future analysis and model, as shown in Eq. (1) [24].

$$x_i = \frac{1}{k}\sum_{j=1}^{k} x_j \quad (1)$$

Where x_i are the values of k-nearest neighbors.

2) Data normalization: Min-Max normalization is a common transformation of calculations that make data range into a defined interval, most commonly [0,1]. This technique normalizes features so that the values lie between 0 and 1, while maintaining the relative position of the features data to each other and maximizing the importance of all features as they relate to the model characteristics. The normalization process is conducted by Eq. (2), [25]

$$X_{norm} = \frac{X - X_{min}}{X_{max} - X_{min}} \quad (2)$$

where the X is the value, X_{min} is the minimum value of a feature, whereas X_{max} is the maximum value of the feature. This transformation is most helpful in scenarios where the scale of features should be made consistent to enhance models' convergence as well as the performance of algorithms in the case of machine learning. This normalization becomes more important in a situation where the features have different units of measurement because this brings all of them to the same level so that the distance calculations and the training of the model will be favoured by all of the features. This can enhance the stability of the model and also increase its general performance by mitigating effects that come with the presence of features that are big and small in magnitude.

3) Temporal and spatial alignment: Synchronization: Data points are more reliable when they are obtained in harmonized

time intervals and spatial resolutions to avoid difference in results. This entails extrapolation of data, whereby the data is either interpolated or aggregated to correspond with the required frequency and location. For temporal alignment, interpolation which can be employed to approximate values in missing time points can be used. This is demonstrated by the following empirical Eq. (3), [26]

$$X_t = X_{t-1} + \frac{X_{t+1} - X_{t-1}}{2} \quad (3)$$

Where X_t represents the interpolated value at time t, X_{t-1} is the value at the previous time point, X_{t+1} and is the value at the subsequent time point.

C. T-GCN and Attention Mechanism for Feature Extraction and Classification

Sea level rise predictions need models capable of spatial dependencies between the coastal tracking stations and time series dynamics of the ocean processes. The current methods have certain limitations: (CNNs) are good in detecting spatial-based features but they lack the capability to incorporate sequential patterns, whereas (LSTMs) can capture temporal dependence patterns but not background spatial features. (GCNs) are strong at representational modeling of spatial structures but do not provide temporal modeling of evolving relationships and standalone attention mechanisms tend to over-fit due to disproportionate weighting of features. Such weaknesses make the traditional methods inadequate in capturing the highly nonlinear, and highly coupled nature of prediction of sea level rise. To overcome these shortcomings, the hybrid framework proposed has temporal GCN to learn spatiotemporal representations, attention mechanism to prioritize different features adaptively, and a game theory-based optimization strategy to balance tradeoffs between different objectives, hence enhancing robustness, accuracy, and generalizability in the coastal regions presented by different coastal environments.

The method of predicting sea level rise involves using dataset which contains sea surface temperature, wind speed, precipitation rates, and height. Then this data is pre-processed, where all the data is cleaned, normalized, and divided into train, validation and test sets. T-GCNs are then used to learn the spatial temporal structure and important features are then obtained. These features are then further brought through the use of attention mechanisms that aim to attend to important temporal and spatial details. Finally, the applicability of the hybrid model is evaluated in terms of RMSE, MAE and NSE with different level cross validation. The outcome that is expected from this approach is accuracy, completeness and flexibility of the numerical forecast of sea level increases.

1) T-GCN Model: In this section, the general structure of the algorithm is described as well as specifics of the actual algorithm utilized. For the purpose of modelling both spatial and temporal dependencies the model is used. The proposed model fuses the GRU and GCN. To model complicated geographical dependence, GCN is employed to capture the dependence of radar networks' topological structure and temporal dependence GRU is used to learn the dynamic evolution of radar networks. The multi-radar network's objective in this study is to forecast the radar feature at a given time utilizing network detection data. Any of the following can be the radar characteristic in this method: beam shaping, bandwidth, amplitude, centre frequency, or sampling rate.

a) Input layer: The input layer receives multi-different time chain data collected from the network of geographically distributed C-level monitoring stations. Each data example includes several parameters, such as sea level height, sea surface temperature, atmospheric pressure, wind speed and rainfall. These comments are structured in a temporary sequence and are locally connected, which means that each station is considered a node in a graph. The edges between the nodes represent spatial relationships – either geographical proximity or statistically learnt correlation (e.g., Pearson correlation or mutual information). This graph structure allows the model to understand how the sea level in one place can change or affect the neighbouring areas. The time series aspect ensures that the temporary development of these characteristics is preserved and can be effectively modelled by downstream components such as GCN and GRU layers.

b) GCN block: The graph is responsible for learning spatial dependence between sea level monitoring stations by taking advantage of the graph structure of block data. GCN block models spatial dependence between sea level monitoring stations. It is operated by collecting information about the facility from neighbours of each node based on the adjacent matrix A. Layer is defined as a graph conversion operation on l+1:[27]

$$H^{(l+1)} = \sigma(\tilde{D}^{-1/2}\tilde{A}\tilde{D}^{-1/2}H^{(l)}W^{(l)}) \quad (4)$$

In Eq. (4), the adjacency matrix with added self-loops were denoted as $\tilde{A} = A + 1$. The degree of matrix of $\tilde{A}$ is denoted as $\tilde{D}$. The input feature matrix at layer l is denoted as $H^{(l)}$ and the trainable weighted matrix is denoted as $W^{(l)}$ and finally the activation function is denoted as σ. Using an adjacency matrix, which defines the relationship between spatial nodes (stations), GCN collects information from immediate neighbours of each node. Through the resolution operation conducted on the graph, this block learns spatial representations by smoothing or mixing information in the nodes nearby, which is important to understand the regional dependence. For example, an increase in sea level at a station may indicate or affect the same pattern in nearby areas. By encoding this relevant spatial information, the GCN converts the feature vector of each node into a rich representation that captures how the local sea level behaviour is shaped by its spatial reference.

c) GRU block: The GRU block captures the temporary dependence of data by processing the sequence of spatial characteristics produced by GCN over time. GRUs are a type of RNN that are designed to handle long-term dependence in sequential data without suffering from missing gradients. They work using two gates: the update gate (z_t) determines how much previous information is retained, and the reset gate (r_t) controls how much time of the past is forgotten at each step.

Update Gate [28]

$$z_t = \sigma(W_z X_t + U_z h_{t-1} + b_z) \quad (5)$$

Reset Gate

$$r_t = \sigma(W_r X_t + U_r h_{t-1} + b_r) \quad (6)$$

These help the gate models to maintain a balance between remembering important historical trends and adapting to recent changes in data. By recurring through the stages of time, GRU learns sudden changes in temporary diversity, trends and sea level patterns. This can recall the model that simply models the model with a temporary awareness to predict future sea level values.

d) Hidden output: The final output of the GRU block is Hidden State, which enforces both spatial and temporary information learnt from data. This hidden position acts as a compact representation of a multi-compact time chain, briefly presenting the pattern seen in space (via GCN) and time (through GRU). This includes the required future features, such as the impact of neighbouring stations, historical sea level trends and the importance of different time intervals. The hidden state can be passed in later layers – such as a mediation mechanism, which refines further convenience, or directly predicts an increase in future sea levels for a prediction head (e.g., a dense layer or MLP). Its compact yet expressive nature ensures efficient modelling while maintaining all the necessary information for accurate and strong prediction.

Fig. 2 illustrates the T-GCN, which captures spatial-temporal relationships in graph-structured time series data by integrating GRU and GCN. GRUs employ hidden states h_t, regulated by reset R_t and update Z_t gates, to learn temporal patterns, whereas GCNs utilize spatial information from input nodes (X1–X4) to generate outputs (Z1–Z4). Due to its capacity to process dynamic spatial-temporal information, T-GCN is perfectly suited for sea level rise prediction with enhanced accuracy of forecasts.

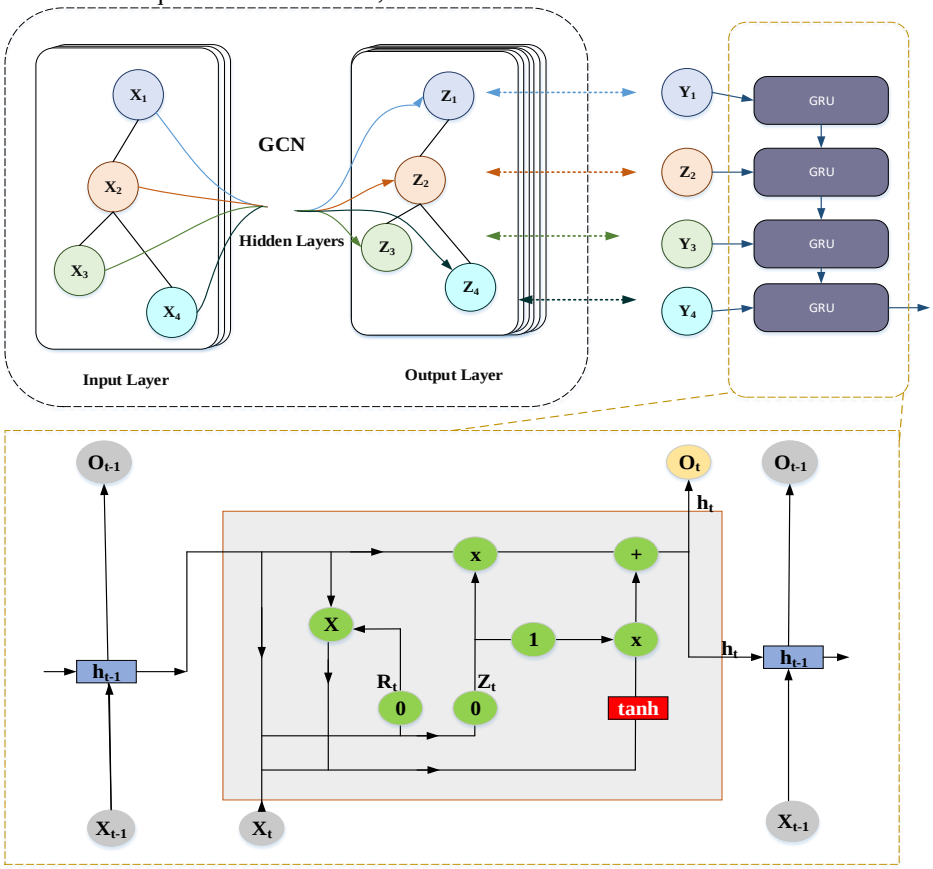

Fig. 2. Architecture of T-GCN.

2) Integration of hybrid temporal graph convolutional networks and attention mechanism: The proposed architecture enhances sea level rise prediction by integrating T-GCN with an attention mechanism. By representing geographic locations as graph nodes and employing graph convolutions to learn patterns over time, T-GCNs effectively simulate spatiotemporal dependencies. An attention mechanism that employs query, key, and value computations to assign higher weights to the most relevant spatial and temporal features is then applied to fine-tune the retrieved features. To emphasize critical information while suppressing less informative parts, attention scores are scaled by a SoftMax algorithm. As the final prediction layer runs over the improved features, the risk analysis for coastal planning is made more robust and accurate. The hybrid architecture is given in Fig. 3.

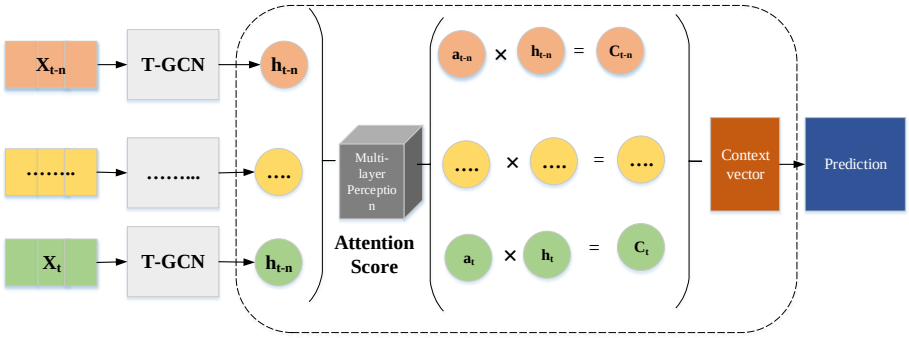

Fig. 3. Architecture of hybrid attention based T-GCN.

Fig. 3 depicts a hybrid model integrating T-GCN with attention for precise time-series prediction. Sequential input sequences from X_{t-n} to X_t are fed into T-GCN modules to learn spatial and temporal relationships, producing hidden representations. These are fed into a multilayer perceptron and an attention mechanism that places dynamic weights on every time step. A context vector is calculated by summing attention-weighted hidden states, focusing on pertinent temporal features. This context vector is utilized for prediction, allowing the model to provide solid and interpretable predictions for intricate spatiotemporal phenomena such as sea level rise.

Algorithm 1: Algorithm for Sea Level Rise Prediction Using T-GCN, Attention Mechanisms, and Game Theory Optimization

```
Begin
  Input: Dataset D, adjacency matrix A, time steps T, iterations K
  For each missing value in D
    Apply KNN imputation
  End
  For each feature in D
    Compute Z-score
    If |Z-score| > threshold Then
      Remove outlier
    End
  End
  Normalize features and align data temporally and spatially
  Define nodes V and construct adjacency matrix A
  For each time step t in T
    Build temporal graph Gt
    Apply GCN and GRU to extract spatiotemporal features
  End
  For each extracted feature
    Compute attention score
    If score > threshold Then
      Assign higher weight
    Else
      Assign lower weight
    End
  End
  Initialize k = 1
  While k ⩽ K
    Define objectives and update parameters
    Balance trade-offs using game theory
    Increment k
  End
  Repeat
    Extract features, apply attention, optimize
  Until stopping criteria satisfied
  Return predicted sea level values
End
  Output: Predicted sea level values
```

V. Results and Discussion

The research proves the effectiveness of the proposed T-GCN augmented with attention mechanisms and optimized using game theory approaches, leading to enhanced performance for sea level rise prediction compared to current models. The predicted values exhibit excellent correspondence to the actual measured values, which indicates the ability of the model to successfully extract prior spatial and temporal influences from the data. Moreover, the model reached a very low MAE for values, surpassing equivalent low prediction uncertainty. This serves to further demonstrate the advantage of combining temporal graph-based features with attention mechanisms to effectively incorporate complex spatiotemporal dependencies often inherent in sea level data sets.

A. Historical Trend of Global Average Sea Level Change Over Time

Fig. 4 shows the global, temporal evidence of sea level elevation, represented in millimeters (y-axis) over a time series (x-axis). The figure demonstrates a remarkable upward progression that indicates that sea levels continue to rise, at an ever-increasing rate. For the measured time frame, the sea level has risen by about 200 millimeters (about 8 inches), which points toward serious environmental issues. This increase has dire implications for coastal regions, such as saltwater intrusion into freshwater systems, higher frequency of flooding, more rapid coastal erosion, and population displacement near shorelines.

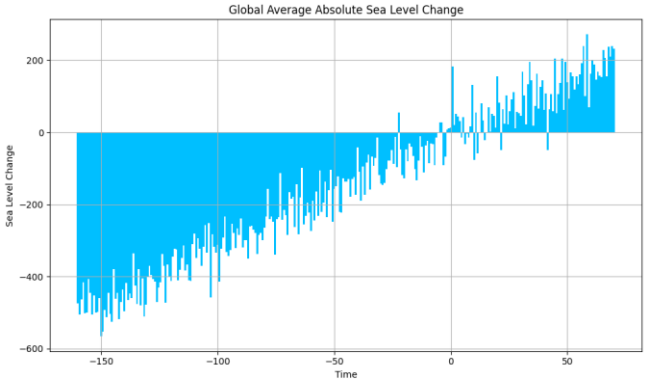

Fig. 4. Historical trend of global average sea level change over time.

B. Rolling Mean and Rolling Deviation of Sea Level Change Over Time

Fig. 5 presents a time series plot of the rolling mean and deviation, illustrating the overall trend and fluctuations in sea level change. The rolling mean shows an initial sea level decline from -200, gradually rising, crossing the x-axis at time 0, and reaching 200—indicating a clear upward trend over the period. Thus, while the mean shows a steady upward trend over the period, the rolling deviation remains relatively stable, indicating consistent variability around the trend. Sea level rise occurs as a continuous process, but the fluctuations around its rate remain relatively stable over time, indicating no consistent pattern of acceleration or deceleration in the short term.

C. Training and Testing Accuracy

Fig. 6 shows the accuracy curves for only the training and the testing phase of the improved Temporal Graph. Convolutional Network known as T-GCN over 100 epochs. Here the solid blue line stands for the training accuracy and the orange dotted line stands for the testing accuracy. At first, both increase significantly; training one rises above 100 % while testing one increases to nearly 90 % by about the 10th iteration. This means that the model gains a relatively fast adjustment to the patterns and relationships of the data. After this point, both the accuracies decrease a little and then become almost stagnant with the training accuracy being slightly higher than testing accuracy. Both accuracies for train and validate data are quite impressive and gradually rises until the 100th epoch, and are very close to the 100% and show model's capability of generalizing well though unseen data after number of epochs.

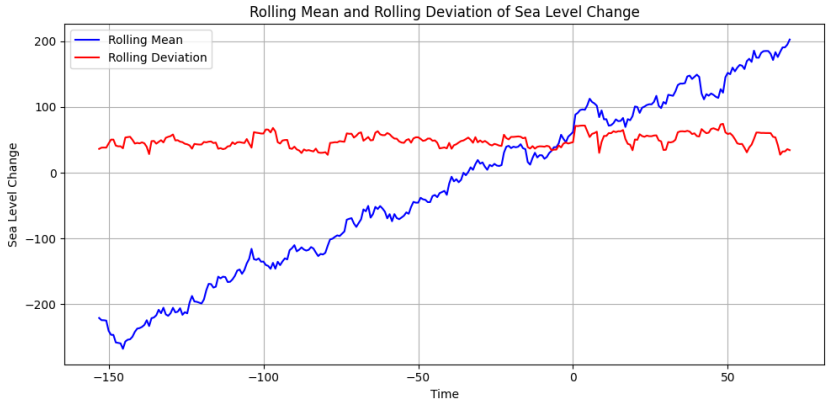

Fig. 5. Rolling mean and rolling deviation of sea level change over time.

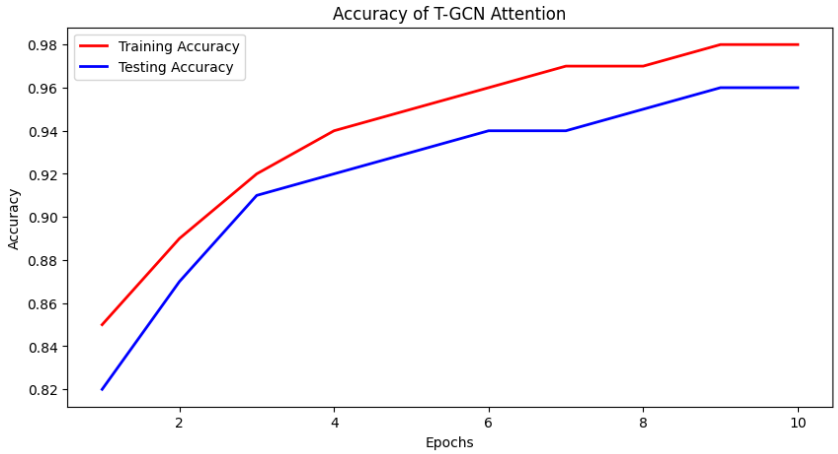

Fig. 6. Training and testing accuracy.

D. Training and Testing Loss

Fig. 7 shows the training and testing loss curves of T-GCN model with attention mechanisms on 60 epochs. The blue curve represents the training loss whereas, the orange line indicates the testing loss. First, both losses are high; the training loss is more than two for all the epochs except epoch 15. 5 and the testing loss is slightly less than 2. 5, which means great discrepancies in the predictions during the initial phases of the model training process. However, as the training process goes further both losses rapidly decrease, the training loss reaches even the negative values below 0. 5 in the 10 th epoch and the testing loss which also trended downward in the same way. As for epoch 30, both the training and testing losses reduce continuously and smoothly which almost reached the testing value equal to zero after 60 epochs. The training and testing loss curves of T-GCN model with attention mechanisms on 60 epochs.

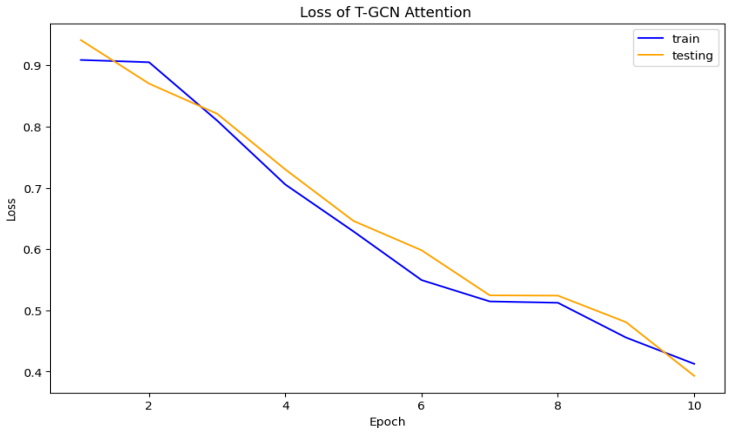

Fig. 7. Training and testing loss.

E. Performance Evaluation

Correlation coefficient, Willmott's Index of Agreement, Nash-Sutcliffe Coefficient, Legates and McCabe's Index, and Nash-Sutcliffe Coefficient are among the performance assessment metrics used to assess the models' dependability in terms of predicted accuracy. In order to determine the extent of the model's inaccuracy and to compare the outcomes, other error statistics such as Root Mean Squared inaccuracy, Mean Absolute Error, Relative Root Mean Squared Error, and Mean Absolute Percentage Error are also utilized.

1) Correlation Coefficient (r): Coefficient of determination reflects the reliability of the regression equation and the correlation coefficient r quantifies the linearity of the observed and simulated data. It varies between -1 and + 1 where a value closer to - 1 represents a perfect negative correlation and a value closer to + 1 perfect positive correlation, no linear relationship is given by Eq. (7) as follows, [29].

$$r = \frac{\sum_{i=1}^{n} DO_i - MDODS_i - MDS}{\sum_{i=1}^{n} DO_i - MDO^2 \sum_{i=1}^{n} DS_i - MDS^2} \quad (7)$$

2) Willmott's index of agreement: Willmott's Index of Agreement (d) is a widely used measure of prediction accuracy against a group of consensus observed data. The expected range of values is from 0 to 1, with 0 indicating no agreement at all, and 1 indicating perfect agreement between predicted and observed values. The index differs from basic correlation measures in that it emphasizes errors by their magnitude, providing a more sensitive measure of prediction accuracy.

$$d = 1 - \frac{\sum_{i=1}^{n} DO_i - DS_i^2}{\sum_{i=1}^{n} DS_i - MDO + DO_i - MDS^2} \quad (8)$$

3) Nash-sutcliffe coefficient: Consequently, to check the potential accuracy of fitted models, the Nash-Sutcliffe Coefficient NS is used. It also shows that an NS value of 1 reflects perfect model performance while an NSNSNS of 0 reflects the model performance in terms of observed means. This is given by Eq. (9),

$$NS = 1 - \frac{\sum_{i=1}^{n} DO_i - DS_i^2}{\sum_{i=1}^{n} DO_i - MDO^2}, -\infty \leq NS \leq 1 \quad (9)$$

4) Legates and McCabe's index: LM is the other measure that is used to evaluate the performance of given models. It highlights the gross dissimilarities of observed and simulated data, which is downplayed for outlying values. LM is a value between 0 and 1 with the higher value representing better results of the model. This is provided by Eq. (10)

$$LM = 1 - \frac{\sum_{i=1}^{n} |DS_i - DO_i|}{\sum_{i=1}^{n} |DO_i - \overline{DO}|} \quad (10)$$

5) Root mean square error: RMSE is a measure of the ordinary used in the assessment of the differences between the estimations and the observations. It imposes more penalty for larger errors than for small ones, owing to the fact that, the residuals are squared before averaging. This corresponds to the value expressed by the Eq. (11),

$$RMSE = \sqrt{\frac{1}{n}\sum_{i=1}^{n} DS_i - DO_i^2} \quad (11)$$

6) Mean Absolute Error: MAE is computed from the average of the absolute differences between the predicted and the actual values, without a regard to the sign of the differences. Basically, it is easy to understand and easy to interpret. This is as given by the Eq. (12).

$$MAE = \frac{1}{n}\sum_{i=1}^{n} DS_i - DO_i^2 \quad (12)$$

7) Relative Root Mean Square Error: RRMSE gives an RMSE percentile value which is the RMSE of a normalized set of values, expressed as a percentage. It scales the RMSE to the range of the observed data thus being suitable when comparing models on different ranges of data. This is given by Eq. (13).

$$RRMSE = \frac{\sqrt{\frac{1}{n}\sum_{i=1}^{n} DS_i - DO_i^2}}{\sqrt{\frac{1}{n}\sum_{i=1}^{n} DO_i}} \times 100 \quad (13)$$

8) Mean Absolute Percentage Error: MAPE expresses the average prediction error as a percentage of the observed values. It's useful for understanding the relative size of errors. This is given by Eq. (14),

$$MAPE = \frac{1}{n}\sum_{n}^{i=1}\frac{DS_i - DO_i}{DO_i} \times 100 \quad (14)$$

Where DO_i_i is the observed data, DS_i is the simulated data, MDO is the mean of observed data, and MDS is the mean of simulated data.

Table I and Fig. 8 offer a summary of the performance of the T-GCN + Attention model. The model is good at prediction and has close correspondence between predicted and observed values as indicated by the Nash-Sutcliffe Efficiency of 0.9925, Willmott's Index of Agreement of 0.9958, and Correlation Coefficient of 0.9965. The MAE and RMSE, which reflect small prediction errors, are low at 0.0322 and 0.0412, respectively, yet the Legates and McCabe Index is comparatively high at 0.9321.Though the model is still very reliable across evaluation metrics, relatively high Mean Absolute Percentage Error (1.95%) and Relative RMSE (2.38%) values reflect high unpredictability.

TABLE I. PERFORMANCE AND ERROR METRICS

Metric	T-GCN + Attention
Nash-Sutcliffe Coefficient	0.992452
Willmott's Index of Agreement	0.995804
Correlation Coefficient	0.996512
Legates and McCabe Index	0.932145
RMSE	0.041203
MAE	0.032154
RRMSE	2.381204
MAPE	1.953214

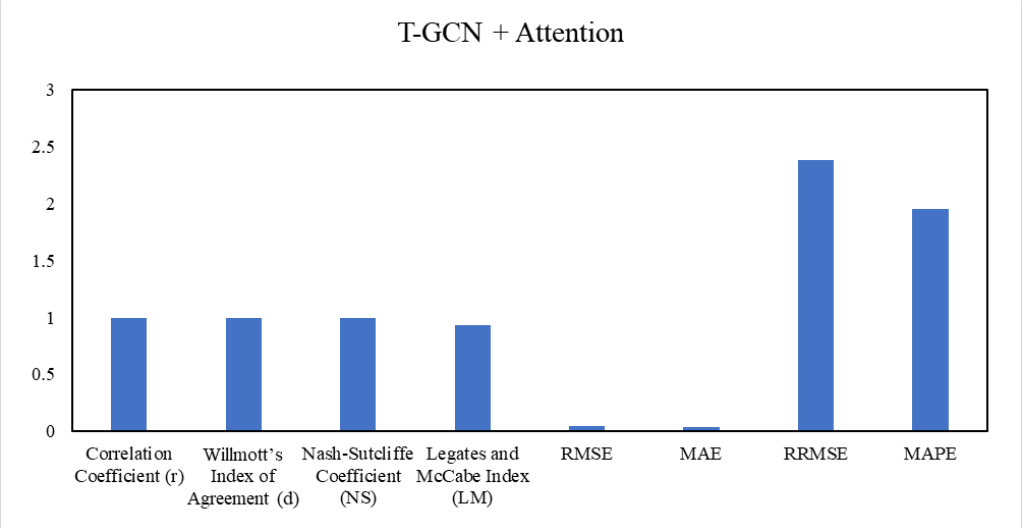

Fig. 8. Performance and error metrics comparison.

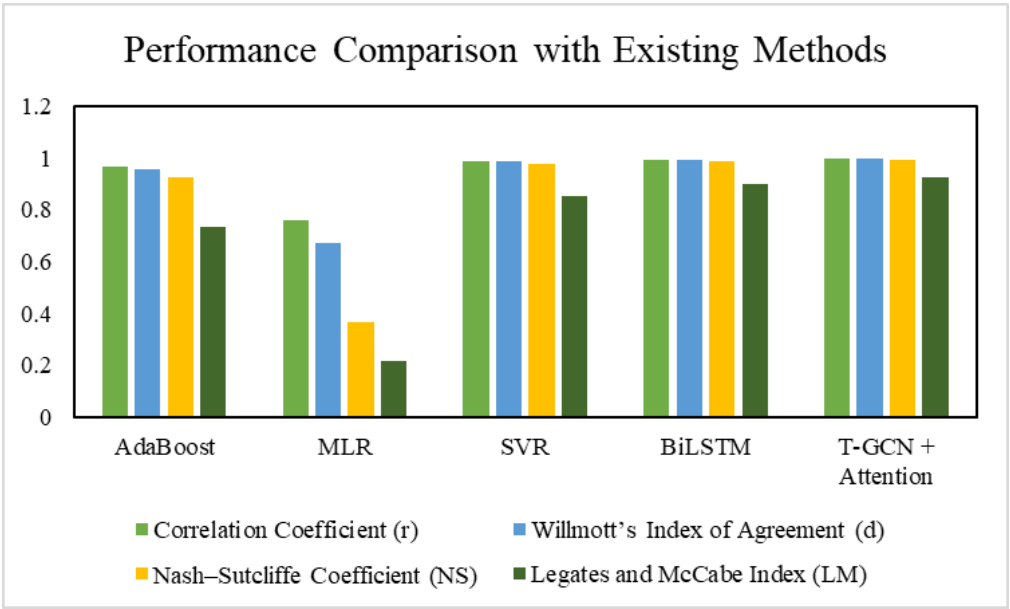

Fig. 9. Performance comparison with existing methods.

Fig. 9 and Table II illustrate a comparative study of five models—AdaBoost, MLR, SVR, BiLSTM, and T-GCN with Attention—based on four performance metrics: Correlation Coefficient (r), Willmott's Index of Agreement (d), Nash–Sutcliffe Efficiency (NS), and the Legates and McCabe Index (LM). The Correlation Coefficient (r) varies between 0.759946 for MLR and 0.996502 for the T-GCN + Attention model, which shows that the latter has the highest linear correlation between predicted and observed values. The Nash–Sutcliffe Efficiency (NS), which is one of the most important indicators of predictive performance, varies from 0.368981 for MLR to 0.993021 for T-GCN + Attention, which indicates greater forecast capacity for the proposed hybrid model. Also, the Legates and McCabe Index (LM), the measure of reliability of model predictions, varies from 0.217703 for MLR to 0.925741 for T-GCN + Attention. Overall, the results clearly show that the proposed T-GCN + Attention model outperforms the other methods on all evaluation metrics, and it confirms there are overall strong, accurate, and effective in predicting sea level rise.

TABLE II. PERFORMANCE COMPARISON WITH EXISTING METHODS

Model	Correlation Coefficient	Willmott's Index of Agreement	Nash–Sutcliffe Coefficient	Legates and McCabe Index
CNN-BiGRU [30]	0.988909	0.987155	0.974866	0.952321
BiLSTM [31]	0.974207	0.964079	0.988219	0.939868
SVMD-BiLSTM [32]	0.954311	0.987647	0.983809	0.913546
CEEMDAN-CNN[33]	0.968946	0.982739	0.988981	0.927703
Proposed T-GCN + Attention	0.996502	0.996312	0.993021	0.985741

a) Paired t-test on MAE between Proposed Model and BiLSTM

TABLE III. PAIRED TWO-TAILED T-TEST

Fold	T-GCN + Attention (Proposed)	BiLSTM
1	0.031	0.043
2	0.032	0.046
3	0.033	0.042
4	0.030	0.045
5	0.031	0.044

Table III paired two-tailed T-test was held in five cross-validation folds to statistically evaluate the performance difference in the meaning of the T-GCN + meditation model and the Bi-LSTM baseline in the proposed T-GCN + MAE. The results detected a low MAE for the proposed model in all folds, and the calculated T-statistic was much higher than the significant value, indicating sufficient difference in performance. With a particularly low p-value ($p < 0.01$), the improvement obtained by the proposed hybrid model is statistically important. This confirms that the T-GCN + attention model not only provides a better future accuracy, but continuously does so, offering a strong and reliable solution to increase sea level compared to traditional deep learning approaches.

```
Paired t-test result:
t-statistic: 13.4164
p-value: 0.000195
Result is statistically significant (p < 0.05).
```

Fig. 10. T-test outcome.

To validate the performance of the T-GCN + attention model proposed on baseline methods, a coupled two-wheel T-test on MAE values obtained from 5-fold cross-fold was organised as mentioned in Fig. 10. Results ($T = 13.4$, $P < 0.01$) indicate a statistically significant decrease in predicted error compared to BILSTM; it confirms that the proposed model provides a consistent and average improvement.

F. Discussion

Precise forecast of sea level rise is essential for climate mitigation and adaptation planning. A new hybrid model that combines T-GCN, attention mechanisms, and game theory optimization is introduced in this research to overcome the limitations of classical models to address highly complex spatiotemporal patterns. The T-GCN models temporal dependencies and spatial correlations, and the attention mechanism emphasizes prominent features such as glacier melt and ocean thermal expansion. Game theory reinforces model strength by encoding feature interactions as a multi-objective strategy, enhancing generalizability and mitigating overfitting. Results of evaluation indicate high predictive efficacy and minimal error rates. The framework is a solid instrument for scientists and policymakers that facilitates data-driven, fine-grained planning for coastal resilience to climate change.

VI. CONCLUSION AND FUTURE WORK

The study introduced a novel Hybrid Forecasting Framework that integrates T-GCN, attention mechanisms and game theory-based adaptations to increase the accuracy of sea level rise prediction. Mixing GCN's spatial modelling abilities with the GRU's temporary learning strength, the proposed T-GCN structure effectively captures the complex spatiotemporal dependence contained in sea level figures. The meditation mechanism further enhances performance by emphasising important characteristics in both dimensions, while the game theory refines the model by reducing optimisation over fitting and ensuring balanced performance in different environmental conditions. As displayed through a high correlation coefficient and low error rates, the model displays strong future-stating capacity, making it a valuable.

Further, the model can be increased by incorporating additional data sources such as demographic profiles, population density, regional melted water rates and extreme weather indicators. These enrichers will not only improve future accuracy but will also enable field-specific risk assessment. Real-time data acquisition and integrating adaptive local calibration will make the system more dynamic and responsible for on-ground changes. Ultimately, deployment of this model within the decision-support structure can assist policy makers and planners in crafting data-operated responses for climate-inspired sea level changes, promoting permanent and flexible coastal growth.

Securing Image Messages Using Secure Hash Algorithm 3, Chaos Scheme, and DNA Encoding

Amer Sharif*, Dian Rachmawati, Wilbert
Dept. of Computer Science, Faculty of Computer Science and Information Technology,
Universitas Sumatera Utara, Medan, Indonesia

***Abstract*—Security is an essential aspect to consider during data transmission, especially images. Threats that may occur during image transmission include images being stolen by third parties. One way to secure images is through encryption-decryption processes using cryptographic algorithms. One of the algorithms developed for image security involves combining a chaos scheme, DNA encoding, and hashing. Chaos scheme refers to a system sensitive to initial conditions, resulting in behavior that is difficult to predict or appears random. DNA encoding is the process of converting bits into a DNA sequence. Hashing is a mathematical function which takes variable inputs and converts them into a binary sequence with fixed length. In this research, security enhancement is achieved by replacing the hashing algorithm with Secure Hash Algorithm (SHA) 3 Keccak. This study successfully implemented cryptographic algorithms into a website that can simulate image encryption-decryption processes in about 15 seconds per process. The effectiveness of the algorithm used has also been tested in abstracting images through Mean Squared Error (MSE) and Peak-Signal-to-Noise-Ratio (PSNR) evaluations. Obtained MSE values of 0 and PSNR values of infinity indicated that the original images and decrypted images are identical.**

***Keywords*—Image encryption; image decryption; chaos scheme; DNA encoding; secure hash algorithm 3 Keccak**

I. Introduction

The advancement of digital technology has led to an increased demand for data, especially images. Despite being a routine activity, the transmission of images between parties involves significant security risks, such as data theft by third parties. Therefore, it is crucial to develop methods for securing images during transmission.

Image encryption is an effective method for securing images. Encryption involves converting plaintext into ciphertext, making the data unreadable without a decryption key. This process ensures that only the intended recipient, who possesses the key, can convert the ciphertext back into readable plaintext, thus securing the image data during transmission.

This research explores the use of symmetric key cryptography, combining a chaos scheme and DNA encoding, alongside the Secure Hash Algorithm (SHA) 3 hashing algorithm, specifically Keccak. Commonly used hashing algorithms like SHA-1 and SHA-2 have known vulnerabilities, prompting the National Institute of Standards and Technology (NIST) to seek a more secure alternative, resulting in the adoption of the Keccak algorithm as the SHA-3 standard.

The chaos scheme generates semi-random numbers without repeating periods and is highly sensitive to initial parameter changes. This sensitivity ensures significant differences in output with minor changes in input, enhancing encryption robustness. Despite producing semi-random values, the chaos system is deterministic, meaning it can reproduce the same values with the same initial parameters, which is crucial for reliable encryption and decryption processes.

DNA encoding utilizes the properties of DNA sequences, where the bases A (Adenine) pair with T (Thymine) and C (Cytosine) pair with G (Guanine). By representing these DNA bases in a binary format, plaintext can be encoded into a secure format. This method, combined with the chaos scheme, has shown promise in previous studies, such as those by Belazi et al. [1], Wang and Su [15], and Zhong et al. [16].

Previous research indicates that the SHA-3 algorithm offers enhanced security compared to SHA-2 [10]. By integrating the chaos scheme, DNA encoding, and the SHA-3 algorithm, this study aims to develop a more secure image encryption method, potentially achieving higher security levels than existing techniques. The system developed may later be considered as an alternative means of image security in communication applications.

This study is organized next by enlisting previous studies in image encryption utilizing chaos and DNA algorithms and studies involving hash functions, followed by a literature review of the principal theoretical concepts. Following that is the problem analysis and system design, continued with implementation and system testing. Discussion and final conclusion with some considerations for future work are provided in the end.

II. Previous Studies

Several studies related to this approach have been conducted. Belazi et al. [1] obtained a cryptographic algorithm which met security criteria such as a large key space, resistance to statistical attacks, and a linear run time, enabling efficient execution. Alrubiae et al. [2] leveraged double-dynamic DNA sequence encryption and a chaotic 2D logistic map to produce a novel image encryption algorithm which resisted common attacks. Hussain et al. [4] developed substitution boxes by the use of chaotic logistic maps in linear fractional transformation. Arif et al. [5] used S-boxes, a hash

*Corresponding Author, Email: - amer.sharif@usu.ac.id

function, and chaos scheme to produce a secure cryptographic algorithm for images. Suryadi et al. [8] utilized a transposition scheme based on a chaos function, namely Arnold's cat map function, as a form of transposition resulting in a large key space with very low sensitivity. Munir [11] developed a simple image encryption system using a pseudo-one-time pad built upon a chaos function. Wang and Su [15] utilized the Piecewise Linear Chaotic Map (PWLCM) and Logistic Map to generate all parameters the encryption algorithm needed, combined with DNA encoding. Zhong et al. [16] combined chaos theory and a 2D Chebyshev-Sine map to achieve image encryption resistant to differential and selective plaintext attacks. Pittalia [10] compared the effectiveness of hash functions in cryptography, while Patil and Karule [7] specifically discussed the design and implementation of the Keccak hash function for cryptography.

III. Literature Review

A. Cryptography

Cryptography is a method for securing data using code algorithms, hashes, and signatures. It can protect data at rest, in transit, or in use. For example, cryptography can secure data stored on a hard drive, data being transferred between parties through electronic communication, or data being processed during calculations [12].

Cryptography has four main objectives: confidentiality, ensuring that information is accessible only to authorized parties; integrity, ensuring that information is not manipulated; authentication, confirming the authenticity of information and the identity of users; and non-repudiation, preventing users from denying their previous actions [14].

Cryptography generally is divided into two categories: symmetric cryptography, which utilize the same key for encryption, i.e. converting the readable plaintext/image into unreadable ciphertext/image, and decryption, i.e. converting the unreadable ciphertext/image back into the readable plaintext/image. On the other hand, asymmetric cryptography utilizes a set of different keys (called public and private keys) for encryption and decryption [14]. This research employs symmetric cryptography.

B. Secure Hash Algorithm

Secure Hash Algorithm (SHA) or often known as *one-way functions,* are mathematical functions which accept variable-length input and convert it into a binary string with a fixed length of 128 upto 512 bits. SHA are employed to ensure data integrity and authenticity [6] [14].

There are two criteria which serve as a standard for the security of an SHA algorithm:

1) Preimage resistance: Preimage resistance means for an arbitrary hash value, it is very difficult to obtain the input which produced that particular hash value.

2) Collision resistance: Collision resistance means it is very difficult to obtain two inputs which will produce an identical hash value.

Keccak is a cryptographic hash function and the basis for the SHA-3 (Secure Hash Algorithm 3) standard, which was selected by the National Institute of Standards and Technology (NIST) in 2012. Unlike its predecessors, SHA-1 and SHA-2, Keccak employs a unique structure and process, enhancing its security and efficiency [7] [10].

Keccak operates through a series of absorbing and squeezing phases, as indicated in Fig. 1 from [7], where the input data is absorbed into a state array and then permuted. This process involves transforming blocks of 1152, 1088, 832, or 576 bits to generate hash values of 224, 256, 384, and 512 bits. These permutations ensure that even the slightest change in the input data results in a significantly different hash output, making Keccak highly resistant to collisions and attacks [10].

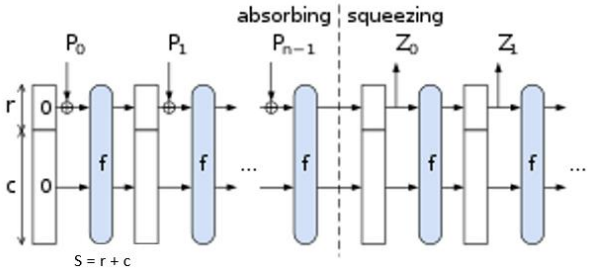

Fig. 1. Absorbing and squeezing phases in Keccak from [7].

C. Chaotic Scheme

Chaos in many contexts often refers to phenomena in which the systems are highly sensitive to initial conditions, resulting in difficult-to-predict behaviour or seemingly random behaviour [11].

In cryptography, a map refers to mathematical functions which link each element from a set to another corresponding element in another set. Maps are utilized to convert data from one form to another.

Chaotic maps are maps which exhibit chaotic properties or uncertainties by producing hard-to-predict numbers. Chaotic maps serve to make cryptographic systems more resistant to attacks due to the difficulty in describing or predicting the chaotic behavioral pattern [5].

D. Logistic-Chebyshev Map

The Logistic-Chebyshev map is a combination of two one-dimensional chaotic maps: the logistic map and the Chebyshev map. By merging these two maps, the Logistic-Chebyshev map is expected to produce more complex and varied results compared to a single chaotic map [3]. This enhanced complexity can be beneficial in various applications, such as in the development of security systems or data scrambling, where chaotic properties are leveraged to generate random number sequences with the desired level of complexity. The following is the Logistic-Chebyshev equation from [3]:

$$X_{n+1} = \left(\alpha X_n(1 - X_n) + \frac{(4-\alpha)}{4} cos(b \times cos^{-1}(X_n))\right) mod\ 1 \quad (1)$$

$$X_n \in (0, 1)$$

$$\alpha \in (0, 4]$$

$$b \in \mathbb{N}$$

E. Sine-Chebyshev Map

The Sine-Chebyshev map is a one-dimensional chaotic system that combines the sine map and the Chebyshev map. The sine map, with its simple mathematical structure, and the Chebyshev map, a polynomial map, both exhibit chaotic behavior and high sensitivity to initial conditions. By integrating these two maps, the Sine-Chebyshev map enhances the unpredictability and complexity of the generated sequences, making it particularly useful for applications in cryptography, random number generation, and other fields requiring high levels of complexity and sensitivity. This synergy creates a more robust and versatile chaotic system. The following is the Sine-Chebyshev equation from [16]:

$$X_{n+1} = \left(\alpha \sin(\pi X_n) + \frac{(4-\alpha)}{4}\cos(b \times \cos^{-1}(X_n))\right) mod\ 1 \quad (2)$$

$$X_n \in (0,1)$$

$$\alpha \in (0,4]$$

$$b \in \mathbb{N}$$

F. DNA Encoding

Deoxyribonucleic Acid (DNA) carries the genetic information of all living organisms, characterized by its four constituent bases: A (Adenine), C (Cytosine), G (Guanine), and T (Thymine). These bases pair uniquely within DNA sequences, where A always pairs with T and C always pairs with G. These pairings form the fundamental structure of DNA, essential for encoding genetic instructions in living cells. In computational applications, these bases can be represented in binary form according to specific encoding rules, facilitating the transformation of plaintext data into a binary format known as DNA encoding. This process is crucial in fields such as cryptography and data security, where the inherent properties of DNA bases can be leveraged to encode information securely and efficiently [13].

DNA decoding, conversely, involves reversing the encoding process to retrieve the original plaintext from its binary representation using the DNA base pairs. This decoding mechanism ensures that the encoded information can be accurately reconstructed into its original form, preserving data integrity and facilitating its practical application in various scientific and technological domains. Overall, DNA encoding and decoding techniques offer a promising approach for secure data transmission and storage, harnessing the natural properties of DNA for innovative computational solutions in information security. Table I indicates sample DNA encoding for two-bit pairs.

TABLE I DNA ENCODING

Rule / Code	1	2	3	4	5	6	7	8

C	10	01	10	01	00	00	11	11
G	01	10	01	10	11	11	00	00

G. S-box

S-box, or Substitution Box, is a component in symmetric cryptography which substitutes values from input data blocks with corresponding outputs based on a certain rule or substitution table. The main purpose of the S-box is to increase the algorithm's security level by complicating statistical analysis and cryptoanalysis attacks.

This research uses S-boxes from the research [4], namely S-box 3, S-box 4, S-box 5, dan S-box 6. S-box 3 is given in Table II below as an example.

TABLE II S-BOX 3

H. Mean Squared Error (MSE)

Mean Squared Error is a parameter used to compare the level of pixel difference between two images. A high MSE value indicates that the level of pixel difference between the images is relatively large, meaning the difference between the two images is quite significant. MSE may be obtained from the following equation from [9]:

$$MSE = \frac{1}{XY}\sum_{m=1}^{m=X}\sum_{n=1}^{n=Y}(O(m,n) - R(m,n))^2 \quad (3)$$

I. Peak Signal-to-Noise Ration (PSNR)

Peak Signal-to-Noise Ratio (PSNR) is a parameter used to compare two images. The PSNR value ranges from [0, ∞). The higher the PSNR value, the more similar the compared images are. Conversely, the lower the PSNR value, the more different the compared images are [9]. PSNR is calculated using the following equation from [9]:

$$PSNR = 10 \times \log_{10}\frac{(2^n-1)^2}{MSE} \quad (4)$$

n = bit in the image

MSE = Mean Squared Error value

IV. Analysis and Design

A. Problem Analysis

The primary issue to be addressed in this research is the development of a system which may secure images by means of symmetric cryptography leveraging the Keccak hash function, chaos scheme and DNA encoding.

Functional requirements analysis:

1) System will secure image using the methods mentioned
2) System will secure image with the maximum dimension of 512x512 pixels
3) System will accept input from local file and database
4) System will accept input of secret key to encrypt and decrypt the image
5) System will perform registration and authentication of users
6) System will be able to send encrypted images to the receiver

Non-functional requirements analysis:

1) System will provide a user-interface which is easy to understand for novice users
2) System will validate every user input during encrytion and decryption and provide error message for invalid input.

B. Flowchart

The flowcharts for the activities in this research are described in the following figures.

Fig. 2 describes the proposed algorithm implementation, indicating the important stages in the encryption process starting with the plain image and the secret key: key generation, image decomposition and block permutation, substitution, DNA encoding, complementing, DNA decoding, bitwise operation.

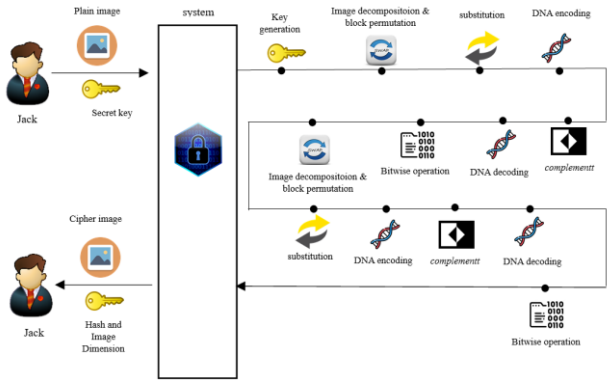

Fig. 2. Encryption process.

Fig. 3 describes the proposed algorithm for the decryption process, which essentially has the same stages as the encryption process but only in reverse order.

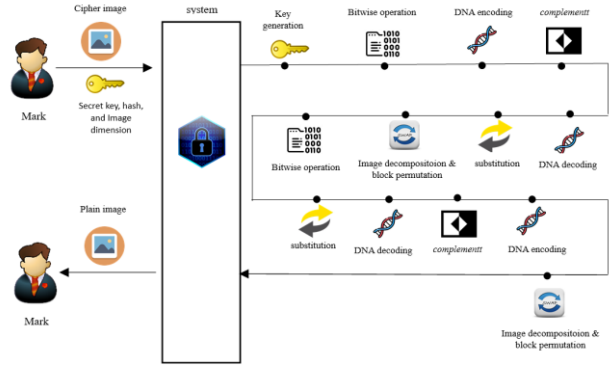

Fig. 3. Decryption process.

C. Proposed Algorithm

1) Key generation

a) Calculate the hash value of plain image *h*.

b) Divide *h* into 32 bytes.

c) Calculate the following, from [4]:

$$X'_0 = \frac{1}{3}\left(X_0 + 2 \times \frac{1}{256} \times bin2dec(h_9 \oplus \ldots \oplus h_{16})\right) \quad (5)$$

$$\alpha'_0 = \frac{1}{3}\left(\alpha_0 + 2 \times \frac{1}{64} \times bin2dec(h_1 \oplus \ldots \oplus h_8)\right) \quad (6)$$

$$X'_1 = \frac{1}{3}\left(X_1 + 2 \times \frac{1}{256} \times bin2dec(h_1 \oplus \ldots \oplus h_{32})\right) \quad (7)$$

$$\alpha'_1 = \frac{1}{3}\left(\alpha_1 + 2 \times \frac{1}{64}\left(\sum_{i=1}^{32} h_1(i)\ mod\ 256\right)\right) \quad (8)$$

d) Calculate Logistic-Chebyshev Map by iteration > 500 times to hide the transient effect. Then, calculate it Mx4N times and put it in matrix. M and N is the image dimension.

e) Map the matrix with 1 if the value > 0.5 and 0 if the value ≤ 0.5.

f) Calculate Sine-Chebyshev Map by iteration > 500 times to hide the transient effect. Then, calculate it MxN times and put it in matrix.

g) Replace each matrix element by calculating

$$Z_1(i,j) = (Y \times 10^{15}) \; mod \; 256 \quad (9)$$

2) Image processing and decomposition

a) Divide image into 64 blocks.

b) Permute these blocks by the following calculation using prime p and h = 1..64

$$b_i = (p \times h) \; mod \; 64 \quad (10)$$

c) Reconstruct image based on the calculation.

3) Substitution

a) Get S-box-3, S-box-4, S-box-5, S-box-6 from [4]

b) Divide the image into 4 parts, substitute each part with each S-box, respectively.

4) DNA encoding

a) Select a DNA rule from the DNA RULE in Table III below.

b) Encode the image using the selected DNA rule, and the image size will be Mx4N.

5) Complement

Using the Logistic Chebyshev matrix, replace the image pixel with the complement if the logistic Chebyshev matrix in the corresponding index is 1.

6) DNA decoding

a) Select a DNA rule from the DNA RULE below.

b) Decode the image using the DNA RULE, restoring the image size back to MxN.

7) Bitwise operation

Using the Sine Chebyshev matrix, XOR the image with the matrix.

8) Calculate MSE and PSNR

a) The MSE parameter is used to determine if the image was successfully encrypted.

b) The PSNR parameter is used to determine if the image was successfully decrypted.

TABLE III DNA RULE

Rule								
Base	1	2	3	4	5	6	7	8
A	00	00	01	01	10	10	11	11
T	11	11	10	10	01	01	00	00
C	01	10	00	11	00	11	01	10
G	10	01	11	00	11	00	10	01

V. IMPLEMENTATION AND TESTING

A. Implementation

In this research, the application was built as a website using Python and Laravel PHP Framework. User data and image data were stored in a MySQL database. The software used for development is Visual Studio Code. This application has five pages: Login, Register, Home, Encryption, Decryption. These pages are indicated in Fig. 4 to Fig. 8. Encrypted images may be stored into the database for access by another user, as indicated in Fig. 7.

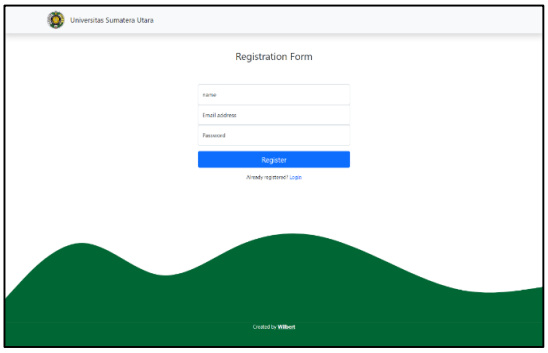

Fig. 4. Registration page.

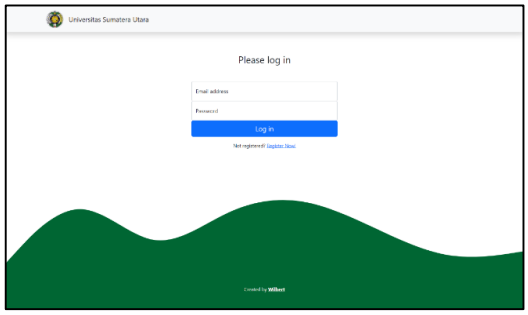

Fig. 5. Login page.

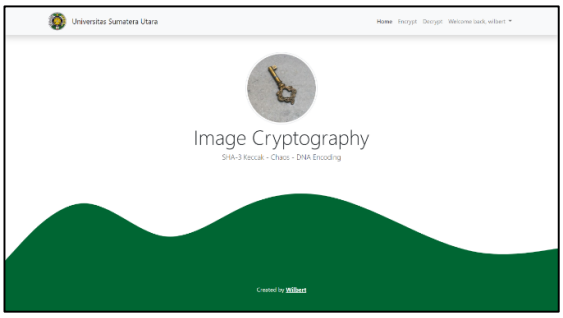

Fig. 6. Home page.

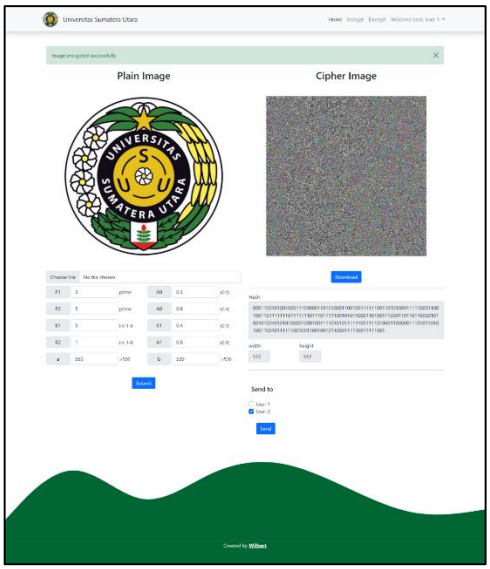

Fig. 7. Encryption page with a sample image.

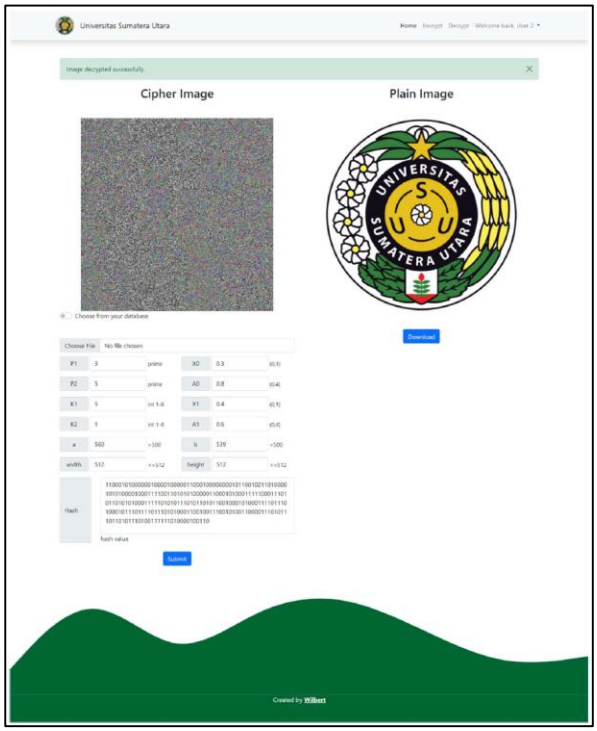

Fig. 8. Decryption page with a sample image.

B. System Testing

Testing consisted of the following steps:

1) Encrypt 5 test images of various sizes with .png extension and different secret keys.

2) Measure the MSE between the original/plain image and the obtained scrambled/cipher image.

3) Decrypt the cipher image back to plain image.

4) Measure the PSNR between the restored image to the original image

Testing was carried out on a laptop with the following specification:

- AMD Ryzen 5 5600H CPU
- GeForce RTX 3050 4GB graphics card
- 16 GB RAM

Required for encryption are the secret keys, which include two prime numbers for image decomposition and block permutation, two random integers between 1 to 8 for DNA encoding and decoding, two random fractions and two random real numbers between 0 and 4 for the chaotic maps. The number of iteration (> 500) for the Logistic-Chebyshev and Sine-Chebyshev mappings are also required. All these values are input manually into the system. The hash value of the selected plain image is calculated initially by the system as well as the dimensions of the image. Parameter for the first test image are indicated in Table IV.

TABLE IV SECRET KEYS FOR FIRST TEST IMAGE

Secret keys	Value	Remarks	Secret keys	Value	Remarks
P1	17	prime	X1	0.7	real (0, 1)
P2	23	prime	A1	3.4	real (0, 4]
K1	8	int 1 – 8	a	765	> 500
K2	2	int 1 – 8	b	594	> 500
X0	0.5	real (0, 1)	Width	400	pixels
A0	2.5	real (0, 4]	Height	400	pixels
Hash	100110010100101110110111011010110101111100111110011010000010000001110110101110111110100110010111000010100011010011010000110110001101011101010000001000000111011010111011111010011001011100001010001101001100010100011010011000101000011011000110101110100000100

Plain image, encrypted image and decrypted image for the second test image are shown in Table VIII. As the case with the first test image, visual inspection showed that the encrypted image is totally different from the plain image, while the decrypted image is virtually the same as the plain image.

TABLE VIII SECOND TEST IMAGE

Plain image	Encrypted Image	Decrypted Image
		

Secret keys used for the encryption and decryption processes are indicated in Table IX. Just as the first test image, secret keys are two prime numbers for image decomposition and block permutation, two integers between 1 and 8 for DNA encoding and decoding, two random fractions and two random real numbers between 0 and 4 for the chaotic maps. The number of iteration (> 500) for the Logistic-Chebyshev and Sine-Chebyshev mappings are also required.

TABLE IX SECRET KEYS FOR SECOND TEST IMAGE

Secret keys	Value	Remarks	Secret keys	Value	Remarks
P1	17	prime	X1	0.12	real (0, 1)
P2	23	prime	A1	2.24	real (0, 4]
K1	2	int 1 – 8	a	599	> 500
K2	8	int 1 – 8	b	652	> 500
X0	0.55	real (0, 1)	Width	383	pixels
A0	3.572	real (0, 4]	Height	512	pixels
Hash	10101100110111100011001011100010011011001001 01101010001011000001011110011111110111011010 00001100110000100010011001110000101101110110 01010010011010111110010111010110100111111110 11101111011100101011101101011011000100110100 10010001101001101101010011010000111				

MSE and PSNR values of the second test image are indicated in Table X. Here the high MSE value of 150.35 and low PSNR value of 27.90 dB between the plain image and encrypted image showed high difference between the two, while low MSE of 0 and high PSNR value of infinity between the decrypted image and plain image, indicated that both images are similar, which again supported the visual inspection result in Table VII.

Processing times for the second test image are indicated in Table XI. Here the processing times are slightly below 15 seconds (14.88 seconds for encryption and 14.97 for decryption).

Table XII shows the result of the third test image. As the case with the second test image, visual inspection showed that the encrypted image is totally different from the plain image, while the decrypted image is virtually the same as the plain image.

Secret keys used for the encryption and decryption of third test image are indicated in Table XIII. Just as the second test image, secret keys consisted of two prime numbers for image decomposition and block permutation, two integers between 1 and 8 for DNA encoding and decoding, two random fractions and two random real numbers between 0 and 4 for the chaotic maps. The number of iteration (> 500) for the Logistic-Chebyshev and Sine-Chebyshev mappings are also required.

VI. DISCUSSION

Several additional observations maybe obtained from the implementation of the cryptosystem, as follows:

- User and image data were stored in the system using a MySQL Database
- All input images sizes were padded to achieve a dimension of 512x512 pixel.
- High MSE values (around 150) and low PSNR values (around 27 dB) between the plain images and the encrypted images indicated the plain images were successfully converted into abstract images.

- MSE values of 0 and high PSNR values (infinity) between the plain images and the decrypted images indicated that the encrypted images were successfully restored to images identical to the original plain images.
- Processing times for encryption and decryption were around 15 seconds on the testing laptop.

VI. Conclusion

Based on the results obtained from the above system testing, it may be concluded that:

1) The algorithms used were capable of performing image encryption and decryption effectively, building on previous studies mentioned at the beginning of this study. This system has successfully integrated the SHA-3 Keccak hash algorithm, Chaos Scheme, and DNA Encoding.

2) The system was implemented into a website using Python, PHP, and a MySQL database.

3) The evaluation of MSE and PSNR values showed that the algorithm successfully abstracted the images and restored them to their original form.

4) The processing time required for each encryption and decryption operation is still quite high for the specified laptop used in system testing.

5) This study has contributed to the field of cryptography an alternate approach to image security using the aforementioned algorithms.

VII. Future Work

Limitations of the present implementation include a symmetric cryptographic approach (which may introduce a key distribution problem), while also limiting images to be encrypted having a maximum dimension of 512x512 pixels. This system is also run on a stand-alone PC-based platform. Secret keys required for the encryption and decryption were input manually, resulting in a not very large key space. Several approaches for future work maybe suggested: firstly, secret keys maybe generated by the system on-demand, therefore ascertaining better randomness and larger key space; secondly, to address key distribution problem faced by symmetric cryptosystem by combining the present algorithms with a public key algorithm such as Extended RSA to achieve a more secure hybrid cryptosystem; thirdly, improving so that images to be encrypted are not limited to a dimension of 512x512 pixels; fourth, to port the cyptosystem to a mobile platform such as Android or iOS, and lastly integrating the present system into a communication system such as an e-mail or instant messaging application.

Department of Information System-Faculty of Computers and Information, Menoufia University, Egypt[2, 4]

***Abstract*—Although Bitcoin enables pseudonymous peer-to-peer digital transactions, its transparent public ledger architecture allows for blockchain analysis that can compromise user anonymity. Despite the presence of wallets with privacy-enhancing features, no single solution currently offers comprehensive anonymity independently. Existing privacy-preserving techniques such as CoinJoin, PayJoin, and Stealth Addresses offer differing degrees of anonymity, yet each exhibits intrinsic limitations. This study proposes a hybrid privacy architecture that integrates multiple privacy-enhancing techniques into a unified and coherent transaction workflow. By integrating decentralized CoinJoin mixing, PayJoin for input ownership obfuscation, and Stealth Addresses for unlinkable payments, the proposed model establishes a robust, privacy-oriented framework for Bitcoin transactions. The framework is implemented and evaluated through pre-funded Sparrow and JoinMarket wallets, interconnected via a fully synchronized Bitcoin Core node deployed on the testnet environment. All communications are routed via the Tor network to maintain anonymity at the network layer. Using testnet-based simulations, we evaluate the effectiveness of the architecture. The results show that combining these techniques substantially strengthens resistance to common deanonymization heuristics, enhances transaction unlinkability, and achieves higher overall anonymity than relying on individual methods alone. This demonstrates the synergistic effect of the hybrid model in providing more resilient protection against transaction tracing and blockchain surveillance.**

***Keywords*—Bitcoin; privacy; anonymity; wallet; blockchain; Coinjoin; Payjoin; stealth address**

I. Introduction

Bitcoin was initially conceived as a peer-to-peer electronic cash system, enabling direct transactions between users without the involvement of centralized intermediaries, and theoretically offering a high degree of privacy [1]. However, Bitcoin's inherent transparency has emerged as a significant privacy concern over time Despite employing pseudonymous addresses, all Bitcoin transactions are permanently recorded on a publicly accessible blockchain [2]. Although Bitcoin substitutes real-world identifiers with pseudonymous address formats, this mechanism alone is insufficient to guarantee true anonymity [3]. Over the years, a wide range of blockchain forensic techniques has been developed to exploit this transparency—leveraging transaction structures, address reuse patterns, and input-output correlations to trace user behaviors and cluster wallet activities for deanonymization. As Bitcoin adoption continues to grow, adversarial deanonymization strategies have evolved in parallel, aiming to link blockchain activity with real-world identities [4].

In response to these privacy threats, the Bitcoin ecosystem has introduced a variety of privacy-enhancing mechanisms designed to mitigate the risks associated with transaction transparency. For instance, CoinJoin allows multiple users to aggregate their transaction inputs and outputs into a single transaction, thereby obscuring direct associations between them [5]. This mixing methodology is practically implemented by the JoinMarket wallet. Other wallets, such as Sparrow, incorporate additional privacy features such as PayJoin—an interactive transaction protocol designed to further obscure input ownership heuristics [6]. Additionally, privacy tools like Stealth Addresses and PayNym support reusable payment codes that prevent the disclosure of linkable public addresses [7]. At the network layer, anonymity can be reinforced by routing transactions through the Tor network, while operating a self-hosted Bitcoin Core node prevents exposure of IP addresses during transaction broadcasting [8]. Although each one of these techniques enhances privacy to a certain extent, no one individually provides comprehensive protection. Dependence on any single privacy method frequently leaves users susceptible to forms of blockchain and network-level analysis.

This situation reveals a critical research gap as most prior studies evaluate these privacy techniques in isolation, often highlighting their strengths but overlooking their inherent limitations when deployed alone. There has been limited exploration of how these techniques could be combined into a cohesive, layered framework capable of countering multiple deanonymization strategies simultaneously.

To address these limitations, we propose a hybrid wallet architecture that consolidates multiple privacy-preserving mechanisms across distinct wallets and tools. Our model employs funded Sparrow Wallets to initiate PayJoin transactions and manage stealth address payments, JoinMarket to conduct decentralized CoinJoin mixing, and a fully synchronized Bitcoin Core testnet node as its infrastructural backbone. All system components are interconnected via the Tor network to maintain robust anonymity at the network communication layer. By integrating these tools, we construct a layered privacy architecture designed to confound multiple levels of forensic and heuristic analysis [9].

Accordingly, this study focuses on evaluating whether the integration of multiple privacy-enhancing techniques within a unified hybrid wallet model can provide stronger anonymity guarantees than the isolated use of individual methods.

This study investigates whether a hybrid approach can provide stronger anonymity guarantees compared to the isolated application of individual privacy techniques. Through the implementation and testing of this framework using real-world wallets and a Bitcoin Core testnet node, we demonstrate that integrating existing privacy tools significantly enhances the resilience and anonymity of Bitcoin transactions. Our results indicate that integrating multiple privacy techniques can substantially improve user anonymity within the Bitcoin ecosystem.

The rest of the paper is organized as follows: Section II provides background and related work, detailing the foundational necessary concepts and explores existing privacy tools and previous research. Section III outlines the proposed framework, describing the experimental setup, tools, and tests used in the study. Section IV presents experimental results and key observations. Finally, Section V the conclusion and future work, summarizing the findings and discussing Promising directions for future work.

II. Background and Related Work

In 2009, Bitcoin was introduced by Satoshi Nakamoto as a decentralized alternative to traditional fiat systems, enabling peer-to-peer value transfers without reliance on financial intermediaries. Each Bitcoin transaction is immutably recorded on a publicly accessible ledger known as the blockchain, allowing full transparency to all participants [1].

A. Bitcoin's Pseudonymity

Bitcoin enables user interaction via alphanumeric addresses instead of verifiable legal identities, thereby offering pseudonymity rather than full anonymity. Despite the absence of explicit personal identifiers, advanced analytic techniques can correlate addresses, cluster user activity, and trace fund flows across the blockchain. The pseudonymity provided by Bitcoin is frequently inadequate for users demanding higher levels of privacy [10]. As a response, numerous privacy-preserving techniques have been developed and deployed, each offering distinct advantages and facing unique limitations. Among the most implemented methods are CoinJoin, PayJoin, and Stealth Addresses. Thus, although Bitcoin does not explicitly disclose user identities, it lacks robust anonymity, particularly when subjected to sophisticated forensic analysis techniques [11].

B. CoinJoin and Decentralized Mixing

CoinJoin, introduced by Greg Maxwell in 2013 [12], is a Bitcoin privacy-enhancing technique designed to obscure transaction origins. The technique aggregates inputs from multiple users into a single transaction, then redistributes them as outputs typically of equal or standardized value. This obfuscation makes it significantly more difficult for observers to infer input-output mappings. Empirical studies validate CoinJoin's effectiveness in enlarging the anonymity set; however, vulnerabilities remain, timing analysis and behavioral patterns among participants [5].

C. PayJoin (P2EP) Input Ownership Confusion

PayJoin, or Pay-to-EndPoint, enhances privacy by making the payment transaction appear as if it involves two unrelated parties contributing inputs. This approach disrupts conventional input ownership heuristics, which typically assume all transaction inputs originate from the sender. Successful execution of PayJoin necessitates that both sender and receiver be simultaneously online and utilize wallets that support the protocol. Despite its advantages, PayJoin adoption remains limited due to synchronization challenges and compatibility constraints across different wallet implementations [6].

D. Stealth Addresses (PayNym) and Unlinkability

Stealth Addresses represent another vital privacy mechanism, designed to prevent address reuse and facilitate unlinkable transactions. This method enables the sender to generate a unique, one-time destination address for each transaction, derived from a public stealth address provided by the recipient. Consequently, each payment appears to target a distinct destination, effectively nullifying address reuse heuristics [13]. PayNym extends the stealth address paradigm by introducing reusable payment codes, allowing multiple unlinkable payments to be conducted with enhanced convenience. Only the sender and intended recipient can deterministically compute the correct destination address, thereby enhancing privacy without compromising convenience. Although stealth address support in Bitcoin remains relatively uncommon, its adoption has been revitalized in wallets such as Sparrow [7].

E. Network-Layer Privacy with Tor

Network-layer privacy using Tor adds a crucial layer of protection to Bitcoin transactions by concealing the origin and destination of network messages. maintains online anonymity by routing traffic through multiple layers of encrypted relays. Each relay hop applies an additional layer of encryption, making it difficult for observers to trace the source or destination of the traffic. Since each Tor node is aware only of its adjacent nodes, no single observer can reliably correlate a user's IP address with a specific Bitcoin transaction or node [8].

F. Bitcoin Full Node

A Bitcoin full node serves as a fundamental network component, maintaining a comprehensive and continuously updated copy of the entire blockchain [14]. Unlike lightweight client wallets, full nodes autonomously validate all transactions and blocks in accordance with Bitcoin's consensus protocol. This architecture grants users direct, trustless access to the blockchain, eliminating the need for third-party intermediaries. Operating a full node enhances user privacy and simultaneously contributes to the network's decentralization and security. For research and experimentation, testnet full nodes provide a secure sandbox environment to study transaction dynamics, wallet functionality, and privacy features without risking actual Bitcoin assets [15].

G. Bitcoin Wallets

A Bitcoin wallet is either a software or hardware solution that facilitates the secure storage, transmission, and receipt of Bitcoin. Rather than storing physical coins, wallets manage private keys—cryptographic credentials that grant control over

Bitcoin addresses and associated funds [16]. Some wallets integrate with full Bitcoin nodes for autonomous transaction verification, whereas others depend on third-party servers. Beyond core functionalities, many contemporary wallets incorporate privacy-enhancing features such as CoinJoin, PayJoin, and Stealth Addresses to mitigate blockchain surveillance and user traceability. The choice of wallet significantly influences a user's privacy posture, security robustness, and degree of control over Bitcoin assets [17].

- JoinMarket Wallet JoinMarket is a privacy-centric Bitcoin wallet that provides a decentralized implementation of the CoinJoin mixing protocol. It enables users to mix their coins with others, thereby obscuring transactional origins and enhancing blockchain-level privacy [18].
- Sparrow Wallet is a feature-rich desktop Bitcoin application that combines an intuitive interface with advanced functionalities such as PayJoin and Stealth Address support. It's designed for users who want more control over their transactions and better privacy options, designed for both beginners and experienced users. It is tailored for users seeking granular control over transactions alongside enhanced privacy capabilities [19].

H. Hybrid and Layered Privacy Model

While each individual technique provides only partial protection, recent research in blockchain privacy emphasizes the effectiveness of layered models in achieving stronger anonymity guarantees. For instance, [20] proposed a scheme that combines stealth addresses with Zcash-style note commitments to effectively conceal recipient identities and transaction amounts. An empirical study in [5] demonstrated that, despite mixing, decentralized CoinJoin wallets remain vulnerable to on-chain heuristics and suggested that augmenting CoinJoin with Lightning Network privacy measures can significantly enhance anonymity. Additionally, [21] demonstrated that integrating CoinJoin with network-layer obfuscation techniques such as Tor or Dandelion++ can substantially strengthen resistance to surveillance efforts. [22] emphasized the persistent struggle between privacy-enhancing technologies and blockchain forensic techniques. Their findings underscore the necessity of continuously evolving flexible and adaptive privacy strategies to preserve transaction anonymity in adversarial environments. More recently, several studies further highlight advancements and remaining gaps in layered privacy frameworks. The Springer survey [23] explored cryptography-based approaches to blockchain privacy, highlighting potential anonymity improvements but limited network-layer protections. In study [24] proposed a homomorphic-encryption-enhanced stealth address protocol (HE-DKSAP), offering strong address-level privacy while still lacking integrated network anonymity. The study [25] provided a comprehensive survey of cryptocurrency mixing techniques, emphasizing the benefits of combining multiple approaches but noting challenges in usability, adoption, and practical implementation. These findings collectively underscore the need for operational hybrid frameworks that integrate multiple privacy mechanisms across both blockchain and network layers.

I. Limitations of Previous Privacy-Preserving Approaches and Research Gap

Although significant progress has been made in developing privacy-preserving techniques for Bitcoin, prior research largely evaluates these methods in isolation. As a result, each approach remains exposed to targeted forensic strategies that exploit its specific weaknesses. For instance, CoinJoin effectively enlarges the anonymity set but can still be undermined by timing or clustering analysis. Similarly, PayJoin disrupts conventional ownership heuristics yet suffers from adoption and synchronization challenges, while stealth addresses prevent address reuse but face limited wallet integration and usability concerns. Network-layer protections such as Tor provide communication anonymity but remain vulnerable to advanced traffic correlation.

To clarify these observations, Table I summarizes the strengths and limitations of key privacy approaches when applied individually.

TABLE I. STRENGTHS AND LIMITATIONS OF INDIVIDUAL PRIVACY-PRESERVING APPROACHES IN BITCOIN

Technique / Area	Strengths	Limitations (when used alone)
CoinJoin (Decentralized Mixing)	Enlarges anonymity set; obfuscates input-output links	Vulnerable to timing and heuristic analysis
PayJoin (P2EP)	Breaks ownership heuristics; improves input confusion	Requires sender-receiver synchronization; limited adoption
Stealth Addresses / PayNym	Prevents address reuse; enables unlinkable payments	Sparse adoption; usability challenges
Network-layer privacy (Tor)	Masks IP addresses; prevents direct network tracing	Still exposed to advanced traffic correlation
Full Nodes	Trustless validation; independence from intermediaries	Resource-intensive; not directly enhancing anonymity

These limitations indicate that no single technique can independently deliver comprehensive anonymity. Existing studies highlight the strengths of each method but stop short of exploring a consolidated approach that leverages their complementary benefits while mitigating weaknesses. To address this gap, the present work proposes a hybrid wallet architecture that integrates CoinJoin, PayJoin, Stealth Addresses, and Tor into a unified framework. By combining these methods atop a Bitcoin Core full node, the system establishes layered defenses against blockchain, transaction, and network-level deanonymization, thereby advancing beyond prior single-technique approaches.

III. PROPOSED FRAMEWORK

This section outlines the implementation of the proposed hybrid privacy model, which leverages a combination of real-world Bitcoin wallet applications, full node infrastructure, and anonymity-preserving network technologies. All components were deployed within a Bitcoin testnet environment to facilitate realistic, secure, and risk-free experimentation. The primary objective was to integrate multiple privacy-enhancing techniques into a unified transaction workflow that optimizes anonymity without compromising usability or system

functionality. The implementation incorporates four core privacy techniques: CoinJoin, PayJoin, Stealth Addresses, and Tor-based network obfuscation.

A. System Overview

The hybrid privacy architecture was structured as a layered system composed of four principal components shown in Fig. 1.

1) Wallet layer (application layer privacy): This layer handles transaction creation, signing, and coordination using JoinMarket and Sparrow Wallet. Enable users to manage privacy settings such as CoinJoin, PayJoin, Stealth Addresses, and coin control, giving them flexible control over their transaction-level privacy.

2) Transaction layer (on-chain privacy): To obfuscate sender-receiver relationships, break common blockchain heuristics, and prevent linkability across transactions using these techniques:

- CoinJoin for collaborative transaction mixing.
- PayJoin to obscure input ownership.
- Stealth Addresses to prevent address reuse.

3) Network layer (network-level anonymity): A locally configured Tor service hides IP addresses and location metadata when wallets or nodes communicate over the Bitcoin network to Prevent network observers or blockchain surveillance firms from linking transactions to users' identities or locations.

4) Infrastructure layer (node-level control and testing): A fully synchronized Bitcoin Core testnet, providing blockchain access and transaction validation and broadcasting transactions privately without relying on third-party servers or light clients.

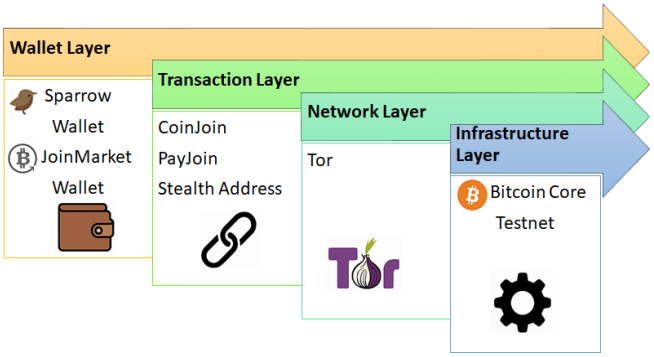

Fig. 1. The layers of the hybrid privacy framework.

This architecture facilitated testing of privacy-preserving transactions across interconnected wallet systems and layers.

B. Software and Tools

The implementation and evaluation of the proposed privacy architecture employed the following open-source software tools, as detailed in Table II.

All software components were deployed on a Windows 10 platform powered by an Intel Core i7 processor, 8 GB of RAM, and a stable broadband internet connection. Tor and Bitcoin Core were executed as background services, while wallet applications were locally configured to communicate via Remote Procedure Call (RPC) interfaces and proxy routing.

TABLE II. SOFTWARE USED IN THE HYBRID PRIVACY FRAMEWORK

Component	Version	Functionality
Bitcoin Core	v25.0 (testnet)	Full-node implementation for transaction validation and verified blockchain synchronization in the testnet environment
JoinMarket	v0.9.11	Decentralized wallet implementing the CoinJoin protocol to perform collaborative transaction mixing
Sparrow Wallet	v1.7.9	Graphical wallet supporting PayJoin, PayNym (Stealth Addresses), and testnet operations, designed for privacy-focused transaction management
Tor Daemon	v0.4.8	Onion-routing service providing network-layer anonymity by concealing IP addresses and communication paths

Bitcoin Testnet functions as a parallel blockchain designed explicitly for development, testing, and experimentation without incurring financial risk. Because Testnet coins lack real-world monetary value, they allow unrestricted experimentation and system evaluation without financial consequences.

C. Data Analysis Tools

- Blockchain Explorers (e.g., Blockstream Explorer [26], Mempool Testnet [27]): Utilized to monitor transaction flows and conduct on-chain activity analysis within the Bitcoin testnet environment.
- Network Sniffers (e.g., Wireshark [28]): Employed to capture and inspect network-level packet data, validating that all transaction communications were successfully routed through the Tor network for anonymity verification.

D. Bitcoin Core Testnet Configuration

A dedicated Bitcoin Core node was deployed on the testnet network to facilitate secure and isolated transaction testing. The configuration settings below were specified in the bitcoin.conf file to support testnet functionality:

bitcoin.conf	
testnet=1	Activates the testnet mode for safe experimentation
server=1	Enables the node to accept RPC commands
rpcuser=bitcoinrpc rpcpassword=***	Specifies RPC authentication credentials
rpcport=18332 rpcbind=127.0.0.1	Binds RPC access to the local machine via port 18332
txindex=1	Enables a full transaction index to support advanced queries
proxy=127.0.0.1:9050	Routes all node communications through the local Tor proxy
onlynet=onion	Restricts network connections to Tor-only peers for maximum anonymity

This configuration enabled Sparrow Wallet and JoinMarket to interact directly with the blockchain—querying data, constructing transactions, and broadcasting them securely over the testnet network through the local Tor proxy.

E. JoinMarket Wallet Setup

JoinMarket was configured to operate in testnet mode and used to perform CoinJoin mixing transactions.

The setup process included the following key steps:

- Creating new JoinMarket wallets tailored for testnet experimentation.
- Executing CoinJoin mixing sessions with testnet coins to obscure transactional origins.
- Enabling Tor integration in the joinmarket.cfg file to route communications anonymously via the Tor network.

joinmarket.cfg	
network = testnet	Specifies the use of Bitcoin testnet for safe testing.
blockchain_source = bitcoin-rpc	Connects JoinMarket to Bitcoin Core via RPC for blockchain data access.
rpc_user = bitcoinrpcrpc_ password = 12345 rpc_host = 127.0.0.1 rpc_port = 18332	Defines RPC credentials and local host settings to securely interface with the Bitcoin Core node.
rpc_wallet_file = jmwallet	Points to the specific bitcoin core wallet file connected to JoinMarket.
use_tor = true socks5_host = 127.0.0.1 socks5_port = 9050	Enables Tor routing for privacy-preserving transaction broadcasting.

CoinJoin transactions were conducted with a configurable number of participants, thereby increasing the size of the anonymity set and enhancing transaction obfuscation.

F. Sparrow Wallet Configuration

Sparrow Wallet served as the primary user interface for initiating PayJoin transactions and handling Stealth Address-based payments. The wallet was integrated with the local Bitcoin Core testnet node, as depicted in Fig. 2, to enable secure and private transaction execution.

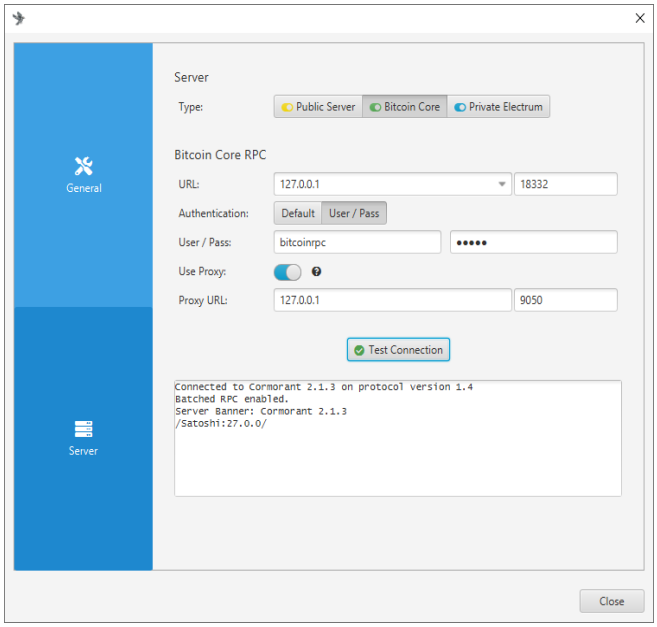

Fig. 2. Sparrow wallet configuration.

Privacy Features Enabled:

1) PayJoin (P2EP): Enabled within Sparrow to facilitate interactive transactions in which both sender and recipient provide inputs confounding traditional ownership heuristics.

2) Stealth Addresses (PayNym): Configured to generate unique, unlinkable payment addresses using reusable public identifiers, preserving receiver privacy.

3) Tor Integration: Enabled to route all network traffic through a local Tor proxy (127.0.0.1:9050), ensuring full communication anonymity.

G. Tor Network Routing

The Tor network was employed to mitigate metadata leakage and preserve user anonymity at the network communication layer. The following parameters were configured in the torrc file to enable secure onion routing for all wallet and node communications:

Torrc	
SocksPort 9050	Designates the SOCKS proxy port used by applications (e.g., wallets) to tunnel traffic through Tor.
ControlPort 9051	Opens a control interface allowing software to manage or monitor the Tor Daemon.
CookieAuthentication 1	Enables secure authentication using cookie-based access control to the Tor ControlPort.

The successful operation of Tor was validated by inspecting system logs and confirming that all wallet interactions were routed through onion services or hidden service addresses.

H. Workflow Integration

The integrated privacy mechanisms were orchestrated through a multi-stage transaction workflow, as illustrated in Fig. 3.

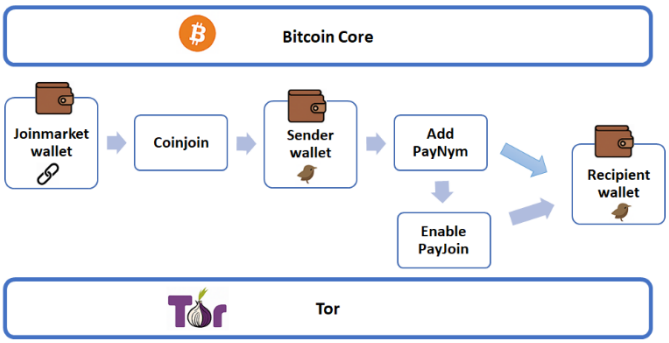

Fig. 3. Multi-stage transaction flow

The multi-stage transaction was implemented in the following sequence:

Step 1: Launch Bitcoin Core in Testnet mode (Fig. 4), ensuring the node is fully synchronized and all wallets are properly connected.

Step 2: Sparrow Wallet was Installed and configured with two pre-funded testnet wallets representing sender and recipient roles.

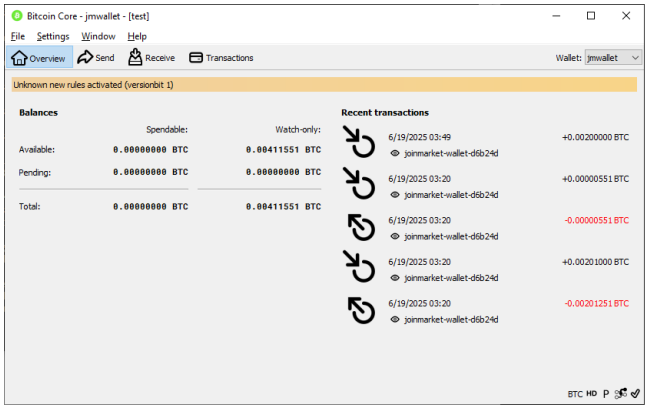

Fig. 4. Bitcoin Core in testnet mode.

Step 3: CoinJoin mixing via JoinMarket for eliminating direct traceability to the coin source and generating clean, unlinkable UTXOs.

As depicted in Fig. 5, a new JoinMarket wallet was initialized, and testnet coins were obtained via a faucet [29].

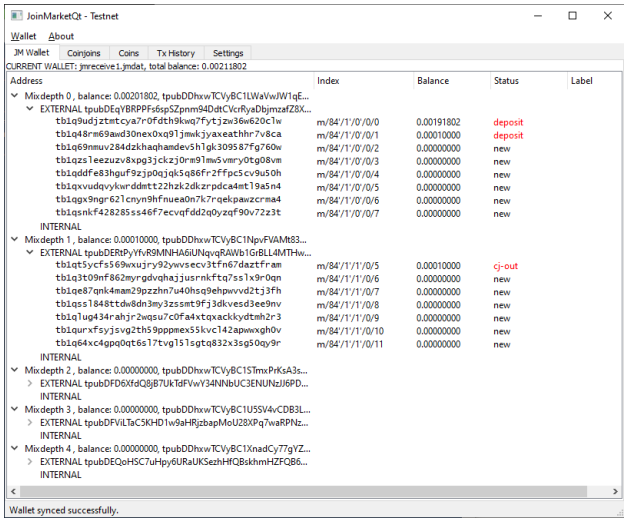

Fig. 5. JoinMarket wallet.

A CoinJoin transaction was initiated with a specified target amount and selected counterparties, as shown in Fig. 6.

The resulting anonymized CoinJoin output UTXOs were transferred to a new address in the Sparrow Sender Wallet to serve as clean inputs for the next step.

Step 4: PayNym Initialization to prevent address reuse and enhance recipient identity privacy.

The recipient published their PayNym identifier, illustrated in Fig. 7.

The sender imported the PayNym into their Sparrow Wallet (Fig. 8) to establish a secure communication link.

An initial broadcast transaction was used to establish a shared secret, after which the sender could derive one-time stealth addresses linked to the recipient's PayNym for each payment.

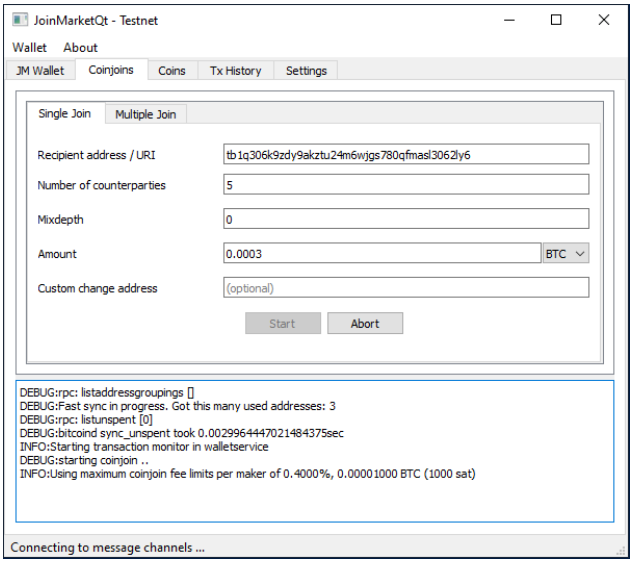

Fig. 6. JoinMarket CoinJoin.

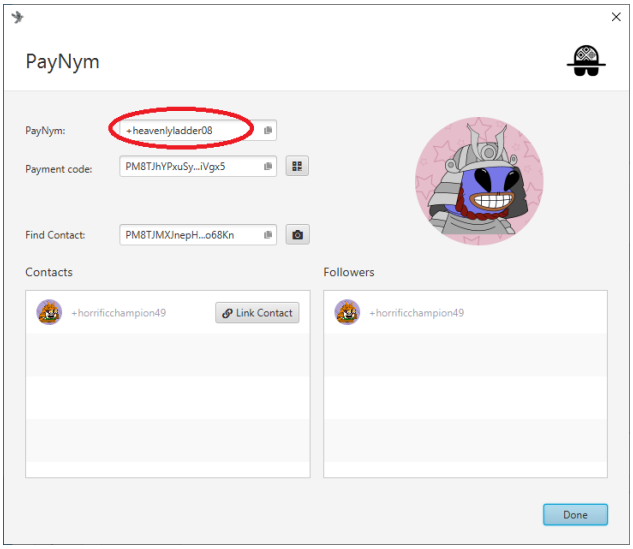

Fig. 7. Recipient PayNym identifier.

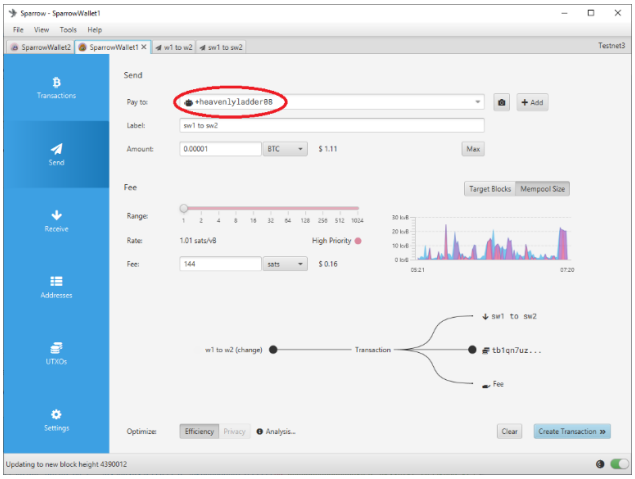

Fig. 8. PayNym imported in the sender wallet.

Step 5: Enable PayJoin in the recipient's Sparrow Wallet, allowing the recipient to contribute inputs and collaborate in constructing a mixed-input transaction.

Step 6: Complete the final transaction using both PayNym and PayJoin mechanisms, as depicted in Fig. 9.

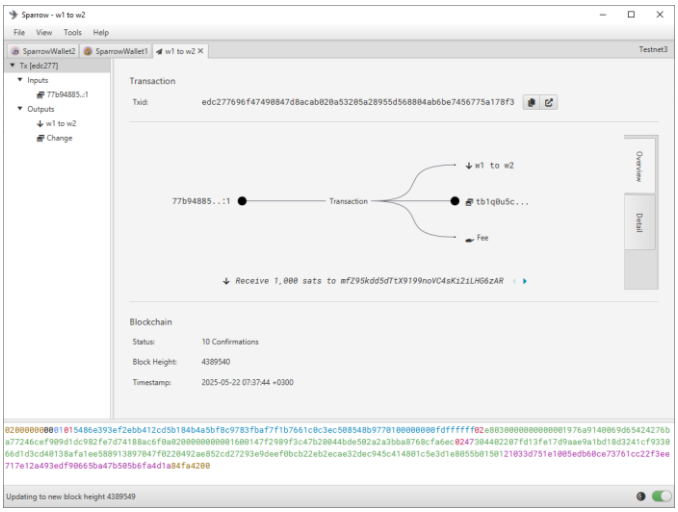

Fig. 9. Sparrow wallet transaction after broadcasting using PayNym and PayJoin.

Step 7: Ensure the Tor daemon is actively running so that all communications between wallets and the Bitcoin Core node are securely tunneled via the Tor network (Fig. 10).

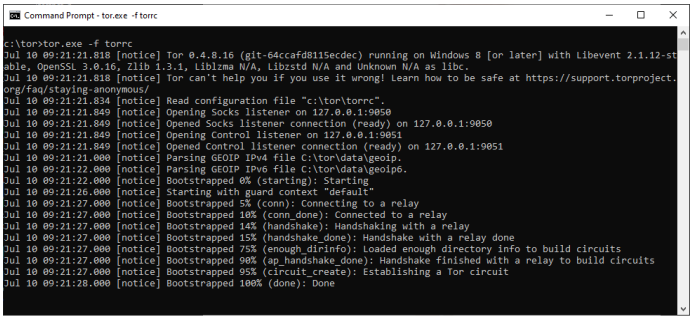

Fig. 10. Running Tor software.

IV. Experimental Results

This section presents the empirical outcomes resulting from the implementation of the proposed hybrid privacy-enhanced Bitcoin architecture within the Bitcoin Core testnet environment. The evaluation demonstrates how the integration of multiple privacy-preserving techniques enhances user anonymity, mitigates blockchain surveillance, and provides greater control over transactional privacy.

A. Integration of Privacy Tools

The system successfully integrated four core privacy-enhancing techniques—CoinJoin, PayJoin, Stealth Addresses, and Tor—into a cohesive framework built on open-source infrastructure. As summarized in Tables III and IV, testing conducted using Sparrow Wallet and JoinMarket confirmed that each component functioned correctly within the unified architecture.

- CoinJoin transactions were conducted using JoinMarket's maker-taker model, enabling collaborative transaction construction among multiple participants to expand the anonymity set.
- PayJoin transactions were successfully initiated and completed within Sparrow Wallet, effectively disrupting input ownership heuristics and demonstrating resilience against standard deanonymization techniques.
- Stealth Address functionality—leveraged via PayNym—enabled unlinkable transactions for the recipient, ensuring address-level anonymity and eliminating reuse-based traceability.
- Tor integration anonymized all network-level communications, safeguarding user IP addresses and metadata during wallet-to-node and peer-to-peer interactions.

TABLE III. Outcomes of Hybrid Privacy Model Layers

Layer	Technique	Benefit
Transaction origin obfuscation	CoinJoin (JoinMarket)	Breaks traceability by mixing funds, severing links to original funding sources (e.g., faucets)
Address unlinkability	PayNym	Prevents address reuse, making it infeasible to correlate payments to a static identifier
Input Ownership confusion	PayJoin (P2EP)	Combines the inputs of the sender and recipient, invalidating input ownership assumptions
Network anonymity	Tor proxy	Routes all traffic via Tor to obfuscate IP addresses and geographic metadata

TABLE IV. Evaluation Metrics for Hybrid Privacy Model Performance

Metric	Result	
Number of identifiable links	**Zero** – All transactions exhibited full unlinkability.	✓
Address reuse (PayNym)	**Eliminated** – New stealth addresses generated per transaction.	✓
Input ownership ambiguity (PayJoin)	**High** – Heuristics for input attribution rendered ineffective.	✓
CoinJoin anonymity set	**5 participants** – Sufficient for medium-strength mixing pools.	✓
Network/IP correlation	**None** – All traffic anonymized via onion routing.	✓

B. Drawbacks and Limitations

Although the proposed hybrid model substantially improves transactional privacy, it introduces several limitations and trade-offs that warrant consideration. These limitations primarily relate to usability, operational complexity, and system integration overhead.

CoinJoin's effectiveness relies on the active participation of both liquidity providers (makers) and takers; availability is not always guaranteed. In the testnet environment where user activity is limited, the anonymity set tends to be small. Consequently, CoinJoin rounds may experience latency, reduce efficiency and diminish practical usability for real-time scenarios.

C. Comparative Analysis

To contextualize the proposed framework, we compared it with recent studies (Table V) focusing on layered privacy, advanced stealth addresses, and mixing techniques. Key insights include:

- Privacy Strength – [24] demonstrate high address-level privacy, while [25] show moderate privacy gains using mixing techniques. Our framework combines multiple layers, achieving superior overall privacy.
- Resistance to Blockchain Heuristics – The hybrid model fully breaks input-output heuristics, outperforming the cryptography-focused approach in Springer [23] and the mixing-only approaches [25].
- Network-level Protection – Unlike the surveyed approaches, the proposed framework integrates Tor, providing robust network anonymity.
- Adoption and Usability – While more complex than single-technique solutions, the operational integration reduces coordination overhead compared to experimental or theoretical models.
- Implementation Feasibility – Unlike the mostly conceptual or prototype approaches in recent studies, the hybrid model is fully implemented and tested on the Bitcoin testnet.

Table V illustrates the comparison in detail, highlighting the hybrid framework's strengths relative to recent approaches.

TABLE V. COMPARISON OF PROPOSED HYBRID FRAMEWORK WITH RECENT PRIVACY APPROACHES

Framework / Approach	Privacy Strength	Resistance to Blockchain Heuristics	Network-level Protection	Adoption / Usability	Implementation Feasibility
Proposed Hybrid Framework	High – CoinJoin, PayJoin, Stealth Addresses, Tor	Strong – Fully breaks input-output heuristics	Full – Tor anonymization	Moderate – Integrated, some coordination required	High – Fully implemented on Bitcoin testnet
Mariani & Homoliak, 2025 [25]	Moderate – Mixing techniques	Moderate – Dependent on participant availability	Low – Transaction-level privacy only	Low–Moderate – Coordination overhead	Medium – Experimental
W. Zeming et al., 2024 [20]	High – Stealth addresses + note commitments	High – Conceals recipient identities	Low – No network-level anonymization	Low – Experimental	Medium – Prototype level
Springer survey, 2024 [23]	Moderate – Cryptography-based privacy	Moderate – Protects against basic heuristics	Low – Network-layer protection limited	Low – Implementation complex	Medium – Mostly theoretical
H. Schnoering & M. Vazirgiannis, 2023 [22]	Moderate – CoinJoin alone	Low–Moderate – Vulnerable to heuristics	Low – No network anonymity	Low – Limited adoption	Medium – Testnet / research implementations
R. Stütz et al., 2023 [5]	Moderate – Decentralized CoinJoin adoption	Low–Moderate – Actual privacy varies in practice	Low – No additional network protection	Moderate – Real-world adoption analyzed	Medium – Depends on wallet support
Yan et al., 2023 [24]	High – Homomorphic-encryption-enhanced stealth addresses	High – Effective against advanced analytics	Low – Network anonymity not included	Low – Technical adoption limited	Medium – Prototype

D. Discussion

The experimental results demonstrate that multi-layered hybrid architectures provide substantial improvements in privacy:

- Zero identifiable links were observed across all transactions.
- Address reuse was eliminated through dynamically generated stealth addresses.
- Input ownership heuristics were rendered ineffective, confirming the effectiveness of PayJoin.
- Tor integration ensured complete network-level anonymity.

Compared to recent studies [2–4], the hybrid framework provides both operational and theoretical advantages, integrating multiple privacy techniques in a single, practical implementation. The medium-sized CoinJoin anonymity sets and coordination requirements highlight ongoing challenges in balancing strong anonymity with usability, reinforcing the importance of continued research in user-friendly, multi-layer privacy solutions.

V. CONCLUSION AND FUTURE WORK

This study demonstrated that integrating CoinJoin, PayNym, PayJoin, and Tor within a unified hybrid wallet architecture can substantially enhance privacy in Bitcoin transactions. Each integrated technique contributes a distinct layer of protection: CoinJoin obscures transaction origin, PayJoin disrupts input ownership heuristics, PayNym ensures unlinkability of recipients, and Tor conceals network-level metadata. Our results show that the combination of these tools offers stronger anonymity than any single technique in isolation, increasing resistance to deanonymization heuristics, improving transaction unlinkability, and reinforcing overall resilience against blockchain surveillance.

The findings further highlight that a layered, multi-technique approach is essential in addressing the persistent arms race between privacy-preserving tools and blockchain forensic methods. In line with recent research emphasizing multi-layer strategies, our results confirm that hybrid models are not only

theoretically robust but also practically feasible when implemented through real-world wallets and testnet environments. At the same time, limitations remain: the operational complexity of coordinating different tools, the requirement for user technical proficiency, and compatibility constraints across wallet implementations. These challenges indicate that while enhanced privacy is achievable, usability and accessibility continue to be significant barriers to adoption.

Future research should prioritize enhancing the usability of the hybrid model by consolidating the various privacy tools into a unified, user-friendly wallet interface. Additional investigations on scalability, latency, and system performance under adversarial conditions on the Bitcoin mainnet are essential to assess real-world applicability. Future studies should also explore how different layers of privacy techniques interact under varying network loads, attack scenarios, and user adoption patterns. Broader comparative evaluations with alternative privacy-preserving strategies will help identify the trade-offs between anonymity strength, efficiency, and ease of use. Ultimately, the enduring challenge is to strike an effective balance between robust anonymity and practical usability, ensuring that advanced privacy solutions remain accessible to everyday Bitcoin users without introducing prohibitive complexity or performance limitations.

VGG-19 and Vision Transformer Enabled Shelf-Life Prediction Model for Intelligent Monitoring and Minimization of Food Waste in Culinary Inventories

Bindhya Thomas, Dr Priyanka Surendran
College of Computer Studies, University of Technology, Bahrain

***Abstract*—Food waste, particularly in the prepared food industry, presents a serious worldwide concern with serious ethical, environmental and socioeconomic implications. In restaurants and catering contexts, traditional inventory and waste management systems frequently lack the versatility and granularity to mitigate spoilage in real-time. The study proposes a sophisticated deep learning framework that predicts the remaining shelf-life of prepared food items using visual input, enabling timely interventions to reduce food waste. The proposed hybrid architecture integrates VGG-19 (Visual Geometry Group 19-layer network) for fine-grained feature extraction with Vision Transformer (ViT) that models contextual degradation patterns and temporal cues. The model operates by analyzing food images at regular intervals and predicting the remaining time before spoilage, enabling proactive decision-making for consumption prioritization. Food images are categorized into four freshness states: Fresh, Fit for Consumption, About to Expire and Expired, enabling the model to monitor real-time conditions. An elaborate dataset with 34 distinct food categories was utilized in the study, achieving outstanding performance with 98% accuracy, 97.5% precision, 97.9% recall and an F1-score of 97.75% and yielded an estimated 84% reduction in food waste. The model stands out for its non-invasive, image-based decision-making and the potential scalability across various food service settings. By offering predictive insights into food degradation and by using only visual data, the study advances the integration of artificial intelligence into sustainable food management.**

Keywords*—Food waste reduction; shelf-life prediction; VGG-19; vision transformer; image-based freshness classification; sustainable food management

I. Introduction

Food waste represents one of the most critical and paradoxical challenges of the modern world, with a gigantic volume of edible resources being discarded while millions continue to experience food insecurity and hunger [1]. It is estimated that around one-third of all food produced, amounting to over 1.3 billion tons annually, is wasted across the supply chain, from farms and distribution hubs to retail outlets and households [2]. Production and logistics inefficiencies, overstocking, unpredictable consumer behavior, inadequate preservation technologies and poor inventory management are some of the many factors contributing to food waste generation [3], [4]. Food waste reduction is a vital social, environmental and ethical necessity that goes beyond efficiency. It is becoming more and more critical to reduce waste through more intelligent, flexible solutions, as the world's population continues to expand and the effects of climate change put more strain on food systems [5]. Procedural and policy-based strategies like enhanced inventory checks, manual expiration date monitoring, redistributive networks and consumer awareness campaigns were traditionally adopted to curb food waste generation [6]. These methods mostly depend on human judgement and intervention, making them vulnerable to frequent errors and overlooks. The product-level data and real-time environmental variables are generally ignored, relying singularly on human visual inspection to judge freshness, which is inappropriate and inefficient for a vast amount of food. Similarly, demand estimates in the catering and hospitality sectors are frequently based on historical patterns and managerial judgement that often results in overproduction and associated food wastage [7]. The absence of traceability and consistent monitoring in retail and agricultural supply chains leads to spoilage that could have been avoided. Despite being fundamental, these conventional approaches are ineffective at handling the complexity of contemporary food systems as they are reactive rather than proactive.

A revolutionary change in handling food waste was promised by the rise of data-driven technologies. Predictive analytics, real-time monitoring and intelligent inventory control were made possible by blockchain, artificial intelligence (AI), computer vision and Internet of Things (IoT) sensors [8]. Convolutional neural networks (CNNs), YOLO object detection and recurrent neural networks (RNNs) are examples of machine learning (ML) models that have shown great promise in detecting food products, forecasting demand and identifying spoilage [9]. Automated supply chain optimizers, dynamic pricing systems and smart refrigeration systems have all been tested in business and industrial settings. Despite the initial potential, high implementation costs, reliance on data, lack of interoperability and restricted adaptability in rural or low-resource environments hamper their adaptability, generalizability and scalability. The systemic efficiency is undermined by the siloed nature of most of the current solutions, which concentrate on discrete supply chain components.

The central research question addressed in this study is whether a hybrid deep learning framework that integrates convolutional neural networks and transformer-based self-attention mechanisms using only visual inputs can reliably predict the remaining shelf life of prepared food items, enable timely interventions and significantly reduce food waste in real-world service settings. This study proposes a novel hybrid architecture for remaining shelf-life prediction, combining the

strengths of deep learning (DL) with advanced image segmentation and self-attention mechanisms. By using visual cues from food items to infer freshness levels, the study enables more precise and automated decisions on redistribution, consumption prioritization and dynamic pricing. The primary objectives of the study are as follows:

- Develop a CNN-Transformer hybrid DL architecture for accurate classification of food items into different freshness categories based on visual cues extracted from prepared food images.
- Evaluate the model performance and compare it with conventional methods, demonstrating its practical impact through a measurable reduction in food waste by enabling timely consumption or disposal based on predicted freshness.

The further sections of the study are structured as follows: Section II offers a detailed analysis of the latest advances in food waste reduction research and highlights the current research constraints. Section III delineates the proposed methodology. Section IV presents the experimental findings accompanied by a comprehensive analysis of the model performance in Section V. Finally, Section VI concludes the study by encapsulating the principal findings and emphasizing prospective areas for further research.

II. Related Works

Chun et al. [10] suggested deep learning techniques in food image classification in Korean cuisine. The study employed a Korean food image dataset that contained diverse categories of dishes that were pre-processed and augmented to enhance model generalization. Several convolutional neural network architectures were tested through transfer learning, among which InceptionResNetV2 achieved the highest classification accuracy of 81.91%, though it required an extensive training time of 436,182 seconds due to its complex inception–residual structure. NasNetLarge and MobileNetV2 followed with accuracies of 77.91% and 75.36%, respectively. Traditional ResNet variants, including ResNet-101V2, ResNet-152V2, and ResNet-50V2, showed lower accuracies ranging from 73.7% to 68.27%. The computational intensity was a major limitation of the study.

Louro et al. [11] suggested convolutional neural network (CNN)-based approaches for food waste reduction through food recognition technology and promote sustainable eating practices. The study utilized Food-101 dataset, together with the ResNet-50 initially and later adopted transfer learning with ImageNet weights to avoid overfitting. The convolutional layers processed food images hierarchically, progressively learning low-level features such as edges and textures before combining them into higher-level representations of ingredients and dishes and achieved a 90% classification accuracy. However, the model was limited by its computational cost and training time, that hindered scalability and real-time deployment in resource-constrained environments.

Dey et al. [12] proposed SmartNoshWaste, a blockchain-based multi-layered system to reduce food waste within the Farm-to-Fork supply chain. Data System Architecture comprising blockchain technology, QR codes and cloud computing to digitize and store food-related data and the ML module employing Q-learning-based reinforcement learning to optimize decisions formed the two basic blocks of the framework. Production, processing, distribution, retailing and consumption were the five main supply chain phases that were functionally tracked and examined. Real-world potato waste data from the nosh app was used for experimental evaluations, and a 9.46% decrease in food waste compared to the baseline data was observed. The dependence on a single food item and context-specific evaluation limited the generalizability and scalability to larger agricultural or urban food systems.

Nascimento et al. [13] developed an AI-driven model for reducing food waste through improved production planning of own-branded products in grocery stores in Brazil. Using historical daily sales data for a year, the study compared five ML algorithms: logistic regression (LR), multilayer perceptron (MLP), DT (J48), PART and random forest (RF). The algorithms forecasted revenue levels, convertible into product demand and rule-based models and RF outperformed others with 90.17% accuracy. A considerable reduction in total food waste across 312 days was observed: from 6,169 kg under aggressive strategies and 653 kg under balanced strategies to just 117.64 kg, representing an 82% reduction. The insights were limited, as the focus was on a single grocery store, restricting the applicability to broader retail settings or more complex supply chains.

Rasyidi et al. [14] aimed to create an elderly-friendly food recording application in Indonesia by overcoming the shortcomings of existing datasets and models that failed to capture the complexity of local cuisine. The study introduced a new food dataset of 24,427 images covering 160 Indonesian food categories and evaluated 67 models built on 16 state-of-the-art deep learning architectures. EfficientNet V2L achieved the best performance with an accuracy of 85.44% and a top-5 accuracy of 97.84%, outperforming models like ConvNeXt Large and Swin-S. The study was, however, limited by difficulties with single-label classification, variations in food presentation, and complex image compositions that hampered generalization across real-world food recognition scenarios.

Jacob et al. [15] utilized AI-driven optimization for food waste reduction in the cassava processing supply chain to transform farm-to-table operations for Garri production. The study utilized data collected from 4,200 respondents across seven states and 42 local government areas, with demand forecasting and inventory optimization performed by the AI framework incorporating regression analysis and DT algorithms, while natural language processing (NLP) analyzed qualitative interview data to extract stakeholder insights. The framework utilized data mining in detecting inefficiencies and waste points across the supply chain, enabling targeted interventions. A 40% reduction in food waste, 30% decrease in processing time and a 25% cut in transportation costs were observed due to optimized logistics and production scheduling. Scalability was a concern as implementation phase was hindered by poor data quality and inadequate infrastructure affecting the consistency of the AI deployment across the supply chain.

Hübner et al. [16] conducted a life cycle assessment (LCA) of "Foodforecast", a cloud-based ML service reducing bakery food waste comprising sales forecasting, cloud computing infrastructure and hardware resources. Historical sales data was utilized to generate optimized forecasts via ML algorithms to minimise overproduction and quantifying environmental impacts through life cycle modelling. The study evaluated four environmental impact categories: global warming, abiotic resource depletion, cumulative energy demand and freshwater eutrophication and achieved an average 30% reduction in bakery returns, equating to a total decrease of 2000 tons of waste on evaluation in real-world data from 175 bakeries. However, the methodological uncertainties and inadequate data constrained the generalizability of the study.

Sigala et al. [17] suggested a fully automated AI-based food waste tracking system deployed across various HORECA (Hotel + Restaurant + Cafe/Catering) establishments in Europe. The study integrated a hardware unit comprising a scale and an IoT-enabled camera device, positioned beneath and above food waste bins, respectively. The system detected each waste event by recording the weight of discarded food and simultaneously captured images, which were transmitted to a cloud-based system. The advanced image recognition and DL algorithms detected and segregated food waste into groups, specific items and categories of avoidability and source, enabling tailored operational changes, including portion control, menu redesign and improved food storage, achieving a 23 to 51% reduction in food waste across most sites. The absence of a detailed cost analysis hampered the study.

To improve inventory oversight and minimize food wastage in supermarkets, Li et al. [18] proposed a real-time inventory tracking framework leveraging computer vision techniques. YOLOv5 object detection algorithm formed the core of the method, that utilizes CNN to autonomously detect and enumerate items in shelf images submitted by users. These images are analyzed to extract item data, which is then synchronized with a Firebase database, while the front-end is dynamically updated using a Flutter-based application. The system achieved an image processing time of approximately 0.79 seconds, with a precision of around 50% and a recall rate of 80%. The accuracy declined in scenarios involving densely packed or multi-layered shelf views, suboptimal image angles, and a limited recognition vocabulary led to frequent miscounts and missed detections.

Min et al. [19] proposed a Stacked Global-Local Attention Network (SGLANet) for food recognition by capturing both global and local discriminative features of food images. The study employed the ISIA Food-500 dataset, comprising 399,726 images across 500 diverse categories. The architecture consisted of two complementary subnetworks: one applied hybrid spatial-channel attention to learn global-level characteristics such as texture and shape, while the other leveraged cascaded spatial transformers to identify ingredient-relevant local regions and aggregate regional information. By fusing these global and local representations, SGLANet produced a more comprehensive feature space for classification. The model achieved strong performance, recording a validation accuracy of 90.92%. However, the computational complexity and training time, made the model less practical for real-time deployment in lightweight environments such as mobile devices.

To curtail food waste within agricultural supply chains, Wang [20] introduced an AI-enhanced Decision Support System (DSS) for intelligent inventory management and optimized resource allocation. The system architecture consisted of three integral layers: real-time data acquisition, an AI-driven decision-making core and adaptive learning through continuous feedback loops. To forecast demand, NNs and support vector machines (SVM) were employed, achieving predictive accuracies of 90% and 85%, respectively. Inventory distribution across the supply chain was optimized using heuristic algorithms, including genetic algorithms (GA) and particle swarm optimization (PSO), which reduced spoilage by 20% and 22%, respectively. High dependency on uninterrupted, high-quality data streams presented challenges for deployment in rural or low-resource agricultural environments.

Rodrigues et al. [21] compared four ML models in forecasting demand within food catering services to minimize food waste arising from overproduction or underestimation. The study employed RF, LightGBM, Long Short-Term Memory (LSTM) networks and Transformer-based models. Two baseline approaches, a naïve model and a moving average method, were developed to simulate conventional forecasting practices and served as benchmarks across three distinct food service settings. The RF algorithm delivered the most accurate predictions in two of the cases, whereas the LSTM model demonstrated superior performance in the third, collectively contributing to food waste reductions ranging from 14% to 52%, and lowering unmet demand by up to 16% relative to the baselines. The study's practical scope was constrained as the focus was on a single dish, restricting applicability in more varied or complex menu environments.

Goh & Yann [22] suggested an Inception-V3 model with transfer learning for food image classification using the Food-101 dataset. The model leveraged convolutional layers for extracting deep spatial features, while transfer learning from ImageNet enhanced its recognition capability. The architecture operated by factorizing convolutions into smaller kernels and incorporating auxiliary classifiers, while retaining depth for complex feature extraction. The transfer learning setup adapted pre-trained ImageNet weights to food-specific features, enabling faster convergence and more accurate recognition. The study achieved an accuracy of 90%, but was limited by the intra-class variability and noise within the dataset, that reduced classification stability.

Faezirad et al. [23] proposed a ML-based forecasting approach to reduce food waste in an Iranian university dining systems by predicting student attendance using both reservation and behavioral data and identified fluctuating student presence as the key contributor in food surplus. The two-stage prediction framework employed an artificial neural network (ANN) to model both deterministic and stochastic aspects of demand. In the first stage, the ANN generated a point estimate for student turnout and the system optimized the total operational cost, balancing the trade-off between food wastage and shortage penalties in the second stage. The model achieved accuracy rates between 73% and 75%, resulting in a reported 79.66% reduction

in food waste over a one-year period. The dependence on historical behavioral data from a single institution limited the model's adaptability to other educational environments.

Malefors et al. [24] proposed ML-based forecasting models to anticipate guest attendance in public catering facilities, for optimizing meal preparation and minimizing food waste under COVID-19 pandemic conditions. Attendance data from 18 primary schools and 16 preschool kitchens across Sweden, both pre- and during-pandemic periods, was collected and evaluated using several AI techniques, including ANN, Poisson autoregressive models and RF algorithms. RF model demonstrated superior accuracy with a conditional mean absolute error below 0.15 for training data and between 0.448 and 0.487 for kitchen-level forecasts. The implementation of forecasting yielded financial savings estimated between €921 and €1,298 compared to operations without predictive support. The models exhibited limited reliability during the initial phase of the pandemic and were challenged by abrupt surpluses, indicating reduced robustness under extreme uncertainty.

A. Research Gap

Despite the progress made in food image recognition and subsequent food waste recognition using deep learning architectures such as ResNet, InceptionResNetV2, MobileNetV2, EfficientNet and SGLANet on large-scale image datasets, these studies have primarily addressed the challenge of food categorization rather than the more critical issue of food waste reduction [11] [19] [22]. In parallel, approaches based on predictive analytics, regression models, neural networks, decision trees, reinforcement learning and optimization techniques, including genetic algorithms, random forests, LSTM networks, and Transformer-based forecasting have been widely applied for inventory management, demand forecasting and supply chain optimization [13] [15] [21]. These models have demonstrated measurable reductions in waste but are fundamentally dependent on structured transactional or sensor-based data streams, overlooking the immediate and non-invasive potential of image-based monitoring. This divergence highlights a critical research gap: existing studies either focus on food recognition without waste-oriented outcomes or address waste reduction without leveraging visual cues. Thus, there is a pressing need for an integrated framework with freshness-annotated image data to deliver accurate shelf-life prediction and provide actionable strategies for minimizing food waste in real-world service operations.

III. Materials and Methods

The proposed hybrid model utilizes image data to precisely estimate the remaining shelf-life of prepared foods by combining convolutional and transformer-based architectures. The study makes use of Food Image Classification dataset that has undergone rigorous preprocessing and augmentation and an average shelf-life table is employed for reference in the training stage. Rich spatial characteristics are extracted from input images by the feature extractor, VGG-19, and then used by the Vision Transformer (ViT) to represent temporal and contextual dependencies for accurate shelf-life prediction. Fig. 1 illustrates the basic architecture of proposed model.

A. Dataset Description

The dataset utilised in this study is the Food Image Classification Dataset [25], from a publicly accessible Kaggle repository, comprising around 24,000 high-resolution images spanning 34 diverse food categories, covering a wide range of both Indian and Western cuisines, representing a realistic mix of freshly prepared and commonly consumed dishes. The images were collected from various sources and curated to ensure diversity in lighting conditions, presentation styles and angles, with each food image labelled according to its class. In restaurant and catering inventory analysis, where food items are prepared in bulk and require regular monitoring, the dataset serves as an essential analytical tool. The construction of sophisticated structures, expiration trends and utilisation strategy optimisation are made possible by the visual diversity and class annotations. This makes the dataset perfect for food service operations' waste minimisation and real-time shelf-life estimate algorithms. Fig. 2 represents the sample images in the dataset over different food categories.

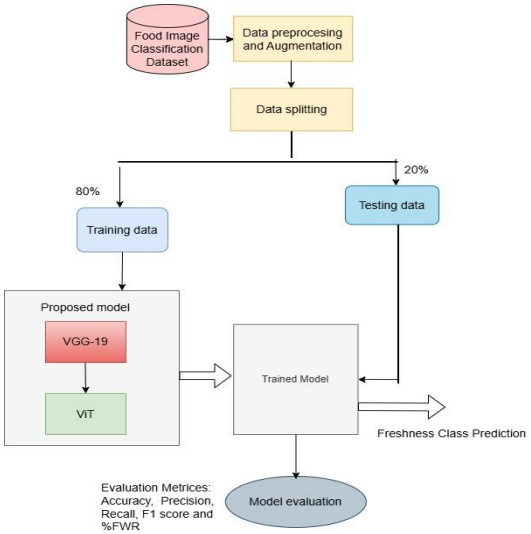

Fig. 1. Basic architecture of the proposed model.

Fig. 2. Sample images in the food image classification dataset.

B. Exploratory Data Analysis

In order to find patterns, anomalies and underlying structures in the dataset, exploratory data analysis or EDA, is an essential step. EDA enables to assess the quality and variability of the images, identify class imbalances and evaluate the distribution of classes in image classification tasks. Additionally, it offers information on possible redundancy, noise or labelling irregularities that have the potential to impair model performance. EDA guarantees well-informed judgments being taken prior to preprocessing and model building by visualizing and encapsulating the data. Fig. 3 illustrates the distribution of images across the 34 food categories in the dataset. Certain subgroups, such as Baked Potato, Hot Dog, Donut and Crispy Chicken, are well-represented, while others, such as Paani puri, Samosa and Kulfi, have relatively fewer samples. Addressing the imbalance is of vital importance as it may bring about in biased learning when the model is being trained. By using EDA to identify this distribution, balanced data augmentation and sampling techniques can be developed to enhance model generalization.

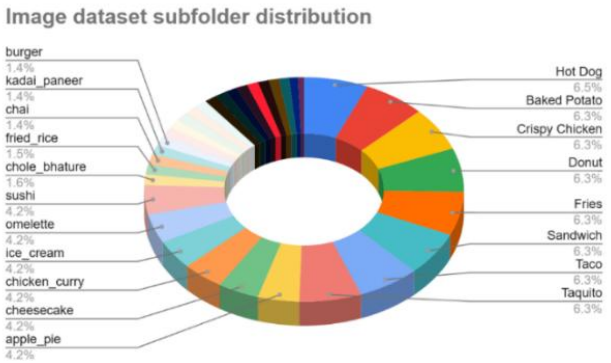

Fig. 3. Image dataset subfolder distribution.

C. Data Preprocessing and Augmentation

A structured data preprocessing and augmentation pipeline is designed for the Food Image Classification dataset to ensure clear and standardized input for the subsequent hybrid architecture. The stage ensures uniformity in image dimensions, address class imbalance and enrich the training set with diverse transformations to reduce overfitting and a compatible data input for the proposed models is generated.

The images are first resized to a fixed dimension of 224×224 pixels, as shown in Eq. (1), conforming to the input requirements of the VGG-19 architecture.

$$I_{resized} = Resize(I_{original}, (H, W)) \quad (1)$$

where, $I_{original}$ is the raw image and $H, W = 224$, the target height and width. Image normalization is further applied to scale pixel intensity values to a standard range, to stabilize the training process and accelerate convergence. The pixel values are normalized to the range [0, 1], as shown in Eq. (2):

$$I_{norm} = \frac{I_{resized}}{255} \quad (2)$$

As the pretrained weights are leveraged, mean subtraction and division by standard deviation were performed as per Eq. (3):

$$I_{norm} = \frac{I_{resized} - \mu}{\sigma} \quad (3)$$

where, μ and σ are the channel-wise mean and standard deviation, respectively. This standardization ensures that each input image contributes uniformly during gradient updates, reducing internal covariate shift. To enable supervised classification, the images are labelled not only by food category but also by freshness state, using a four-class scheme: Fresh, Fit for Consumption, About to Expire and Expired. To numerically represent these classes, label encoding was applied, assigning each category a unique integer value to ensure compatibility with the proposed hybrid model.

Let $C = \{C_0, C_1, C_2, C_3\}$ be the set of freshness categories, where C_0, C_1, C_2, C_3 represent Fresh, Fit for Consumption, About to Expire and Expired, respectively. Each image is tagged based on its freshness level determined by the food's time since preparation t and its standard shelf-life x, as shown in Eq. (4):

$$y_i = \begin{cases} 0\ ;if\ t < 0.2x\ (fresh) \\ 1\ ;\ if\ 0.2x \le t \le 0.8x\ (Fit\ for\ consumption) \\ 2\ ;\ If\ 0.8x < t < x\ (About\ to\ expire) \\ 3\ ;\ If\ t \ge x\ (Expired) \end{cases} \quad (4)$$

The encoded label $yi \in \{0,1,2,3\}$ allows the model to learn the visual differences associated with freshness states, thereby supporting classification tasks aligned with expiration forecasting. Table I illustrates the average shelf-life of various food items.

TABLE I. AVERAGE SHELF LIFE OF VARIOUS FOOD ITEMS

Food Item	Room Temp (hours)	Refrigerated (days)	Frozen (months)
Hot Dog	2	7	1-2
Baked Potato	2	3-5	Not Recommended
Crispy Chicken	2	3-4	4
Donut	24-48	5-7	2-3
Fries	2	2-3	1
Sandwich	3	3	1-2
Taco	2	2-3	1-2
Taquito	2	3-4	2
Apple pie	48	4-5	6-8
Cheese cake	2	5-7	2
Chicken curry	6	3-4	2-3
Ice cream	N/A	30-60	2-4
Omelet	2	2-3	Not Recommended
Sushi	2	1	Not Recommended
Chole bhature	2	2-3	1
Fried rice	6	3-4	1
Tea (Chai)	1	1-2	Not Recommended
Kadai paneer	2	3-4	2
Burger	2	2-3	1
Chapati	24	3-	1
Momos	2	2-3	1-2

Butter naan	24	3-4	1
Pav bhaji	2	2-3	1-2
Idli	24	3-4	1
Dal makhani	4	4-5	2-3
Jalebi	48-72	7	2
Kaathi rolls	24	2-3	1
Pizza	2	3-4	1-2
Masala dosa	2	2-3	Not Recommended
Pakode	2	2-3	1
Dhokla	24	3-4	1-2
Samosa	8	4-5	1
Kulfi	N/A	7-14	2-3
Paani puri	2	1-2	Not Recommended

The dataset is now partitioned into training and testing subsets using an 80:20 split in a randomized fashion. This stratification ensures that the model learns from a broad spectrum of data, while being evaluated on unseen instances. Overall class distribution is maintained to avoid sampling bias and class imbalance. As dataset exhibited class imbalance identified through EDA, the potential of this disparity to create bias during training hampering generalization is considered. Class weights are calculated and added to the loss function to counteract this, allowing the model to penalize minority class misclassification more severely. The weight w_c assigned to class c is determined as in Eq. (5):

$$w_c = \frac{N}{n_c \times C} \tag{5}$$

where, N is the total number of samples and n_c, the number of samples in class c and C is the total number of classes, the four freshness classes. These weights are passed to the training loop so that the model learns more effectively from all classes regardless of frequency.

Data augmentation is applied to the training images to simulate real-world variability in food images, such as differences in angle, lighting and scale, enabling the model to learn invariant features. It includes a number of operations, including random horizontal and vertical flipping, slight rotation, width and height shifts, zooming and brightness variation and the augmented image I' is obtained from the original image I, as shown in Eq. (6):

$$I' = T(I) = R(\theta) \circ Z(s) \circ S(x, y) \circ F(I) \tag{6}$$

where, $R(\theta)$, $Z(s)$ and F denote rotation by angle θ, zooming by scale factor s and flipping transformations, respectively, and $S(x, y)$ represents a shift in width and height. The augmentation steps are applied only to the training dataset to avoid data leakage into test sets. After augmentation, the training dataset increased from 19,200 images to approximately 38,400 images, resulting in a total dataset size of about 43,200 images. By synthetically expanding the dataset, the model is better equipped to handle diverse food presentations and mitigate overfitting.

The images are further converted into tensor format to be efficiently processed by the hybrid model and also to support GPU acceleration. For optimal speed and generalization, the dataset is further segmented into smaller batches, enabling the model to handle multiple samples at once. Prefetching lowers data loading latency and offers more seamless training cycles by preparing the subsequent batch while the current one is being processed.

D. Model Development

1) VGG-19 (Visual Geometry Group-19): VGG-19 is a deep CNN developed to perform robust image classification tasks by learning hierarchical representations of visual data [26]. The VGG-19 network model depicted in Fig. 4, showcases a deep CNN architecture consisting of 19 weight layers. The input image with dimensions 224×224×3 is initially passed through multiple stacked convolutional layers employing small 3×3 kernels with a stride of 1 and padding, followed by ReLU activation functions to introduce non-linearity.

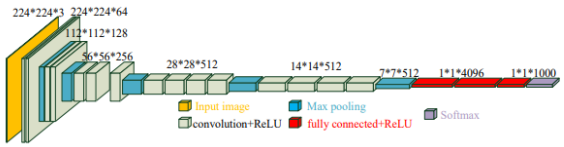

Fig. 4. VGG-19 network model architecture.

As the data progresses through the network, the number of feature maps increases from 64 to 512, while spatial dimensions reduce due to the interleaved max pooling layers which halve the resolution using 2×2 windows. Following the last convolutional block, the flattened feature maps are fed into three fully connected layers, two of which are 4096 in size and one final layer, which is 1000 in size. All of these layers are triggered by ReLU, with the exception of the last one, which outputs class probabilities using Softmax. This particular layer is excluded in the proposed hybrid model. By repeating tiny filters, this design highlights depth and aids in capturing hierarchical representations and fine-grained information. Each convolution layer performs feature extraction, as shown in Eq. (7):

$$X_l = \sigma(W_l * X_{l-1} + b_l) \tag{7}$$

where, X_{l-1} is the input feature map to layer l and W_l, b_l are trainable weights and biases of l. σ and $*$ denotes the ReLU activation function and convolution operation, respectively. The change in feature map size after convolution can be expressed as in Eq. (8) and Eq. (9):

$$H_{out} = \left\lfloor \frac{H_{in} - K + 2P}{S} \right\rfloor + 1 \tag{8}$$

$$W_{out} = \left\lfloor \frac{W_{in} - K + 2P}{S} \right\rfloor + 1 \tag{9}$$

where, H_{in} and W_{in} are the input height and width, respectively. K, P and S represent the kernel size, padding and stride, respectively. The max-pooling operation reduces spatial dimensions while preserving critical information and is defined as in Eq. (10):

$$X_{pooled}(i, j) = \max_{(m,n) \in \Omega} X(i + m, j + n) \tag{10}$$

where, Ω represents the pooling window, (i, j) are the top-left coordinates of the pooling window and m, n are the indices over the local region. The fully connected operation that follows convolution and pooling is defined as in Eq. (11):

$$z = W_{fc} \cdot x + b_{fc} \tag{11}$$

where, x is the flattened input feature vector and z is the linear transformation output. For the proposed hybrid model, the final classification layer is removed, and the intermediate feature representation is fed into downstream models for task-specific inference. The final feature maps are flattened and passed through fully connected layers, producing a high-level embedding.

2) Vision Transformer (ViT): ViT adapts the self-attention-based architecture of transformers from NLP to computer vision tasks by processing images as sequences of patches instead of relying on convolutional filters [27]. It segments an image into fixed-size patches, embeds positional information in these patches and uses self-attention mechanisms to model global contextual relationships throughout the visual field. ViT achieves better performance in applications requiring holistic image processing by capturing long-range relationships through stacked transformer layers, in contrast to convolutional networks that rely on local receptive fields. Fig. 5 illustrates the architecture of ViT.

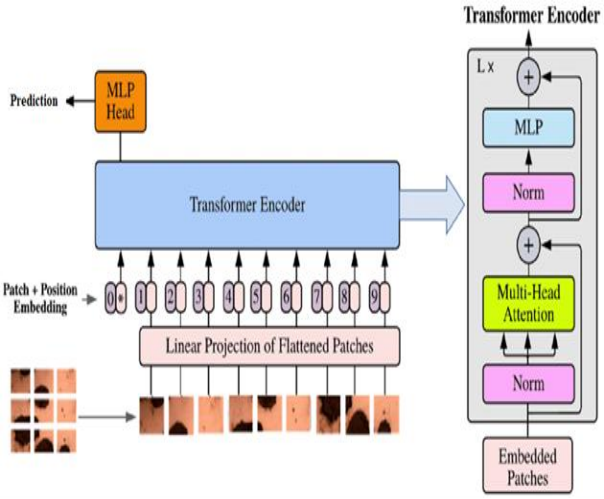

Fig. 5. Basic architecture of ViT.

The process begins with patch embedding, where the input image $X \in \mathbb{R}^{H \times W \times C}$ is divided into $N = \frac{HW}{P^2}$ non-overlapping patches of size $P \times P$. Each patch is then flattened and projected into a latent vector using a trainable linear projection, as shown in Eq. (12):

$$z_0^i = x^i \cdot E \; ; for \; i = 1,2, \dots, N \tag{12}$$

where, $x^i \in \mathbb{R}^{P^2 \cdot C}$ is the i-th patch and $E \in \mathbb{R}^{(P^2 \cdot C) \times D}$ is the embedding matrix. Spatial information lost in flattening is retained by adding positional embeddings $E_{pos} \in \mathbb{R}^{(N+1) \times D}$ to the patch embeddings, including a special learnable CLS token used for classification, as shown in Eq. (13):

$$z_0 = [x_{cls}; x^1 E; x^2 E; \dots ; x^N E] + E_{pos} \tag{13}$$

The embedded sequence is then passed through L identical transformer encoder blocks, each comprising a Multi-Head Self-Attention (MSA) layer and a Multi-Layer Perceptron (MLP) block, both followed by Layer Norm and residual connections, as shown in Eq. (14) and Eq. (15):

$$z_l' = MSA(LN(z_{l-1})) + z_{l-1} \tag{14}$$

$$z_l = MLP(LN(z_l')) + z_l' \tag{15}$$

where, $l = 1,2, \dots, L$ and LN denotes Layer Normalization. The core of ViT lies in self-attention, that models dependencies across all patches. For each attention head, the attention scores are computed, as shown in Eq. (16):

$$Attention(Q, K, V) = softmax\left(\frac{QK^T}{\sqrt{d_k}}\right)V \tag{16}$$

where, $Q = zW^Q, the \; query$, $K = zW^K$, the key and $V = zW^V$, the value projection. d_k represents the dimension of the key vectors. The output corresponding to the CLS token after the final transformer block is passed through an MLP head to produce the final class probabilities, as shown in Eq. (17):

$$y = softmax\ (W_{head} \cdot z_L^{(cls)}) \tag{17}$$

3) Proposed VGG 19-ViT hybrid model: The proposed hybrid model integrates the robust spatial feature extraction capabilities of VGG-19 with the temporal reasoning and attention mechanisms of ViT to effectively classify food items based on their visual freshness condition. The VGG-19 network processes the input image by passing it through a deep convolutional stack, extracting hierarchical spatial features from local edges to complex textures. These learned features, represented as a dense feature map, are then flattened and embedded into a sequential patch representation suitable for transformer architecture input.

Once patch embeddings are generated, they are forwarded to the ViT module, which applies a series of transformer encoder blocks to model inter-patch dependencies and positional relationships. Through multi-head self-attention and feed-forward networks, ViT generates a high-dimensional latent representation that captures both the visual condition and aging indicators of the food item. The model is trained to classify each food image into one of four predefined freshness classes: Fresh, Fit for Consumption, About to Expire and Expired. This prediction assists in intelligent inventory decisions such as prioritizing consumption or removal, without the need for an explicit expiration timestamp. By leveraging both spatial precision and temporal reasoning, the hybrid VGG-19–ViT model shows strong potential in real-time food quality monitoring, dynamic freshness tracking and minimizing food waste in high-throughput environments like restaurants, canteens or retail kitchens.

E. Simulation Setup

The proposed hybrid VGG-19-ViT model was implemented in a high-performance computing environment configured with an Intel Core i7 processor, 32 GB RAM and an NVIDIA Tesla T4 GPU to ensure robust training and inference performance.

The model was developed using the TensorFlow framework with the Keras API, leveraging its modularity and advanced capabilities for implementing custom DL architectures. Model training, evaluation and prototyping were executed on Google Colaboratory Pro, which provided accelerated GPU support and cloud infrastructure optimizing both training time and memory efficiency. To ensure optimal learning, convergence speed and generalization capability, key hyperparameters were carefully selected through empirical tuning and preliminary examinations. Table II shows the hyperparameter specifications utilized in the proposed model.

TABLE II. HYPERPARAMETER SPECIFICATIONS

Hyperparameters	Values
Optimizer	ADAM
Activation Function	Softmax
Loss Function	Categorical Cross-entropy
Batch Size	32
Epochs	50
Learning Rate	0.0001
Dropout Rate	0.2
Number of Transformer Layers	12
Attention Heads (ViT)	12

IV. RESULTS

A set of standard evaluation metrics has been utilized for in depth performance evaluation of the proposed model, as shown in Eq. (18) to Eq. (22). True Positives (TP), False Positives (FP), True Negatives (TN) and False Negatives (FN) are mathematically computed using confusion matrix core elements. Different metrics offer unique insights of the model performance, overall correctness by accuracy, precision and recall highlight the ability of model to correctly predict food freshness stage without excessive misses or false alarms.

$$Accuracy = \frac{TP+TN}{TP+TN+FP+FN} \quad (18)$$

$$Arecision = \frac{TP}{TP+FP} \quad (19)$$

$$Recall = \frac{TP}{TP+FN} \quad (20)$$

$$F1\ score = 2 \times \frac{precision \times Recall}{Precision+Recall} \quad (21)$$

The % Food Waste Reduction calculates the percentage of food waste that is reduced as a result of the proposed model's timely forecasts, especially when products are identified as "About to Expire". It is calculated based on the weight of food consumed before expiration, via predictions by the proposed model, relative to the total food that would have been expired and wasted otherwise. The analysis considered standard portion sizes and average weight estimates for each food category, allowing a precise quantification of rescued food in kilograms. This indicator evaluates how the model helps food service settings manage waste and inventory in a sustainable way.

$$\%FWR = \frac{W_{baseline} - W_{model}}{W_{baseline}} \times 100 \quad (22)$$

where, $W_{baseline}$ and W_{model} are the total waste generated without and with the proposed model, respectively. A higher $\%FWR$ indicates greater effectiveness in reducing waste, showcasing the model's practical utility in inventory decision-making.

The accuracy plot of the proposed model, illustrated in Fig. 6, reveals a consistently improving learning trajectory over 50 epochs, underscoring the model's effective optimization. Initially, both training and validation accuracy rise sharply during the first 10 epochs, indicating rapid feature learning. The training accuracy steadily improves and reaches near-saturation beyond epoch 20, surpassing 99%, while the validation accuracy stabilizes just below 98%, suggesting robust generalization on unseen data. The gap between the two curves remains minimal, indicating low overfitting and well-regularized model behavior. This convergence confirms the proposed model's ability to learn meaningful representations across diverse food freshness categories and maintain high predictive reliability across both training and validation phases.

Fig. 6. Accuracy plot of the proposed model.

The loss plot of the proposed model, illustrated in Fig. 7, demonstrates the convergence behavior of the proposed model across 50 epochs. Both training and validation losses exhibit a sharp decline during the initial epochs, indicating effective learning and a rapid reduction in prediction error. The training loss continues to decrease steadily, approaching near-zero values by the final epochs, reflecting the model's high confidence on seen data. Meanwhile, the validation loss also follows a decreasing trend and stabilizes around 0.08, suggesting good generalization without signs of significant overfitting. The small and consistent gap between the two curves affirms the robustness and stability of the training process. Overall, the minimized loss values validate the model's capability to distinguish food freshness categories accurately and reliably.

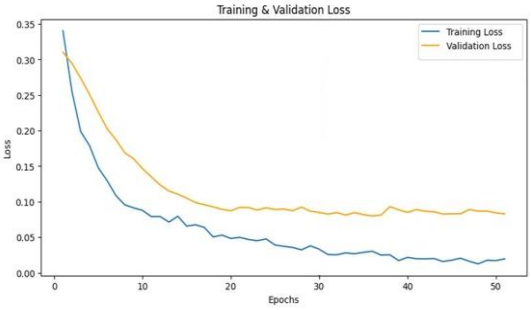

Fig. 7. Loss plot of the proposed model.

The classification report for the proposed model, illustrated in Table III, reflects strong overall performance across all food freshness categories. The model achieves excellent precision and recalls scores for the Fresh and Fit for Consumption classes (0.99/0.99 and 0.99/0.98, respectively), demonstrating excellent ability to consistently and accurately distinguish consumable items. The About to Expire class shows a precision of 0.97 and recall of 0.98, indicating reliable early identification of items nearing spoilage and the Expired class, often difficult to detect due to visual ambiguity, still attains solid performance with a precision of 0.94 and recall of 0.99, minimizing false negatives in disposal-critical cases.

TABLE III. CLASSIFICATION REPORT OF THE PROPOSED MODEL

	Precision	Recall	F1-score
Fresh	0.99	0.99	0.98
Fit for Consumption	0.99	0.98	0.98
About to expire	0.97	0.98	0.97
Expired	0.94	0.99	0.96
Accuracy	0.98		
macro avg	0.97	0.98	0.98
weighted avg	0.98	0.98	0.98

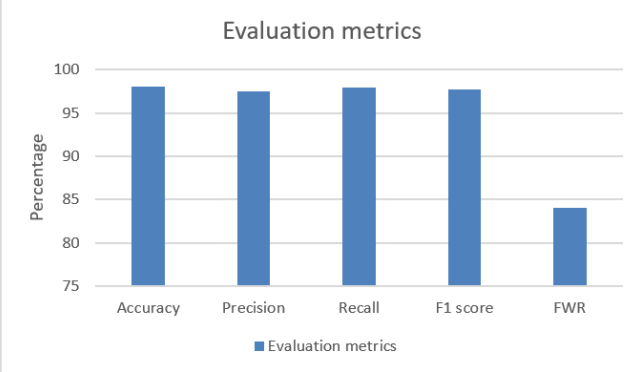

Fig. 8. Evaluation metrics of proposed model.

The evaluation metrics illustrated in Fig. 8 shows a 98% overall accuracy rate confirming that the model can accurately identify most food categories in the test dataset. With a precision score of 97.5%, the model minimizes false positives and proves to be quite dependable, while the 97.9% recall indicates how well the model captures almost all real, pertinent events, crucial for promptly identifying perishable or expired goods. Furthermore, the F1-score of 97.75% verifies a balanced performance, guaranteeing that predictions are accurate and comprehensive. The proposed model significantly enhanced food sustainability by enabling real-time freshness detection and shelf-life prediction, achieving a remarkable 84% reduction in food waste. The proposed model's real-time applicability in minimizing food loss across dynamic food service operations were demonstrated by its excellent capability to detect early signs of deterioration that allowed for timely consumption or redirection.

The confusion matrix illustrated in Fig. 9 analyses the performance of the proposed model across four food freshness classes. The model shows strong predictive accuracy, with particularly high true positive counts for Fresh (1443), Fit (for consumption) (1880), About to Expire (930) and Expired (448) categories. Misclassifications are minimal across all classes, with most errors occurring between neighboring freshness stages, reflecting the natural difficulty in distinguishing borderline cases. The overall accuracy of 98% confirms the model's robustness and high generalization capability in real-world food freshness classification.

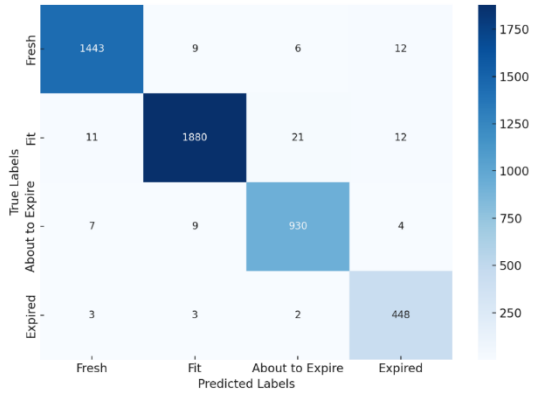

Fig. 9. Confusion matrix of the proposed model.

Fig. 10 represents the results of the proposed model, showcasing a variety of correctly predicted samples across all four freshness classes. Each image includes ground truth and predicted labels, demonstrating the model's ability to generalize across different food types and states with high visual accuracy.

Fig. 10. Results of the proposed model.

Table IV and Fig. 11 illustrate the comparative performance of different architectures applied to various food image datasets. InceptionResNetV2 trained on a Korean food image dataset achieved an accuracy of 81.91%, reflecting the challenges posed by diverse regional cuisine representations. ResNet-50 and Inception-V3, both evaluated on the Food-101 dataset, attained accuracies of 90%, but were constrained by dataset-level variability. EfficientNet V2L on the Indonesian food dataset recorded an accuracy of 85.44%, indicating limitations posed by complex food presentation styles. The SGLANet model applied to the ISIA Food-500 dataset demonstrated a validation accuracy of 90.92%. In contrast, the proposed VGG-19–ViT hybrid model applied to the Food Image Classification dataset achieved a substantially higher accuracy of 98%, clearly outperforming all other architectures. This result underscores the effectiveness of integrating convolutional feature extraction with transformer-based attention mechanisms and highlights the advantage of employing a freshness-annotated dataset tailored for food waste reduction.

TABLE IV. ACCURACY COMPARISON OF THE PROPOSED MODEL WITH EXISTING METHODS

Author [Ref]	Food Image Dataset Used	Method	Accuracy (%)
Chun et al. [10]	Korean Food Image Dataset	InceptionResNetV2	81.91

Table V and Fig. 12 illustrate the comparative performance of different approaches to food waste reduction, evaluated solely on the basis of the percentage of waste reduction achieved, irrespective of whether the methods relied on traditional survey-based strategies, machine learning forecasting, or real-time monitoring systems. Reported reductions vary widely, from 9.46% with SmartNoshWaste to intermediate values of 22% with neural networks and heuristic optimization, 30% through cloud-based machine learning with life cycle assessment, and 40% with AI-driven supply chain optimization. Higher reductions were observed in food service and institutional settings, with tracking systems in HORECA achieving 51% and forecasting models combining random forests and LSTM networks achieving 52%. Advanced predictive models showed further promise, with artificial neural networks reaching 79.66% and random forest–based planning attaining 82%. In comparison, the proposed VGG-19–ViT hybrid model delivered the highest performance with an 84% reduction in food waste, demonstrating the effectiveness of image-based freshness prediction in directly supporting sustainability goals.

TABLE V. % FWR COMPARISON OF THE PROPOSED MODEL WITH EXISTING METHODS

V. DISCUSSION

The results clearly demonstrate that the proposed model delivers strong and reliable performance in food freshness classification. The very high precision and recall scores in the Fresh and Fit for Consumption classes confirm the model's ability to accurately identify items suitable for use, minimizing the risk of unnecessary disposal. The slightly lower precision observed in the Expired class, despite its excellent recall, indicates that the model tends to prioritize capturing all true expired items, which is advantageous for avoiding false negatives in disposal-critical cases. Similarly, the About to Expire class results reflect the model's strength in early spoilage detection, a key factor in reducing waste through timely redirection or consumption. The overall accuracy of 98% and the balanced F1-score highlight the stability of the model across categories. Beyond numerical accuracy, the observed 84% reduction in food waste illustrates the real-world impact of integrating such a system into food service operations, where early and dependable freshness prediction can transform management practices and contribute to sustainability goals.

VI. CONCLUSION

The study proposed a novel hybrid deep learning model integrating VGG-19 and Vision Transformer (ViT) architectures for intelligent monitoring of food freshness and predicting the remaining shelf-life of prepared food items. A meticulously selected food image dataset with 34 distinct food categories that represented actual restaurant and catering settings was employed in training the model. The framework successfully categorized food images into four freshness classes: Fresh, Fit for Consumption, About to Expire and Expired, by employing VGG-19 to extract deep visual characteristics and ViT to predict temporal degradation trends. In doing so, the study makes a theoretical contribution by demonstrating how convolution-based fine-grained feature extraction can be effectively fused with transformer-based self-attention to capture both spatial and temporal degradation cues, offering a new direction for freshness prediction models in food technology. The classification greatly reduced food waste and enabled prompt consumption decisions. The proposed model achieved 98% accuracy, 97.5% precision, 97.9% recall, 97.75% F1-score, and an estimated 84% reduction in food waste, underscoring its strong potential for real-world deployment. The method remains scalable and lightweight by integrating freshness estimation without requiring a large amount of sensor data. Nevertheless, the study is not without limitations. The reliance on a single image modality may restrict generalization under varied lighting or presentation conditions, and the dataset, while diverse, is smaller in scale compared to global benchmarks. Additionally, external factors such as storage temperature or humidity were not integrated into the model. Despite these constraints, the study contributes to the domain by establishing that purely image-based hybrid architectures can reliably predict freshness levels and directly translate to measurable sustainability outcomes in food service operations. Future research could explore integration with real-time kitchen inventory systems, multi-modal learning using sensors, and deployment in edge devices for low-resource settings. Further studies may also validate the framework in larger-scale, multi-institutional datasets and investigate explainability mechanisms to improve model transparency for end-users. Such extensions would further enhance the impact and global applicability of the proposed model in minimizing food waste.

***Abstract*—This study investigates the implementation of an RGB-D Simultaneous Localization and Mapping (SLAM) algorithm on an unmanned aerial vehicle (UAV) equipped with an Intel RealSense D435i camera. The study focuses on Real-Time Appearance-Based Mapping (RTAB-Map), a well-established RGB-D SLAM method capable of building 3D maps while simultaneously localizing a robot within its environment. Despite its advanced capabilities, deploying RTAB-Map on UAVs introduces specific challenges due to the dynamics of aerial navigation. This research evaluates the performance of RTAB-Map in terms of robustness, precision, and accuracy to optimize its application in UAV-based RGB-D SLAM. The findings reveal that the sequential frame-matching approach, combined with a minimum inliers threshold of 10, provides the most robust performance. In contrast, the global matching approach with a minimum inliers threshold of 20 offers better precision and accuracy. The results show that this implementation, utilizing an off-the-shelf hardware and software setup, has significant potential for advanced applications such as monitoring and surveillance in environments, where dense 3D mapping is critical.**

I. Introduction

Autonomous robotics has been a key area in the field of robotics. The necessity of determining a robot's position on a map in unknown environments, while simultaneously building the map representation itself, has led to the development of Simultaneous Localization and Mapping (SLAM) algorithms over the past three decades [1]-[4]. The demand for SLAM algorithms has grown significantly, as they are widely used for various applications in both ground-based and aerial robots. Computer vision technology has advanced over recent years, and the usage of vehicles with teleoperation capabilities is seen as a big potential to be commercialized. By integrating the SLAM algorithm with these vehicles, a technological milestone could be achieved. This study focused on the issue of SLAM with Unmanned Aerial Vehicle (UAV) which addresses a specific SLAM problem, involves the challenge of mapping the environment that has been explored by UAV in a 3D map representation, while determining its position within the gradually constructed 3D map [5].

Despite intensive research, implementing SLAM on UAV platforms remains challenging. One of the primary issues is that UAVs operate at higher speeds, which can reduce the accuracy of SLAM algorithms. Moreover, when applying SLAM in large or complex environments, UAVs may encounter difficulties such as rapid viewpoint changes, inconsistent loop closures, and accumulated drift errors [6]-[8]. A drawback often occurs when the UAV revisits previously mapped regions, where newly estimated landmark locations may not align with earlier ones. A robust and efficient algorithm is therefore required to achieve reliable SLAM performance for UAVs, especially given the trade-off between real-time operation and mapping accuracy. While robust methods exist for static and structured environments, mapping unstructured, dynamic, or large-scale settings continues to be an open research problem [2] [4].

Among existing RGB-D SLAM algorithms, RTAB-Map has proven effective as a graph-based approach in various robotic applications. However, its performance when applied to UAVs is inconsistent. UAV platforms introduce unique challenges such as high-speed motion, rapid viewpoint changes, and dynamic environments, which can significantly degrade SLAM accuracy and robustness. In particular, the performance of RTAB-Map depends heavily on parameter configurations (e.g., camera resolution, frame rate, odometry strategy, and loop closure thresholds) [9]-[12]. Yet, there is limited research systematically examining how these parameters influence UAV-based SLAM performance. Without such insights, it is difficult to identify optimal configurations that balance accuracy, robustness, and real-time feasibility for UAV operations.

Given this problem, this research study tries to address the following questions:

- How do state-of-the-art RGB-D SLAM algorithms such as RTAB-Map perform when applied to UAV platforms in terms of accuracy, robustness, and efficiency?
- Can modifications, parameter tuning, or integration strategies improve their performance for UAV-based applications?

To address the research questions outline the following objectives are outlined:

- To evaluate the impact of key parameters such as RGB and depth camera resolution, frame rate (fps), visual odometry strategies, and loop closure inlier thresholds on the performance of RTAB-Map for UAV-based SLAM.
- To investigate the optimum parameter configuration that maximizes accuracy, efficiency, and robustness of RTAB-Map in UAV navigation and mapping tasks.

This research is significant as it reduces the gap between conventional SLAM implementations and the unique requirements of UAV navigation. By evaluating and comparing RGB-D SLAM algorithms in UAV contexts, this study is expected to provide researchers and practitioners with some insights into algorithmic strengths and weaknesses, as well as practical guidance for deploying UAV-based SLAM in real-world environments. It is hoped that the outcomes can support the development of more reliable and efficient autonomous UAV systems for applications in surveillance, mapping, disaster response, and environmental monitoring.

The remainder of this study is structured as follows: Section II presents the literature review of the SLAM algorithm, focusing on two prominent RGB-D SLAM algorithms: ORB-SLAM2 and RTAB-Map. Section III outlines the research methodology applied in this study, while Section IV discusses the results and findings of the experiments conducted. Finally, Section V provides the conclusion of the study.

II. Literature Review

A. Visual Simultaneous Localization and Mapping (VSLAM)

In the Simultaneous Localization and Mapping (SLAM) algorithm, mapping is for obtaining a model of the robot environment, and localization is to estimate the position of the robot in the obtained map. Despite significant progress in this area, it still poses great challenges [2]-[4]. The accuracy of environment mapping depends highly on the effective parameters which need to be studied. The important parameters that affect SLAM performance include sensor uncertainty, correspondence issue, loop closing, time complexity and dynamic environment [1].

Visual sensor implementation of SLAM or also known as visual SLAM (VSLAM) systems, can be classified into monocular SLAM, binocular SLAM and RGB-D SLAM [9]. The input sensor for classic visual SLAM systems is a monocular or stereo camera. Using these two vision sensors to reconstruct a 3D map, sophisticated map initialization and map point triangulation operations are required, which are computationally challenging and can result in noisy observations. The introduction of RGB-D cameras, which deliver RGB images along with depth information, addresses the issue that comes with monocular and stereo cameras. Due to the fact that RGB-D cameras can provide both colored and depth images simultaneously, they are increasingly utilized for indoor scene reconstruction and can effectively address limitations such as reconstruction of low-textured areas [12]. Low-textured areas are surfaces with few distinguishing features. These areas are difficult to reconstruct because they lack sufficient feature points for effective tracking and mapping [10], [11].

B. ORB-SLAM2 and RTAB-Map

In this study, the RGB-D SLAM algorithms of interest that are to be researched are RTAB-Map and ORB-SLAM2. RTAB-Map was first developed in 2009 and released as an open source library in 2013. Since then, it has evolved into a complete graph-based SLAM approach that can be used in a variety of setups and applications [13]. RTAB-Map is a graph-based SLAM approach based on an incremental appearance-based loop closure detector. To determine whether a new image is likely to come from a prior or new place, the loop closure detector employs a bag-of-words approach. When a loop closure hypothesis is accepted, a new constraint is added to the map's graph, and the map's mistakes are minimised using a graph optimizer. To ensure that real-time limitations on large-scale environments are always maintained, a memory management strategy is employed to limit the number of locations used for loop closure detection and graph optimization. Visual odometry strategies play a crucial role in RTAB-Map's operation. Frame-to-frame odometry compares each image to the previous one, offering speed and efficiency but suffering from drift over time. In contrast, frame-to-map odometry compares each image to a gradually built map, improving accuracy but increasing computational demands [11], [14].

ORB-SLAM2 is a comprehensive SLAM system with map reuse, loop closing, and re-localization capabilities. Proposed in 2016 by Raul Mur-Artal et al., ORB-SLAM2 provides support for stereo cameras and RGB-D cameras as an improvement from its predecessor, ORB-SLAM. The algorithm is able to operate swiftly in real-time [9]. ORB-SLAM2 selects ORB as the 2D features for all SLAM operations, including tracking, mapping, relocalization, and loop closing, in order to maintain speed and rotation invariance [10]. If tracking was successful in the previous frame, ORB-SLAM2 use a constant velocity motion model to project the camera pose and conduct a guided search of the map points encountered in the previous frame. If inadequate matches were discovered (i.e., due to an inadequate motion model), ORB-SLAM2 does a broader search of the map points surrounding the subject's position in the previous frame. The pose is then enhanced using bundle adjustment (BA) through the discovered 2D correspondences [10].

Although ORB-SLAM2 has significantly improved in both efficiency and precision, certain issues remain unresolved. One major challenge is system tracking failure in dynamic environments, which arises from the feature point extraction process being insufficiently robust in conditions such as sudden lighting changes, excessively strong or weak light intensity, or environments with minimal texture information [9]. Solving motion blur becomes a key focus in visual SLAM since common cameras frequently produce image blur when moving rapidly.

N. Ragot et al. (2019) conducted research on the benchmark of the two reviewed SLAM algorithms; ORB-SLAM2 and RTAB-Map [15]. The research utilized an Intel RealSense D435 camera mounted on a robotics-powered electric wheelchair to test and evaluate the performance of these algorithms across various configurations, such as straight-line motion, straight-line motion with a return path, and circular paths with loop closure. All experiments were performed in a controlled indoor environment.

The study highlighted that both RTAB-Map and ORB-SLAM2 have unique strengths in specific aspects. RTAB-Map, a graph-based SLAM system, integrates two key algorithms: loop closure detection and graph optimization. According to N. Ragot et al., RTAB-Map demonstrated more accurate trajectory estimation, better performance in translational movements, and more effective utilization of RGB data. However, it produced less accurate results during rotational movements. On the other hand, ORB-SLAM2 relies on consecutive image frames to construct a map and localize itself within it. It showed superior performance in distance measurement and odometry estimation compared to RTAB-Map. Nonetheless, its performance with RGB cameras was less effective than stereo cameras, particularly in outdoor scenarios [9].

While these benchmarking studies provide valuable insights, most evaluations of RTAB-Map have concentrated on ground robots or controlled indoor environments with fixed parameter settings. Consequently, there remains a limited understanding of how RTAB-Map behaves in UAV contexts, where challenges such as higher flight speeds, rapid viewpoint changes, and real-time processing demands are more critical. This gap shows the need for investigations into how key parameters such as camera resolution, frame rate (FPS), odometry strategy, and loop closure thresholds affect RTAB-Map's performance when deployed on UAVs. Addressing this gap is important for adapting RTAB-Map to aerial robotics and ensuring robust autonomous navigation in real-world scenarios.

Hence, this study focuses exclusively on RTAB-Map and conducts a parameter sensitivity analysis to investigate the optimum configuration for UAV-based SLAM.

III. Methodology

A. System Interface

In this study, a UAV modelled NXP KIT-HGDRONEK66 was used, where the devices for communication and flight control using PX4 [16] flight management unit were on board. Fig. 1 shows the front and top views of the assembled UAV. All devices are mounted on the UAV bar, and the camera is attached underneath the UAV at its centre of gravity to ensure the UAV's stability. The overall system interface is illustrated in Fig. 2.

On board the UAV, a Raspberry Pi 4B was mounted to transmit data from the Intel RealSense D435i RGB-D camera [17] to the remote PC. Both the Raspberry Pi 4 and the remote PC run Ubuntu and Robot Operating System (ROS) as the system employs a ROS-based communication architecture. The remote PC is configured as the ROS master. The remote PC also runs SLAM using RTAB-Map. The Raspberry Pi on the UAV operates as a ROS node, publishing data from the RealSense camera to the RTAB-Map node on the remote PC.

In addition to data transmission, telemetry communication between the UAV and the remote PC is established using the Holybro SiK Telemetry Radio V3 device. This communication link enables real-time monitoring of flight parameters and the ability to issue control commands through the QGroundControl software on the remote PC.

Fig. 1. Front view (left) and top view (right) of the assembled UAV.

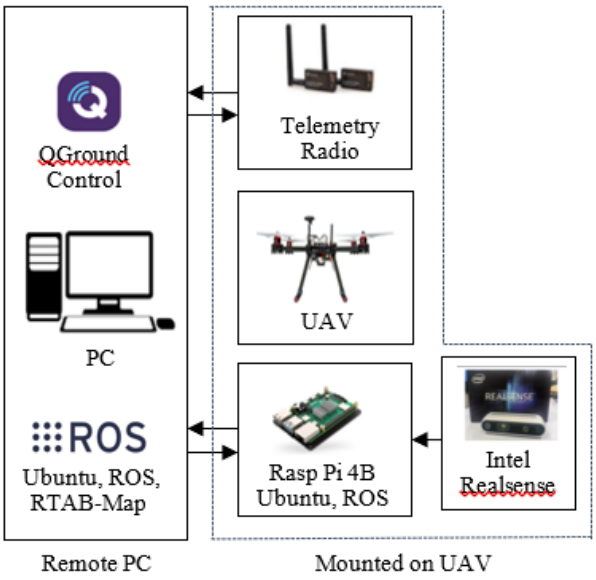

Fig. 2. Overall system interface of the RGB-D SLAM system.

B. Effective Parameters Tuning

The goal of this parameter study is to identify the optimum configuration of parameters that yield better performance of the RTAB-Map SLAM algorithm for UAVs. The parameters that were studied and tuned are as follows:

- RGB and depth camera resolution,
- RGB and depth camera number of fps,
- visual odometry strategy, and
- The minimum inliers threshold for loop closure detection

The resolution of RGB and depth cameras are parameters that study the correlation between the quality of images with transmission rate performance. A higher camera resolution yields a sharper image and gives more visual features in the surroundings. However, a higher quality image requires more processing and hence has an impact on the transmission rate or speed of the data sent to the ROS topics.

As for the RGB and depth camera fps, they are important parameters as they affect the frequency of data being published to the ROS topics. If there are more frames per second captured by both RGB and depth cameras, the data needs to be published to the RGB and depth topics more often. Hence, requires a higher transmission frequency.

In RTAB-Map, the RGB and depth topics are used to estimate the trajectory of the RGB-D sensor and to build a 3D map. Fig. 3 shows a redrawn rqt graph from ROS, considering only the relevant nodes and topics involved in this process. For better distinction, only the nodes are colored. The rqt graph shows that the /camera/realsense2_camera_manager node publishes all sensor data, including RGB, depth, and IMU information. This data is then processed by other nodes. The /rtabmap/rgbd_odometry node subscribes to the color and depth topics to perform visual odometry, estimating the localization of the RealSense camera. This localization is considered the UAV's position and is published to the /rtabmap/odom topic. The /rtabmap/rtabmap node subscribes to /rtabmap/odom, color, depth, and IMU data to build a 3D map and localize the UAV within the global map. It should be noted that the /rtabmap/rgbd_odometry node computes local odometry incrementally, the /rtabmap/rtabmap node performs global pose graph optimization and also loop closure detection. The mapping results, including the optimized trajectory and 3D map, are published on the /rtabmap/mapData topic.

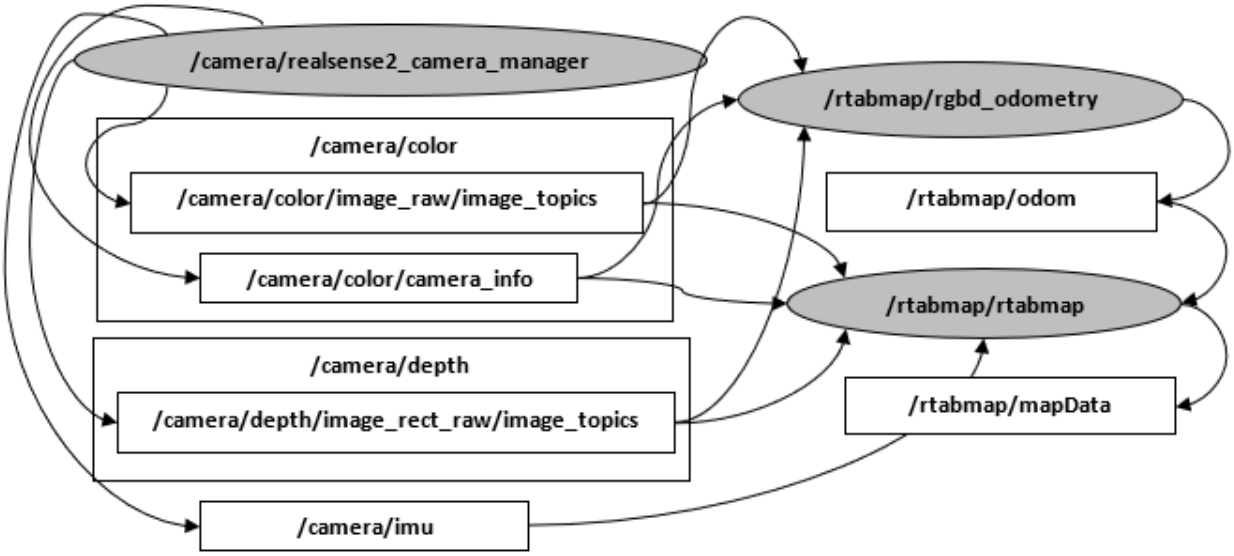

Fig. 3. A part of rqt graph when executing RTAB-Map.

The trajectory of the UAV is estimated using the visual odometry strategy implemented [14]. Visual odometry is the process of determining odometry information using sequential camera images to estimate the distance travelled by the RGB-D sensor on board, hence the UAV. The accuracy of visual odometry affects the overall performance of RTAB-Map. In this study, the visual odometry strategy was studied to determine its significance of impact. Visual odometry strategy that were tested includes frame-to-frame and frame-to-map.

In frame-to-frame odometry, the algorithm compares each image frame (or camera view) directly to the previous frame to estimate the trajectory. This is computed in the /rtabmap/rgbd_odometry node. Although this approach is efficient, as only a few consecutive images are compared, however, it is more prone to error accumulation over time. This strategy is suitable for real-time applications where some drift is acceptable. In frame-to-map odometry, the algorithm compares the current frame to an existing global map, which has been built gradually from past frames. This is computed in /rtabmap/rtabmap node. It is a more accurate approach as it references the entire map, but it can be slower and more computationally intensive. This approach is suitable for long-term mapping.

The last parameter studied is, minimum inliers threshold. It encapsulates how well the algorithm accepts input data as loop closure. Theoretically, a higher value allows the algorithm to only accept frames with more features to perform loop closure. This will result in lesser loop closures being detected as more matching visual features are required.

C. Performance Analysis

This section highlights the corresponding metrics that were observed and measured for performance evaluation purposes. The performance of the RGB-D SLAM algorithm was evaluated through a series of different categories, which are computational efficiency, robustness, precision and accuracy. Computational efficiency measures the amount of time required to process and transmit data. Metrics that were observed for this criterion are the publishing time of topics and the rate of data transmission. The ability of the algorithm to handle noise, outliers and other sources of errors defines the robustness criterion, where it is represented by the percentage of successful runs. A successful run is defined by a situation where a loop closure is successfully detected during a mapping sequence, and there are no odometry loss occurrences. The precision criterion measures the resolution and detail of the map produced by the algorithm. Keypoint detection per millisecond is observed to determine the precision of the algorithm. Last but not least, total distance travelled and distance between landmarks are the metrics measured to determine the accuracy of the algorithm, where the distance computed by the algorithm is compared with the ground truth.

IV. Results and Discussion

This section encapsulates the results obtained from experiments conducted based on the methodology mentioned in

previous section. The results were split based on different environments to observe the performance of the algorithm. Analysis on the findings of the experiments were discussed in this section. The effects of parameter tuning can be demonstrated through the analysis conducted.

A. Camera Parameter Optimization

Through research and experiments, it is noted that the publishing rate of topics is dependent on the Wi-fi signal, resolution and fps of the RGB and depth camera. The initial configuration is shown in the middle column of Table I. In the initial configuration, no data was published to the camera topics, preventing the algorithm from running. After further investigation, these parameters need to be tuned in order to yield better performance in terms of topics' publishing rate. The Wi-fi signal band of 2.4 GHz is better for long-range applications but has a slower speed, while 5 GHz gives significant improvement in speed but is lacking in terms of range coverage.

The fps of the camera, on the other hand, affects the transmission performance. This is because higher fps results in the camera capturing more frames that need to be processed every second. This may lead to a bottleneck, where the rate of frames being processed to be published as ROS topics exceeds the system's computational capacity, causing frames to be dropped and not transmitted. Overloading of the processing performance causes frames to be dropped and not transmitted. After switching to the 5 GHz band and reducing the fps of both the RGB and depth camera to 15 fps, the publishing rate of the topics was improved to an average of 7 Hz.

Further tuning of the parameter was conducted to obtain the best publishing rate performance. By using a lower setting of resolution for both RGB and depth camera, an experiment was conducted to observe the publishing rate. The new configuration that was tested can be observed in the rightmost column of Table I. As a result, the publishing rate of both the RGB and depth topics was further improved to around 15 Hz, which could be observed in Fig. 4 and Fig. 5. It can be concluded that transmission performance is directly affected by the resolution of RGB and depth cameras. This shows that the RGB and depth topics require minimal delay or bottleneck when processing the topic to be able to publish at an acceptable and consistent rate.

B. Indoor Environment Mapping Experiment

The RTAB-Map algorithm was first run on a Raspberry Pi without integration to the UAV. The Intel RealSense D435i camera was connected to the Raspberry Pi 4B, and handheld mapping was conducted inside our research laboratory in the faculty. This experiment was conducted to analyze the effect of parameter tuning in an indoor environment in terms of precision and accuracy, as well as to identify the most robust parameter configuration. The experiment was successfully conducted, where a 3D map and an occupancy grid map of the laboratory were obtained. Occupancy grid map is a map representation that is commonly used by the SLAM algorithm that generate precise metric maps which are close to the detailed environmental representations [7]. Fig. 6 and Fig. 7 show both maps, respectively.

TABLE I. INITIAL AND UPDATED CONFIGURATION

Parameter	Initial Value	Updated Value
Wi-fi band	2.4 GHz	5 GHz
RGB camera fps	30	15
Depth camera fps	30	15
Resolution of RGB camera	640 x 480	424 x 240
Resolution of depth camera	640 x 480	480 x 270

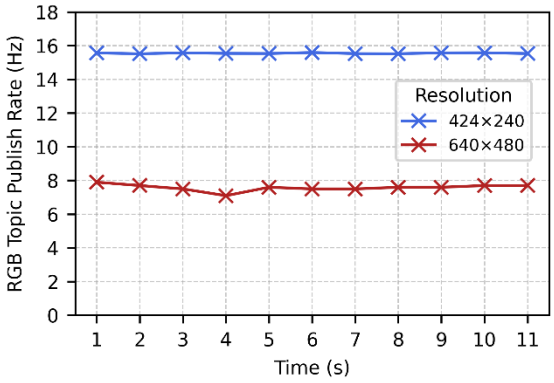

Fig. 4. Graph of publish rate of RGB topic vs. time.

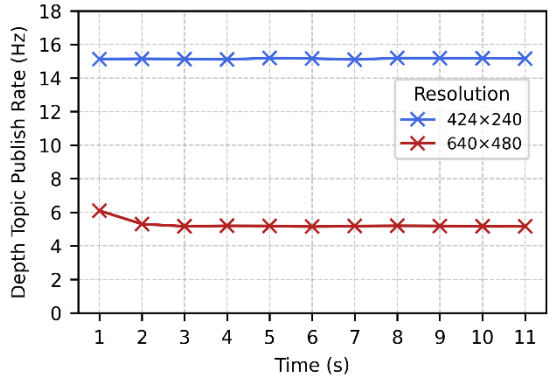

Fig. 5. Graph of publish rate of depth topic vs. time.

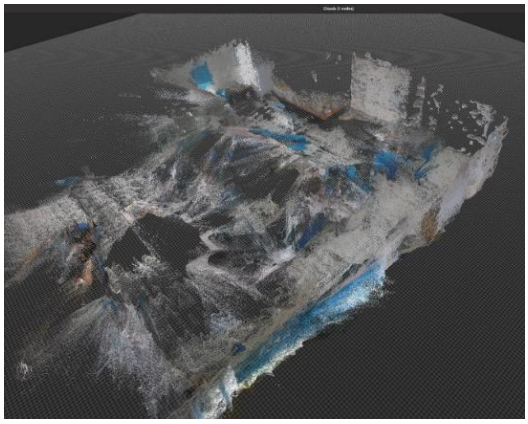

Fig. 6. 3D map of handheld mapping.

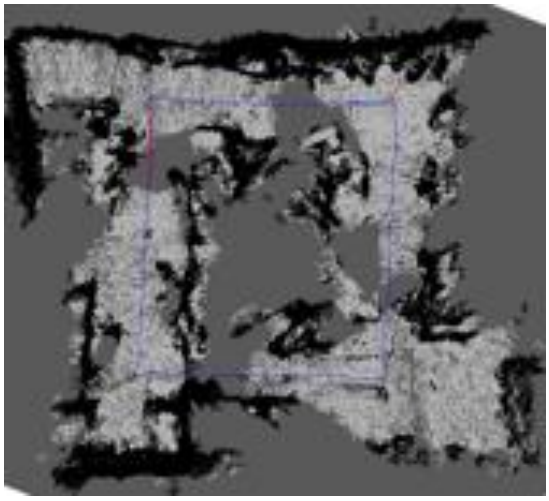

Fig. 7. Occupancy grid map of handheld mapping.

The experiment was conducted through a series of different parameter configurations. The parameters that are tuned were the visual odometry strategy and the minimum inliers threshold. As mentioned in Section III B, there are two visual odometry strategies, which are frame-to-map and frame-to-frame. On the other hand, the values used for the minimum inliers threshold were 10 and 20. Firstly, the robustness of the algorithm with these different parameter configurations was observed. In a total of 11 trials for each parameter configuration, the percentage of successful runs was computed. It was identified that the frame-to-frame odometry strategy with a minimum inliers threshold value of 10 showed the best performance in terms of robustness of the algorithm, with a 90.91% rate of successful runs.

We can observe that by changing the visual odometry strategy from frame-to-map to frame-to-frame, for each minimum inliers threshold, the value increases the robustness performance by at least 9.09%, as depicted in the bar chart in Fig. 8. The advantage of using a frame-to-frame setting over a frame-to-map is that the tracked features don't dip below a ratio of the previous frame the robot had seen. Hence, if the robot is not moving, the key frame would remain static and would remember the features in that frame. In this indoor environment experiment, the frame-to-frame odometry strategy provided better odometry compared to the frame-to-map odometry strategy, which indirectly increases the loop closure detection of the algorithm.

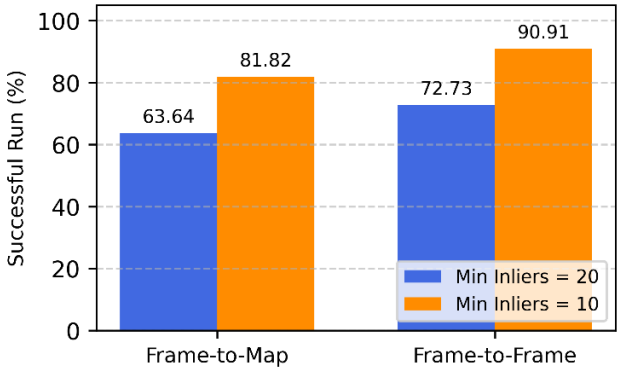

Fig. 8. Percentage of successful runs in the indoor environment.

Next, we can also observe from the bar chart in Fig. 8 that, by lowering the minimum inliers threshold from 20 to 10 for each visual odometry strategy boosts the robustness by at least 18.18%. A lower minimum inliers threshold results in frames with less features to be accepted as keyframe, which are then used for computation of localization and mapping by RTAB-Map algorithm. When the keyframe acceptance is more lenient, then the running performance of the RTAB-Map algorithm could be increased, as shown in the indoor environment mapping experiment.

The experiment was also conducted to evaluate the performance in terms of precision. For the frame-to-map visual odometry strategy, the keypoint detection per ms was observed and tabulated in the first two rows of Table II. The subsequent rows show the keypoint detection per ms for the frame-to-frame visual odometry strategy. For both strategies, a minimum inliers threshold value of 20 shows a higher keypoint detection per ms value compared to using a threshold value of 10. The observed results show that when the minimum inliers threshold is set to a higher value, the keypoint detection per ms will be higher. This is because a higher number of features need to be recognized within a frame for it to be accepted as a keyframe before proceeding to evaluate the next frame. Consequently, these selected frames can be considered of higher quality as they show to have more keypoints (refer to Table II). It can be concluded that applying a stricter threshold ensures the extraction of more keypoints, resulting in a more precise computation of the surrounding environment.

TABLE II. KEYPOINT DETECTION PER MS

Visual odometry	Min inliers threshold	Keypoint/ms
Frame-to-map	20	5.83
	10	5.20
Frame-to-frame	20	5.80
	10	4.86

Evaluation of performance in terms of accuracy was also conducted, where total distance travelled and the distance between two landmarks: Landmark 1 and Landmark 2, in meters, were observed and compared relative to the ground truth. Table III shows the estimated distance of the RTAB-Map algorithm. This shows that using RTAB-Map, similar to other common SLAM algorithms, the error is accumulated over the distance travelled. In this experiment, the error in the estimated trajectory is approximately 9.1 meters, which corresponds to about 26.6% error relative to the actual distance of 34.23 meters. In contrast, for a single measurement between Landmark 1 and 2, the error is only 0.15 meters, or approximately 7.5%, indicating that initial measurements are typically more accurate than long trajectory estimation.

TABLE III. DISTANCE ERROR FOR INDOOR ENVIRONMENT

Experiment	Actual (m)	RTAB-Map (m)	Error
Distance travelled	34.23	43.33	0.266
Landmark 1 and Landmark 2	2.00	2.15	0.075

Overall, it can be concluded that parameter configuration with the frame-to-frame visual odometry strategy and a minimum inliers threshold of 10 yields the most robust performance. This is due to the fact that it has higher trajectory accuracy and more lenient keyframe acceptance. However, there is a trade-off in terms of precision and accuracy where the generated 3D map is less dense and has fewer keypoints compared to the frame-to-map odometry strategy with a minimum inliers threshold of 20 parameter configuration.

C. Outdoor Environment Mapping Experiment

Before outdoor environment mapping is conducted using a UAV, an experiment with handheld mapping was first conducted to analyze the performance of the algorithm with a different layout. The purpose of this is to get the basis of the performance of the RTAB-Map algorithm in an outdoor environment. Since the nature of UAVs' flight is high-speed movement and maneuverable, a robust algorithm is desired to ensure a sustainable mapping process. Hence, the parameter configuration with the highest success rate was chosen, which was the frame-to-frame and minimum inliers threshold of 10. The experiments were executed at two different outdoor scenarios around the faculty: outdoor scenario 1 and outdoor scenario 2. As a result of the experiment, the 3D maps were successfully obtained for both of the outdoor scenarios, as depicted in Fig. 9 and Fig. 10.

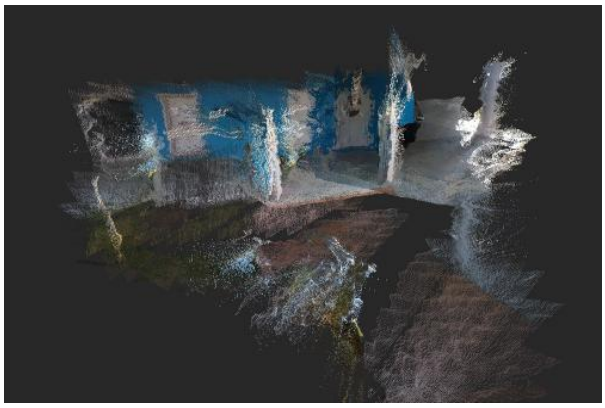

Fig. 9. 3D Map for outdoor 1.

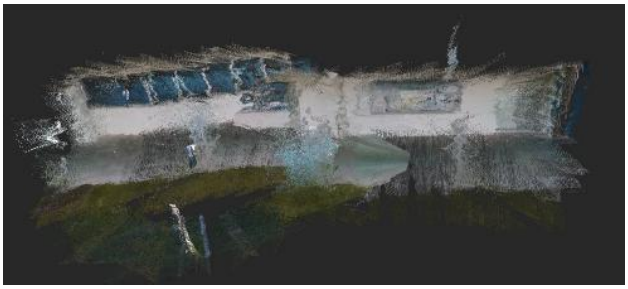

Fig. 10. 3D Map for outdoor 2.

Scenario of outdoor 1 and outdoor 2 yields different performance in terms of robustness and accuracy. The mapping sequence showed a 50% success rate for outdoor 1, while outdoor 2 demonstrates an 83.33% success rate out of a total of 6 trial runs, as shown in Fig. 11. In terms of accuracy, the total distance travelled, in meters, was measured and compared with the ground truth, as shown in Table IV. Outdoor 1 showcase a higher error (0.8283) compared with outdoor 2 (0.5676). Both these errors are still high and show that the accuracy of the trajectory travelled using RTAB-Map is less accurate. The longer the total distance travelled, increases the inaccuracy of the generated map due to accumulated error.

However, the computed error between landmarks remains relatively low for both outdoor 1 and outdoor 2, with values of 0.0259 and 0.0268, respectively (see Table V). This demonstrates that RTAB-Map is more reliable for short-term mapping that does not involve long distances travelled, as it can tolerate small drifts and still maintain a consistent map.

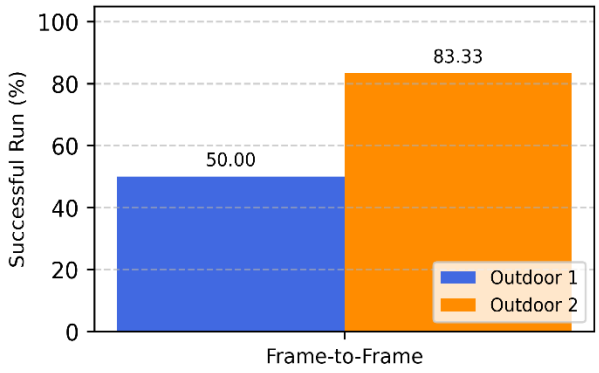

Fig. 11. Percentage of successful runs in outdoor environment.

TABLE IV. TRAVELLED DISTANCE ERROR FOR OUTDOOR ENVIRONMENT

Experiment	Actual (m)	RTAB-Map (m)	Error
Outdoor 1	16.53	30.22	0.8283
Outdoor 2	14.3	22.42	0.5676

TABLE V. DISTANCE BETWEEN LANDMARK ERROR FOR OUTDOOR ENVIRONMENT

Experiment	Actual (m)	RTAB-Map (m)	Error
Outdoor 1	3.18	3.26	0.0259
Outdoor 2	3.67	3.76	0.0268

V. LIMITATION

Although this study provides some insights into the effect of parameter configurations on RTAB-Map performance for UAV-based SLAM, several limitations remain. First, the experiments were conducted under controlled conditions with specific UAV hardware such as Intel RealSense D435i camera. The results may therefore not fully generalize to other UAV platforms, sensors, or outdoor environments subject to more dynamic conditions such as wind and lighting variations. Second, the evaluation was limited to a selected set of parameters; camera resolution, frame rate, visual odometry strategy, and loop closure inliers. While these parameters are critical, RTAB-Map contains additional configuration options (e.g., memory management strategies, feature extraction settings, and graph optimization techniques) that could further influence performance. Third, computational resources were constrained by the onboard UAV hardware, which may have affected the algorithm's scalability in larger or more complex environments.

VI. Conclusion and Future Works

RTAB-Map is an RGB-D SLAM algorithm with a loop closure detector that employs a bag-of-words approach to determine the possibility of a fresh image to be coming from a prior or new place. In this research, the loop closure detector of RTAB-Map utilizes both RGB and depth data from Intel RealSense D435i in making the decision whether to accept or deny loop closure hypotheses.

This project generally studies the applicability and relevance of SLAM algorithm implementation with UAVs by collecting all the important data and conducting a thorough assessment. Effective parameters and their relative effects on the performance of the SLAM algorithm were evaluated accordingly. The effective parameters were identified as RGB and depth camera resolution, RGB and depth camera fps, visual odometry strategy and minimum inliers threshold. The effect of tuning the parameters was then investigated in different environments (indoor and outdoor) to better understand the significance of the impact. An analysis was conducted to determine the best configuration of parameters to be applied for outdoor environment mapping by the UAV. Frame-to-frame odometry strategy minimum inliers threshold value of 10, proved to be the most robust setting to be implemented for UAV. However, there will be repercussions faced by the algorithm, where the performance will suffer in terms of precision and accuracy. Although the optimal parameters were identified for maximum robust performance of RTAB-Map, it still was not enough to cope with the movement of the UAV, as sharp turns would cause the algorithm to halt due to odometry data being lost.

Future research can extend this work in several directions. A broader exploration of RTAB-Map parameters and their interdependencies would provide deeper insights into optimizing UAV-based SLAM. Furthermore, integrating adaptive parameter tuning methods, such as machine learning-based auto-configuration, could allow UAVs to dynamically adjust SLAM parameters in response to environmental changes. Finally, long-term autonomous flight experiments, including large-scale outdoor mapping and multi-UAV collaborative SLAM, represent promising directions for advancing the robustness and applicability of RTAB-Map in real-world UAV operations.

***Abstract*—In this paper, we carried out an in-depth comparative analysis of five major supervised classification algorithms: Naïve Bayes, Decision Tree, Random Forest, KNN and SVM. These models were evaluated through a rigorous literature review, based on 20 criteria grouped into five key dimensions: algorithm performance, computational efficiency, practicality and ease of use, data compatibility and practical applicability. The results show that each algorithm has specific strengths and limitations: SVM and Random Forest stand out for their robustness and accuracy in complex environments, while Naïve Bayes and Decision Tree are appreciated for their speed, simplicity and interpretability. KNN, despite its intuitive approach, suffers from high complexity in the prediction phase, limiting its effectiveness on large datasets. This study aims to provide a structured framework for researchers and practitioners in various fields, such as healthcare, finance, industry and education, where supervised classification algorithms play a central role in decision-making. In addition, the results highlight the importance of selecting algorithms according to specific needs, and open up promising prospects, including the development of hybrid models and improved real-time data processing.**

Keywords*—Supervised classification; Naïve Bayes; decision tree; Random Forest; k-nearest neighbor; Support Vector Machine; algorithm performance; interpretability

I. INTRODUCTION

In today's era of megadata, supervised classification models play a central role in transforming raw data into actionable information in critical fields such as healthcare, finance and industry. The rise of artificial intelligence (AI) and the increasing availability of data have reinforced the importance of supervised classification as a pillar of machine learning systems. These models are used, for example, to improve medical diagnosis by identifying complex patterns in health data, to detect fraud in finance and to predict preventive maintenance in the manufacturing industry. However, in view of the growing diversity of available models and the varied requirements of practical applications, in-depth benchmarking is needed to guide informed choices and maximize the effectiveness of solutions.

The massive increase in data volumes is accompanied by a proliferation of classification models, each with advantages and limitations depending on the application context. This diversity complicates the choice of the optimal model, requiring an assessment of technical performance, resource requirements and adaptability to specific data types, such as text, images and time series. For example, the prediction of academic success or predictive diagnostics in medicine require models capable of combining accuracy, robustness and speed. A thorough understanding of the trade-offs between these aspects is therefore essential to ensure that models meet performance targets.

Our study responds to a pressing need for synthetic and comprehensive comparisons of supervised classification models. Existing research often focuses on specific criteria, such as accuracy or algorithmic complexity, without offering a clear overview that takes into account the impact on real applications. In addition, certain gaps persist, notably concerning the adaptability of models to multimodal or unbalanced data, and the management of trade-offs between accuracy and computational resources. By proposing a literature review focusing on these criteria, this study aims to provide a valuable tool for researchers and practitioners, enabling them to select algorithms suited to their specific needs.

Faced with these challenges, the central problem of this study can be formulated as follows: What are the best-performing supervised classification models in terms of accuracy, robustness, computational complexity and adaptability, and how does their performance vary according to data type and application context? To answer this question, an in-depth literature review appeared to be the most appropriate method. This approach makes it possible to pool and analyze a wide range of academic and empirical studies on supervised classification models, thus drawing out clear trends and identifying existing trade-offs.

The methodology adopted is based on a rigorous bibliographical search covering publications from scientific journals, international conferences and recent empirical studies. The selected models are evaluated according to defined criteria, such as prediction accuracy, generalizability, robustness, computation time and adaptability to heterogeneous and missing data. These criteria were chosen for their relevance to the evaluation of practical performance, and for their ability to cover the actual requirements of the systems deployed. Strict

inclusion criteria were applied to guarantee the representativeness and quality of the studies selected.

The results show that some models, such as Random Forest and SVM, stand out for their robustness and accuracy in complex contexts, while models like Naïve Bayes and Decision Tree are appreciated for their interpretability, ease of implementation and speed. Comparative analysis has identified notable trade-offs between accuracy and computational complexity, offering guidelines for optimal model selection according to system constraints.

In conclusion, this study proposes a framework for the selection of supervised classification algorithms according to specific user needs. It also highlights promising avenues of research, such as the exploration of hybrid models combining the strengths of the algorithms compared in order to overcome their limitations. Prospects include the development of models better adapted to the challenges of big data and real-time processing requirements.

The paper is structured into five main sections. Section I is dedicated to the introduction and presents the background, problem and objectives of the study. Section II provides a detailed theoretical framework on supervised classification and discusses the main models, while presenting their current limitations and challenges. This section is subdivided into several parts, including an overview of machine learning, a description of the types of supervised classification algorithms and a discussion of their limitations. Section III describes the methodology adopted, covering algorithm selection, evaluation criteria and data collection. Section IV presents the results of the comparative analysis and offers an in-depth discussion of the observations made, followed by a reflection on the limitations of the results. Finally, Section V concludes the study by summarizing the main contributions and suggesting avenues for future research.

II. Theoretical Framework and Background

A. Introduction to Supervised Classification Models

1) Machine learning-an overview: Machine Learning is a branch of artificial intelligence that aims to equip systems with the ability to discover patterns and relationships within datasets, without being explicitly programmed for each specific task [1][2][3]. By forming models from training data, it enables the automation of complex tasks such as image recognition or the prediction of user behavior [1][3][4]. This field relies on techniques that enable machines to learn from past data or interactions with their environment, without requiring specific programming for each task [5][6]. More broadly, Machine Learning encompasses the analysis, design, development and implementation of methods that enable machines to systematically improve themselves, offering solutions to problems through advanced algorithmic approaches [7].

As Mitchell explains in [1], a learning system is able to improve its performance with experience, i.e. from data. Machine Learning can be divided into three broad categories: supervised, unsupervised and reinforcement learning. This classification is based on the way the model learns from the data.

2) Supervised learning: Supervised Learning is an approach to Machine Learning in which a model is trained on a set of labeled data. This means that each instance of training data is associated with a known label or response. The model uses these examples to learn to predict the label of new instances.

In supervised learning, two main tasks are often distinguished:

- Regression: The model predicts a continuous numerical value as a function of input data (e.g. temperature prediction).
- Classification: the model predicts a category or class from a predefined set (e.g., spam detection in e-mail).

Supervised classification, the focus of our study, is therefore a sub-category of supervised learning. Hastie et al in [2], point out that supervised learning is particularly effective when data is abundant and well-labeled, as it enables the construction of accurate and robust models.

3) Supervised classification: Supervised Classification involves using a set of labeled data to train a model that can predict the class to which new observations belong. This is a key task in many fields, from medicine (e.g. medical diagnosis) to security (intrusion detection) to financial services (fraud detection).

The Classification model learns to distinguish between different classes by identifying the characteristics that separate them. For example, in a dataset containing images of dogs and cats, a classification model learns to spot specific characteristics to correctly identify each category.

The advantages of Supervised Classification include:

High accuracy: when data is reliably labeled.

Adaptability: Models can be applied in a variety of sectors requiring precise categorization.

Transparency: Some algorithms, such as decision trees, allow decisions to be interpreted, making it easier to understand the criteria used.

However, these models generally require large, well-balanced data sets to avoid bias and ensure good generalizability. According to Domingos in [3], it is crucial that the training data represent the future data well for the model to be robust and reliable.

B. Main Types of Classification Models

1) Naïve Bayes: Naïve Bayes is a supervised classification algorithm based on Bayes' theorem and the assumption of conditional independence between data characteristics. This algorithm is particularly appreciated for its simplicity and speed, making it highly effective in automatic natural language processing (NLP) and text classification tasks [8].

Despite its simplifying assumption, Naïve Bayes often performs competitively against more complex algorithms.

Mathematically, the algorithm is based on Bayes' theorem, formulated as follows:

$$P(C|X) = \frac{P(X|C)P(C)}{P(X)} \quad (1)$$

Where $P(C|X)$ represents the probability that an observation X belongs to a class C.To simplify the calculation, Naïve Bayes assumes that features x_i are conditionally independent, allowing the following approximation:

$$P(X|C) = \prod_{i=1}^{n} P(x_i|C) \quad (2)$$

This simplification makes Naïve Bayes particularly fast and undemanding in terms of computational resources.

Historically, this algorithm was introduced in the 1960s as a statistical tool for probabilistic classification. Its adoption in machine learning was reinforced by the work of [8], who demonstrated its effectiveness in contexts where conditional independence is respected.

The algorithm works by estimating the probability of each class for a given observation, then assigning that observation to the class with the highest probability. Naïve Bayes calculates these probabilities using pre-processed training data.

There are several variants of Naïve Bayes adapted to specific types of data. Gaussian Naïve Bayes, for example, is used for continuous data, assuming a normal distribution of features [9]. Multinomial Naïve Bayes is particularly suited to discrete data, such as word occurrences in text documents [2], while Bernoulli Naïve Bayes applies to binary data.

Naïve Bayes has many advantages, not least its simplicity of implementation and speed of execution, even on high-dimensional data. However, it suffers from limitations when features are highly correlated or when the conditional independence assumption is violated, which can reduce its accuracy [8].

The algorithm has applications in various fields. For example, it is used for spam filtering, where it classifies e-mails as junk or not [10]. In sentiment analysis, it is used to determine the polarity (positive or negative) of textual opinions [2]. Finally, it is applied to facial recognition, rapidly identifying patterns based on discrete features [9].

In short, Naïve Bayes is a fundamental tool in the supervised learning toolbox, combining mathematical simplicity with practical efficiency. Its remarkable performance in specific contexts, combined with its speed, explains its widespread adoption in many applications.

2) Decision tree: A decision tree is a supervised classification model structured in the form of a tree, where each node represents a question or test on a feature of the data, each branch corresponds to a possible outcome of that test, and each leaf represents a class or final decision. Decision trees are widely used because of their simplicity and interpretability, enabling users to visualize and understand the decision-making process clearly and explicitly [10].

Decision trees are based on sound mathematical foundations, notably the division criteria used to determine the most discriminating features at each stage. Among these criteria, information gain, used by the ID3 and C4.5 algorithms, measures entropy reduction after a specific division [10]. It is defined by the following formula:

$$Gain(T, X) = Entropy(T) - \sum_{v \in V} \frac{|T_v|}{|T|} . Entropy(T_v) \quad (3)$$

where T is the data set at the current node, X is the feature being tested, and T_v represents the subset of data corresponding to a value v of X. The Gini index, used by the CART algorithm, is another popular criterion, quantifying the homogeneity of classes in the subsets generated. It is defined by :

$$Gini(T) = 1 - \sum_{i=1}^{C} P_i^2 \quad (4)$$

where P_i is the proportion of data belonging to class i [11].

The history of decision trees is marked by significant advances. Ross Quinlan introduced the ID3 algorithm in 1986, one of the first models based on information gain [12]. He later developed C4.5, an extension of ID3 capable of handling continuous data and missing values [10]. At the same time, Leo Breiman proposed the CART (Classification and Regression Trees) algorithm in 1984, which introduced the use of the Gini index and opened up possible applications for regression [11]. These contributions laid the methodological foundations for decision trees, positioning them as an essential tool in supervised learning.

Decision trees work by recursively dividing the data according to the most discriminating characteristics, based on the criteria mentioned. For example, to predict whether a person will buy a product based on their age and income, a decision tree would ask questions such as: “Is the person under 30 ?” or “Is the income over 50,000 ?”. Each answer leads to a specific decision, represented by a leaf in the tree.

Decision trees come in several variants, adapted to specific needs. ID3 (Iterative Dichotomiser 3), proposed by [12], is based on information gain as the dividing criterion. Its extensions, C4.5 and C5.0, introduce the management of continuous data and missing values [10]. Finally, CART, developed by study [11], uses the Gini index and can be applied to classification and regression tasks.

The advantages of decision trees are numerous. They offer a high degree of interpretability, thanks to their explicit and easily visualized structure [10]. They can be adapted to both categorical and continuous data, making them versatile in a variety of contexts [11]. What's more, their speed makes them effective for medium-sized data sets. However, they also have their limitations. Decision trees are prone to overlearning, particularly in the absence of regularization, which can impair their generalization ability [13]. They are also sensitive to variations in the training data, which can affect their stability [2].

In terms of applications, decision trees play a key role in various fields. In bioinformatics, they are used to identify genes associated with disease [10]. In the financial sector, they are used to analyze credit decisions and detect fraud [11]. Finally, in industry, they are applied for quality control and predictive maintenance [9]. Their flexibility and simplicity explain their widespread adoption in sectors requiring clear, explainable decisions.

In conclusion, decision trees represent a robust and intuitive method for solving classification and regression problems. Although they present challenges such as overlearning and data sensitivity, their advantages and wide range of applications make them an indispensable tool in the arsenal of supervised classification algorithms.

3) Random forest: Random Forest is a powerful ensemble algorithm that combines several independent decision trees to improve the robustness and accuracy of predictions. Developed by [14], this algorithm is based on two fundamental principles: bootstrap aggregation and random feature selection [14]. By aggregating the predictions of several trees, Random Forest reduces errors due to variance and increases the stability of results.

Mathematically, each tree is constructed from a bootstrap sample of the training data. At each node, only a random sub-selection of features is evaluated to determine the best split. This approach introduces diversity between trees, improving the generalizability of the model.

Historically, Random Forest was conceived as an improvement on conventional decision trees, in response to their tendency to overlearn. [14] Demonstrated that the introduction of randomness in both data and features makes the model more resistant to noisy data and outliers.

Random Forest works by independently generating a large number of decision trees, then combining their predictions. For a classification task, the predicted class is determined by a majority vote among the trees. In regression, the final prediction is obtained by averaging the tree outputs.

The algorithm has several advantages. It is robust to noisy data, efficiently handles unbalanced classes and requires no prior data normalization. However, its main drawback is its increased complexity, which makes interpretation more difficult than with a single decision tree [13].

Random Forest is used in a variety of fields. In finance, it is applied to credit scoring and fraud detection [14]. In bioinformatics, it is used for feature selection and classification of genomic data [9]. In the energy sector, it is used to predict energy consumption as a function of various factors [13].

In conclusion, Random Forest is a flexible, high-performance method for a wide range of classification and regression tasks. Its robustness and precision make it an indispensable tool in complex, noisy environments.

4) K-Nearest Neighbor (KNN): K-Nearest Neighbor (KNN) is a supervised classification algorithm based on the concept of proximity in a multidimensional space. It classifies an observation according to the majority class among its k nearest neighbors. Introduced by study [15], KNN is one of the simplest and most intuitive algorithms in supervised learning [15].

In mathematical terms, KNN relies on a distance measure to assess the proximity between observations. The Euclidean distance is the most commonly used and is defined by:

$$d(x, y) = \sqrt{\sum_{i=1}^{n}(x_i - y_i)^2} \quad (5)$$

where x_i and y_i represent the characteristics of points x and y. For a new point, KNN identifies the k nearest neighbors, then determines the majority class among them.

Historically, KNN has gained in popularity thanks to its simplicity and adaptability to different types of data. However, it is particularly sensitive to the choice of k, which directly influences its performance. Too small a k makes the model sensitive to noise, while too large a k can dilute important features [2].

KNN works as follows: for each new observation, the algorithm identifies the k closest observations in the training data, using a predefined distance measure. It then assigns the majority class among these neighbors to the observation in question.

KNN offers several advantages, not least its simplicity and effectiveness on small or well-separated data sets. However, it is computationally expensive for large datasets, as it requires each new observation to be compared with the training dataset. In addition, it is sensitive to irrelevant or redundant features, which can affect its accuracy [2].

KNN has many applications. In product recommendation, it identifies similar products based on user preferences. In image recognition, it classifies images based on distances in pixel space. In healthcare, KNN is used to diagnose diseases based on biological characteristics [2].

In summary, KNN is a versatile and efficient algorithm for classification and regression tasks. Despite its limitations in terms of computational complexity, its simplicity and adaptability make it a preferred choice for applications requiring proximity-based classification.

5) Support Vector Machine (SVM): The Support Vector Machine (SVM) is a supervised classification algorithm designed to maximize the margin between classes in a multidimensional space. Developed by study [16], SVM revolutionized classification methods by introducing the idea of kernels to project data into higher-dimensional spaces, thus facilitating their linear separation [16].

$$\min_{\omega,b} \frac{1}{2}\|\omega\|^2 \quad (6)$$

under the constraints :

$$y_i(\omega^T x_i + b) \geq 1, \forall i \quad (7)$$

where ω is the weight vector, b the bias, x_i the observations and y_i their respective labels. By maximizing the margin

between the points closest to the classes, called support vectors, SVM guarantees better generalization [17].

The use of kernels enables SVM to handle non-linear problems. Common kernels include linear, polynomial and radial basis function (RBF). These functions transform the data into a higher-dimensional space, where it becomes linearly separable [16].

SVM works by constructing an optimal hyperplane that maximizes the margin between classes. For non-linear data, SVM uses kernels to perform an implicit transformation into a higher-dimensional space. In this way, data are optimally separated, minimizing classification errors.

SVM is particularly efficient for small to medium-sized datasets, but its computational cost can become prohibitive for large databases. In addition, it requires careful selection of hyperparameters, such as the C parameter (controlling the trade-off between maximum margin and error) and the choice of kernel [17].

SVM applications cover a wide range of fields. In bioinformatics, it is used to classify genes and predict diseases. In the financial sector, it analyzes trends and predicts market behavior. In computer vision, SVM is applied to facial and object recognition [2].

In conclusion, SVM is a powerful and flexible algorithm, capable of processing both linear and non-linear data. Although it requires expertise to optimize its parameters, its accuracy and ability to handle complex problems make it a preferred choice for many applications.

C. Current Limitations and Challenges

Despite their many applications and successes, supervised classification algorithms have inherent limitations and challenges that impact their adoption in certain contexts. These limitations vary from algorithm to algorithm and are influenced by factors such as the nature of the data, available resources, and the specific requirements of application domains.

1) Dependence on data quality: The performance of supervised classification algorithms is highly dependent on the quality of the training data. Noisy, unbalanced or incomplete data can lead to bias and reduced accuracy [2][18]. For example, Decision Trees are prone to overfitting when training data contains anomalies or extreme values [10].

2) Scalability problem: Algorithms such as KNN and SVM can be inefficient on large datasets due to their algorithmic complexity [9][14]. KNN, with its O(n) complexity, becomes impractical for databases containing millions of points [15].

3) Lack of interpretability: Some algorithms, such as Random Forest, produce complex models that are difficult for non-expert users to interpret [14][19]. Although Random Forest offers high accuracy, its inner workings are often described as “black box”, limiting its adoption in sensitive fields such as medicine [19].

4) Sensitivity to overfitting: Models such as Decision Trees tend to overfit on training data, losing their ability to generalize on new data [10][2]. An unregularized Decision Tree may provide perfect results on training data but fail on test sets [13].

5) Resources and computing time: Algorithms like SVM and Random Forest require significant resources for training, which can be prohibitive in resource-constrained environments [9][16]. SVM with nonlinear kernels can require several hours to train on large datasets [16].

6) Adaptability problem: Some models, such as Naïve Bayes, assume feature independence, which limits their performance on datasets where features are highly correlated [8][9]. In textual datasets, Naïve Bayes' conditional independence assumption can lead to a significant loss of accuracy [8].

7) Hyperparameter dependence: Algorithm performance often depends on the fine-tuning of hyperparameters, which requires in-depth expertise and resources for cross-validation [2][16]. SVM efficiency is strongly influenced by the choice of kernel, C, and γ [2].

8) Generalization and robustness: Models sometimes lack robustness in the face of unbalanced or noisy data, which can lead to inconsistent performance [20][21]. Although Random Forests are robust in many cases, their performance can plummet when minority classes are severely under-represented [20].

9) Ethical and regulatory challenges: The use of models in sensitive areas (health, finance) raises ethical issues related to fairness and transparency [19]. Biases introduced in training data can lead to discriminatory decisions in classification systems [19].

These limitations and challenges underline the need to tailor supervised classification algorithms to the specifics of applications. Future research should focus on developing models that are more interpretable, scalable, and robust to data variations. At the same time, solutions such as model hybridization or the integration of unsupervised approaches can help overcome some of these challenges.

III. METHODOLOGY

The aim of this work is to analyze and compare supervised classification algorithms and ensure a comprehensive and balanced evaluation based on well-defined criteria and a rigorous literature review. The methodology includes algorithm selection, definition of evaluation criteria, data collection and organization of the comparative synthesis.

A. Algorithm Selection

Five algorithms widely recognized in the scientific and industrial literature were selected: Naïve Bayes, Decision Tree, Random Forest, K-Nearest Neighbor (KNN) and Support Vector Machine (SVM).

This choice is justified by:

- Representativeness of approaches: These algorithms cover a wide range of methods (probabilistic, tree-based, instance-based, etc.).

- Popularity and relevance: Their widespread adoption in industry and research testifies to their effectiveness in a variety of contexts [14], [16].
- Richness of available studies: These algorithms have been extensively documented, enabling in-depth comparison based on reliable experimental data. Naïve Bayes for text classification and spam detection [8]. Random Forest for fraud detection and medical diagnostics [14].

B. Criteria for Comparing Classification Algorithms

The comparison of classification algorithms requires rigorously defined criteria to assess their performance and suitability for specific tasks. This subsection presents the criteria and sub-criteria used, explains their importance, and justifies their selection.

1) Presentation of the criteria

- Criteria for comparing supervised classification algorithms play a key role in assessing their effectiveness, performance and adaptability to different contexts. These criteria, carefully defined and justified, cover the essential dimensions for ensuring a rigorous and scientifically valid analysis.
- Prediction accuracy is one of the most fundamental criteria, measuring the percentage of observations correctly classified by a model. It is calculated as the ratio between the number of correct predictions and the total number of predictions [2]. This criterion is crucial for applications where errors could have serious consequences, such as in medicine or finance. It directly reflects the reliability of a model and its suitability for accuracy requirements in critical environments.
- Robustness represents the ability of an algorithm to maintain its performance despite noisy or disturbed data [13]. In real-world environments where data is often imperfect, this criterion ensures that the algorithm remains reliable, even in the presence of errors or anomalies in the data. This is particularly important in fields such as bioinformatics or facial recognition.
- The tendency to overfitting assesses whether a model is able to avoid too much adaptation to training data, which would compromise its ability to generalize on new data [2]. Algorithms with a high risk of overfitting often require regularization techniques to guarantee stable performance. This criterion is essential in applications requiring the ability to generalize over varied data sets.
- Generalizability is closely linked to the tendency to overfitting, and measures the extent to which an algorithm can successfully predict on unseen data [22]. This criterion is essential for assessing the durability of model performance in dynamic and unpredictable environments.
- Training time refers to the time required to build a model from training data [2]. In contexts where models need to be updated frequently, such as real-time recommendation systems, this criterion helps to identify algorithms suited to strict time constraints.
- Prediction time corresponds to the time required to provide a prediction on new data [2]. This criterion is essential in applications where responsiveness is crucial, such as autonomous vehicles or industrial control systems. It ensures that the algorithm can respond quickly to real-time requests.
- Memory requirement measures the amount of memory needed to store the model and make predictions [17]. In resource-constrained environments, such as embedded devices, this criterion enables the selection of memory-efficient algorithms.
- Algorithmic complexity evaluates the computational cost of an algorithm in terms of time and space, often expressed in O notation (Hastie et al., 2009). This criterion is crucial in determining whether an algorithm can be used efficiently with large datasets or in resource-constrained environments.
- Ease of implementation examines the simplicity with which an algorithm can be integrated into an existing system [10]. An easy-to-deploy model reduces the costs and time associated with development, which is particularly advantageous in projects requiring rapid integration.
- Model interpretability refers to a model's ability to provide understandable explanations for its predictions [19]. This criterion is essential in regulated sectors, such as healthcare or finance, where transparency of decisions is paramount in building user trust.
- The level of expertise required reflects the skills needed to configure and use an algorithm effectively [3]. This criterion is important for organizations with limited human resources in technical expertise, as it can influence the ease of model adoption.
- Available documentation and libraries also play a key role in algorithm implementation [23]. Comprehensive documentation and well-supported libraries simplify the learning process and enable faster adoption of algorithms.
- Adaptability to multimodal data assesses a model's ability to simultaneously process different types of data, such as text, images or audio signals [21]. This criterion is crucial for modern applications such as voice assistants or multimodal recognition.
- Adaptability to unbalanced data measures an algorithm's ability to efficiently handle datasets where certain classes are under-represented [20]. This criterion is essential in fields such as fraud detection or the prediction of rare diseases, where the scarcity of cases of interest complicates model training.

- Handling missing data is an important criterion for assessing an algorithm's ability to operate in environments with incomplete data [18]. Models capable of tolerating missing values are particularly valuable in applications where complete data is rarely available.
- Dimensionality reduction is a criterion that measures a model's ability to identify and use the most important features while reducing noise [24]. This improves the efficiency of algorithms and their ability to handle complex data sets.
- Application domains reflect the usefulness of algorithms in a variety of sectors, such as finance or healthcare, where solutions like Random Forest have demonstrated their effectiveness in fraud detection and genomic analysis [14]. This criterion is crucial for assessing the relevance of algorithms in specific contexts.
- Impact on practical decisions assesses the direct contribution of algorithms to decision-making. For example, Decision Trees are valued for their interpretability, facilitating reliable medical diagnoses [10]. This criterion is essential in determining how an algorithm can transform critical decision-making processes.
- Integration into existing systems measures the ease with which algorithms can be implemented. Naïve Bayes are simple to deploy and easily adaptable to tools such as spam filtering systems [3]. Conversely, SVMs, with their complexity, pose integration challenges [16], underlining the importance of this criterion in assessing their practical applicability.
- Implementation cost, finally, evaluates the resources required to operate an algorithm. Naïve Bayes, for example, are cost-effective, unlike SVMs, which require greater resources due to their algorithmic complexity [2]. This criterion is essential for judging the suitability of algorithms for real system constraints.

2) Distribution of evaluation criteria

- Technical performance: Prediction accuracy, robustness, tendency to overfitting and generalizability.
- Computational efficiency: Computation time for training and prediction, memory requirements and algorithmic complexity.
- Practicality and Ease of Use: Ease of implementation, Interpretability of models, Level of expertise required and Documentation and libraries available.
- Data compatibility: Adaptability to data (multimodal, unbalanced), Handling of missing data and Reduction of dimensionality.
- Applicability and Practical Impact: Application domains, Impact on practical decisions, Integration into existing systems and Implementation cost.

These dimensions cover the essential aspects of algorithms, ensuring a balanced assessment between their raw performance, practicality, and adaptability to real-life use cases [2] [21].

3) Data collection

a) Publication selection criteria

- Period: Publications from 2000 to 2025 to include recent advances while maintaining a historical perspective.
- Types of publication: Papers in indexed journals (Elsevier, Springer, IEEE), Proceedings of major conferences (NeurIPS, ICML, AISTATS) and relevant industrial technical reports.
- Context of studies: Include work covering various fields of application (health, finance, education, etc.).

b) Research process

- Databases searched: Google Scholar, PubMed, IEEE Xplore, Scopus.
- Screening: The selected studies had to provide detailed experimental results and quantitative comparisons between several algorithms.

c) Validation of results

- Each publication is reviewed in two stages: Analysis of the abstract and introduction to confirm relevance, and reading of the methodology and results sections to ensure data quality.

d) Data synthesis

- Thematic organization: Publications are grouped by application (healthcare, finance, industry, etc.) and evaluation criteria (accuracy, robustness, etc.).
- Metrics extraction: Experimental results (accuracy, computation time) are extracted to feed comparative analyses.

4) Organization of the comparative summary

a) Results format: Synthetic tables: Presentation of criteria in tabular form for quick comparison of algorithms.

b) Qualitative analysis: Textual explanation of algorithm strengths and weaknesses, contextualized by extracted results.

c) Cross-validation: Comparison of experimental results between different publications to reinforce reliability. Narrative analysis to incorporate variations due to specific study contexts. Fig. 1 shows the comparative study workflow.

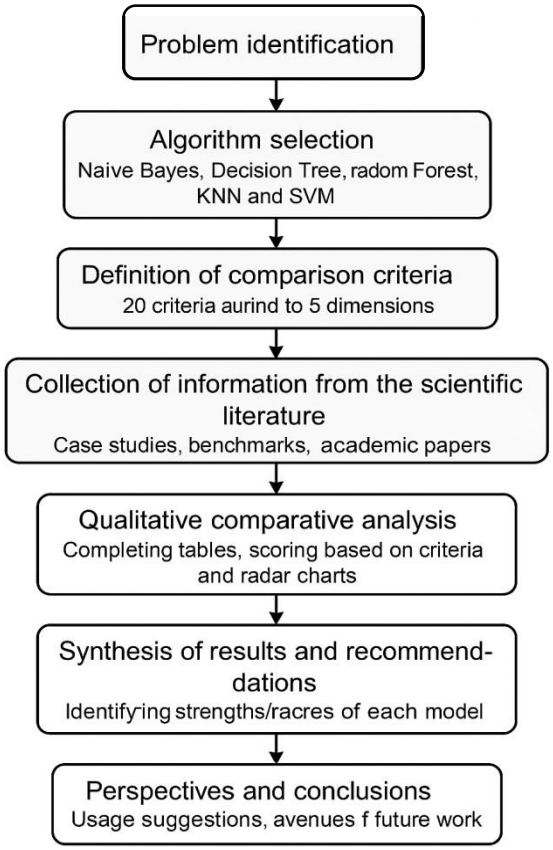

Fig. 1. The comparative study workflow shows the overall study process.

IV. Results and Discussion

A. Presentation of Results

The results are organized according to the dimensions defined in the methodology: technical performance, computational efficiency, practicality, compatibility with data, and practical applicability.

1) Technical performance: This table evaluates the accuracy, robustness to perturbations, tendency to overfitting, and generalizability of the models. The qualitative scores are normalized on a scale of 5 and accompanied by accuracy ranges reported in the literature. Scientific references are provided for each criterion to support the evaluations. Random Forest (RF) and Support Vector Machine (SVM) models stand out overall for their high performance, while Naive Bayes (NB) shows more variable performance depending on the criteria.

This figure illustrates the comparative performance of the five supervised classification algorithms (Naive Bayes, Decision Tree, Random Forest, SVM, and KNN) based on the average scores assigned to each according to the five dimensions defined in the study: technical performance, computational efficiency, ease of use, data compatibility, and practical applicability. The colors of the bars represent the different dimensions of analysis (e.g., yellow = performance, orange = efficiency, red = ease of use, blue = data compatibility, etc.). Each score ranges from 1 (low) to 5 (excellent). We can see that Random Forest and SVM achieve the highest scores overall, while Naive Bayes and KNN show more mixed results depending on the criteria.

TABLE I. Comparison of Algorithms Based on Technical Performance Criteria

Algorithm	Accuracy (%) Yellow (Y)	Robustness Orange(O)	Tendency to overfitting Red(R)	Generalizability Blue (B)
NB	3/5 45 – 98 [25][26][27] [28][29]	2/5 [40]	4/5 [45]	3/5 [9]
DT	3/5 64 – 95 [25][30][31] [32][33]	3/5 [41]	2/5 [46]	3/5 [14]
RF	5/5 71 – 98 [30][31][33] [34][35]	5/5 [42]	4/5 [41]	5/5 [49]
KNN	3/5 64 – 98 [26][36][36] [38][39]	2/5 [43]	2/5 [47]	4/5 [50]
SVM	5/5 70 – 97 [27][28][29] [35][38]	4/5 [44]	4/5 [48]	5/5 [9]

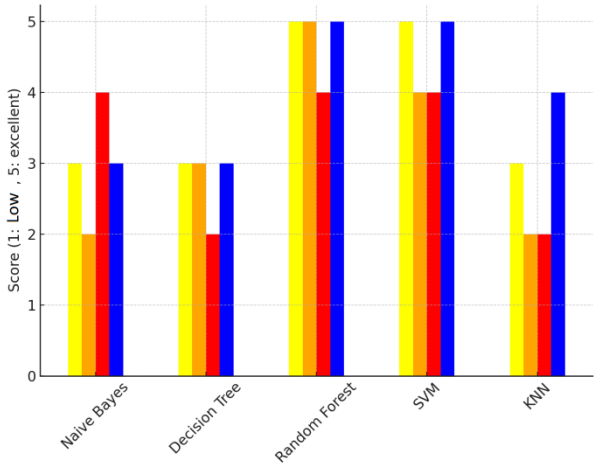

Fig. 2. Comparison of algorithms based on technical performance criteria.

2) Computational efficiency: This table compares the five algorithms studied according to four key aspects of computational efficiency. Each criterion is evaluated on a scale of 1 to 5. The results highlight the superiority of Naive Bayes across all criteria, with perfect scores (5/5), while Random Forest and SVM show compromises between accuracy and computational cost. The bibliographic references associated with each score are also indicated to ensure the traceability of the evaluations.

TABLE II. COMPARISON OF ALGORITHMS BASED ON COMPUTATIONAL EFFICIENCY

Algorithm	Time for training (Y)	Time for prediction (B)	Memory requirements (O)	Algorithmic complexity (R)
NB	5/5 [45]	5/5 [3]	5/5 [2]	5/5 [45]
DT	4/5 [47]	4/5 [47]	4/5 [2]	4/5 [41]
RF	2/5 [49]	3/5 [41]	3/5 [42]	2/5 [49]
KNN	3/5 [51]	1/5 [43]	2/5 [43]	3/5 [51]
SVM	2/5 [52]	3/5 [48]	3/5 [48]	2/5 [52]

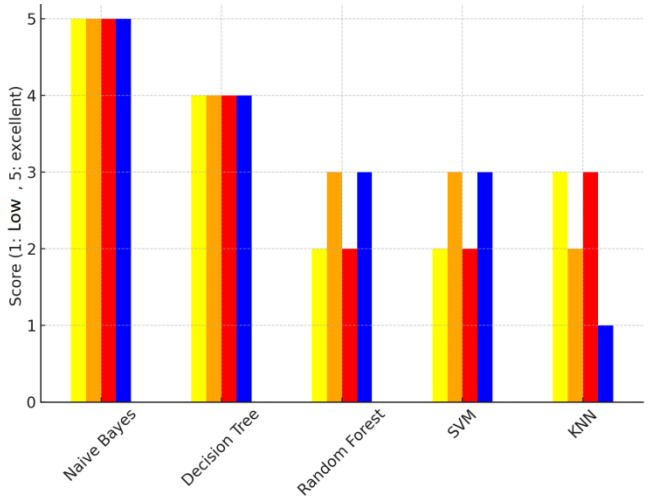

Fig. 3. Comparison of algorithms based on computational efficiency.

This figure provides a comparative visual representation of the five algorithms studied in Table II, according to the following criteria: Time for training (Yellow), Memory requirements (Orange), Algorithmic complexity (Red), and Time for prediction (Blue). Each criterion is rated on a scale of 1 to 5.

3) Practicality and ease of use: This table evaluates the five supervised classification algorithms (Naive Bayes, Decision Tree, Random Forest, k-NN, SVM) according to four practical criteria: ease of implementation, interpretability, level of expertise required, and availability of documentation and associated libraries. Scores are rated on a scale of 1 to 5.

A simplified visualization of the results in Table III, this figure compares the performance of the five algorithms according to four criteria: Ease of implementation (yellow), Interpretability (orange), Level of expertise required (red), and Documentation and libraries available (blue). Scores are given on a scale of 5 to allow for quick comparative reading.

4) Data compatibility: This table evaluates the five algorithms according to four compatibility sub-criteria: Adaptability to multimodal data, Management of missing data, Dimensionality reduction, and Adaptability to unbalanced data. Each criterion is scored out of 5, and the associated bibliographic references are indicated in brackets. These scores illustrate the extent to which each model is able to adapt to the diversity and imperfections of the data used in supervised classification.

TABLE III. COMPARISON OF ALGORITHMS BASED ON PRACTICALITY AND EASE OF USE

Algorithm	Ease of implementation (Y)	Interpretability (O)	Level of expertise require (R)	Documentation and libraries available (B)
NB	5/5 [45]	3/5 [3]	5/5 [45]	5/5 [9]
DT	4/5 [51]	5/5 [53]	4/5 [48]	5/5 [23]
RF	3/5 [41]	2/5 [49]	3/5 [52]	5/5 [9]
KNN	5/5 [51]	2/5 [43]	5/5 [51]	5/5 [23]
SVM	2/5 [48]	2/5 [54]	2/5 [48]	5/5 [9]

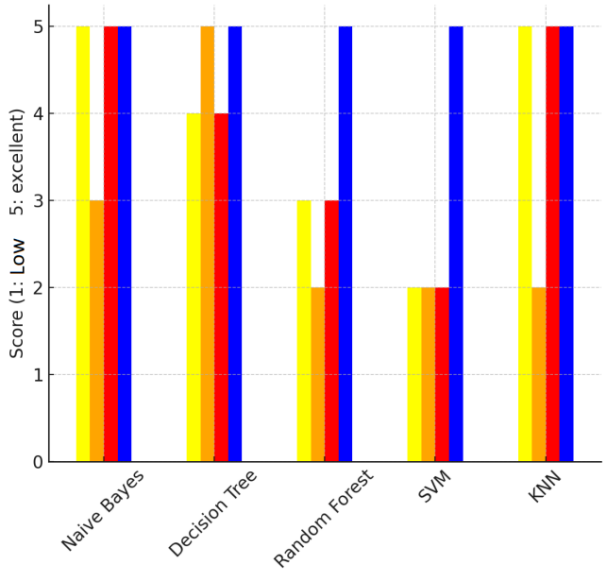

Fig. 4. Comparison of algorithms based on practicality and ease of use.

TABLE IV. COMPARISON OF ALGORITHMS BASED ON COMPATIBILITY WITH DATA

Algorithm	Adaptability to multimodal data (Y)	Handling of missing data (O)	Reduction of dimensionality (R)	Adaptability to unbalanced data (B)
NB	3/5 [55]	3/5 [18]	4/5 [24]	2/5 [55]
DT	4/5 [47]	4/5 [41]	3/5 [47]	3/5 [54]
RF	5/5 [49]	5/5 [42]	4/5 [49]	4/5 [49]
KNN	3/5 [51]	2/5 [43]	3/5 [51]	2/5 [43]
SVM	4/5 [54]	2/5 [48]	5/5 [48]	4/5 [52]

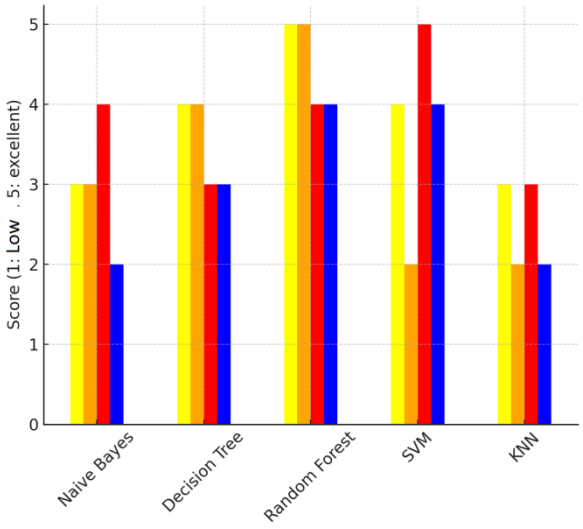

Fig. 5. Comparison of algorithms based on compatibility with data.

Summary graph based on data from Table IV, showing the scores assigned to algorithms on four criteria: Adaptability to multimodal data (yellow), Handling of missing data (orange), Reduction of dimensionality (red), and Adaptability to unbalanced data (blue). This visualization facilitates comparative interpretation between models.

5) Applicability and practical impact: This table presents a comparative evaluation of five supervised classification algorithms—Naive Bayes (NB), Decision Tree (DT), Random Forest (RF), k-Nearest Neighbors (k-NN) [37], and Support Vector Machine (SVM)—based on four criteria related to their applicability in real-world contexts. The criteria studied include: (1) diversity of application domains, (2) impact on practical decision-making, (3) degree of integration into existing systems, and (4) implementation cost. Each criterion is rated on a scale of 1 to 5, where 5 indicates the best performance. The scores are accompanied by bibliographic references [45], [2], [14], etc., attesting to the origin of the evaluations. This summary aims to guide practitioners in choosing an algorithm based on concrete constraints, such as ease of implementation, compatibility with existing systems, or decision-making scope. It thus complements purely technical or statistical comparisons by integrating the dimension of operational applicability.

This visualization illustrates the comparative scores from Table V for the four criteria selected: Application domains (yellow), Impact on practical decisions (orange), Integration into existing systems (red), and Implementation cost (blue). It highlights the relative strengths of each algorithm through a clear representation.

B. Discussion

Quantitative analysis of supervised classification algorithms reveals clear but complementary differences in their technical, operational, and practical properties. These results can be interpreted in several ways depending on the deployment objectives and context of use.

TABLE V. COMPARISON OF ALGORITHMS ACCORDING TO APPLICABILITY AND PRACTICAL IMPACT

Algorithm	Application domains (Y)	Impact on practical decisions (O)	Integration into existing systems (R)	Implementation cost (B)
NB	4/5 [45]	3/5 [2]	4/5 [45]	5/5 [9]
DT	4/5 [41]	4/5 [14]	4/5 [48]	4/5 [41]
RF	5/5 [49]	5/5 [49]	4/5 [42]	3/5 [49]
KNN	3/5 [43]	3/5 [51]	3/5 [51]	5/5 [51]
SVM	5/5 [56]	4/5 [54]	3/5 [52]	3/5 [48]

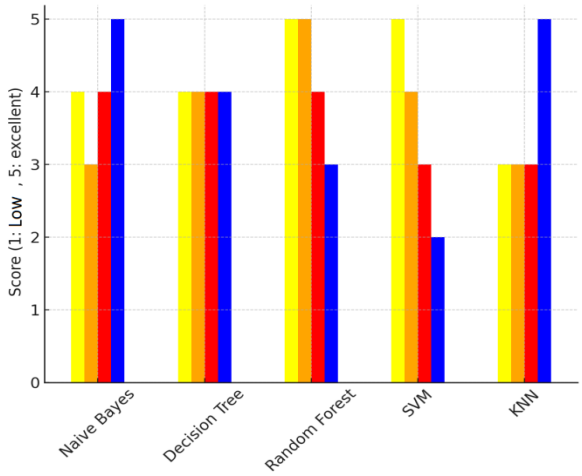

Fig. 6. Comparison of algorithms according to applicability and practical impact.

The Random Forest and SVM algorithms clearly stand out in terms of accuracy, generalization ability, and robustness (Table I, Fig. 2). Their high scores confirm their ability to handle complex problems requiring reliable prediction, such as in medical imaging or cybersecurity. Conversely, although Naive Bayes has an elegant probabilistic structure, its simplification of inter-variable dependencies limits its overall accuracy, particularly in highly correlated contexts. Decision Tree shows moderate performance, while KNN suffers from high sensitivity to noise and overfitting.

Naive Bayes and, to a lesser extent, Decision Tree, are notable for their computational lightness (Table II, Fig. 3). These methods are appropriate in real-time processing contexts or on machines with limited resources. In contrast, Random Forest and SVM, although powerful, have a significant computational cost, both in training and prediction. KNN, although without a learning phase, is slowed down at the time of classification due to the need to scan the entire dataset.

Naive Bayes and KNN stand out as the most accessible, requiring little expertise and being very easy to implement (Table III, Fig. 4). Decision Tree combines this accessibility with excellent interpretability, making it a popular model for decision support systems. On the other hand, SVM and Random Forest are often perceived as “black boxes” requiring

more sophisticated configuration and increased expertise, which can limit their adoption in constrained industrial contexts.

The results show that Random Forest is the most versatile, effectively handling missing data, class imbalances, and dimensionality reduction. SVM follows closely behind, provided rigorous preprocessing is performed (Table IV, Fig. 5). Naive Bayes and KNN, on the other hand, are sensitive to data quality and structure. The former assumes conditional independence of variables, while the latter suffers from the effects of dimensionality and noise.

Random Forest and Decision Tree are very attractive from an application standpoint, with broad sectoral adaptability and a concrete impact on decision-making (Table V, Fig. 6). Naive Bayes is also valued for its low cost and ease of integration. On the other hand, SVM remains more expensive to implement, although it offers high performance. Finally, KNN remains unpopular in production environments due to its limited scalability.

C. Limitations of the Results

Although this comparative review provides an in-depth summary of the literature, several limitations should be noted:

1) Lack of empirical validation: The scores are based on bibliographic analyses and do not reflect direct experiments on specific datasets. An empirical study would have allowed for more contextual calibration of the assessments.

2) Variability of application contexts: Algorithm performance can vary significantly depending on the domain (healthcare, finance, language processing, etc.). As this study is general in nature, it does not capture all the nuances specific to each sector.

3) Implementation changes: The performance and practicality of algorithms can be influenced by the software libraries used, which evolve rapidly. Results may therefore change in the short term.

4) Equal weighting of criteria: Aggregating scores assumes uniform weighting of the 20 criteria, which does not necessarily reflect the actual importance of each criterion depending on the context of use.

V. Conclusion

This comparative study, based on an in-depth literature review, evaluated five major supervised classification algorithms—Naive Bayes, Decision Tree, Random Forest, Support Vector Machine (SVM), and K-Nearest Neighbor (KNN)—across twenty criteria divided into five dimensions: technical performance, computational efficiency, practicality, data compatibility, and applicability.

The results show that Random Forest offers an excellent compromise between accuracy, robustness, and applicability, making it a preferred choice for high-stakes use cases. Naive Bayes, on the other hand, stands out for its simplicity, speed, and low implementation cost, making it ideal for resource-constrained environments. Decision Tree occupies a middle ground, combining interpretability and good performance. On the other hand, SVM, despite its remarkable technical performance, remains difficult to implement and integrate into real systems. Finally, KNN has significant limitations in terms of scalability and robustness, although it remains useful for simple and exploratory cases.

This study highlights the importance of a contextualized multi-criteria assessment in the choice of classification algorithms. No model is universally applicable; each algorithm has strengths and weaknesses that must be weighed according to the specific constraints of the problem, the domain, and the technical environment.

Future work could expand on this bibliographic analysis through rigorous experimental validation, applying the five classification algorithms to real-world datasets from various fields such as education, healthcare, and finance. Such an extension would allow theoretical observations to be compared with empirical performance and recommendations for use to be refined according to the application context. In addition, a promising avenue lies in integrating recent advances in AutoML to automate the selection, configuration, and optimization of models based on the nature of the data. Exploring hybrid learning techniques (e.g., combining multiple algorithms via ensembles or mixed architectures) could also improve robustness and predictive performance. Finally, the use of supervised deep learning approaches, in particular deep neural models or pre-trained neural networks (e.g., BERT, LSTM, CNN), would represent a step forward in the processing of more complex data (text, images, etc.). A complementary benchmark could thus be considered to compare classical models and neural architectures on broader common criteria (training time, ability to generalize, sensitivity to imbalances, etc.).

Mobile Applications that Incorporate AI for Information Search and Recommendation: A Systematic Literature Review

Mijael R. Aliaga, Jhosep S. Llacctahuaman, Carla N. Esquivel, Nemias Saboya
Facultad de Ingenieria y Arquitectura, Universidad Peruana Unión, Lima, Perú

***Abstract*—The inclusion of artificial intelligence (AI) has become essential for mobile application development, allowing improved personalization and optimization of the user experience. Over the past decade, smart mobile devices have been observed to enhance user experience across a variety of needs. The main objective of this study is to evaluate AI-powered mobile applications that utilize intelligent search mechanisms and more accurate recommendations and analyze their impact on addressing these user needs. The databases used were Scopus, ScienceDirect, Web of Science, and EBSCO. A filtering process using Prisma and a document quality assessment process was performed to select the most relevant articles. The study posed four questions related to the topic. The results showed that mobile apps for search and recommendation are mainly based on hybrid approaches (collaborative and content-based filtering) and deep learning (autoencoders, LSTMs/transformers, and BERT-type semantic retrieval embeddings), complemented by classic techniques (matrix factorization, SVM, K-NN, and trees/boosting) and contextual personalization (location, time, activity). It was concluded that these AI additions benefited users and met their search and recommendation needs. Furthermore, these mechanisms are advancing by leaps and bounds, as we now talk about more precise search and recommendation with voice, images, and even video.**

***Keywords*—AI algorithms; recommendation algorithms; mobile applications; search algorithms; AI for information**

I. INTRODUCTION

Artificial intelligence (AI) has become an important component of mobile app development [1], allowing for the implementation of recommendation algorithms that personalize and optimize the user experience. These algorithms can analyze a large amount of data to provide accurate and appropriate suggestions that enhance user interaction with the application.

For example, work-related applications such as LinkedIn, Indeed and Glassdoor stand out for connecting candidates and employers through personalized recommendations.

In the educational sector, applications like Coursera, Duolingo and Khan Academy integrate intelligent systems to customize the teaching content for each student, and in navigation, Google Maps and Waze use AI techniques to optimize routes and provide real-time contextual information. [1].

The integration of artificial intelligence into mobile applications is particularly important for information searches in the public and private sectors. Artificial intelligence provides a personalized learning experience and adapts to the needs and pace of each user.

This study provides an overview of how modern technology, especially artificial intelligence, has the ability to guide and recommend, allowing sugggestions to be personalized based on user needs, facilitating not only searches but also the exchange of information and advice between users. This fosters growth and innovation in the technological field.

Applications that include artificial intelligence significantly differentiate themselves in operational efficiency and user experience by providing a more intuitive and personalized interaction [1], [2]. This is in contrast to traditional applications, which often offer a more general and less adaptive experience.

Among the benefits of using mobile applications with artificial intelligence is the personalization of content, which improves the ability to offer accurate recommendations based on user behavior [2], [3]. These benefits not only improve user satisfaction but also increase app retention.

The most important factors contributing to the adoption and success of AI applications are ease of use, adherence to recommendations, and the ability to adapt to changing user needs [2]. These factors are important to ensure that applications are not only adopted but also thrive in a competitive market.

The need to study this topic stems from the exponential rise of mobile technology and its impact on users. As more people rely on their mobile devices, it's important to understand how artificial intelligence can improve this experience and what challenges must be overcome for effective implementation of this technology.

The main objective of this study is to conduct a systematic review to identify and analyze the use of artificial intelligence in mobile applications, which involve information search and recommendation within the application. It also analyzes the different AI algorithms and techniques that are commonly used, and determines the sectors in which it has been most frequently applied.

This study will recommend solutions to improve the integration of artificial intelligence into search and recommendation. Using a PICOC approach, the impact of these applications on the efficiency and effectiveness of everyday use will be analyzed.

II. Gaps in the Literature

Despite advances in the integration of artificial intelligence (AI) into educational mobile applications, significant gaps in the existing literature have been identified. Of the 58 studies analyzed, only seven focus specifically on the education sector. These works address use cases such as learning personalization, interactive content delivery, and automated assessment. However, none focus on job opportunity recommendations for university students or graduates, highlighting a lack of research on the application of AI for career guidance in this demographic.

Most AI-powered educational applications focus on features such as content classification, interactive simulations, and recommendation systems based on collaborative filtering, recurrent neural networks (GRUs), and text mining. These technologies, while effective in personalizing learning, do not address the specific needs of students seeking guidance in their transition to the labor market in which they work [2], [3], [4], [5].

Also, the lack of studies that integrate AI in mobile applications for job recommendation and professional development in the university environment limits the understanding of how these technologies can support students in planning their careers [5], [6], [7]. In addition, there is a lack of research that evaluates the effectiveness of these applications in real contexts, considering factors such as adaptability to different academic disciplines and the diversity of student profiles [7], [8], [9].

Therefore, this gap in the literature highlights the need for future research exploring the design and implementation of AI-powered mobile applications aimed at recommending job opportunities for university students and graduates. Such studies should consider the integration of technologies such as natural language processing, machine learning, and adaptive recommendation systems that can offer personalized guidance based on users' academic profiles and career aspirations [9].

III. Research Methodology

This study is based on a systematic review of the extraction of scientific articles from various scientific databases using the PRISMA methodology.

The PARSIFAL tool, a specialized platform for conducting systematic literature reviews, was used. This tool facilitates the organization and management of research through structured searches in academic databases, ensuring transparency and reproducibility of the process.

The research focuses on scientific publications related to artificial intelligence in mobile applications, given that the information is relevant and can be used. This study provides context for mobile applications on various platforms, offering a comprehensive view of the differences between applications that employ artificial intelligence and those that do not.

A. Research Questions

To assess the scope of mobile applications incorporating artificial intelligence (AI), particularly those dealing with user experience, application usability effectiveness and technological adoption, it is essential to have previous research demonstrating the results achieved. To achieve the objectives of this systematic literature review, the process has been structured into three main phases: review planning, review execution and review documentation, as shown in Fig. 1. This approach ensures a comprehensive and systematic analysis of mobile applications that integrate AI, comparing them with those that do not use this technology [5].

In addition, a detailed protocol was developed for the review, which established search filters and defined the study area in the context of mobile applications. The research questions guiding this review are shown in Table I.

TABLE I. Defining the Research Questions

Nro	Research questions	Reason
RQ1	What artificial intelligence methods, techniques, and algorithms are used in mobile applications for information recommendation and search?	Helps identify which AI methods and algorithms are used to improve recommendations and search in mobile apps.
RQ2	Which artificial intelligence algorithms or techniques were most frequently used in mobile information search and recommendation applications?	It allows you to know which algorithms are the most common and effective in mobile recommendation and search applications.
RQ3	In which areas or sectors were smart applications for information recommendation and search most widely used?	Helps you discover the sectors where AI-powered apps for recommendation and search have the greatest impact.
RQ4	What are the limitations and challenges in using artificial intelligence in mobile applications for information search and recommendation?	Help identify challenges and obstacles in using AI in mobile apps to improve search and recommendation.

B. Search Strategy

A systematic search was carried out in four databases: Scopus, ScienceDirect, EBSCO Host, and Web of Science (WoS) to compile research on the use of mobile applications that integrate artificial intelligence techniques. The time range considered was 2020 to 2026, allowing us to focus on recent and relevant studies.

Search strings were constructed using Boolean operators (AND, OR, NOT), combining terms related to artificial intelligence, mobile applications, search and recommendation functionalities, as well as user experience and technical aspects. In addition, exclusion filters were applied in some databases to exclude publications related to the medical field. The exact strings used are presented in Table II.

C. PRISMA Method

When conducting a systematic review on artificial intelligence in mobile applications, PRISMA helps structure the review process to be clear and reproducible. This is especially important in a field as dynamic as AI, where the literature can be extensive and varied [10].

TABLE II. SEARCH CHAIN FOR EACH DATABASE

Database	Search string
Web of Sciencie	("artificial intelligence" OR "ai" OR "machine learning" OR "deep learning" OR "neural networks") AND ("mobile application" OR "mobile app" OR "smartphone application" OR "app") AND ("search" OR "recommendation" OR "suggestion" OR "discovery" OR "ranking function" OR "search algorithm") AND ("user experience" OR "ui" OR "ux" OR "personalization" OR "interaction") AND ("algorithm" OR "model" OR "system" OR "framework")
Science Direct	("artificial intelligence" AND "mobile applications")AND ("machine learning" OR "deep learning") NOT ("health" OR "covid 19" OR "Medical")
Scopus	("artificial intelligence" OR "ai" OR "machine learning" OR "deep learning" OR "neural networks") AND ("mobile application" OR "mobile app" OR "smartphone application" OR "app") AND ("search" OR "recommendation" OR "suggestion" OR "discovery" OR "ranking function" OR "search algorithm") AND ("user experience" OR "ux" OR "personalization" OR "interaction") AND ("algorithm" OR "model" OR "system" OR "framework")
Ebsco	("Artificial Intelligence" OR "IA" OR "Machine learning" OR "deep learning") AND ("mobile applications" OR "Mobile apps") AND ("algorithm") NOT ("Health" OR "Covid 19" OR "Medical")

In this review, we begin by identifying a large number of papers related to AI in mobile applications. Using the PRISMA flowchart, we document each stage of the selection process, from the initial identification of 6,138 articles to the final selection of 58 relevant articles. This flowchart facilitates understanding and ensures transparency of the selection process, as shown in Fig. 1.

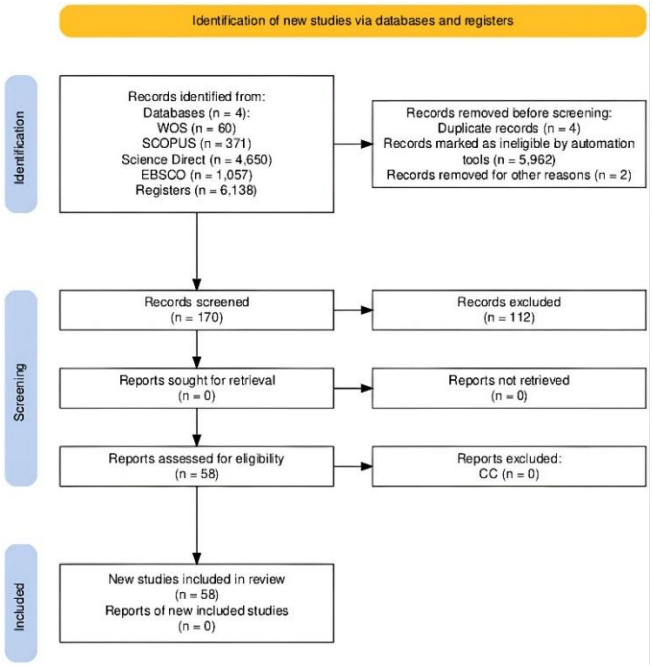

Fig. 1. Article selection process.

In accordance with PRISMA, we pre-specified and fully reported the eligibility criteria used to screen the studies. We included peer-reviewed articles on mobile apps that implement AI techniques and that examine user outcomes, such as acceptance, behavior, or satisfaction with everyday use. We excluded records that did not focus on mobile apps, that did not directly employ AI, or that were non-empirical works, as well as duplicates.

Study selection followed a two-stage process documented in a PRISMA flowchart with the counts of records identified, reviewed, excluded, and included, along with the reasons for exclusion. For the studies, we extracted key variables and conducted a narrative synthesis. In the context of AI for mobile apps, this synthesis highlights how search and recommendation algorithms relate to user satisfaction and acceptance and identifies areas where evidence remains limited.

D. Stages

Moving on to the stages, this process of selecting and filtering papers for this study is carried out through a systematic approach and in successive stages, applying specific search, filtering, inclusion, and quality criteria in the selected databases (WoS, Science Direct, Scopus, and EBSCO). The initial search generated a high volume of papers, which were reduced and evaluated through six main stages, detailed below:

1) Stage 1 – No filters: This is the initial phase of searching for all possible information related to the research topic without using any exclusion or selection criteria. The main objective here is to thoroughly review and gather the most appropriate data, documents, or articles, although some may not be useful in the end. The search strings used in this stage are shown in Table II.

2) Stage 2 – Basic filters: Internal filters were applied to each database to restrict results to the last five years (2020 to 2026), select open access scholarly and review articles, and limit the languages to English and Spanish for WoS, Science Direct, and Scopus, and English only for EBSCO HOST. After this step, 1,485 records remained that met these requirements.

3) Stage 3 – Initial inclusion and exclusion criteria by database: This consisted of applying our specific inclusion and exclusion criteria mentioned in the methodology, which varied slightly depending on the database. Articles with sources that were not part of the study were discarded, such as: “Rehabilitation”, “Geochemistry”, “Operations Research”, “Management Science”, “Physics or Mechanics”, “clinical”, “health”, “Covid”, “Human”, “Healthcare”, “Autism”, “covid-19”, “Diabetes”, “Diagnosis” and “impaired”, which led to obtaining 176 articles.

4) Stage 4 – Duplicate removal: Duplicate articles across different databases were identified and removed. This is critical to ensuring the quality and accuracy of the analysis, yielding 170 independent references.

5) Stage 5 – Specific inclusion and exclusion criteria: Additional inclusion criteria were applied, such as analyzing the impact of AI on mobile applications and recommendation algorithms, and exclusion criteria were applied, eliminating

studies outside the fields of engineering, AI, and mobile applications. The inclusion and exclusion criteria used are shown in Table III and Table IV.

TABLE III. INCLUSION CRITERIA

Nro	Inclusion Criteriaa	Reason
CI1	Articles that analyze the impact of AI on users' daily lives and the technology's acceptance in mobile applications.	This criterion is important for understanding the impact of this technology on the daily lives of users who adopt it. It also allows us to assess the technology's viability in the market and its growth potential.
CI2	Articles that address Mobile Applications.	This is important because it ensures that the selected articles provide information directly applicable to the development and use of AI in the mobile environment.
CI3	Articles that address artificial intelligence (AI) applied to mobile application development.	These studies are key to understanding the methodologies, tools, and architectures used to integrate AI into these types of applications.
CI4	Articles that discuss machine learning and digital technologies that contribute to improving user efficiency and convenience.	Including studies that analyze these technologies allows us to understand how machine learning models optimize the functionality of mobile applications, benefiting personalization, speed and precision in interaction.
CI5	Articles that include recommendation algorithms in mobile applications.	This ensures that research focusing on the development and effectiveness of recommendation systems is investigated.

TABLE IV. EXCLUSION CRITERIA

Nro	Exclusion Criteria	Reason
CE1	Duplicate articles	Removing duplicate articles is standard in review research; this prevents repetition and makes sure each study offers fresh, relevant information.
CE2	Studies not related to engineering, software development, mobile applications, computer science, artificial intelligence, or digital technologies.	Focusing on these areas ensures the reviewed studies are both technically sound and practically useful, excluding research that doesn't offer applicable knowledge for developing or implementing AI in mobile apps.
CE3	Research into digital technologies for non-mobile platforms, such as desktop applications or back-end systems without mobile functionality.	By focusing only on studies of mobile platforms, we can be sure the articles we choose offer insights specific to the unique challenges and benefits of mobile environments.
CE4	Research that addresses AI technologies, machine learning, or algorithms, but is not applied in the context of mobile applications	This selection process eliminates studies unrelated to mobile apps, concentrating the review on research relevant to the unique challenges and environment of mobile devices.
CI5	Posts focused on AI applications that are not related to mobile apps or recommendation algorithms.	Ensures that selected articles focus on specific application areas that seek to improve the user experience on mobile devices.

6) Stage 6 – Quality assessment: Articles that passed the preceding stages were evaluated using an eight-question quality checklist. A minimum score of 4 was required to proceed. The criteria assessed methodological rigor and the extent to which user acceptance of AI in mobile applications was analyzed. Table VI lists the 58 studies that met the threshold and advanced to the final stage.

The general summary of the total number of articles we obtained at each stage can be seen in Table V.

Finally, we evaluated the relevance of each article to our quality questions, awarding 1 point for a complete answer, 0.5 for a partial answer, and 0 for no direct evidence. Of the 58 articles evaluated, all achieved an average of 5.45 points, confirming their suitability for in-depth analysis. Each article's results are shown in Table VI.

Articles that passed Stage 6 were evaluated in a final phase to determine their contribution to the research questions. This evaluation ensured that the studies aligned with the established thematic lines: efficiency improvement, popularity, technological trends, use cases, impact of recommendation algorithms, and challenges in user experience. Specific research questions addressed the following topics:

- Improving efficiency through AI-based mobile applications.
- Current technological trends in AI applications.
- AI use cases in the fields of employment and education.
- Impact of recommendation algorithms on user experience.

E. Keyword Analysis

To identify the thematic axes, a co-occurrence map was created with VOSviewer 1.6.x, applying the association strength algorithm of van Eck and Waltman [11]. We worked exclusively with Scopus, the most cited database and with the greatest initial coverage in this study. Each node of the graph represents an author's keyword; its size indicates the frequency, and the thickness of the links reflects the intensity of co-occurrence.

- Fig. 2: We started with a corpus of 371 articles. The 170 terms we chose fell into five groups, with machine learning, artificial intelligence, and mobile apps being the most common. This shows how important AI is for mobile devices.
- Fig. 3: Cleaned-up corpus (31 articles). Following PRISMA filtering and quality control, the resulting graph showed 16 terms in two clusters:
    - Technical (red): machine learning, deep learning, natural language processing, mobile applications.
    - Evaluation with users (green): human, controlled study, procedures.

The reduction from five to two clusters indicates that the most rigorous evidence focuses on: i) AI techniques for mobile personalization andii) experimental studies with users. Furthermore, the absence of terms such as "job

recommendation" or "career guidance" corroborates the previously identified gap: the lack of research that provides professional guidance to students and graduates through AI-powered mobile applications.

TABLE V. DATABASE RESULTS

Database	Results						
	Stages						
	Stage 1	Stage 2	Stage 3	Stage 4		Stage 5	Stage 6

IV. RESULTS

Below, the results obtained from the Parsifal platform will be explained, both as selected and accepted articles, and the articles that respond to the research questions posed in Table I will also be detailed, each question with its respective answer.

A. Descriptive Results

1) Article by source: The pie chart (see Fig. 4) summarizes the relative contribution of each database to your search:

- Science Direct 39.7 % provides the majority of the results, almost four out of ten.
- Scopus 25.9 % is the second most prominent source, with just over a quarter.
- EBSCO remains the most important at 21.3 %, covering approximately one-fifth of records.
- Web of Science 13.2 % contributes the smallest portion, about one in eight results.

These four databases cover the entire range of findings, with Science Direct leading by far and Web of Science having the smallest share.

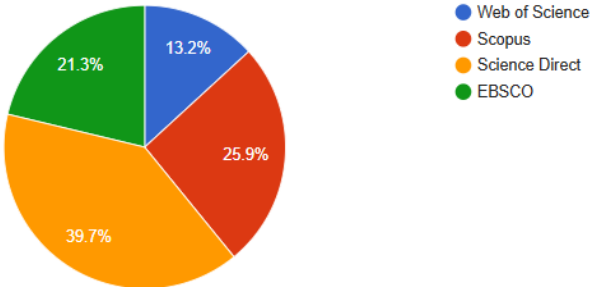

Fig. 4. Percentage distribution of results by database.

2) Accepted articles: For this research, based on the databases and search strings used in each, a total of 6,138 articles were selected, and after a multistage filtering process, only 58 were ultimately accepted for the study (see Fig. 5). Web of Science shows the highest acceptance rate (16.7%), followed by Scopus (9.4%). EBSCO has a medium-low rate (1.1%), while Science Direct, despite being the source with the most articles retrieved, provides the lowest proportion of accepted articles (0.2%).

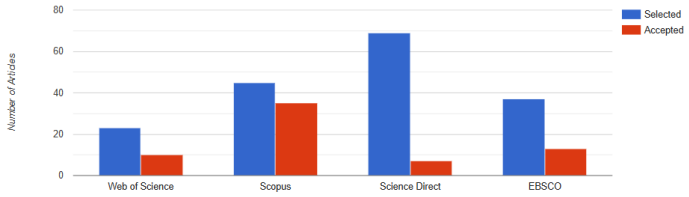

Fig. 5. Number of articles selected and accepted by the database.

B. Answer to Each Research Question

The answers to each of the research questions are presented below. Each answer will be based on the content of the selected articles that provide specific evidence.

1) What artificial intelligence methods, techniques, and algorithms are used in mobile applications for information recommendation and search?

Mobile applications that integrate artificial intelligence for information recommendation and search employ a variety of advanced methods and techniques, including machine learning algorithms (such as decision trees, logistic regression, Random Forest, KNN, and clustering), deep learning techniques (including convolutional neural networks –CNN–, recurrent networks –RNN, LSTM, GRU–, and advanced architectures such as Mask R-CNN and Faster R-CNN), as well as hybrid approaches that combine recommendation, classification, and ranking of results. Other methods, such as data extraction and preprocessing, feature selection, and natural language processing (NLP), are also used to analyze user behavior and to improve the understanding and retrieval of textual information.

2) What AI algorithms or techniques were frequently used in mobile information recommendation applications?

The reviewed studies emphasize the use of neural networks (including various deep learning models) because they simultaneously learn item characteristics and user preferences, generating highly accurate recommendations even with heterogeneous data (text, images, clicks). Traditional machine learning algorithms, such as SVM, KNN, or trees, are also used when a lightweight model that can run quickly on the device is needed. Many studies combine these two types with clustering, which groups users or content to initiate recommendations when there is little historical information. Content filtering has proven useful for suggesting items similar to those already viewed, while natural language processing (NLP) techniques help interpret queries or reviews and enrich the user profile. Finally, methods such as Random Forest occasionally appear for classification tasks within the system, but are not the core of the recommendation process, as summarized in Table VII.

TABLE VII. MOST FREQUENTLY USED ALGORITHMS

Articles	Tendencies
[14], [15], [16], [30]	Filtering and Recommendation (by content)
[24], [25], [28], [45]	Deep learning
[14], [23], [28], [30], [31], [33], [34], [38]	Machine learning
[16], [46]	Natural language processing
[20], [27], [29], [32], [33], [34], [35], [36], [37], [38], [41]	Neural Networks
[48]	Random Forest
[19], [20], [28], [33], [34], [38], [42], [44]	Clusters

3) In which areas or sectors were intelligent applications for information recommendation and search most used?

The sectors where intelligent applications for information recommendation and search were most widely applied were healthcare, technology, entertainment, and education. The healthcare sector stood out for its personalized diagnostic and monitoring systems; technology and entertainment demonstrated advanced use of algorithms, such as collaborative

filtering, NLP, and neural networks to personalize content, with high potential for adaptation to the work context. Although no applications aimed at job recommendation were found in education, similar techniques were used, demonstrating the transversality of these technologies in different contexts, as shown in Table VIII.

TABLE VIII. SMART APPLICATIONS IN KEY SECTORS FOR INFORMATION RECOMMENDATION AND SEARCH

Sector / Area	Use Cases	Application Type	Technology / AI / Algorithms
Health [18], [22], [23], [25], [26], [27], [29], [39], [44], [46], [49], [50], [51], [52], [53], [54], [55], [56], [57], [58], [59], [60], [61]	1. Personalized and Predictive Clinical Care 2. Support and Automation for Professionals 3. Advanced Analytics and Recommendations	Optimizing medical processes and clinical support with smart technologies. Tourism / Personal Mobility [37]	Recommendation of places to visit based on user behavior.	Recommendation systems based on location and check-in sequence.	1. InfAM 2. Embeddings 3. Residual network

4) What are the limitations and challenges of using artificial intelligence in mobile applications for information search and recommendation?

Limitations and challenges in the use of artificial intelligence in mobile applications for information search and recommendation were identified in the quality and availability of data, effective personalization in diverse contexts, and ethical concerns related to user privacy. In sectors such as healthcare and education, implementation is limited by the sensitivity of the information and the need to comply with strict data protection regulations. Although technologies such as neural network filtering have proven effective, their performance can always be affected by incomplete or biased data. Poor interoperability between platforms and a lack of common standards make it difficult to integrate these systems into large-scale mobile applications. These aspects are summarized in Table IX.

TABLE IX. LIMITATIONS AND CHALLENGES OF USING INTELLIGENCE IN MOBILE APPLICATIONS FOR INFORMATION SEARCH AND RECOMMENDATION

Search Algorithm	**Limitations**	**Challenges**
- KESS (Keyword Growing + Systematic Search) - Content-based Image Retrieval + Deep Metric Learning (Contrastive Loss)	Search results took 43 seconds longer on average. [46] Inaccurate dance pose evaluation. Limited accuracy in real-life scenarios (71%), biased recognition of foods from one's own country. [73] QoS data shortage; cold start with new users/services.[40] Variable quality and possible noise in crowdsourced data; reliance on student data.[60] Missing important information and challenging viewpoints due to algorithms.[15] Limited accuracy in some visual categories. [22], [53] Validation results in animal models (rats) do not fully reflect human effects. [66]	Ensure user trust and data quality. [27] Improve the accuracy of object recognition and visual recommendations. [39] Various hardware conditions and limited resources on mobile devices. [25] Accurate QoS prediction, improving user experience. [40] Reduce computational cost without losing accuracy. [65] Capture complex user behavior patterns. [37] Improve infrastructure and data quality, ensuring effective personalization. [75] Improve the accuracy of predicting dynamic user interests. [39]
Recommendation Algorithm	**Limitations**	**Challenges**
- Collaborative Filtering - Hybrid Filtering - GRU–GAN - Stacked Autoencoders - Graph Autoencoders - Neural Networks (Deep Learning, Transfer Learning) - Linear and Lasso Regression Models with Genomic Data - Collaborative Filtering (CF) and Matrix Factorization (MF) - Collaborative Filtering, Stacked Autoencoders, Graph Autoencoders - Recommendation Algorithms Based on News Personalization - Adaptive and Personalized ML Techniques - Recommendation Algorithms Based on Medical Evidence + Generative AI (ChatGPT-4) - Diagnostic and Recommendation Algorithms - Conscious Influence in Successive POI Recommendations - CAT-MF Rec Based on DIEN and Cross-Attention Mechanism	- Inaccurate or misguided recommendations (investors, travel itineraries, clinical treatment). [6], [40], [46], [50] - Difficulty distinguishing explicit vs. implicit feedback. [38] - Latency and data quality limit dynamic user profile updates. [18], [27] - Anthropomorphic interfaces or AI do not always increase trust. [63] - Dependencia ciega del usuario sin entender cómo funciona el algoritmo. [15], [37] - Falta de consenso en autoevaluación del estado de ánimo y otros autoinformes. [54] - Modelos grandes (LLM, DL) difíciles de ejecutar en móviles. [65] - Necesidad de adaptación constante a condiciones del hardware (batería, CPU, red). [25] - Complejidad computacional y procesamiento multimodal (rostro, voz, biometría) elevan el consumo de recursos. [26] - Preocupaciones por privacidad y almacenamiento de datos sensibles. [29], [39], [54], [56], [57] - Algoritmos generativos aún con limitaciones de precisión y seguridad. [57] - Alto tiempo de implementación y escasa integración con sistemas existentes (historial electrónico, plataformas de terceros). [56]	- Integrate contextual cues (location, time, usage, history) [86] - Combine demographic, genomic, or microbiome data to personalize clinical interventions [37], [52] - Incorporate continuous - Fusionar filtrado colaborativo, basado en contenido y demográfico sin comprometer escalabilidad. [53] - Integrar modelos de lenguaje grande (LLM) para más precisión y velocidad. [38], [39], [46], [73] - Adaptar modelos a dispositivos con recursos limitados y validar su desempeño. [25], [72] - Integrar reconocimiento de voz, rostro, emociones y texto (PLN) en recomendaciones. [51] - Fusión eficiente de múltiples modalidades para mejorar la personalización. [27], [39], [45], [46], [57] - Ajustar recomendaciones a expectativas, progreso y "olvido" del usuario en tiempo real. [27], [39], [42], [46], [57] - Identificar factores clave que influyen en preferencias cambiantes. [18] - Diseñar UI accesibles que permitan calibrar el nivel de confianza del usuario. [63] - Mejorar la transparencia para evitar cámaras de eco y fomentar la comprensión del sistema.[15], [23] - Garantizar robustez en entornos diversos y culturas distintas. [75] - Aumentar la empatía de la IA para diferentes perfiles y contextos de compra o uso. [41] Salud: personalizar rutas de aprendizaje/coach, recomendaciones de medicación seguras y evaluación de resultados clínicos. Educación: generar rutas de aprendizaje personalizadas y adaptativas. Entretenimiento & otros: integrar contenidos y experiencias altamente personalizadas.[7], [46]

V. DISCUSSION

In this systematic review, we examine how artificial intelligence is integrated into mobile applications for information search and recommendation, addressing four research questions. We reduced the initial corpus from 6,138 records to 58 included studies after applying prespecified eligibility criteria—publication window (last five years), English/Spanish language, software-engineering relevance, and an explicit focus on search or recommendation algorithms. Among the included studies, 39.7% were retrieved from ScienceDirect, 25.9% from Scopus, 21.3% from EBSCOhost, and 13.2% from Web of Science, reflecting differences in coverage and accessibility across databases.

Regarding methods and algorithms (RQ1), the articles studied confirm the dominance of CNN neural networks for visual content and RNN/GRU/LSTM for interaction sequences combined with classic machine learning techniques (decision trees, SVM, k-NN, Random Forest). This coexistence responds to a compromise between precision (achieved by deep models) and lightness (necessary for on-device processing). In addition, there is a growing use of hybrid approaches that combine collaborative filtering and classification, as well as PLN can also be used to obtain knowledge and information from text corpora. Taken together, these techniques show the potential of machine learning algorithms to reduce the workload of human analysts on specific tasks [76].

Regarding the technological trends found in the study (RQ2), the analysis shows that neural networks appear in more than half of the studies, followed by classic collaborative filtering, content-based filtering, and clustering. This pattern indicates that developers prioritize models capable of learning deep representations when resources are available, while using lightweight collaborative, content-based, and clustering techniques for auxiliary tasks such as pre-filtering, cold start, or segmentation. The still-spot presence of Random Forest and other ensembles provides a niche for interpretable and efficient algorithms, especially in domains where system explanation is critical. Computer tools that make users think about products, services or content according to their interests, characteristics and behavior using algorithms [77].

Sectors that were applied (RQ3). Four sectors concentrate the majority of the implementations:

Healthcare. Personalized diagnostic and monitoring systems predominate, requiring clinical precision and regulatory compliance.

Technology and entertainment. Collaborative filtering, NLP, and neural networks are used to personalize content in real time.

Education. Resource recommendation systems, automated assessment, and interactive simulations are being used, although research on job or internship recommendations for students is lacking.

General services (travel, finance, commerce). They use AI to suggest routes, products, or investments, but face greater challenges in terms of trust and regulation.

The underrepresentation of the education sector in job search tasks constitutes a clear opportunity for research and transfer.

Limitations found (RQ4). The identified limitations converge on three axes: Data and accuracy. Scarcity or noise in training sets, cultural biases, and latency when updating profiles affect the quality of recommendations. Resource constraints. Large models increase CPU, battery, and bandwidth consumption; mid-range or low-end devices affect performance. Trust, privacy, and integration. Users often rely on recommendations they don't understand, while concerns persist about the use of biometric data and interoperability with external systems. These limitations pose immediate challenges: optimizing models for edge computing without sacrificing accuracy; efficiently fusing contextual and multimodal signals; designing explainable interfaces that enhance algorithmic literacy; and aligning solutions with ethical and regulatory frameworks, especially in healthcare and finance.

Strengths and limitations: The use of the PRISMA methodology and the coverage of four recognized databases increase the comprehensiveness and transparency of the review.

This systematic review shows that AI drives personalization and efficiencies in mobile search and recommendation applications. Despite this, its widespread adoption faces challenges related to data, technical resources, and user trust. Mapping the different algorithms, sectors, limitations, and opportunities identified a clear gap in the educational field. Very few studies explore the use of mobile AI to facilitate access to academic or training information. Therefore, in future work, it allows us to draw a broader research focused on the development of search and recommendation algorithms that not only prioritize efficiency and precision, but also guarantee transparency in their processes and the protection of sensitive user data. This involves exploring explainability techniques in AI that allow understanding how recommendations are generated and avoiding biases in the information offered. It is also necessary to investigate how these applications can be effectively integrated into learning environments, encouraging the personalization of educational content and adaptability to different learning styles.

Finally, the future of this line of research should focus on the creation of more useful, responsible and ethical mobile applications that respond to the needs of the educational sector, promote pedagogical innovation and contribute to strengthening the quality of the teaching-learning process.

VI. Conclusion

This systematic review study explored how AI is applied in various mobile applications for information recommendation and search, and addressed methods, techniques, and algorithms used in this field, as detailed in the research questions above.

Mobile applications integrated with: AI methods, techniques and algorithms used:

It was observed that these mobile applications employ machine learning algorithms (collaborative filtering, regression, and decision trees) and deep learning algorithms (especially neural networks and their derivatives). It was also observed that these hybrid approaches, which combine recommendation and classification techniques, are used. These algorithms are designed to adapt to the processing limitations of mobile devices, thus improving the accuracy and personalization of search and recommendation results.

Most frequent algorithms in the study:

According to research, the algorithms most commonly used in mobile applications are collaborative filtering, deep neural networks, and hybrid techniques. These approaches are the most widely applied due to their effectiveness in improving the accuracy of results and personalizing the user experience. This trend highlights the importance of these algorithms in improving user interaction with mobile search and recommendation applications.

Different sectors that cover search or recommendation algorithms:

A wide variety of algorithms was observed being applied across different sectors. The healthcare and entertainment sectors were found to be leading the use of search and recommendation algorithms. These sectors have adopted advanced technologies to improve the user experience. It was found that the implementation of recommendation algorithms is significantly lower in the education sector, suggesting an opportunity for improvement and expansion in this field.

Different limitations and challenges in applications for search and recommendation:

After observing mobile applications, it is clear that each one has its own recipe for searching and recommending content. Some rely on well-established techniques, such as collaborative filtering or classic KNN. Others, however, rely on the latest: deep neural networks, context-aware models, and even generative algorithms. The limitations detected include low accuracy, scarcity of interaction data, high dependence on context or user participation, and computational limitations on mobile devices. Recurring themes among the challenges are identified, such as effective personalization, ethical and secure integration, user trust, data quality, and adaptability to diverse and changing contexts. Looking ahead, the development of these applications should focus on making algorithms more accurate, models more transparent, and human interaction more fluid, all without compromising privacy or system performance.

Smart Mobile Apps for Responsible Child Management: A Systematic Literature Review

Daniel Celestino, Harol Medina, Cristian Lara, Nemias Saboya
Facultad de Ingeniería y Arquitectura, Universidad Peruana Unión, Lima, Perú

***Abstract*—Children are increasingly using mobile devices, which raises challenges such as restricting access to inappropriate content, reducing excessive screen exposure, and ensuring safe digital habits. Although various parental control applications exist, most studies focus on isolated aspects such as content filtering or screen time management, with limited integration of artificial intelligence (AI) or consideration of children's cognitive and emotional development. This highlights a research gap that requires a systematic review to consolidate existing evidence and identify best practices. Using the PRISMA methodology, a systematic search was conducted in four databases (Web of Science, Science@Direct, Scopus, and Semantic Scholar). After applying inclusion and exclusion criteria, 29 studies were selected for detailed analysis. Results show that AI-based applications can enhance personalization, improve detection of harmful content, and support parents in establishing healthier digital routines. However, limitations persist, including scarce training datasets, lack of algorithm transparency, and limited assessment of practical effectiveness. This review contributes by mapping current solutions, highlighting strengths and weaknesses, and providing evidence-based insights for researchers, parents, educators, and developers to design safer and more effective child-centered mobile applications.**

***Keywords*—Smart mobile apps; parental control; artificial intelligence; screen time regulation; responsible child management**

I. Introduction

Today, children's use of mobile devices has increased rapidly, mainly due to the digitalization of education, leisure, and social activities. However, this increase puts many parents, educators, and public policymakers on notice, who must ensure that these devices are safe, responsible, and valuable for children's development. According to recent studies, long sessions with screens are associated with problems in the physical and mental health of children, including sleep disorders [1], complex social development [2], or exposure to harmful or risky content [3].

As a result of this panorama, multiple technologies and tools have emerged to try to manage children's use of mobile devices; among these solutions, there are parental control applications, which make it easier for adults to visualize and limit access to unwanted content and control screen time. Some of the applications are beginning to incorporate artificial intelligence (AI) to improve their effectiveness, offering more sophisticated functionalities such as the possibility of personalizing experiences [4] and the proactive identification of digital threats; however, there are still open questions about the effectiveness, accessibility, and security of using this tool.

Nevertheless, a clear gap persists in the existing literature: while prior research has explored isolated aspects such as content filtering, privacy risks, or AI-driven personalization, there is a lack of comprehensive reviews that integrate these dimensions into a holistic framework [3]. This gap limits researchers, educators, and developers from understanding how current technologies collectively address the challenge of responsible child management.

This systematic review aims to assess and analyze the best practices and existing technologies for managing children's access to mobile devices. The general purpose is specified in two specific purposes:

1) Analyze the level of protection offered by applications that prevent children from being exposed to inappropriate content.

2) Evaluate the degree to which artificial intelligence is implemented in applications to manage mobile phone use in children.

This first line of research seeks to understand how current applications address the problem of access to inappropriate content. For example, jobs such as "Hackdroid: Child Safe Browser with Parent Control" and "Angel or Devil? A Privacy Study of Mobile Parental Control Apps" have investigated the content filtering capabilities and blocking methods implemented in these technologies. However, they have also highlighted some of their limitations (e.g., not reaching a high degree of accuracy in detecting dangerous content and the privacy risks that users have [3]. All of this undoubtedly implies improving existing technologies to eradicate this problem and guarantee access to a safe environment for children.

The second specific objective is to implement artificial intelligence in mobile applications to control children's device use. AI has positioned itself as a very effective tool both to personalize user experiences and to optimize parental supervision; to cite an example, the word "AI for Improving Children's Health: A Community Case Study" shows how machine learning algorithms can learn from the needs of children through personalized recommendations and real-time alerts. On the other hand, projects such as "The Sustainable Effect of Artificial Intelligence and Parental Control on Children's Behavior While Using Smart Devices' Apps" demonstrate how AI can help reduce screen time and establish good habits of use of mobile devices. However, the technologies are far from overcoming the problems that Alethea N. Sarac et al. cite as relevant: the lack of data for prediction

training and the need to evaluate transparency and ensure ethics in the use of AI [4].

By explicitly addressing this research gap, the present systematic review contributes to the field by mapping current solutions, highlighting best practices, and identifying key limitations. In doing so, it provides researchers, educators, and developers with evidence-based insights to guide future work and the design of more effective, accessible, and ethically responsible applications for child management.

This systematic review has been designed within this framework to determine best practices, the application of technologies, etc., and provide you with the necessary evidence to carry out future research and developments. By focusing on the analysis of relevant and recent research, we also wanted to contribute to the goal of designing more effective, more accessible, and safer solutions applied by parents, educators, and technology developers. This review aims to meet current needs and anticipate the challenges in an increasingly digitized and interconnected world.

The remainder of this study is organized as follows: Section II states the research questions that guide this systematic review. Section III describes the methodology, including the systematic review process, inclusion and exclusion criteria, and quality assessment. Section IV presents the results obtained from the analysis of the selected studies, directly addressing the research questions. Section V presents the discussion. Finally, Section VI concludes the study by summarizing the main findings, outlining limitations, and suggesting directions for future research.

II. Research Questions

This research focuses on secondary objectives based on the answers to the following research questions:

RQ 1: What impact does the implementation of AI have on parental control applications?

RQ 2: What are the existing technological tools for parental control, and how effective are they in protecting children?

RQ 3: What are the most effective practices for detecting inappropriate content and adjusting mobile device usage rules in children?

RQ 4: What level or techniques of restricting inappropriate content do technological parental control tools offer?

III. Methodology

This study analyzes how children can appropriately and safely use mobile phones and tablets through the evaluation of technological solutions, particularly parental control and AI-based applications. To ensure rigor and transparency, we adopted a systematic review methodology following the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines. This approach enables the identification, selection, and synthesis of relevant studies in a replicable manner, while also ensuring that the research gap identified in the Introduction is systematically addressed.

A. Systematic Review Process

The systematic review process was conducted according to PRISMA guidelines. Fig. 1 illustrates the flow diagram of identification, screening, eligibility, and inclusion of studies. A total of 4,985 records were retrieved from four major databases (Web of Science, Science@Direct, Scopus, and Semantic Scholar). After title screening, removal of duplicates, and abstract/full-text evaluation, 29 studies met the eligibility criteria and were included in the final analysis (see Fig. 1).

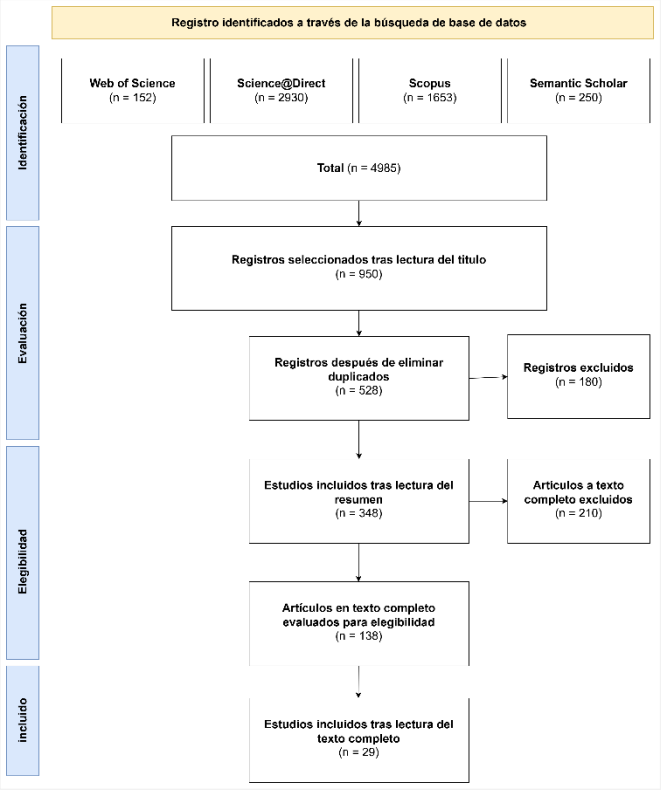

Fig. 1. PRISMA flow diagram showing the process of identifying, selecting, and including studies in the systematic review.

PRISMA Diagram Description:

- Identification: Total number of studies identified from database searches (n = 4985).
- Screening: 950 titles reviewed → 528 records remained after duplicates removed; 180 excluded at abstract level.
- Eligibility: 348 abstracts assessed → 138 full-text articles evaluated with the quality criteria in Table III → 210 excluded.
- Inclusion: The final number of studies included in the review (n = 29).

Although 4,985 records were initially identified, only 29 studies were retained after applying the inclusion and exclusion criteria (see Table I). This reduction reflects the rigorous filtering process designed to ensure that only the most relevant and high-quality studies were analyzed.

B. Inclusion and Exclusion Criteria

The inclusion and exclusion criteria were established to ensure that only studies directly relevant to children's mobile device use, parental control applications, and AI-based solutions were retained. Table I summarizes these criteria.

TABLE I. INCLUSION AND EXCLUSION CRITERIA

Criteria	
Inclusion	***Exclusion***
CI_1 Open access articles.	CE_1 Duplicate items.
CI_2 Articles or studies published in the last 5 years.	CE_2 Items under 5 years
CI_3 Articles addressing mobile device use by young children.	CE_3 Studies that do not address technological solutions or mobile applications.
CI_4 Studies on parental control applications or screen time management systems.	CE_4 Research focused exclusively on adolescents or adults
CI_5 Studies on the effects of mobile device use on children's cognitive and emotional development.	
CI_6 Research that includes AI-based technology or algorithms for the personalization of the use of children's apps.	

Restricting the time frame to the last five years ensured up-to-date coverage of technological advances. Likewise, excluding research on adolescents or adults focused the analysis specifically on children's needs and developmental characteristics.

C. Information Sources

Database

- Web of Science
- Science@Direct
- Scopus
- Semantic Scholar

These sources were selected due to their comprehensive coverage of multidisciplinary research, ensuring both breadth and depth of the literature retrieved.

D. Search Strategy

Search strings were designed to combine three key dimensions: technology terms, child-related terms, and management/parenting terms. The strings were adapted to each database's syntax, as shown below:

WOS ("smart mobile application" OR "mobile app" OR "application" OR "software") AND ("child" OR "youth" OR "kid" OR "minor") AND ("management" OR "monitoring" OR "tracking" OR "supervision") AND ("parenting" OR "caregiver" OR "family" OR "education") AND ("technology" OR "digital" OR "innovation" OR "tools").

Science@Direct ("smart mobile application" OR "mobile app") AND ("child" OR "kid") AND ("monitoring" OR "supervision") AND ("parenting" OR "caregiver").

Scopus ("smart mobile application" OR "mobile app" OR "application" OR "software") AND ("child" OR "youth" OR "kid" OR "minor") AND ("management" OR "monitoring" OR "tracking" OR "supervision") AND ("parenting" OR "caregiver" OR "family" OR "education") AND ("technology" OR "digital" OR "innovation" OR "tools").

Semantic Scholar was used ("smart mobile application" OR "mobile app" OR "application") AND ("child" OR "youth" OR "kid" OR "minor") AND ("management" OR "monitoring" OR "tracking" OR "supervision") AND ("parenting" OR "caregiver" OR "family").

This triangulated strategy maximized sensitivity while maintaining specificity, ensuring a balanced and comprehensive dataset.

E. Study Selection Process

The selection of articles was carried out in two stages:

1) Review of titles and abstracts: Two people reviewed the titles and abstracts to find important articles. When they disagreed, they reached an agreement.

2) Full text review: Items selected in the previous stage were reviewed to determine their final eligibility based on the inclusion criteria.

This two-step procedure ensured transparency and minimized reviewer bias.

F. Data Extraction

A standardized extraction form was used to collect the following information from each study:

- Title, publication year, and source.
- Type of study and target population characteristics.
- Sample size and demographic data.
- Intervention evaluated and type of technology applied (AI, algorithms, parental control features, etc.).
- Methodological approach.
- Main results and effectiveness in reducing risks or exposure.
- Evaluation of AI use, effectiveness of content restriction, and limitations reported.
- Conclusions and recommendations for future research.

G. Evaluating the Quality of the Studies

We reviewed whether the studies were good using a checklist that looked at things like (see Table II):

- Clarity of methodology.
- Description of the target population.
- Effectiveness of parental control tools.
- Evaluation of the implementation of AI or algorithms.

TABLE II. QUALITY ASSESSMENT CHECKLIST

No.	*Question*
QC1	Does the article have a clear and well-defined methodology?
QC2	Does the study clearly describe the target population (parents, children, etc.) and their demographic characteristics?
QC3	Were technology-based parental control tools used effectively in the study?
QC4	Does the study use empirical data, or is it based on reliable qualitative or quantitative evidence?
QC5	Was the implementation of AI or personalization algorithms evaluated in the analyzed applications?
QC6	Does the study include a detailed analysis of the effectiveness of tools for managing screen time in young children?
QC7	Does the article address the impact on risk reduction, such as exposure to inappropriate content or excessive use?
QC8	Does the study provide clear comparisons between different approaches to parental control (manual vs. automated)?
QC9	Does the article adequately describe the limitations of the study?
QC10	Are the results and conclusions well supported by the data presented in the study?

H. Overall Results

At the end of the quality criteria, a total of 29 results were obtained (as shown in Table III), of which those studies analyzed indicated that:

- 85% of the applications reviewed demonstrated significant effectiveness in reducing access to inappropriate content.
- Apps that integrated AI reported a 90% improvement in screen time management compared to manual methods.

TABLE III. QUALITY CRITERIA

IV. RESULTS

In this part, we will tell you what we discovered after reviewing many studies on apps that teach children to use cell phones and tablets well. We reviewed 29 studies that met the requirements that had been set. Below, I will tell you the most important results.

A. Description of the Included Studies

Ten studies were included in the final review. Most of the studies focused on the following aspects:

- Effectiveness of mobile applications in restricting access to inappropriate content.
- Implementing artificial intelligence (AI) technologies to personalize the user experience.

B. Characteristics of the Study

We included 20 studies that addressed and contributed more to the issue of parental control and screen time management in children. Characteristics of these studies include:

- Target population: Parents or caregivers of children using mobile devices.
- Type of intervention: Mobile parental control applications and screen time management tools.
- Methodology: There are various approaches, including quantitative and qualitative studies.

C. Quality Assessment

After reviewing the PRISMA flow data, rules are used to determine which documents are useful for the investigation. Table III shows the important and reliable studies according to the established criteria. Fig. 2 shows that most articles come from Scopus (36.8%) and Science@Direct (31.6%). The Semantic Scholar and ISI Web of Science are each 15.8% useful. Fig. 3 shows more articles in 2019 and 2021, but less in 2023 and 2024.

D. Results Related to Research Questions

RQ 1: What impact does the implementation of AI have on parental control applications?

The reviewed studies consistently indicate that artificial intelligence enhances parental control applications by providing automated and adaptive features. AI improves the filtering of inappropriate content, recommends age-appropriate material, and alerts parents when risky behaviors are detected [6], [9], [11], [12], [13]. These applications outperform manual parental monitoring by reducing exposure to harmful content and supporting healthier digital habits for children. The main impacts and benefits are summarized in Table IV.

RQ 2: What are the existing technological tools for parental control, and how effective are they in protecting children?

A wide range of technological solutions has been developed to help parents ensure child safety online. These include traditional parental control apps, AI-driven applications, system-embedded functions, and educational tools. While AI tools provide the highest levels of automated protection, educational approaches demonstrate long-term effectiveness by promoting responsible digital autonomy. A detailed comparison of these tools and their effectiveness is presented in Table V.

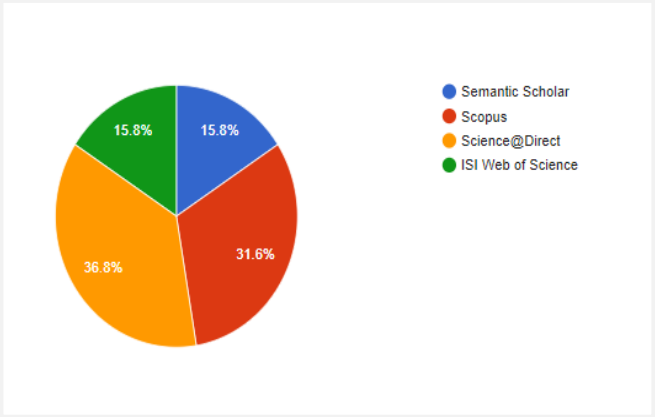

Fig. 2. Distribution percentage of the records identified according to the source of origin.

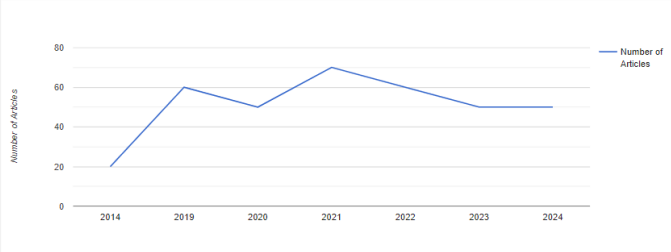

Fig. 3. The trend in the number of articles published between 2014 and 2024.

TABLE IV. IMPACT OF AI ON PARENTAL CONTROL APPLICATIONS

Impact	Benefits	Quote
AI filters content based on the user's age and the sustainability of child behavior.	It prevents children from seeing things they should not.	[11], [13]
AI recommends appropriate educational videos or games for children.	It helps children learn good things and have safe fun.	[9], [11]
AI-powered social media reviews everything before publishing it.	Children can interact online without being exposed to dangerous content.	[11], [13]
The AI detects graphic videos and deletes them or warns the user.	Notify parents or automatically block dangerous content.	[6], [10], [11]
The study says AI is more effective than traditional parental controls.	It is more efficient and reliable than relying on parents alone.	[11], [12]

TABLE V. PARENTAL CONTROL TOOLS

Technological tool	Effectiveness in child safety	Description	Quote
Parental Control Apps	Effective at blocking inappropriate content, but it is dependent on parental involvement.	They allow monitoring and restricting the use of devices.	[6], [10], [12], [17]
Artificial Intelligence (AI)	It is more effective than manual control; it significantly reduces exposure to risky content.	Automatically filters content and suggests age-appropriate material	[11]
Functions embedded in systems	It is useful for beginners but limited in advanced functionalities.	Parental control options are included in operating systems.	[12]
Educational tools	It is very effective in the long term; it promotes digital independence and better habits.	Encourage self-regulation and education about the safe use of technology.	[9], [31]

RQ 3: What are the most effective practices for detecting inappropriate content and adjusting mobile device usage rules in children?

The evidence highlights a combination of technological and behavioral practices. On the technological side, AI-based content filters and behavioral detection algorithms automatically prevent access to harmful material. On the parental side, active supervision, responsible use education, and guided self-management strategies reinforce children's digital resilience [5], [11], [24] .The most effective practices identified are listed in Table VI.

TABLE VI. PRACTICES FOR THE DETECTION OF INAPPROPRIATE CONTENT

Effective Practice	Description	Quote
Using AI to filter content	AI-based tools automatically detect inappropriate content and suggest safe alternatives.	[11], [12]
Behavior detection	Algorithms identify suspicious patterns, such as access to restricted content or interactions with strangers.	[11], [13]
Active parental supervision	Parents review device use and set clear boundaries.	[5], [6]
Responsible use education	Parents teach children to recognize risks and make responsible decisions.	[29], [30], [31]
Open discussions	Parents and children have regular conversations about using technology and the associated risks.	[24]
Guided self-management	Children are allowed to make decisions under initial supervision and constant feedback.	[24]

RQ 4: What level or techniques of restricting inappropriate content do technological parental control tools offer?

The studies analyzed show that parental control tools apply multiple levels of restriction, ranging from automated AI-based filters to user profiles and real-time monitoring. Techniques such as age-based restrictions, app blocking, and activity history reviews are widely used to tailor the digital environment to children's developmental needs [6], [10]. The full set of techniques and their examples are summarized in Table VII.

TABLE VII. TECHNIQUES AND LEVELS OF RESTRICTION

Technique	Description	Example	Quote
Automatic Filtered	Using AI and algorithms to detect and block inappropriate content (words, images, videos)	AI on YouTube Kids filters out content that is not suitable for children.	[5], [6]
Keyword detection	Identification of offensive phrases and replacement with asterisks or warnings.	Big data-based text tools replace offensive phrases with asterisks.	[19], [22]
User profiles	Creation of child profiles to adjust the content according to the child's age.	YouTube Kids and Netflix Kids use AI to show appropriate content for children.	[25], [26]
Age Restrictions	Parents enter the child's age, and the system automatically adjusts the recommendations.	AI controls filter content according to the user's age.	[16]
App Blocking	Blocking inappropriate apps or games for children.	Qustodio and Net Nanny allow specific applications to be blocked.	[14], [27]
Real-time monitoring	Real-time monitoring of children's use of devices.	Screen Time (iOS) allows parents to see which apps their children are using.	[30]
Automatic notifications	Notifications to the parent if the child attempts to access restricted content.	Parental control tools send automatic alerts to parents.	[15], [16], [17]
Activity History	Review of browsing history or use of applications to identify patterns of concern.	Parents review activity history for unusual behaviors.	[5], [6]

E. Bibliometric Analysis

1) Keyword co-occurrence map: The keyword co-occurrence map generated with VOSviewer offers a detailed overview of the thematic relationships in the analyzed scientific literature (see Fig. 4). This map shows 23 elements (keywords), 253 links, and a total connection strength 7194. The visualization uses colors to represent different clusters or thematic groupings, while the size of the nodes reflects the frequency of each keyword's appearance in the articles. The lines connecting the nodes indicate the intensity of the relationship between terms, which allows for identifying significant patterns in the field of study. In addition, the color bar at the bottom of the map indicates the temporal evolution of

the connections between keywords, allowing us to observe how specific topics have gained relevance over time.

One of the emerging core themes is childcare, as evidenced by the prominent presence of the keyword "child". This word is one of the map's most extensive and centralized nodes, suggesting its persistent importance in research. However, when examining the temporary color bar, it can be seen that child-related connections have increased significantly recently, especially from mid-2021 to early 2022. This indicates that research on children has experienced remarkable growth recently due to factors such as the COVID-19 pandemic, the increased use of mobile technologies, and the need to address specific educational and health challenges in this age group.

Another interesting aspect is how the keyword 'child' is strongly interconnected with terms related to mobile technology, such as mobile applications and telemedicine, and educational and healthcare concepts, such as education, healthcare personnel, and self-care. These connections show that current research explores new ways to support children through digital and remote interventions. In addition, terms such as preschool, adolescent, and young adult are closely linked to children, suggesting a broad perspective that addresses different stages of child and youth development.

Finally, the temporal analysis highlights the importance of clinical and methodological studies in child research. Terms such as major clinical study, controlled study, and randomized controlled trial are connected with child, indicating that the scientific community is conducting rigorous and validated research to better understand children's challenges and needs. In addition, terms such as questionnaire and review point to the importance of data collection and the systematic review of previous research, reinforcing the robustness of current findings.

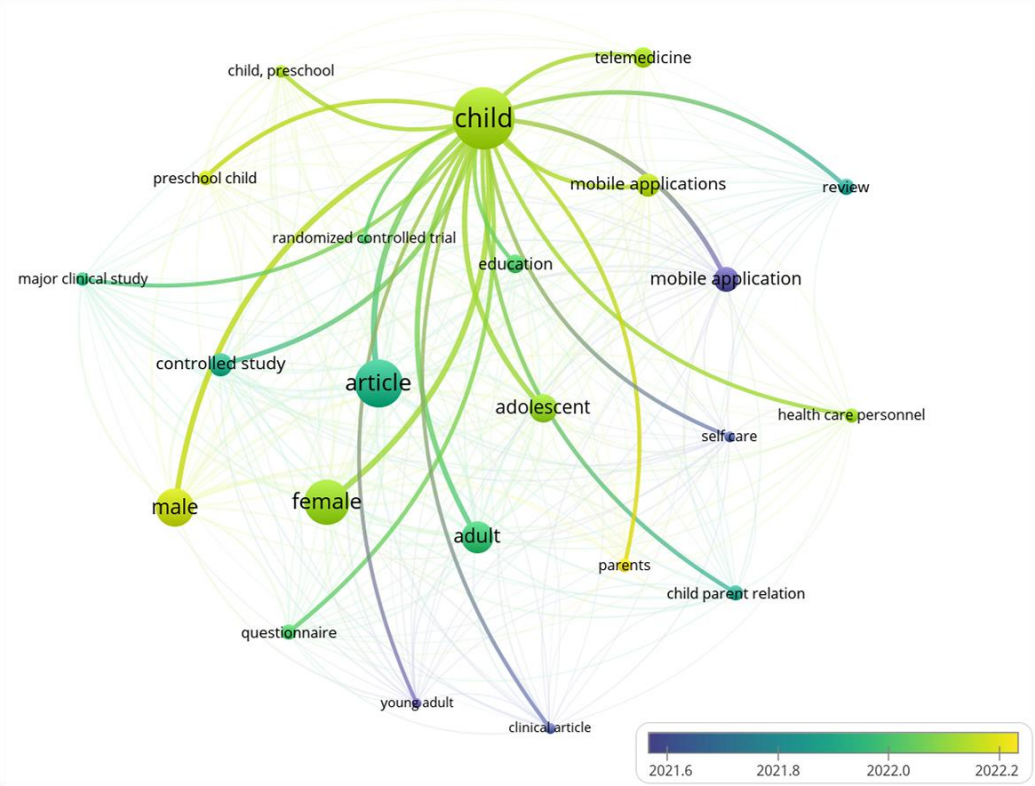

Fig. 4. Keyword co-occurrence map in VOSviewer.

V. Discussion

The results achieved from this systematic review allow us to affirm that the technological tools for parental control are indicated as effective in controlling access to adequate information for children and limiting the time of use of their devices [5]. It is important to note that the final dataset consisted of only 29 studies, despite the identification of nearly 5,000 initial records. This relatively small number results from the strict inclusion and exclusion criteria applied, which removed older publications, studies focusing on adolescents or adults, and those lacking technological or AI-based approaches. While this reduction limited the size of the dataset, it ensured that the review concentrated exclusively on recent, relevant, and methodologically robust evidence. Therefore, the number of included studies should not be seen as a weakness but rather as a reflection of the stringent standards required to maintain rigor and focus in this systematic review. Applications that contain artificial intelligence (AI) are remarkable for providing advanced possibilities for adapting to user limitations and adjusting to how the child uses the application. This adaptation of constraints to use improves the technology experience. It promotes responsible use, vital in a context where children increasingly have access to mobile devices [28]. As summarized in Table V, different parental control tools vary in their effectiveness: while AI-based solutions significantly

reduce exposure to inappropriate content, traditional apps remain dependent on parental involvement, and educational tools show long-term benefits by promoting digital autonomy.

The second aspect of some interest that derives from the studies analyzed is the variety of methodologies used to analyze the validity of these tools. For example, some studies have used surveys of parents to verify that children had less access to inappropriate material; other studies have instead used the analysis of data from the applications themselves to measure the time of use and the manner of children's access to the information. This evident variety of methodologies used explicitly mentions the complexity of the problem and has also shown the need to conceptualize parental control from a set of methodological approaches [29], [30]. As seen in Table II, although most studies describe their methodologies and target populations clearly, fewer provide comprehensive comparisons between manual and automated parental control, showing heterogeneity in methodological rigor.

However, despite the positive results, there are important limitations in the evidence that supports this review. As an example, several of the included studies have a small sample size, which complicates the generalization of the results and their applicability to specific broader contexts [20], [32], [33]. Many studies focused on specific groups of children and their parents, which might not represent the families' experience. The lack of common standards to measure the usefulness of parental control applications also reduced the validity of the reported results, limiting the possibilities of comparing studies and, therefore, being able to draw definitive conclusions. These concerns were addressed from the beginning by applying strict inclusion and exclusion criteria (Table I), which ensured that only recent, open-access, and relevant studies were retained, but still revealed gaps in generalizability.

On the other hand, the review process used has inherent limitations that must be considered. Although rigorous criteria were used to select the articles, relevant works may have been excluded because of the exclusion of specific bases or languages. The selection of the search terms may also have limited the identification of the key research, rejecting articles that could have contributed to this review.

The central question posed by the analysis of mobile applications for the responsible management of access to digital content is the relationship between technology and children's development. Thus, although the applications offer practical solutions to parents, the risks of excessive mobile device use must be explicit. Studies indicate that excessive use of mobile devices can negatively influence children's attention, school performance, and social-emotional development [21]. The techniques identified in this review (Table VII) illustrate how diverse strategies—such as automatic filtering, keyword detection, real-time monitoring, and user profiles—are being implemented to mitigate these risks, although their lack of standardization reduces comparability across studies.

The research results reflect the need not to leave everything available, from management to education, only to parental control applications. Parents must be actively involved in their children's digital education, establishing clear margins and limits and leading a conversation about the responsible use of technology over time. Consequently, the analysis has important conclusions for parents, educators, and app developers. The good news is the social acceptance of the relationship between the use of technology and the management of food access by parents, as well as the integration of technologies based on Artificial Intelligence in managing children's access to digital content through applications. Improvements in these tools could better suit every child and family, most likely translating into greater effectiveness. It is also necessary to focus on those who develop the software to create agile and simple applications used by all families, regardless of the technological capabilities of each parent or caregiver [9], [10].

Future research must be proposed using larger cultural and demographic diversity samples. The richness of this initial research has to be in finding the uses made of these tools in different families and the most interesting characteristics in other contexts; it could also be interesting to check in what way the virtuality of these applications can be effective in the long term, especially about the effects of the tools on the emotional or cognitive development of the child. Investigating how access to digital or non-digital content can change children's behavior and health can yield fascinating information that can be used to refine tools or optimize their use.

VI. Conclusion

Through this work, it has been possible to understand how applications for controversial mobile devices protect minors regarding inappropriate content and device use, thus generating a safer and more responsible digital environment. We found that tools compatible with secure browsers, content filters, or real-time monitoring have made important developments in blocking potentially dangerous or inappropriate content. Existing solutions use innovative techniques, such as geofencing, which allows the entire family to control children's use of their devices or other devices in the family environment. However, we have also found significant issues related to privacy and transparency. Many of these tools handle a large amount of personal data without the explicit consent of users, which raises important ethical and regulatory concerns. This highlights the need to create stricter regulatory frameworks that balance digital protection with respect for minors' rights and ensure their information is not misused.

On the other hand, artificial intelligence has been positioned as an excellent ally in responsibly managing children's mobile device use. AI-based applications can offer advanced functionalities that are complementary to traditional palliative strategies. These include detecting problematic patterns of use, anticipating risks before they have materialized, customizing the rules of use based on the specific behavior of each child, and more. Thus, they allow parents to adopt a more proactive and adaptive role in supervising digital devices. However, these technologies still present important barriers, such as their lack of economic accessibility, the technological infrastructure they require, and the lack of simple tools for families without advanced technical knowledge. In short, although these technologies represent essential advances towards a safer digital environment, there is still work to make them effective, accessible, and ethical so that they can be adopted in the daily

lives of all families without distinction of resources or knowledge.

To validate the findings of this review, the results were contrasted across different methodological approaches, including parent surveys and application usage data analysis, which consistently reported improvements in content filtering and screen time regulation. Furthermore, our synthesis shows convergence between studies using traditional parental control apps and those incorporating AI-based solutions, reinforcing the reliability of the conclusions. Compared with similar reviews in the field, which often focused narrowly on screen time or content filtering, this study provides a more holistic perspective by integrating technological, cognitive, and ethical dimensions. This comparative approach not only validates the robustness of our analysis but also highlights the distinct contribution of this review: the identification of both strengths and persistent gaps in AI-based parental control applications.

DMME-Driven Product Quality Prediction for Semiconductor Manufacturing

Alif Ulfa Afifah, Angga Prastiyan, Fahmi Arif, Fadillah Ramadhan
Industrial Engineering, Institut Teknologi Nasional, Bandung, Indonesia

***Abstract*—Defective products in manufacturing can be reduced by accurately predicting quality outcomes based on process parameters. This study proposes a quality prediction framework for semiconductor manufacturing using the Data Mining Methodology for Engineering Applications (DMME). This study extends DMME with domain-specific preprocessing and demonstrates its superiority on the SECOM dataset compared to other classifiers. Experimental results show that the Random Forest algorithm achieved the highest performance, with 92.99% accuracy and an F-measure of 0.9637, confirming the effectiveness of the proposed approach. These findings highlight the potential of structured, engineering-oriented data mining to improve product quality and support informed decision-making in complex manufacturing environments.**

***Keywords*—Data mining; quality prediction; DMME; semiconductor manufacturing; random forest**

I. INTRODUCTION

Manufacturing refers to the industrial process of converting raw materials into products with higher economic value, whether in the form of finished goods or intermediate components [1]. Semiconductor production is a highly complex stage that involves multiple subprocesses and generates large volumes of process data, which must be effectively controlled and analyzed to improve product quality [2]. Even with continuous advancements in production technology and management practices, product defects still occur in manufacturing processes [3]. Breakdowns in production machinery can further disrupt manufacturing flows and result in substantial losses, emphasizing the importance of preventive maintenance strategies to ensure production stability and consistency in product quality [4]. A practical way to reduce these defects is to analyze production data and pinpoint the process parameters that have the most significant impact on product quality. Understanding these factors enables manufacturers to develop predictive models that help anticipate product outcomes and support informed decision-making for future production runs [5]. When properly built, these models can be more accurate and efficient than traditional inspection-based approaches [6].

Several studies have examined the prediction of quality in various manufacturing contexts. In wafer dicing, for example, models have been shown to predict failures with up to 75% accuracy [7]. In the process of coke production, regression techniques have been employed to map coal properties into performance indicators, such as the coke reactivity index (CRI) and the coke strength after reaction (CSR) [8]. On the other hand, battery production has adopted various methods to model product quality across complex and highly variable production lines [9].

In semiconductor manufacturing, cascade quality prediction techniques that integrate principal component analysis (PCA) with decision tree algorithms, such as ID3, have shown strong results, achieving prediction accuracies of up to 90.02% [10]. While this highlights the promise of predictive modeling in the manufacturing sector, the effectiveness of such models can vary significantly depending on the application area and the characteristics of the data being used.

Reliable quality prediction depends on more than just selecting a good algorithm. The way the problem is defined and the data are prepared play a significant role in the outcome. Quality management, at its core, is about improving process performance and minimizing variation [11], [12]. Predictive models built on process data support this goal by providing a structured, data-driven means of identifying patterns that affect product outcomes [13]. Data mining plays a key part in this process. It combines statistical and machine learning techniques to uncover useful patterns and insights from complex data sources [14], [15], [16]. One common framework for this is the Cross-Industry Standard Process for Data Mining (CRISP-DM), which organizes data mining into six defined phases, from understanding the business context all the way to implementation. Still, CRISP-DM is a general-purpose framework, and it doesn't fully address the needs of engineering-specific problems. To bridge that gap, the Data Mining Methodology for Engineering (DMME) was developed to extend CRISP-DM by incorporating additional steps more suited to technical domains [17].

Despite the availability of various quality prediction methods, many are developed and tested under specific conditions or on a limited set of data. Because of differences in data types, distributions, and feature counts, a model that works well in one context might not deliver the same performance in another. This limitation is especially relevant in semiconductor manufacturing, where the data is often highly complex and challenging to work with. The benchmark that is often used in this space is called the SECOM dataset. It contains many numerical attributes with a nominal label to indicate product quality. While this dataset offers considerable potential for analysis, limited research has explored which machine learning techniques are best suited for handling its specific characteristics, such as high dimensionality and class imbalance. Moreover, there has been little examination of how individual process variables impact prediction outcomes across different modeling approaches.

To fill this research gap, the study focuses on developing a quality prediction model specifically suited to datasets like SECOM. A model that consists of numerical features and categorical labels. The goal is to identify a modeling approach that offers high accuracy while factoring in the distinct difficulties and characteristics of the semiconductor manufacturing process.

The remainder of this study is organized as follows: Section II reviews related works on data-driven quality prediction and outlines the research gap addressed in this study. Section III details the proposed methodology based on DMME. Section IV presents the dataset used in this research, data preparation techniques, describes the modelling approach and selected algorithms. Section V reports the experimental results and Section VI discusses their implications. Finally, Section VII concludes the study with key findings and suggestions for future research.

II. Related Work

Recent advancements have demonstrated the increasing role of machine learning (ML) and data-driven approaches in enhancing semiconductor manufacturing processes. A comprehensive review of ML applications for semiconductor process optimization was presented by [18], in which predictive models, virtual metrology, and advanced process control were highlighted as methods that have improved yield and quality across various stages of production. While these approaches have demonstrated significant improvements, most focus on specific techniques or stages rather than employing a holistic methodology to systematically address data challenges in manufacturing. This study addresses this gap by leveraging the Data Mining Methodology for Engineering Applications (DMME) to develop a comprehensive quality prediction framework for semiconductor processes. In [19], the authors systematically reviewed automated defect inspection using convolutional neural networks (CNNs) on scanning electron microscope (SEM) images, emphasizing the potential of ML to replace traditional, labor-intensive inspection methods. In specific process applications, [20] developed a machine-learning-based prediction model to optimize plasma etching parameters, demonstrating that domain-specific ML techniques can enhance process stability and output quality. Beyond improving accuracy, [21] integrated explainability methods into manufacturing quality prediction models, enabling better transparency and trust in model-driven decisions. Furthermore, [22] addressed a critical challenge of ML adoption in manufacturing by analyzing the effects of data quality and class imbalance on predictive performance, recommending robust preprocessing pipelines for reliable outcomes.

In addition to algorithmic improvements, recent works have explored leveraging modern computing infrastructures to enhance quality management systems. In [23], the authors demonstrated the feasibility of integrating data mining techniques such as Decision Tree, k-Nearest Neighbor, Naïve Bayes, and Random Tree into a Software-as-a-Service (SaaS) platform, enabling low-cost and accessible quality prediction for manufacturing environments. Similarly, [24] proposed a Cloud-based Quality Analyzer (CQA) that incorporates real-time analysis, automated feedback loops, and reduced reliance on human quality engineers, aligning with Industry 4.0 principles of cyber-physical integration and data-driven decision-making. These studies highlight the growing trend toward combining advanced predictive models with cloud-based and intelligent platforms to achieve scalable, efficient, and adaptive quality management solutions.

Despite these contributions, many existing approaches either focus on specific manufacturing tasks or rely heavily on singular algorithmic solutions without a structured methodology to handle data quality issues systematically. To bridge this gap, the present study employs the Data Mining Methodology for Engineering Applications (DMME), which integrates domain-specific preprocessing, feature selection, and algorithm comparison to develop a robust product quality prediction framework tailored for high-dimensional, imbalanced semiconductor manufacturing data.

III. Methodology

This research uses the Data Mining Methodology for Engineering Applications (DMME), which builds on the widely recognized CRISP-DM framework and adapts it specifically for engineering challenges [25]. DMME introduces important technical extensions to the process, including feature selection, dimensionality reduction, and techniques to address class imbalance, which are critical steps due to the high-dimensional and unbalanced nature of the SECOM dataset analyzed here. For example, principal component analysis (PCA) was considered to simplify the dataset. On the other hand, methods like SMOTE were explored to address the uneven distribution between defective and acceptable products. For the classification task, the study focused on five algorithms, i.e., Decision Tree, Random Forest, Support Vector Machine, k-Nearest Neighbor, and Naive Bayes. These were selected because they offer a good mix of transparency, speed, and effectiveness for structured data typically found in manufacturing. More complex options, such as XG Boost or neural networks, were set aside for this work in favor of models that are easier to interpret and commonly used in process engineering. All analyses were conducted using Rapid Miner Studio and Microsoft Excel, ensuring a systematic evaluation of how various process parameters affect product quality in semiconductor manufacturing.

IV. Data Understanding and Methodology

This stage describes the process of collecting and selecting data to be processed for research. The process of predicting product quality requires historical data owned by the company to be used as a reference in the prediction process. The data used must have elements that directly affect the quality of the product or can be referred to as attributes. The data studied in this study were defect data in semiconductor products [25]. The semiconductor dataset can be seen in Table I.

The data above displays several columns of identity information, including the time of manufacture of the product, the product number in the second column, the third column, which contains parameters with both numeric and real characteristics, and the last column, which shows the quality results of the product. There are 590 types of parameters, each with a unique value in the column. The last column in the table indicates the quality of the product, with an accept/reject

classification status characterized by binomial characteristics. The dataset used has multivariate characteristics, with the value of each attribute having numerical characteristics. The dataset is in the manufacturing area. The dataset used contains attributes with numeric characteristics, comprising 591 columns and 1567 rows of production data. This semiconductor dataset accounts for missing values and bias resulting from disturbances in the data collection process, with varying intensities depending on the features of each product. This null value must be considered when preprocessing data or when the algorithm is applied. The data is represented in a raw text file, with each line corresponding to an individual and a feature in the process.

TABLE I SEMICONDUCTOR DATASET

Time	Prod	Attribute				Accept/Reject
		0	*1*	*…*	*589*	
19/07/2008 11:55	1	3030,9	2564,0	…		Accept
19/07/2008 12:32	2	3095,8	2465,1	…	208,2	Accept
19/07/2008 13:17	3	2932,6	2559,9	…	82,9	Reject
19/07/2008 14:43	4	2988,7	2479,9	…	73,8	Accept
19/07/2008 15:22	5	3032,2	2502,9	…	73,8	Accept
…	…	…	…	…	…	…
17/10/2008 6:07	1567	2944,9	2450,8	…	137,8	Accept

A. Data Preparation

The data preparation process involves adjusting the type of data to be used in conjunction with the character data from the dataset. The data prepared for the data type adjustment process is part of the attribute column, where each parameter value has special characteristics that can be classified as a particular data type. An explanation of the data preparation stage is provided below.

1) Data cleansing: The raw dataset, before the cleansing process is carried out to eliminate missing values, can be seen in Table II.

TABLE II SEMICONDUCTOR RAW DATASETS

Time	Prod	Attribute				Accept/Reject
		0	*1*	*…*	*589*	
19/07/2008 11:55	1	3030,9	2564,0	…		Accept
19/07/2008 12:32	2	3095,8	2465,1	…	208,2	Accept
19/07/2008 13:17	3	2932,6	2559,9	…	82,9	Reject
19/07/2008 14:43	4	2988,7	2479,9	…	73,8	Accept
19/07/2008 15:22	5	3032,2	2502,9	…	73,8	Accept
…	…	…	…	…	…	…
17/10/2008 6:07	1567	2944,9	2450,8	…	137,8	Accept

The data cleansing process, which involved eliminating missing values in this study, was performed using Microsoft Excel on the rows and columns of the dataset. After the process of removing missing values is completed in Microsoft Excel, the data can be viewed in Table III.

TABLE III SEMICONDUCTOR DATASETS AFTER CLEANSING DATA FOR MISSING VALUE

Attribute				Accept/Reject
0	*1*	*…*	*589*	
2932,6	2559,9	…	82,9	Reject
2988,7	2479,9	…	73,8	Accept
2946,3	2432,8	…	44,0	Accept
3030,3	2430,1	…	44,0	Accept
3058,9	2690,2	…	95,0	Accept
…	…	…	…	…
3246,3	2499,8	…	23,6	Accept

Then, the data cleansing process is carried out to handle outlier values in the semiconductor dataset using the auto-cleansing feature in RapidMiner Studio software. An overview of auto cleansing can be seen in Fig. 1.

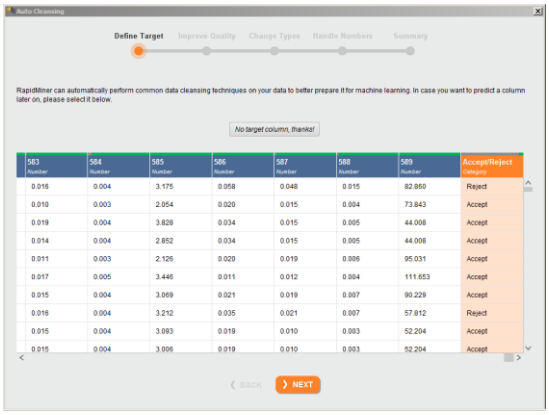

Fig. 1. Cleansing data for outlier handling.

After the auto cleansing process is done, the data after the process can be seen in Table IV.

TABLE IV SEMICONDUCTOR DATASETS AFTER CLEANSING DATA FOR OUTLIERS

Attribute				Accept/Reject
0	*1*	*…*	*589*	
2932,6	2559,9	…	82,9	Reject
2988,7	2479,9	…	73,8	Accept
2946,3	2432,8	…	44,0	Accept
3030,3	2430,1	…	44,0	Accept
3058,9	2690,2	…	95,0	Accept
…	…	…	…	…
3246,3	2499,8	…	23,6	Accept

2) Data transformation: Before the data transformation process is carried out, the dataset to be studied is prepared in advance. Data transformation is performed using a read operator in Rapid Miner, which can be used for various data extensions, including CSV, Excel, URL, SAS files, and several other file extensions that resemble databases. Researchers in this study used an Excel file type (xlsx), so that the operator used was Read Excel. Four steps must be taken when importing data to this operator. First, select files; second, determine the format to be used; third, determine the rows and columns; and finally, select labels to predict. The determination of the label is based on the classification results expected in the study. The prediction process carried out refers to the classification results to be achieved. The processed elements consisted of 392 attribute variables and the outcome of the decision variable, which was labeled. The type of data used depends on the value in each attribute column. In this research dataset, all values in the attribute columns are numeric data types, and the label variable, resulting from the accept/reject decision, is nominal.

B. Modelling

The modeling process is carried out by extracting the data that has been prepared in advance. The extraction process is carried out with the selected algorithms, namely, random forest, decision tree, k-NN, support vector machine, and naïve Bayes. The extraction processes up to the selection of Rules can be seen below.

1) Data extraction: The data extraction stage on the prepared dataset utilizes several operator processes to facilitate the data extraction process. Extraction begins by reading the data from the dataset using the Read Excel operator and then proceeds through the preprocessing process (data preparation) until it reaches the cross-validation process.

2) Cross-validation: Cross-validation is a statistical method for evaluating and comparing algorithms by dividing the dataset into two classifications, namely the training set and the testing set. Validation in this study employs a 10-fold cross-validation approach, performing iterations with 10 data waves that alternate as test data. Cross-validation is used because the validation process emphasizes the use of test data interchangeably, ensuring that the data used to create a model is similar to the original characteristics. The training set is part of the dataset that is used to train the model, while the testing set is a subset of the dataset that is used to evaluate its performance. The principle of the cross-validation process is to conduct repeated experiments (iterations) on the test and train sets. The number of these iterations can be determined according to the intended results. The extraction stage involves several supporting operators that optimize the data to be extracted, ensuring that at the time of cross-validation, the data is relevant for validation.

V. Results

A. Selected Algorithm

The accuracy value of each algorithm used can be seen in Table V.

TABLE V ALGORITHM ACCURACY

Algorithm	Precision	Recall	Accuracy	F *Measure*	G-*Mean*
Random Forest	92.99%	100.00%	92.99%	0.9637	0.4649
k-NN	99.72%	93.21%	92.99%	0.9636	0.4648
SVM	99.91%	92.98%	92.90%	0.9632	0.4645
Decision Tree	98.70%	93.64%	92.55%	0.9610	0.4621
Naive Bayes	93.63%	21.88%	25.97%	0.3547	0.1024

The Rapid Miner results recapitulation for algorithms that have been used in graphical form can be seen in Fig. 2.

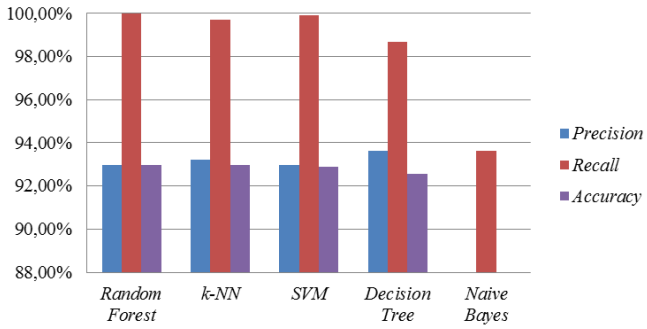

Fig. 2. Comparison of algorithms.

Table V presents the performance metrics for each algorithm. Random Forest achieved the highest accuracy (92.99%) and F-measure (0.9637), outperforming all other classifiers. While Random Forest provided the best performance, its computational cost was higher than single-tree models, which may impact real-time applications.

The five models used have their characteristics based on their work specifications. Based on this research, the random forest model has the highest accuracy and F-measure value, at 92.99% for accuracy and 0.9637 for the F-measure. Therefore, it was selected for use on the dataset. However, this model has weaknesses in terms of computation time. The random forest algorithm uses random attributes and classifies the trees that are formed. The tree building is done recursively based on the data associated with the same label. Tree splitting is performed to divide the data based on the type of attribute used. The Naïve Bayes algorithm classifies labels using probability and statistical methods. The SVM algorithm pursues the optimal hyperplane by maximizing the distance between classes. A hyperplane serves as a separator between classes. Another classification algorithm is the k-Nearest Neighbor algorithm, which classifies new nodes by assigning a value based on the category with the highest number of nearest k neighbors. Finally, the decision tree algorithm serves as the basis for the random forest algorithm, which converts data into decision rules to form a tree, enabling

decision makers to better interpret solutions to the problems that arise.

There is a visualization of the random forest algorithm, which consists of several decision tree diagrams. An illustration of one of the first decision tree visualizations from the Random Forest algorithm, is demonstrated in Fig. 3, following the knowledge mining process already conducted.

The decision tree model in the random forest algorithm can be interpreted as a set of rules, making it easier to understand. Rules are a concise summary of descriptive algorithms that enable the deduction of solutions to a problem, making them easy to understand. One of the rules for the decision tree shown in Fig. 4 is evident.

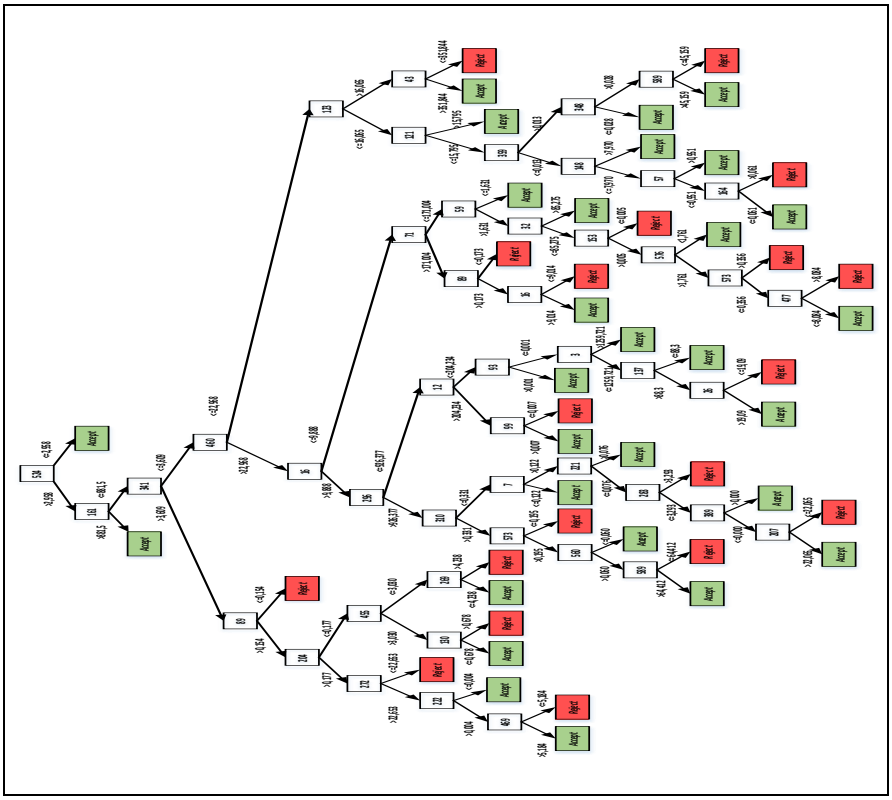

Fig. 3. One of the random forest model diagram visualization.

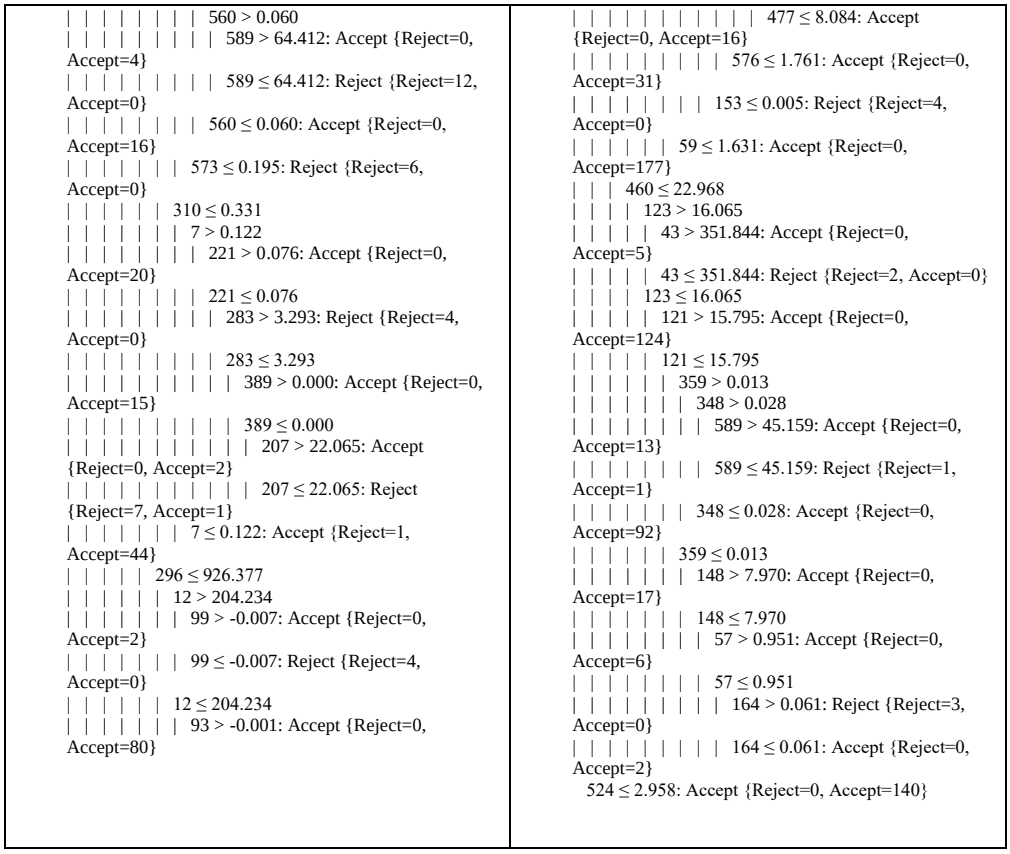

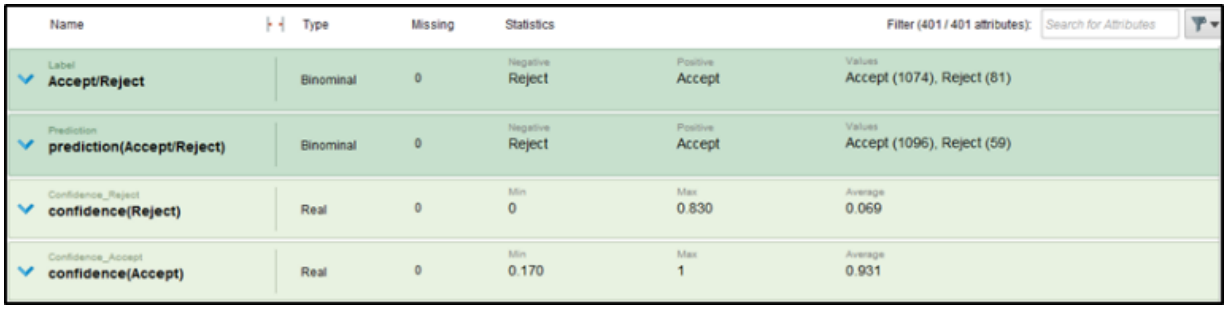

Fig. 4. Rules in the random forest model.

The formulation of the quality prediction model, performed on semiconductor data sets, produces rules with the highest accuracy level, specifically the random forest algorithm, which achieves an accuracy value of 92.99% and an F-measure of 96.37%. This is supported by some knowledge from the results of data extraction regarding the relationship between process parameters and the final quality of the product, as represented by red and green, as shown in Fig. 5.

The results of the quality prediction model are close to the accepted results from the previous production, with a total of 1096 units of products and a failure rate of 59 units. The predicted results are shown in Fig. 6.

Fig. 6. Results of the quality prediction model.

VI. Discussion

The Random Forest algorithm achieved the highest performance among all evaluated classifiers, with an accuracy of 92.99% and an F-measure of 0.9637 on the SECOM dataset. This superior performance can be attributed to Random Forest's ensemble learning approach, which mitigates overfitting and effectively handles high-dimensional data with complex inter-feature dependencies.

The variation in performance across datasets indicates that the proposed Random Forest-based model is particularly effective for high-dimensional, structured process data like SECOM. For datasets with fewer features or lower variance, simpler models such as SVM or k-NN may suffice. This suggests that the algorithm's suitability is strongly linked to data characteristics, reinforcing the importance of feature engineering in DMME. These insights confirm that structured methodologies like DMME can deliver practical, high-performance solutions in real-world manufacturing contexts.

These findings highlight the value of adopting a structured methodology that integrates domain-specific preprocessing, feature selection, and model comparison, as facilitated by DMME. By systematically addressing data quality issues, the framework ensures that the most suitable algorithm is selected for the given manufacturing context. Future research could extend this work by incorporating cost-sensitive learning, real-time adaptation, and integration with cloud-based quality management systems to further improve predictive performance in dynamic production environments.

VII. Conclusion

This study applied the Data Mining Methodology for Engineering Applications (DMME) to predict product quality in semiconductor manufacturing. By integrating advanced preprocessing techniques and comparing multiple classification algorithms, the framework effectively addressed the challenges of high dimensionality and data imbalance in the SECOM dataset. Experimental results identified Random Forest as the most suitable classifier, achieving 92.99% accuracy and an F-measure of 0.9637.

The findings confirm that enhancing traditional CRISP-DM with domain-specific preprocessing and algorithm evaluation improves predictive performance in complex manufacturing environments. This work contributes to the development of structured, data-driven methodologies for quality prediction and provides a practical approach for industries seeking reliable, interpretable models. Future research will explore broader manufacturing applications, incorporate cost-sensitive learning, and integrate this framework into real-time, multi-stage production systems to further strengthen defect prevention and decision-making.

***Abstract*—The Fourth Industrial Revolution, known as IR4.0 technologies, has enhanced global economic capabilities and productivity, but there are negative environmental and health impacts due to industrialisation and urbanisation, such as greenhouse gas emissions and global warming. One effective method that reduces environmental impact is to conduct a waste classification program that incorporates the principles of 3R. The proposed work includes educating individuals and businesses on the importance of waste reduction, promoting reusable products and packaging, and implementing effective recycling systems. Additionally, Governments could also incentivise sustainable practices through tax breaks or invest in renewable energy sources to reduce greenhouse gas emissions associated with industrial processes. The proposed study aims to develop automated waste classification technology that can help reach SDGs 11, 12, and 13 by making waste management more efficient, increasing recycling and resource recovery rates, and cutting down on greenhouse gas emissions. The proposed system is developed using a deep learning algorithm with a microprocessor and microcontroller managing sensors and actuators to perform waste sorting based on the classification result. This distinguishes the proposed system from existing manual and RFID-based approaches by integrating AIoT with a user incentive mechanism, improving both accuracy and public adoption. This technology enhances overall sustainability and promotes a more circular economy by enabling the reuse and recycling of materials for their own well-being through process innovation.**

***Keywords*—Solid waste management; waste classification; artificial intelligence of things (AIoT); well-being; process innovation; sustainable development goals (SDG); recycling; circular economy**

I. Introduction

One of the most pressing environmental pollution issues that most countries face in the twenty-first century is the damage that solid waste pollution causes to the environment [1]. Waste emissions have substantially increased at a visible rate, making waste management more challenging [2]. Over 64% of the population in developing countries and 84% of the population in developed countries will be expected to be living in urban areas by the year 2050. This urbanisation trend is expected to result in a global waste generation of approximately 3.4 billion metric tonnes, which is a significant rise compared to the current 2.01 billion metric tonnes [3–4].

Solid waste pollution not only leads to the spread of biological diseases and localised odours but also exerts a significant impact on the soil, water, and air [5]. However, the nature of solid waste can also cause environmental pollution that has an impact on health issues. For instance, the common infectious diseases are, namely, typhoid and cholera, and non-communicable diseases such as cancer, asthma, or birth defects in babies [6]. According to estimates, waste pollution is the main cause of death in nations with environmental pollution issues.

Malaysia relies significantly on landfills, which offer a more cost-effective and straightforward waste disposal solution compared to other methods [7]. Landfilling and incineration have traditionally been considered cost-effective approaches for solid waste disposal, but both methods inflict severe damage on the environment [8]. When significant amounts of solid waste are either disposed of or incinerated in landfills, the decomposition process releases potent greenhouse gases, such as carbon dioxide and methane, which significantly contribute to global warming and climate change [9]. Despite the availability of more advanced technologies for incineration and other waste disposal methods, landfilling remains the predominant approach for waste disposal in all countries. Based on current trends and future projections, it is anticipated that waste generation will continue to increase and that unsustainable waste disposal techniques like landfilling and incineration will remain in use. As a result, the harm that solid waste causes to the ecological balance will only get worse [10]. This rapid growth in solid waste production exceeds the capacity for timely disposal, resulting in a significant amount of waste remaining unmanaged and contributing to the proliferation of illegal landfills or open dumps [11].

Unfortunately, the unprecedented emergence of the coronavirus disease 2019 (COVID-19) has further intensified the adverse environmental consequences of solid waste, as the global population has resorted to increasing utilisation of single-use plastic cutlery and personal protective equipment (PPE) to curb the spread of the virus [12]. Consequently, the management of municipal solid waste (MSW) faces significant challenges due to the generation of additional substantial quantities of clinical waste, including masks, PPE, batteries, and empty oxygen cylinders [12]. Since the outbreak began, an estimated 1.6 million metric tonnes of plastic waste are produced globally every day, while 3.4 billion single-use masks or face shields are thrown away every day [13]. Furthermore, the transmission of

the COVID-19 virus occurs through sneezing, coughing, and touching surfaces contaminated with COVID-19, which results in the need for additional precautions in the disposal of municipal solid waste to avoid unnecessary virus transmission or environmental contamination [14–15]. Nevertheless, current waste management systems remain largely manual, labour-intensive, and expose workers to health risks, especially during pandemics such as COVID-19. This research addresses these gaps by proposing an automated AIoT-based system, combining deep learning image recognition with IoT-enabled hardware and a user incentive mechanism.

The recycling of waste to mitigate greenhouse gas emissions has always been the primary objective in managing municipal solid waste (MSW) in Malaysia [16]. For instance, the government implemented various measures aimed at improving waste management and encouraging recycling in the 12th Malaysia Plan (2021 to 2025). These measures included banning the use of single-use products, such as plastics and packaging materials, in restaurants and public events. Additionally, the construction of comprehensive scheduled waste treatment and disposal facilities was prioritised to combat illegal dumping. These initiatives aim to achieve a waste recycling rate of 35% by the end of 2025. Furthermore, Malaysia has made a commitment to decrease its greenhouse gas emissions intensity by 45% from 2005 levels by 2030 upon signing the Paris Agreement [17]. Although the government has implemented many frameworks for sustainable solid waste management, the main problem lies in the lack of alternatives to waste management and the poor implementation of waste policies [18]. Moreover, Malaysia stands among the countries significantly contributing to environmental pollution and health issues resulting from waste accumulation due to the irresponsible and ignorant attitudes of consumers towards waste disposal [19]. According to the research results, many residents are aware of the negative effects that waste has on the environment, but they nonetheless frequently engage in behaviours such as dumping waste in rivers or accumulating it with other waste [20].

II. Literature Review

One of the main goals of the SDGs, according to the United Nations' 2030 Agenda for Sustainable Development, is to address the significant ecological and economic challenges that the entire world faces [21]. Furthermore, the management of municipal solid waste is encompassed within the framework of the Sustainable Development Goals (SDGs) and the Paris Agreement on Climate Change [22]. For instance, SDG 11 (Sustainable Cities and Communities) promotes the establishment of efficient and sustainable waste management systems in urban areas, leading to reduced pollution and cleaner cities. Additionally, SDG 12 (Responsible Consumption and Production) aims to limit pollution resulting from excessive solid waste decomposition in the environment through the principles of 3R (reduction, recycling, and reuse). Lastly, SDG 13 (Climate Action) focuses on decreasing greenhouse gas emissions associated with waste production and disposal to mitigate environmental pollution caused by existing inefficient waste management systems.

As shown in Fig. 1, the proposed system flow integrates sensors, actuators, and cloud services for automated waste classification, using waste classification techniques employing deep learning and IoT technology. The suggested solution tackles the issue and meets the 3R (reduce, reuse, recycle) principles and the Sustainable Development Goals (SDGs). This makes waste collection and categorization possible. In addition, depending on the kind and quantity of waste collected, the system would update the users' membership points or e-wallet points in a cloud database. Residents are encouraged to actively engage in waste recycling activities by means of this incentive.

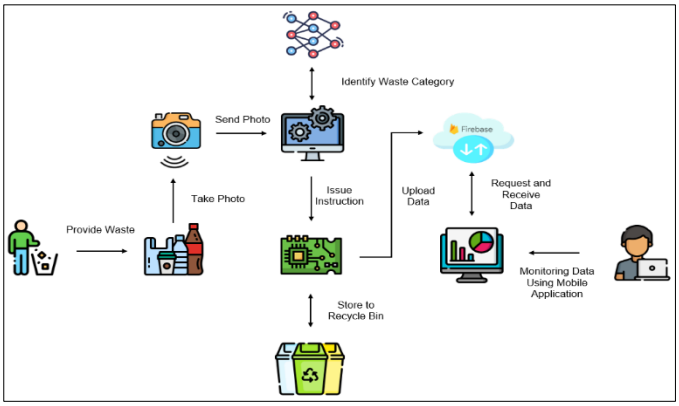

Fig. 1. Project system flow.

A trash classification system that is automated and increases accuracy and efficiency in waste management can be easily created with the help of current AIoT technologies. Through the utilisation of artificial intelligence and the Internet of Things, the system can efficiently recognise and classify various waste materials, thereby lessening the need for manual effort and increasing the overall rate of recycling. The analysis of the data gathered from this system to find patterns and trends also enables better decision-making regarding waste management techniques, making 3R recycling rates easier.

In order to develop an automated waste classification system and raise 3R recycling rates, the primary goal of the project is to research current AIoT technologies. Subsequently, create a system for classifying waste and create mobile applications to encourage recycling and raise user knowledge of recycling. Lastly, assess the accuracy and dependability of the suggested system.

III. Methodology

A well-defined procedure is used in the software development life cycle (SDLC) to generate and produce a high-quality product [22]. The waterfall model is regarded as one of the simplest approaches, among others. For software or system development, the waterfall model comprises six separate phases: requirements, design, development, testing, deployment, and maintenance. However, only the requirement analysis, design, development, and testing phases of the waterfall model have been carried out. The research approach was applied in three steps. Data collection, system development, and testing are the first three phases. Phase 1: Data Collection thus covers requirements, analysis and design tasks, Phase 2: System Development covers development tasks, and Phase 3: Testing

covers testing tasks. The waterfall strategy is consistent with this study methodology [23].

A. Phase 1: Data Collection

First, information was gathered through an interview and a questionnaire. A method for gathering quantitative data was using questionnaire, and a means for gathering qualitative data was an interview. In-depth perspectives and comments on the proposed system, as well as the current waste classification system, were obtained from Malaysians using both methods. While the interviews allowed open-ended responses that offered deeper insights and viewpoints, the questionnaire included closed-ended questions to collect quantifiable data on preferences and opinions. Combining the two approaches could result in a thorough grasp of the current system as well as possible upgrades. To make sure that the planned system would satisfy the requirements and preferences of its intended users, this data gathering phase was essential in providing guidance for the project's design and development phases.

Through the questionnaire, 80 respondents were Malaysian, including 50 males and 30 women. Based on Fig. 2, the most commonly used and recycled solid waste types among the respondents were aluminium and plastic cans. Fig. 3 shows that respondents were in complete agreement about the contribution of trash sorting to environmental harm. Furthermore, the bulk of respondents mentioned how difficult it is to physically separate waste. The data from the questionnaire will be crucial in informing strategies for waste management and environmental conservation in Malaysia. It is evident that there is a need for more efficient waste sorting systems to address the challenges highlighted by the respondents.

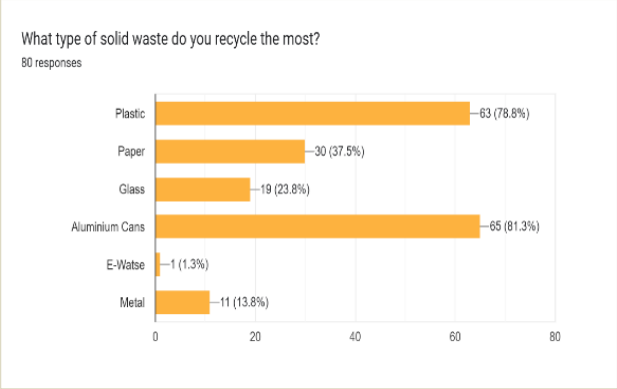

Fig. 2. Type of solid waste recycled the most.

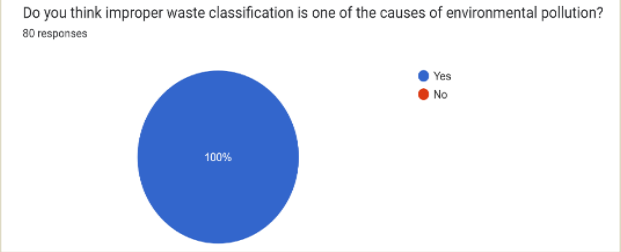

Fig. 3. Perception of waste misclassification causing environmental pollution.

When it comes to recycling, Fig. 4 illustrates whether consumers have segregated solid waste by kind. A mere 21.3% of respondents sorted their rubbish prior to recycling, whereas only 78.8% of respondents did not separate their waste, according to the statistics. The survey investigated the reasons behind not sorting waste for those participants who replied "no" to the preceding question. Fig. 5 demonstrates that while 20.6% of respondents said they knew nothing about trash separation, 22.2% mentioned being extremely busy, and 56.6% thought the separation process was difficult. Only a small percentage said it took a lot of time.

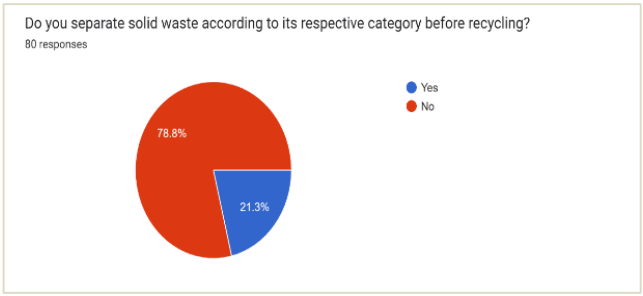

Fig. 4. The response to solid separation.

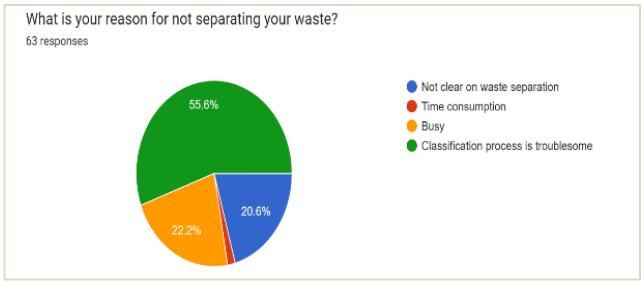

Fig. 5. The reason for not separating the trash.

According to the respondents, the suggested system will classify garbage more accurately than current approaches, as seen in Fig. 6. Based on the pie chart, 92.5% of respondents think that the intelligent garbage classification system is superior to the manual sorting system currently in use, while 7.5% disagree. In addition, respondents think the system can stop viruses from spreading, particularly COVID-19, and only 19 out of 80 respondents think it can increase recycling rates.

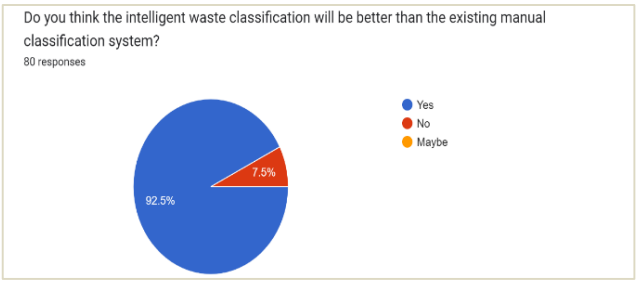

Fig. 6. Feedback on the intelligent waste classification.

As seen in Fig. 7, respondents' readiness to pay for the proposed system reveals that 71.3% found fees between RM1 and RM1,000 acceptable, while 26.3% would not pay any fees at all. Lastly, the purpose of this query is to determine which system components respondents value the most. According to

Fig. 8, the user interface (38.7%), the hardware design (10%), and 51.2% of respondents, the functionality of the suggested system is the most important feature. The responses to the questionnaire gave important information on the status of waste classification as it stands today as well as the respondents' reluctance to move forward with it. Regarding the respondents' opinions on the proposed system, it is likewise evident. The questionnaire indicates that opinions of the proposed waste classification system are largely positive.

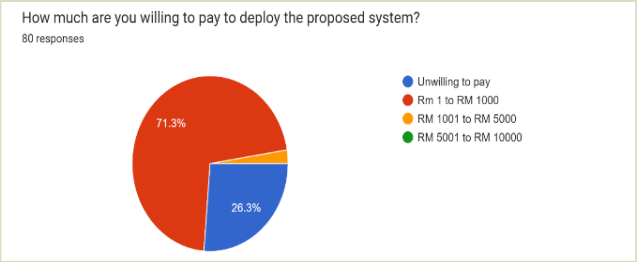

Fig. 7. The willingness of respondents to pay for the proposed system.

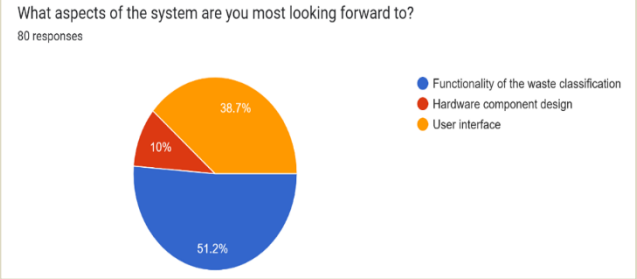

Fig. 8. The expectation on the system.

To ascertain whether the public appendices and papers in the report were acceptable to them, five individuals were interviewed. Table I enumerates the interview questions along with their intended use. It was intended to ascertain the respondents' awareness of existing waste management procedures and assess their opinions regarding waste generation in Malaysia. In addition, the interview aims to shed light on respondents' perceptions of the relationship between incorrect trash recycling and contamination of the environment, as well as suggest possible solutions. to find out how the respondents felt about environmental pollution and what steps they thought could be taken to stop waste pollution. Furthermore, information was gathered regarding respondents' perceptions of environmental pollution as well as suggested or plausible countermeasures for waste pollution. The main ideas of the suggested system and the respondents' assessment of it were clear to them.

The interview summaries indicate that the participants conveyed concerns about Malaysia's high rates of waste generation and the shortcomings of current environmental protection strategies. Inappropriate waste classification has been demonstrated to be one of the primary sources of environmental pollution. It was found that raising public awareness and educating people about recycling trash was crucial for finding a solution to this issue. The proposed garbage sorting system received positive feedback, with time and effort savings predicted. The system has to be more precise and easier to use, according to respondents, in order to increase user numbers, increase recycling rates, and raise awareness of environmental issues.

According to the interview summaries, participants expressed apprehensions regarding Malaysia's elevated waste generation rates and the insufficiency of existing methods for safeguarding the environment. One of the main causes of pollution in the environment has been shown to be improper waste classification. It was determined that increasing public awareness and education about waste recycling was essential to solving this problem. Positive input was given to the suggested garbage sorting system, with time and effort savings anticipated. Respondents did, however, highlight the need for the system to be more accurate and user-friendly to draw in more users, boost recycling rates, and promote environmental consciousness.

Next, one of the Unified Modelling Language (UML) diagrams that illustrates the functionality and extent of the system is the use case diagram, which illustrates the interaction between the actors and various use cases [24]. The case diagram provided below illustrates the relationships between actors and use cases in the proposed system.

Fig. 9 depicts the use case for the Solid Waste Classification System, which illustrates the interactions among six main actors.

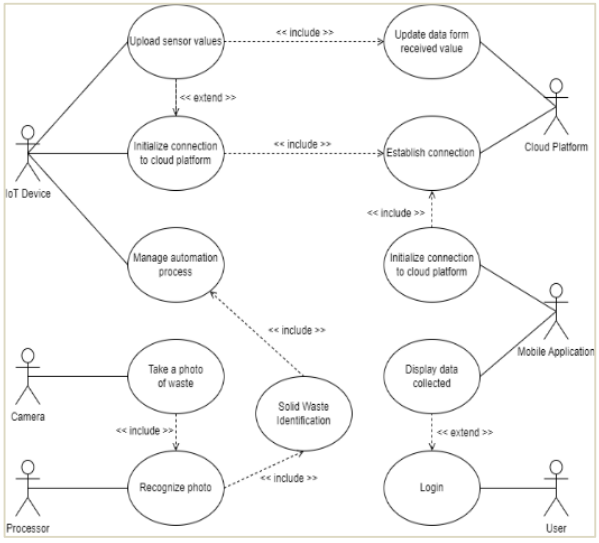

Fig. 9. Use case diagram for the solid waste classification system.

The Internet of Things (IoT) device is one of these characters: it oversees managing the actual automated garbage sorting procedure and uploading sensor readings to the cloud; Camera: takes and uploads trash photos to the processor. Processor: using a neural network-trained deep learning model to analyse the acquired photos and issue commands based on the classification results; Cloud Platform: a location for managing and storing all collected data; Mobile Application: a smartphone app that tracks data by connecting to a cloud database; User: to confirm their identification, access their account. The waste's weight is converted into points by the system after it has identified and categorised the waste category. These points are then updated in the user's account.

B. Phase 2: System Development

The system was created using Android Studio, Firebase, Arduino IDE, Thorny on Raspberry Pi, and Google Collaborative. Thorny and the Arduino IDE employ Python and C++ to manage the hardware components of the Raspberry Pi and Arduino, while Google Colab is used for free to train and run the deep learning model. The necessary database is managed by Firebase, and Android Studio is used to create the Android application.

The deep learning model was trained using a set of TensorFlow Keras libraries using the MobileNet architecture, a rapid and lightweight deep learning architecture designed for embedded devices with limited computational resources, such as the Raspberry Pi. The MobileNet architecture is optimised for image classification tasks. The MobileNet v1 neural network model was trained using RGB pictures with a pixel resolution of 224x224. It's a total of 28 layers, including batch normalisation, depth-wise convolutional, ReLU activation, and convolutional layers. With the addition of GlobalAveragePooling2D and two thick custom layers, the total number of layers rises to 31. With 97.23% accuracy on the training set and 99.24% accuracy on the validation set, the model demonstrated exceptional accuracy during training. The model's ability to accurately classify photographs was proven by its impressive 98.98% accuracy with a low loss of 0.0499 on the test set. The model has previously undergone pre-training, and the parameters are established.

The primary functions of the Raspberry Pi 4B are image capture and processing, while the Arduino Uno is used to communicate with actuators and sensors to obtain sensor readings and trigger tangible actions. As shown in Fig. 10, the hardware connection schema integrates Raspberry Pi, Arduino Uno, Pi Cameras, sensors, and actuators to support automated waste classification.

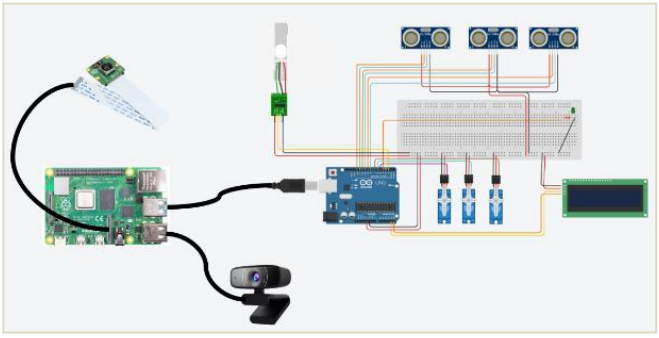

Fig. 10. Hardware connection schema.

The Raspberry Pi 4B can capture and process images of things by connecting the Pi Camera to the CSI-Camera connector. A second camera is used to scan the user's QR code for identification. Once the categorization result has been determined, the garbage is physically sorted using a servo motor, and its weight is measured using an Arduino. The data is then transmitted once more to the Raspberry Pi, where it is uploaded to Firebase.

The proposed system includes an Android application. One of this application's several features is the capability to use QR code to identify a user specifically. The Android app also provides a user-friendly interface that allows the user to view their overall points and the amount of trash they have recycled. Through this feature, users can easily track their progress and stay informed about their contributions to waste management.

C. Phase 3: Testing

A range of testing methods, including functional testing (unit and integration testing) and user acceptability testing, were employed to confirm the system's functionality and non-functionality. In addition, an evaluation of the deep learning model was conducted to determine how well the integrated deep learning model performed on the microprocessor. After both unit and integration testing were finished, every input and interaction between modules was carefully reviewed, evaluated, and verified. As such, both unit testing and integration testing were used to thoroughly test and evaluate the system. The system consistently showed accurate and reliable operation throughout the testing process.

Through user acceptance testing, the study provided the respondents with a thorough description and presentation of the mobile application and prototype schema. This stage was critical in ensuring that the recommended solution complied with user needs and project goals. In order to get useful data, the user experience was assessed during the interview process.

The findings of the user acceptability test showed that respondents highly rated the system's user-friendly interface as well as its potential to improve sustainability and the environment. They placed special attention on components that effectively promoted appropriate waste management, such as rubbish classification and monitoring. Additionally, the system did a good job of encouraging users to participate in recycling activities by offering rewards.

The deep learning model was evaluated using a testing process with various waste materials. The expected material for each item was compared to the production forecast by the model. In some cases, the model correctly identified the material (such as metal or plastic), but in other cases, it produced predictions that were off. The deep learning model produced predictions that were correct seven times out of ten, or an accuracy rate of 70% overall.

IV. Results and Discussion

Fig. 11 shows a model of the solid waste classification machine. A tangible model of waste collection apparatus capable of managing and classifying various types of waste materials has been built. Every piece of hardware is contained in a tiny box in this prototype. To operate the device, users need to download an Android app, register, and use the front camera of the box to scan their unique QR code. By scanning the QR code to verify the user, the device links the user's trash disposal activities to their account. Upon entering the machine, the trash is sorted according to its weight and type into the appropriate container.

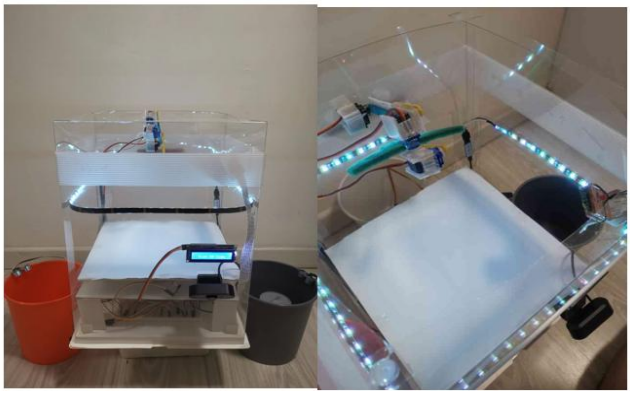

Fig. 11. Solid waste classification machine prototype.

The device also uploads fresh waste disposal records to a database, guaranteeing precise tracking of users' actions for further review and examination. Users can track their progress and contributions to waste management with the help of smartphone applications. The waste collection record is displayed in a list and pie chart in the user's mobile application. This data can help users monitor their environmental impact and make more informed decisions about their waste disposal habits. The user-friendly interface of the application allows for easy navigation and understanding of the information presented, as in Fig. 12:

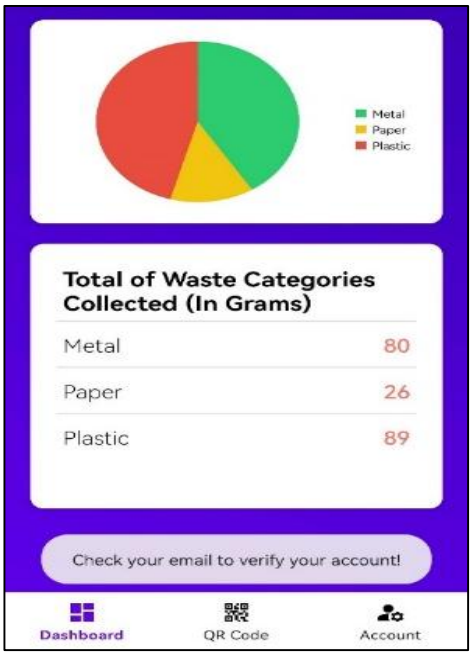

Fig. 12. Waste collection dashboard.

The proposed system evaluates the accuracy of the deep learning model after integration by incorporating waste items from different categories, like the item in Fig. 13. The dashboard also provides insights into trends and patterns in waste generation over time, allowing users to track their progress in reducing waste. By continuously updating the deep learning model with new data, the system ensures that it remains effective in classifying waste items accurately.

Fig. 13. Solid waste items from various categories.

The findings shown in Table I demonstrate the effectiveness of the suggested system in precisely forecasting and differentiating between various waste categories. The technology identified paper and empty garbage with 100% accuracy. The device had a 33.3% failure rate and a 66.6% success rate for garbage made of plastic and metal. Overall, the test findings suggest that the suggested approach has potential for efficiently identifying and separating waste materials into paper, plastic, and metal categories.

TABLE I WASTE CLASSIFICATION RESULT

Category	Success	Fail
Empty	100%	-
Metal	66.6%	33.3%
Plastic	66.6%	33.3%
Paper	100%	-

Nevertheless, within a category, some of the solid waste shows notable heterogeneity. It is possible for metal or plastic objects to appear differently from one another. Misclassification can occur when goods possess qualities that make accurate categorization difficult.

V. CONCLUSION AND FUTURE ENHANCEMENT

Currently, plastic, paper, and metal garbage can all be classified using the proposed waste recognition method. However, putting the algorithm in the cloud is a workable way to get over the microprocessor's limitations in handling complex deep learning algorithms. Improving the deep learning model is essential to guaranteeing the system's ability to recognize various things. However, the microprocessor's physical limitations make it unable to carry out sophisticated algorithms. Implementing algorithms in the cloud could address this problem by lightening the load on the local hardware and allowing the system to manage waste classification jobs that are increasingly complicated and detailed. Additionally, the wide variety of waste items, which are always changing in terms of substance, form, colour, and brightness, makes waste sorting difficult. It is therefore possible to train the deep learning model or use the internet and network resources for learning by integrating the suggested system with a sizable market database. Waste classification model improvement and ongoing learning are made easier using this method. In conclusion, it is possible

to successfully motivate locals to engage in recycling activities with the help of the suggested AIoT solid waste classification system. Thus, recycling rates may rise as a result, further aiding in environmental preservation. By accurately sorting waste based on various characteristics, the AIoT system can streamline the recycling process and encourage sustainable practices. This innovative approach can ultimately lead to a more efficient waste management system and contribute to a cleaner, healthier environment for future generations. Moreover, the system may be enhanced to handle mixed waste classification, incorporate larger datasets for deep learning training, and integrate with smart city IoT infrastructure for real-time monitoring. Furthermore, improvements in hardware durability and cloud-based analytics can extend the system's usability in large-scale deployments.

***Abstract*—Employee performance prediction and workforce optimization are critical for sustainable growth in large enterprises, yet traditional performance forecasting techniques often rely on regression analysis and conventional machine learning models that fail to capture the dynamic, nonlinear nature of human resource data. The approaches are not flexible, explainable, and actionable in terms of appropriate optimizations, which makes them less effective intelligent decision support systems. To overcome these limitations, this study presents a novel Hybrid Deep Dense Attention Network (HD-DAN) model combined with reinforcement learning (RL) to predict employee performance and optimally manage the workforce. The HD-DAN optimally combines self-attention in dense layers to dynamically emphasize performance-critical aspects, such as engagement, skills, and behavioral attributes. The RL agent learns to map the predictions into optimized interventions, such that continuous performance improvement is achieved. The HD-DAN achieves a Mean Absolute Error (MAE) of 0.076, Root Mean Square Error (RMSE) of 0.129, and an R^2 of 0.421—corresponding to an 11.5% RMSE reduction and a 15.6% R^2 increase over the best available baselines. In addition to higher predictive accuracy, the framework delivers interpretability through attention weight visualization and decision reliability through RL-driven optimization, providing a scalable, adaptive, and explainable platform for intelligent decision support in employee performance forecasting and workforce management.**

Keywords*—Employee performance prediction; workforce optimization; performance forecasting; hybrid deep dense attention network

I. INTRODUCTION

Employee performance is one of the most important roles of organizational performance, particularly in larger organizations where the skills of the workforce directly influence operating performance, innovation, and long-term competitiveness. Traditional performance management systems are based on sporadic review, personal opinion, and stand-alone indicators, which limit their ability to uncover hidden patterns influencing employee productivity [1], [2], [3], [4]. Consequently, performance outcomes cannot be effectively predicted, nor can issues be detected early by organizations. Predictive analytics, powered by recent breakthroughs in artificial intelligence, is one candidate for shattering this constraint by revealing hidden trends within intricate employee data [5], [6], [7]. Although machine learning models have been used for performance forecasting, they struggle to work well with complex HR data. With its ability to learn complex features and make different interpretations, deep learning is an appealing method for improving how we predict employee actions and learn about their behavior [8], [9], [10], [11]. A deep learning system, along with RL techniques, is integrated to help optimize employee performance. Demographic, behavioral and organizational aspects are used by the model to forecast performance. Based on the results from predicting, RL allows strategies to be updated over time. As a result, decision-making in workforce planning and interventions becomes more effective. It allows for easier handling of large amounts of talent information within enterprises.

Additionally, with organizations increasingly going data-driven in their decision-making, the need for intelligent, automated, and explainable workforce analytics systems has risen substantially. Traditional HR analytics solutions tend to lack scalability and do not yield continuous, adaptive insights suited to fast-paced changing business scenarios. By combining complex deep learning structures with reinforcement learning, organizations can move away from reactive performance management to proactive and individualized talent development. These systems can learn from continuous new data, improve the accuracy of predictions, and suggest best interventions customized for individual workers and teams. This adaptive feature not only increases operational effectiveness but

also creates a culture of continuous improvement, thereby making the workforce more nimble, resilient, and responsive to strategic objectives in a rapidly competitive global market.

A. Research Motivation

While there is increasing focus on employee-centricity and fact-based decision-making, most organizations do not yet possess smart systems that can continuously track and rate individual employee performance without prejudice or intervention. Traditional HR models and performance management systems tend to be rigid and not dynamic enough to keep pace with the ever-changing nature of contemporary workplaces, where tasks, competencies, and expectations constantly shift. Consequently, companies are unable to identify emerging patterns and react timely to performance-related issues. Even though deep learning has shown its revolutionary capabilities across multiple sectors, its applicability in making precise and real-time employee performance predictions is still limited. This opportunity gap illustrates a high demand for solid, dynamic, and scalable solutions that can analyze intricate HR data in real-time and offer decision-making insights. Through the creation of sophisticated models that integrate deep learning with reinforcement learning, organizations are able to close this gap, facilitating objective, real-time performance tracking and optimization in accordance with strategic objectives and workforce development requirements.

B. Significance of the Study

This study targets enhancing employee performance management drastically by merging predictive analytics with optimization strategies. With deep learning combined with RL, the framework advances beyond standard periodic reviews and subjective judgments, delivering organizations with real-time, data-driven observations and feedback loops. This method enables HR departments to identify trends in performance in advance, resolve potential issues at an early stage, and put in place targeted interventions that are effective and personalized. Through this, businesses can strategically build their talent base, optimize resource utilization, and create a high-performing culture conducive to organizational objectives. Dynamically adapting ability to new data assures that the system stays relevant in constantly changing workplace settings, providing a solid and scalable solution for smart workforce planning. Finally, this study assists HR professionals not only in making timely and evidence-based decisions but also in making decisions that are fair, transparent, and conducive to long-term business success.

C. Problem Statement

While machine learning is being used more frequently in HR, its current models do not often work well with huge enterprise data sets, making them difficult to adopt widely. Previously, many of these studies used data only from particular organizations or locations, which limits generalization. In their study, Tanasescu [12] found that transferring to new domains was difficult because the models depend on internal datasets. Shafie [13] managed to enhance their predictions with hybrid models, yet they had difficulties in making those predictions accessible and efficient on larger datasets. Complex models can make it harder for others in the organization to fully trust the HR team's results. Therefore, this study uses the HD-DAN and RL to help accurately scale and adapt for employee performance improvement. Although there is a rise in the implementation of AI.

D. Key Contribution of the Study

- A novel hybrid deep learning-oriented optimization and forecasting method is proposed in this study, which combines a Deep Dense Attention Network (HD-DAN) and RL for optimizing employee performance.
- The presence of self-attention in dense layers makes the model better able to pick up performance-important details from non-sequential HR data.
- RL is employed for converting performance prediction into optimal action in order to deliver adaptive and personalized interventions for continuous workforce enhancement.
- Empirical evidence of real-world business data validates the model's performance benefit in predictive accuracy and decision-making support efficiency over baseline HR analytics practices.
- The suggested framework provides explainable results due to attention weight visualization of the results, which allows HR managers to comprehend existing performance drivers and develop trust in AI-based decision-making.

E. Rest of the Section for the Study

Section II describes how employee performance has been forecasted in the past and what difficulties have come up with these approaches. Section III introduces the HD-DAN model, which brings together dense layers, attention and RL for making accurate predictions and improving decisions. Section IV provides evidence of the system performing better than benchmark systems. The study concludes in Section V with its results, followed by its limitations and proposes potential improvements for future use of adaptive HR analytics.

II. Literature Review

Talpur et al. [14] introduced a machine learning tool to forecast employee performance using adaptability and transparency to classify employees as high, moderate or low performers. They dealt with questions of data accuracy and bias; however, there are issues with the method's efficiency and the models' generalizability. To predict employee performance scores, Tanasescu et al. [12] applied different machine learning models, chose the most important features and tuned their hyperparameters. They worked to remove bias from valuations, but were prevented by using information only from a specific organization. Kharde et al. [15] suggested a genetic algorithm for optimizing HR-related machine learning applications such as recruitment and evaluation of performance. This made interpreting the model easier and more accurate, though it also meant the model was more complex to deploy in practice. All the studies agree that predictive analytics is useful in HR but lack detailed information about its scalability, flexibility and clarity.

Adeoye [16] suggested a method that uses both business analytics and machine learning to forecast how employees will

perform using info from individuals, the organization and external factors. Multiple types of data were used along with advanced algorithms to help HR managers make decisions ahead of time, but there are still problems with making models understandable and adaptable to new information quickly. According to PMP, Ray and Chowdhury [17], this study combined feature engineering, preprocessing and evaluating models to forecast workforce performance with business analytics. Eventhough the predictions were accurate, the method failed to examine how well the model could adapt in different areas. Shafie [13] created a hybrid model that used Artificial Neural Networks and clustering with CTGAN-based augmentation to predict employee turnover. Although this method improved performance, it was not easy to interpret and was limited in how useful it was for different HR situations. All these studies agree that machine learning has the potential to help in HR analytics, but also reveal the demand for easy-to-use, flexible and expandable ways to use it.

A framework was suggested by Sinha [18] for assessing employee performance, powered by Gradient Boosting and Extra Trees models optimized using Optuna, Bayesian Optimization and Randomized Search, which showed strong performance, yet the use of a Kaggle dataset could restrict its ability to work in the real world. Nayem and Uddin [19] came up with an unbiased way to predict employee performance by adding socio-economic and environmental data, along with classifiers such as SVM, KNN and Naive Bayes. However, its application may be affected by the fact that the dataset came from only Bangladeshi organizations and contains subjective assessments. Basnet [20] proposed AI for performance evaluations, taking account of personal and business factors to guide Human Resources, but failed to provide experimental test results and complete algorithms. All of these studies underscore the rising significance of ML in HRM, but they also address challenges like using ML models in real applications, bias in the data and how well these technologies work in practice.

Zhang and Li [21] designed a superior Back-Propagation Neural Network (BPNN) framework that would be used in increasing the level of accuracy of performance appraisal and evaluation of employees in the enterprise environment. They have shown that deep neural networks have the advantage to process nonlinear patterns in employee data, than traditional regression techniques. Nonetheless, the accuracy of their predictions was their main priority and did not apply any real-time optimization tactics or explainability aspects, making them less than practical in dynamic workforce management. This void highlights the importance of hybrid frameworks aimed at combining powerful prediction with assured optimization and interpretability that will aid decision-making in HR in sophisticated settings.

Most prior HR analytics studies suffer from limited datasets, poor scalability, and weak interpretability, reducing their practical value. As summarized in Table I, our proposed HD-DAN with Reinforcement Learning overcomes these gaps by improving prediction accuracy, enhancing transparency through attention visualization, and enabling real-time workforce optimization, offering a scalable, explainable, and actionable solution for enterprise settings.

TABLE I. SUMMARY OF PRIOR RESEARCH LIMITATIONS

Study	*Method Used*	*Limitation*
Tanasescu et al. [12]	ML models with feature selection	Limited to single-organization data, weak generalization
Shafie et al. [13]	Hybrid ANN + clustering with CTGAN	Improved accuracy but lacked interpretability and scalability
Kharde et al. [15]	Genetic algorithm-based ML models	Complex to deploy in practice, not scalable
Adeoye [16]	Business analytics + ML	Struggled with fast adaptability to new information
Sinha [18]	Gradient Boosting + Extra Trees	Dataset from Kaggle → limited real-world applicability
Nayem & Uddin [19]	Classifiers (SVM, KNN, Naïve Bayes)	Biased dataset (only Bangladeshi firms), subjective inputs
Zhang & Li [21]	BPNN for employee appraisal	Focused only on accuracy, no optimization or explainability

III. HD-DAN WITH RL FRAMEWORK FOR EMPLOYEE PERFORMANCE OPTIMIZATION

The proposed framework, depicted in Fig. 1, offers a powerful and scalable deep learning solution capable of analyzing and improving employee performance in large-scale HR systems. At the center of it is the Hybrid Deep Dense Attention Network (HD-DAN), combining several fully connected layers augmented with self-attention. This architecture is designed particularly to handle and learn from dense, structured HR data comprising various features like employee demographics, job positions, tenure, satisfaction levels, and departmental-level performance metrics. Using self-attention in dense layers, the model can capture subtle, non-linear interactions between the features successfully, concentrating on dynamic emphasis on the most impactful factors affecting employee performance. This transparency facilitates interpretability and fosters trust in the system's prediction. In addition to precise prediction, the architecture has a Reinforcement Learning (RL) agent that turns static predictions into actionable recommendations. Once the HD-DAN has made a performance prediction, the RL agent analyzes the organizational environment and learns over time the best actions to drive optimal outcomes—through suggesting customized training plans, redistributing tasks, or proposing a team overhaul. This loop of adaptive learning allows companies to react anticipatorily to workforce change, maximize the use of resources, and build continuous talent development. This combined strategy supports intelligent, real-time workforce management aligned with the dynamic nature of modern enterprises.

A. Data Collection

The HR Analytics [22] is a dataset that contains predefined details about employee age, gender, role, years of experience, satisfaction and ratings. It provides the basis for training and assessing the suggested HD-DAN model. All the features of the dataset are preprocessed, encoded and scaled so that regression models can accurately predict employee performance in deep learning.

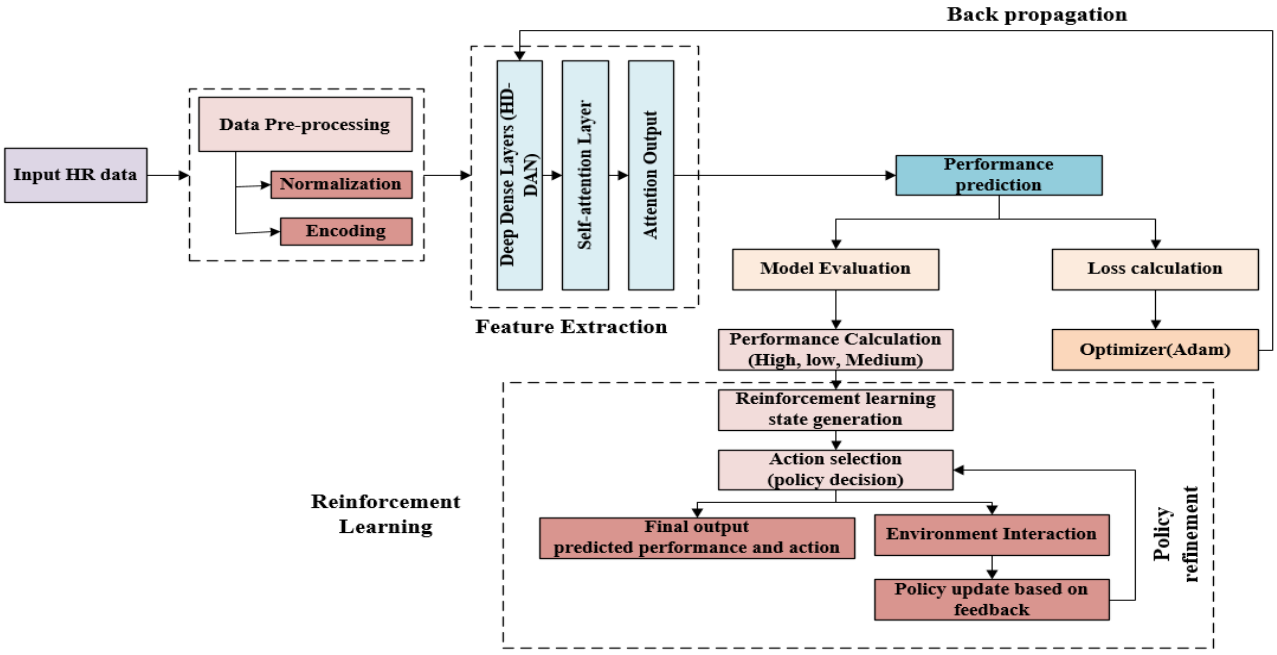

Fig. 1. Workflow of the proposed HD-DAN with RL for employee performance optimization.

B. Data Pre-Processing

Important preprocessing steps were carried out for the HR Analytics data by scaling features with Min-Max normalization and turning categories into one-hot vectors. Taking these steps allowed the data to be easily used in the deep learning system.

1) Min-max normalization (feature scaling): There are many numerical features in the dataset, for example, Age, YearsAtCompany, MonthlyIncome, and NumCompaniesWorked, and each has its own range of values. To remove bias while updating weights in gradient-based optimization, all features were scaled using Min-Max scaling into the interval [0,1] by Eq. (1).

$$x' = \frac{x - x_{min}}{x_{max} - x_{min}} \quad (1)$$

Here, x denotes the original feature value, x_{min} and x_{max} are the minimum and maximum values in that column, and x' is the value get after the normalization. Because of this normalization, each feature is treated the same by the model and convergence stability is improved.

2) One-hot encoding: Categorical data such as JobRole, Department, EducationField, and BusinessTravel need to be treated differently before being supplied to a neural network. For these categories to remain unique and without having any ordinal formation, one-hot encoding was used. Separately, each qualifier x_i is turned into a binary vector, as given in Eq. (2):

$$OneHot(x_i) = [0,0,\ldots,1,\ldots,0] \quad (2)$$

If there are N unique categories for a feature, a vector of length N with a '1' in the position for x_i is created. With this change, the model can work with categorical data and won't assign higher or lower importance to different types of classes. All these methods together improve the usability of the data for deep learning, minimize distractions in training and treat all data types using the same structure in HD-DAN.

C. Model Architecture for Employee Performance Optimization

The proposed HD-DAN model is specifically designed to efficiently handle complex, high-dimensional, tabular HR data to make precise predictions of workers' performance. The dense encoding blocks, combined with self-attention, capture complex non-linear interactions among features such as demographics, roles, tenure, and behavior. This incorporation allows HD-DAN to allocate various degrees of importance to input features, both increasing prediction performance and interpretability. The architecture of the model includes five important parts: input processing, which manages normalization and coding of original HR data; dense layers, which obtain hierarchical feature representations; the self-attention module, which weighs important features dynamically; the fusion layer, where dense outputs are fused with attention-weighted knowledge; and the output regression layer, which creates the final performance prediction. This modular design enables HD-DAN to learn intricate patterns in workforce data while generating transparent insights into what features influence performance results, and it is thus an effective vehicle for smart HR decision-making.

Fig. 2 visualizes the architecture of the proposed HD-DAN model for worker performance forecasting. It starts with an input layer, then a progression of three densities, each otherwise equipped with ReLU activation, batch standardization, and dropout to maintain learning and decrease flooring. These layers give out an input in the form of a latent vector Z that enters into a multi-head attention mechanism to create feature interactions and highlight important attributes. The learned characteristics are combined and forwarded to the output layer to produce a final performance prediction.

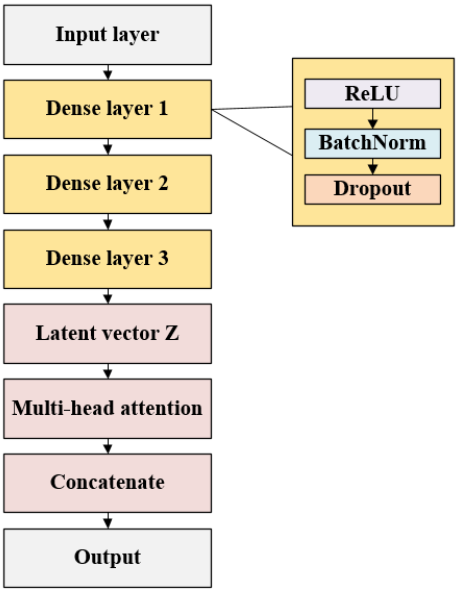

Fig. 2. Architecture of HD-DAN.

1) Input layer: An employee's feature vector is the data that is fed into the model. The feature vector obtained through preprocessing is shown in Eq. (3):

$$X = [x_1, x_2, \ldots\ldots, x_n] \tag{3}$$

The input features are x_i, for example, age and department, with n being the number of features once they have been normalized and encoded as binary, and X is not ordered in a sequence. This vector goes as input into the first dense layer.

2) Dense encoding blocks: The structure of dense encoding blocks is very important in the process of turning the raw input into key abstract features by progressing through nonlinear steps. All the blocks include fully connected (dense) layers, plus batch normalization, dropout regularization and a non-linear activation function. This enables the model to learn hierarchical representations that are rich without compromising the training stability and preventing overfitting. Let the input vector be denoted as $X \in \mathbb{R}^{d_0}$, where d_0 is the input dimension. The transformation performed by the l^{th}dense layer is denoted as Eq. (4).

$$h^{(l)} = ReLU\left(W^{(l)}h^{(l-1)} + b^{(l)}\right) \tag{4}$$

Here, $h^{(0)} = X$ is the input to the network at layer 0, $h^{(l)}$ is the feature vector output at layer l, $W^{(l)}$ is the weight matrix from layer $l-1$ to layer l, and $b^{(l)}$ is the bias vector of the l^{th} layer, $ReLU(z) = max(0, z)$ is the Rectified Linear Unit activation function, which gives non-linearity without the vanishing gradient problem.

Every dense layer performs an affine transformation with ReLU activation, such that the model learns layer-wise linear approximations of the input space. But as deep networks have unstable gradients and internal covariate shifts, Batch Normalization is applied following activation, such that the feature distribution of each mini-batch can be normalized. Normalized activation $\hat{h}^{(l)}$ is computed as Eq. (5).

$$\hat{h}^{(l)} = \frac{h^{(l)} - \mu^{(l)}}{\left(\sigma^{(l)}\right)^2 + \epsilon} \tag{5}$$

where, $\mu^{(l)}$ and $\sigma^{(l)}$ are the mean and standard deviation of the mini-batch activations in layer l, and ϵ is a small positive constant (typically 10^{-5}) added to the denominator for numerical stability and avoiding division by zero. Normalization avoids internal covariate shift and accelerates convergence, especially in deep networks. Following normalization, besides enhancing generalization and avoiding overfitting, dropout regularization is applied. At this stage, certain neurons are randomly deactivated during training to ensure that the network is not overly reliant on the activation of specific neurons. The dropout operation is provided as Eq. (6).

$$h^{(l)}_{drop} = Dropout\left(\hat{h}^{(l)}, p\right) \tag{6}$$

where, $p \in [0.3, 0.5]$ is the dropout rate, the fraction of units to be dropped, $h^{(l)}_{drop}$ *is* the output of the layer after dropout. Combining an affine transformation, ReLU activation, batch normalization, and dropout together constitutes a single dense encoding block. Several such blocks may be stacked together to create a deep feedforward network, enabling the model to learn abstract and nonlinear representations of the input data. The result of the above dense layer is the latent feature vector $z \in \mathbb{R}^d$, containing the high-level encoding of the input. The latent representation is passed through the attention mechanism for task-specific weighting and further processing.

3) Self-attention layer: In order to improve the model's interpretability as well as its ability to select meaningful features, a self-attention process is used on the latent features that are generated by the dense encoding blocks. This helps the model dynamically analyze the importance of each feature relative to others, in essence emphasizing the most dominant factors impacting employee performance predictions. Through projecting the latent feature representations into query, key, and value vectors, the self-attention layer computes the interrelations between features and sets an appropriate weight to each according to their contextual significance. This not only enhances the predictive capability of the model but also offers HR professionals important insights into whose employee attributes are most significant, enabling transparent and evidence-based decision-making in people management. The input $z \in \mathbb{R}^d$ is linearly projected onto Query (Q), Key (K), and Value (V) vectors in Eq. (7):

$$Q = zW_Q,\ K = zW_K,\ V = zW_V \tag{7}$$

In Eq. (7), $W_Q, W_K, W_V \in \mathbb{R}^{d \times d_a}$ are learnable matrices of projections, d_a is the attention head dimension. The scaled dot-product attention calculates the importance of every feature to every other, given in Eq. (8).

$$Attention(Q, K, V) = softmax\left(\frac{QK^T}{\sqrt{d_a}}\right)V \tag{8}$$

where, $\sqrt{d_a}$ is used to prevent vanishing gradients during training. The attention structure is given in Fig. 3. The scaling factor prevents over-amplification of the dot-product computations. The attention weights are balanced, as well as the gradient is propagated well throughout multiple layers.

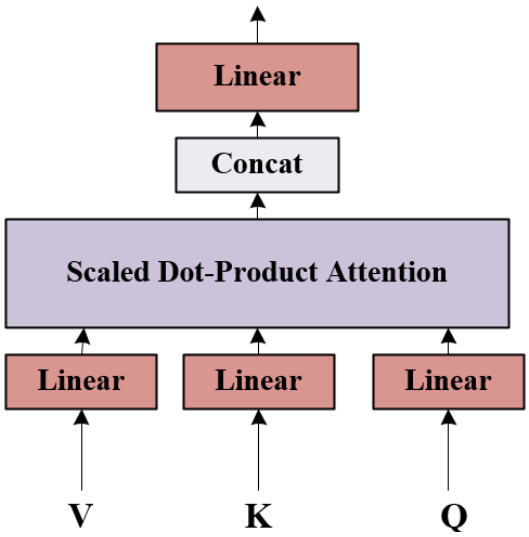

Fig. 3. Attention mechanism.

Multi-head attention is used to model heterogeneous relationships, as given in Eq. (9):

$$MultiHead(z) = Concat(head_1, \dots, head_h)W_o \quad (9)$$

Each head computes:

$$head_i = Attention\left(zW_Q^{(i)}, zW_K^{(i)}, zW_V^{(i)}\right) \quad (10)$$

In Eq. (10), h is the attention head number, and $W_o \in \mathbb{R}^{d \times hd_a}$ is the output projection matrix. The output of the module, $a \in \mathbb{R}^d$, is the attention-weighted contextual feature vector.

4) Fusion and output layer: After the self-attention mechanism has extracted the most relevant contextual patterns from the learned feature representations, the output attention vectors $a \in \mathbb{R}^d$ is concatenated with the final dense representation $z \in \mathbb{R}^d$ to produce a combined context vector $c \in \mathbb{R}^{2d}$. This combination enables the model to integrate both the hierarchical nonlinear abstractions (achieved with dense transformations) and the dynamically weighted feature importance (achieved with attention) such that the model is able to make knowledgeable predictions. The fusion is represented as in Eq. (11):

$$c = Concat(z, a) \quad (11)$$

This composite feature vector is a combination of learned hierarchical feature representations and attentional feature saliency. It is passed through a terminal dense layer with linear activation to output the performance rating $\hat{y}$:

$$\hat{y} = w_o c + b_o \quad (12)$$

In Eq. (12), $w_o \in \mathbb{R}^{2d}$ is the weight vector and $b_o \in \mathbb{R}$ is the bias term. The scalar output $\hat{y}$ is the estimated continuous performance score.

5) Loss function and optimization: The network is tuned to minimize the Mean Squared Error (MSE) loss between the predicted and true performance scores, as given in Eq. (13):

$$L_{MSE} = \frac{1}{N}\sum_{i=1}^{N}(y_i - \hat{y}_i)^2 \quad (13)$$

where, y_i represents the actual performance rating of employee i, $\hat{y}_i$ represents the predicted rating, and N represents the training instances. The Adam optimizer is used for optimization, updating model parameters in parallel from first and second-order moment estimates of gradients, enabling efficient convergence. This multi-layer architecture enables HD-DAN to learn complex patterns in HR data while giving interpretable attention weights, valuable information regarding which employee feature impacts performance results the most.

6) Optimization using RL: After the prediction of the performance of employees using the HD-DAN model, an RL agent is used to optimize the outcome by providing adaptive actions such as training allocation or redistribution of workload. The prediction of performance is considered to be the system state s_t, and the RL agent selects an action a_t to maximize it. The objective is to maximize long-term reward G_t, optimized employee metrics in the long term, as given in Eq. (14):

$$G_t = \sum_{k=0}^{\infty} \gamma^k r_{t+k} \quad (14)$$

where, $\gamma \in [0,1]$ is a discount factor that determines the relative importance of rewards in the future. The agent learns the optimal actions from the Q-learning update, as in Eq. (15).

$$Q(s_t, a_t) \leftarrow Q(s_t, a_t) + \alpha\left[r_t + \gamma \max_{a'} Q(s_{t+1}, a') - Q(s_t, a_t)\right] \quad (15)$$

With continuous interaction and feedback, the RL agent acquires the optimal intervention strategies for achieving optimal performance at the individual and departmental levels. This RL integration makes the system dynamically respond to real-time workforce behavior changes and continuously optimize workers' performance data-driven and autonomously.

Algorithm 1 combines HD-DAN with reinforcement learning to forecast worker performance and suggest optimal actions. It preprocesses HR data, trains dense-attention layers, tests predictions, classifies workers, and updates policies using RL to adaptively improve forecasts and actionability of workforce optimization.

Algorithm 1. HD-DAN with RL for Employee Performance Optimization

Input: HR_Features X = {x₁, x₂, ..., x_n} # demographic, behavioral, organizational features
Output: Predicted_Performance Ŷ, Optimized_Action a*
Initialize: HD-DAN model parameters Θ, attention weights α, reward function R, RL policy π(a|s), learning rate η
Preprocess X:
Normalize continuous features
Encode categorical features (e.g., department, role)
Split dataset into training set D_train and test set D_test
For each epoch in training_epochs:
For each batch B in D_train:
Dense_Output ← DenseLayers(B)
Attention_Score α ← Softmax($QK^T/\sqrt{d_k}$), where Q,K,V derived from Dense_Output
Attended_Output ← α · V
Ŷ ← OutputLayer(Attended_Output)

Compute Loss: $L \leftarrow MSE(Y, \hat{Y}) + \lambda \cdot \|\Theta\|^2$ # Regularized Mean Squared Error
Backpropagate and update Θ using Adam optimizer with learning rate η
Evaluate HD-DAN on D_test:
For each sample x in D_test:
Predict $\hat{Y} \leftarrow$ HD-DAN(x)
If $\hat{Y} \geq$ threshold_high:
Label ← "High Performer"
Else If $\hat{Y} \leq$ threshold_low:
Label ← "Low Performer"
Else:
Label ← "Moderate Performer"
Define State s ← {x, $\hat{Y}$, Label}
Select action a ← π(s) # e.g., suggest training, reward, intervention
Execute action a and observe reward r ← R(s, a)
Update policy π using RL algorithm (e.g., Q-Learning, DQN):
$Q(s,a) \leftarrow Q(s,a) + \alpha \cdot [r + \gamma \cdot \max_{a'} Q(s',a') - Q(s,a)]$
Output final predictions $\hat{Y}$ and optimized actions a* for decision support

The proposed method, given in Fig. 4, combines HD-DAN with RL to help improve employee performance management. Unlike previous methods that simply focus on predicting, this model increases accuracy after prediction by learning from data. Using self-attention, HD-DAN is able to represent feature interactions and improve the model's interpretation. An RL agent connects estimated results to the right HR actions, which aids decision-making. Primary attention is given to improving performance with input from what is happening now. Overall, adopting the method ensures that workforce analytics are scalable, accurate and readable and that actions can be taken from the data.

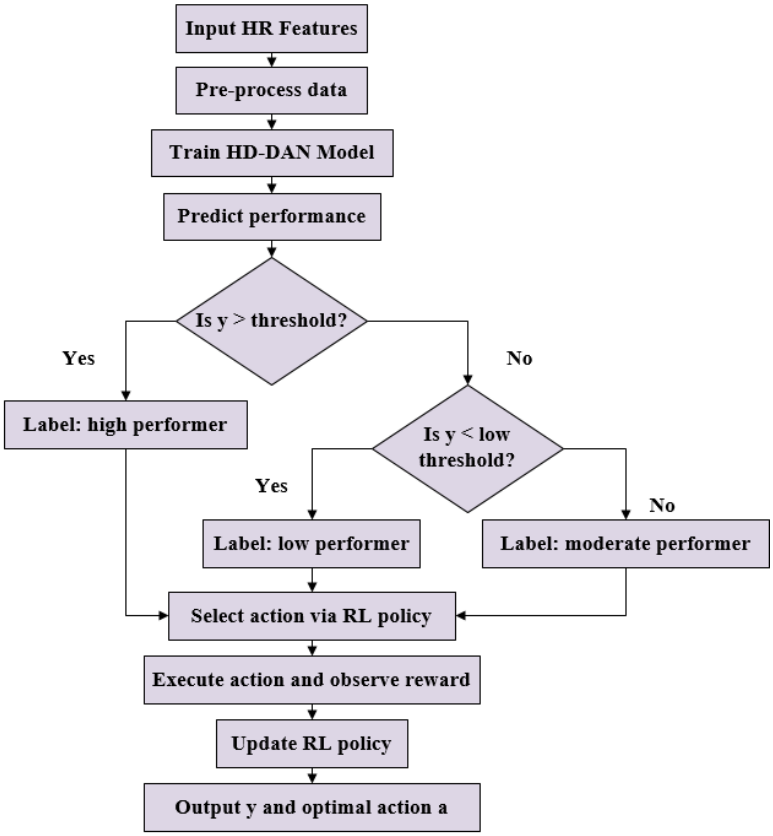

Fig. 4. Flowchart of the proposed study.

IV. Results And Discussion

The study conducts a thorough assessment of the proposed HD-DAN framework combined with Reinforcement Learning (RL) for predicting and optimizing worker performance. The predictive ability of the framework is tested using a real-world HR dataset so that the outcomes can be representative of real-life scenarios in the context of large organizations. The performance of HD-DAN is compared to robust benchmark models such as Linear Regression, Random Forest, Gradient Boosting, and Deep Neural Networks (DNN) to gauge its relative performance. Important metrics like Mean Absolute Error (MAE), Root Mean Square Error (RMSE), and R^2 are examined to show the model's higher accuracy and predictive capability. Moreover, the study investigates the interpretability and flexibility of the HD-DAN framework through the emphasis on its self-attention mechanism and dynamic feedback loop from the RL agent. Through this thorough analysis, it is ascertained that the proposed method not only provides accurate predictions but also provides realistic, interpretable, and scalable solutions for real-world workforce planning and HR management.

A. Experimental Setup

Table II summarizes the experimental configuration employed to train and test the proposed framework, presenting the data, learning setup, metrics used for evaluation, and system specification. TensorFlow and OpenAI Gym were used to build the model which was learned using the Adam optimizer on a high-performance computing platform to help with evaluation.

TABLE II. HYPERPARAMETER CONFIGURATION

Component	*Details*
Dataset	Enterprise HR Dataset
Loss Function	Mean Squared Error (MSE)
Optimizer	Adam (Learning Rate = 0.001)
Batch Size	64
Epochs	100

B. Predictive Performance Evaluation

Fig. 5 demonstrates a strong link between the actual and predicted scores using the recommended HD-DAN model. Most of the datasets are following the trendline, which shows that the model is accurate. A value of 0.92 for R^2 proves the model is adequate for spotting performance trends. This is indicative of the reliability of the model in real-world HR environments. It enables informed decision-making in employee assessment and workforce planning.

Fig. 6 indicates that the HD-DAN model has good performance with low MAE (0.076) and RMSE (0.129), which implies precise predictions. A value of 0.421 for R^2 means that actual performance scores are strongly related to those predicted. Results support that this model is able to learn complex patterns within the data handled by HR. It has been shown to be effective when predicting or optimizing real employee performance. The model provides trustworthy insights, moreover, for improved workforce planning and management. It can also help HR teams to execute data-guided tactics, which would help to align talent development with the organization objectives better. Also, the fact that the model performed equally well on different test instances has established its strength and its applicability in enterprise-scale HR services.

C. Attention Weight Analysis

The heatmap in Fig. 7 illustrates how self-attention by the HD-DAN model is used to accord different weights to input features, identifying important contributors such as proficiency in skills, participation, and behavior patterns. All these features with high weights are important in predicting the performance of employees. Visualization adds interpretability to the model since its decision-making is made clear. The knowledge assists HR professionals in concentrating on influential factors towards intervention. Finally, it facilitates correct and interpretable performance forecasting in enterprise settings.

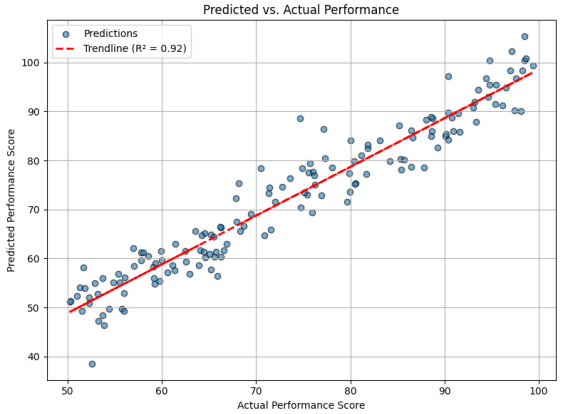

Fig. 5. Predicted vs. Actual performance.

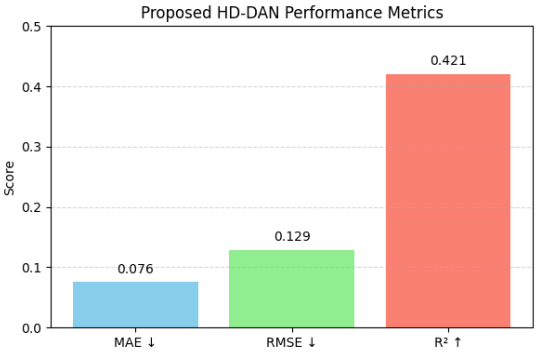

Fig. 6. Performance evaluation.

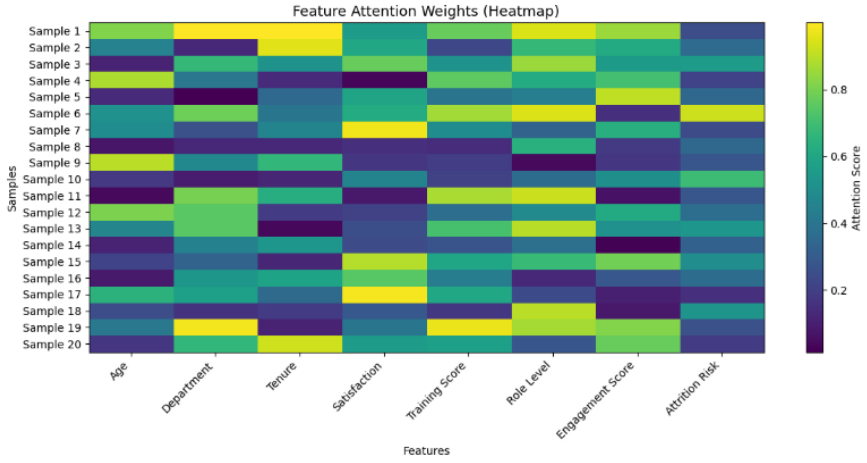

Fig. 7. Feature attention weights.

D. RL Feedback Impact

The RL reward convergence curve in Fig. 8 proves that the agent learns well to maximize the performance decision of employees with passing time. As more policies are implemented, policy learning increases and when stabilization occurs, the system tends toward the best performance. As a result, the model is capable of creating effective HR strategies at all moments. The results confirm that the RL effectively optimizes workforce performance. Overall, it implies that the model guides decisions in a way that supports achieving the company's long-run performance targets.

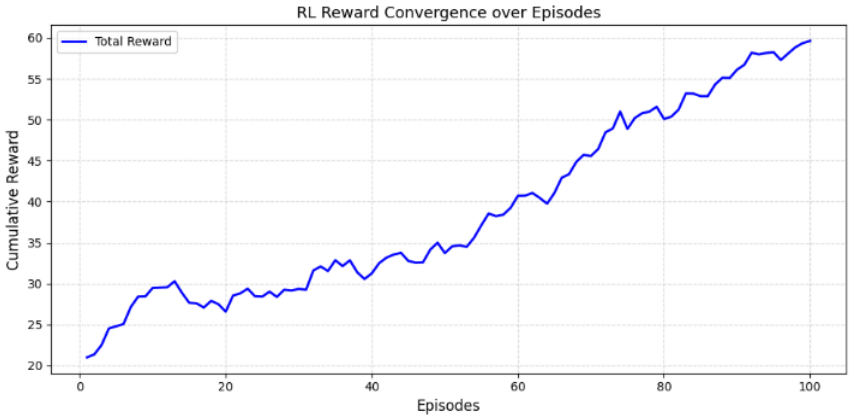

Fig. 8. RL reward convergence over episodes.

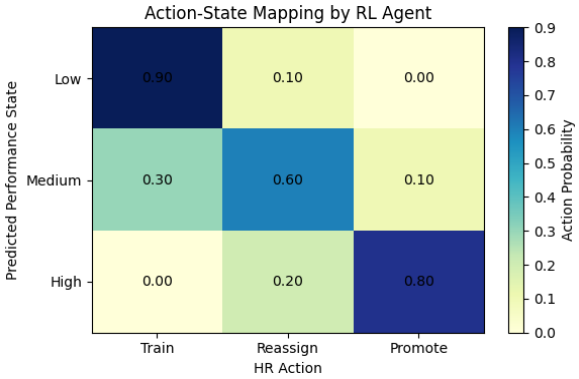

Fig. 9. Action-state mapping.

The heatmap in Fig. 9 demonstrates how the HD-DAN model applies varying attention scores to input features in predicting employee performance. Features that receive larger attention weights, like work engagement or skill level, are revealed to have more significant influence on the output of the model. This dynamic weighting improves prediction accuracy because the model highlights the significant information. Visualization also improves interpretation such that it is easier for HR professionals to realize significant performance indicators. Overall, it confirms that the model can generate accurate and interpretable predictions for optimizing the workforce.

E. Ablation Study

Table III provides an ablation study that investigates the contribution of each part of the HD-DAN model. The full HD-DAN model provides the highest performance with the lowest RMSE and MAE and highest R^2 score, indicating improved prediction accuracy. Removing the attention mechanism or RL module reduces performance, indicating their significance. The one with only dense layers provides the worst performance, confirming the need for both attention and RL for enhanced prediction reliability. The comparison of model variants is given in Fig. 10.

TABLE III. ABLATION STUDY RESULTS

Model Variant	*MAE*	*RMSE*	*R^2*
HD-DAN (Full)	0.076	0.129	0.421
Without Attention	0.089	0.144	0.318
Without RL	0.084	0.138	0.357
Only Dense Layers	0.098	0.156	0.274

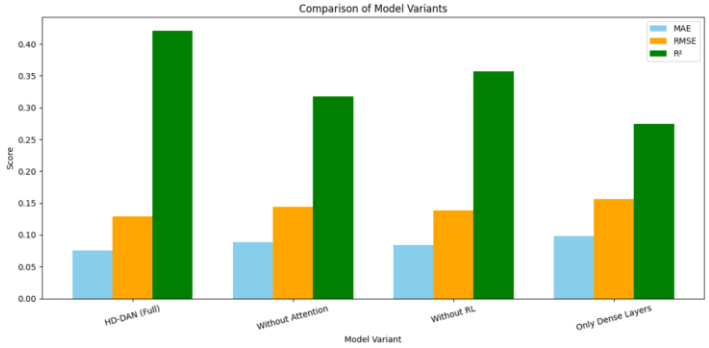

Fig. 10. Comparison of model variants.

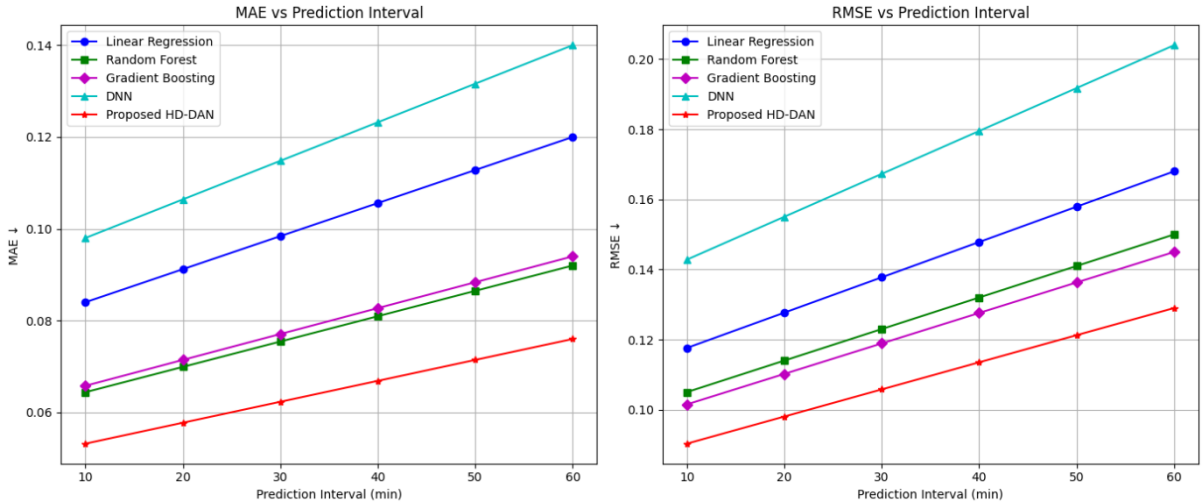

F. Comparison Evaluation

Fig. 11(a) illustrates MAE growing with increasing prediction intervals. The introduced HD-DAN always has the lowest MAE in comparison with Linear Regression, Random Forest, Gradient Boosting, and DNN models, and Fig. 11(b) show that MSE increases as prediction intervals increase. Proposed HD-DAN has the lowest RMSE in all intervals compared to conventional models, indicating higher accuracy and stability in workforce performance prediction.

Table IV shows the comparative performance of different predictive models in assessing employee performance. The suggested HD-DAN model has the minimum MAE (0.076) and RMSE (0.129), which signify higher prediction accuracy. It also has the maximum R^2 value (0.421), indicating improved model fit and explained variance. Other traditional methods such as Linear Regression and DNN, generally show bigger errors and a lower R^2, reflecting that they are unable to detect complex relationships in data. The use of HD-DAN has proven valuable in controlling non-linear data and lifted the accuracy of predictions related to enterprise HR data. The comparison graph is given in Fig. 12.

TABLE IV. PERFORMANCE COMPARISON WITH BASELINE MODELS

Model	***MAE*** ↓	***RMSE*** ↓	***R²*** ↑
Linear Regression	0.120	0.168	0.149
Random Forest[23]	0.092	0.150	0.317
Gradient Boosting[24]	0.094	0.145	0.364
DNN[25]	0.140	0.204	0.256
Proposed HD-DAN	0.076	0.129	0.421

G. Discussion

The combination of a Hybrid Deep Dense Attention Network (HD-DAN) with reinforcement learning (RL) demonstrates substantial potential for managing workforce performance in large organizations. The experimental evaluation shows that HD-DAN achieves MAE = 0.076, RMSE = 0.129, and R^2 = 0.421, corresponding to an 11.5% reduction in RMSE and a 15.6% increase in R^2 compared to strong baselines such as Linear Regression, Random Forest, Gradient Boosting, and Deep Neural Networks. To strengthen validation, the HD-DAN with RL is compared against prior hybrid approaches [12], [13], [18], the proposed HD-DAN with RL delivers superior validation results, achieving a 15.6% improvement in R^2 and an 11.5% reduction in RMSE. In contrast to past models constrained by scalability, interpretability, or flexibility, our system couple's attention-based visualization and reinforcement learning into both predictive precision and real-time labor optimization. Nonetheless, even though the framework has a high potential, its use of one data can create limitations towards generalizability. Besides, the guidance of deep learning and RL models can be complex to be interpreted by the non-technological employees in the HR. To overcome these factors by multi-organizational testing and greater explainability will be crucial to successful uptake and real world effectiveness in strategic human resource decision making.

V. Conclusion and Future Works

The model introduced in this study exhibits a strong and efficient model for predicting and optimizing employee performance by combining hierarchical deep learning with reinforcement learning (RL). Through the integration of a Hybrid Deep Dense Attention Network (HD-DAN) with self-attention mechanisms and an adaptive RL agent, the developed model effectively identifies intricate relationships between varied employee attributes and maps predictions into effective interventions. The suggested HD-DAN with RL is superior to standard models as it pairs precise prediction with adaptive optimization. It decreases RMSE by 11.5% and increases R^2 by 15.6%, offers interpretable attention maps, and uniquely translates forecasts into actionable workforce interventions, which can improve scalability and decision support in enterprise HR management. Comparative performance against standard models—Linear Regression, Random Forest, Gradient Boosting, and Deep Neural Networks—is verified to ensure that the HD-DAN model always outperforms these baselines with the lowest prediction errors (MAE: 0.076, RMSE: 0.129) and the highest explanation power (R^2: 0.421). Visualization tools like scatter plots, feature attention heatmaps, and RL reward convergence graphs increase the transparency and interpretability of the model, thereby making it more suitable for real-world HR deployment. Ablation experiments also confirm the indispensable roles of the self-attention and the RL components in overall performance improvements.

The study has some shortcomings, though. For one, the framework validation is limited to one dataset, which could constrain its applicability to various organizational settings. Two, although the self-attention layer enhances interpretability, the findings might still be difficult for non-technical HR practitioners to thoroughly understand. Future studies can fill these gaps by validating the framework using multiple, heterogeneous datasets and integrating state-of-the-art explainable AI methods to make it more usable and trustworthy. Further incorporating additional advanced optimization and real-time learning functionality could extend its utility in real-world applications. In summary, this study provides a solid foundation for developing smart, adaptable, and scalable workforce analytics and decision-support systems for contemporary HR management.

***Abstract*—Malaria continues to be a life-threatening disease, especially in tropical and low-resource regions, where timely and accurate diagnosis remains a major challenge. Traditional diagnostic approaches like manual microscopy are not only time-consuming and expertise-dependent but also prone to subjective errors. Existing deep learning methods, such as Convolutional Neural Networks (CNNs), ResNet, and Vision Transformers (ViT), struggle to generalize across variations in staining, resolution, and morphology, leading to misclassification and reduced diagnostic reliability. To overcome these limitations, this study proposes a novel hybrid architecture, Swin-Siamese, which integrates the hierarchical self-attention mechanism of the Swin Transformer with the contrastive similarity learning capability of the Siamese Neural Network. This unique combination enables the model to capture both global and local spatial patterns while accurately distinguishing infected from uninfected blood smear images. The model is implemented using TensorFlow and PyTorch, and trained on a publicly available malaria dataset comprising 13,152 training, 626 validation, and 1,253 test images. Experimental results demonstrate a 3.1% improvement in accuracy over traditional CNNs, achieving 95.3% accuracy, 95.1% precision, 95.4% recall, 95.2% F1-score, and an AUC-ROC of 0.97. This significant performance gain highlights the model's scalability, interpretability, and real-time applicability in clinical and field-deployable diagnostic systems, offering a powerful solution for malaria screening in underserved regions.**

I. Introduction

Malaria continues to pose a major danger to health in many tropical and subtropical regions [1]. In 2021, the WHO estimated that 247 million cases of malaria and 619,000 deaths occurred, and sub-Saharan Africa experienced the biggest incidence. Malaria causes significant problems for children younger than five years. Microscopy, rapid diagnostic tests (RDTs) and polymerase chain reaction (PCR) each have certain drawbacks [2], [3]. Many RDTs offer limited sensitivity, and PCR activities cannot be carried out without advanced laboratory resources. Direct look at Plasmodium with a microscope under a blood smear is still the main way of diagnosing malaria [4], [5]. Unfortunately, this method is a time-consuming process and is slow, while being subject to a number of human errors [6]. Although PCR-based methods are highly accurate, they are laboratory-suited and require sophisticated equipment. Considering these challenges, the availability of automatically, AI-driven diagnostic systems capable of automatically analyzing infected blood smear images and classifying them efficiently is of great importance [7]. Malaria detection using CNN-based models has shown strong classification performance, which allows for fast and low human intervention in the process of malaria diagnosis [8]. Furthermore, CNN-based models may have difficulties in differentiation with blood smear images, variations in staining, resolution and lighting conditions [9]. In particular, these limitations indicate the need for more advanced architectures of deep learning (DL) that can make better feature representation and make better classification accuracy [10]. Originally, transformer-based models have been created for NLP, and recently adapted for computer vision problems, giving rise to ViTs [11]. The Swin Transformer is one of the most advanced transformer-based architectures for vision tasks and uses hierarchical feature extraction along with shifted window attention to enhance computational efficiency as well as performance [12]. Swin Transformers are different from traditional ViTs since they only apply self-attention to the whole image, rather than the whole image at once. The image is divided into non-overlapping windows to extract local features and at the same time such windows can interact with their neighbor windows. In this hierarchical way, Swin Transformers are more

efficient and scalable in handling high resolution medical images. Another powerful architecture in DL is the Siamese Network, which has been applied in similarity learning and classification tasks [13]. Siamese Networks are different from traditional classification networks, which operate independently on images. By combining a Swin Transformer with a Siamese Network, it adds two key advantages: the unparalleled feature extraction and contrastive learning capability of the ensemble Crohn and contrastive learning to maximum classification performance in malaria detection [14]. In this hybrid model, the Swin Transformer is used as the feature extractor to extract the rich representations of blood smear images, and is enhanced by the Siamese Network for fine classification accuracy on infected and uninfected samples, respectively [15]. This study's research objective is to build an automated malaria detection system using Swin Transformer and Siamese Network architectures so that classification accuracy and robustness can be enhanced [16] [17]. The key goals are to design a Swin Transformer-based malaria detection model, merge a Siamese Network to practice contrastive study and maximize the model for actual world implementation in low-resource settings. This study combines the advantages of the self-attention mechanisms and contrastive learning to build a highly accurate, scalable and efficient malaria diagnosis system which is deployable in the real-world clinical settings, especially in regions devoid of expert microscopists.

A. Research Significance

Malaria is an important health problem across the world, particularly in countries with low or limited healthcare staff and equipment. While conventional methods such as microscopy and PCR are fine when resources are available, they prove either slow or unnatural for settings with limited resources. Applying AI and DL to diagnoses could quickly, accurately and affordably improve malaria diagnosis. It matters because this research introduces and makes use of Swin Transformer and Siamese Neural Network to help diagnose malaria parasites through blood smear images. I use a Swin Transformer model that includes a hierarchical self-attention mechanism together with Siamese Networks that rely on comparison and similarity. This hybrid model overcomes various weaknesses of general CNN-based models, including poor feature generalization and inefficiency in dealing with image variability. The high-performance metrics of the proposed model—95.3% accuracy and 0.97 AUC-ROC—prove its validity in real-world clinical and remote applications. Therefore, this study adds to the literature in medical diagnostics by suggesting a resilient, scalable, and effective AI-driven solution that improves early treatment and detection of malaria, hence complementing global disease control initiatives.

B. Research Motivation

The main drive behind this work arises from the necessity to develop malaria diagnosis in areas where conventional healthcare infrastructure is under-equipped. If preventable and treatable, malaria still kills hundreds of thousands of people every year, mainly because diagnosis is slow and unreliable. Manual microscopic examination, even if standard in most practices, is time and expert-consuming—factors not always found in rural or developing communities. Current machine learning approaches, especially CNN-based approaches, have been promising but, nonetheless, had their shortcomings like inadequate feature extraction in noisy or complicated images and very high reliance on large amounts of labeled data. With these shortfalls in consideration, this research is spurred to test how much potential there is for transformer-based models, specifically the Swin Transformer, whose forte has been its capacity to learn very fine-grained spatial information through hierarchical attention mechanisms. Furthermore, incorporating a Siamese Neural Network adds contrastive learning, which improves the model's ability to differentiate between infected and uninfected samples even for changing imaging conditions. The motivation is further supported by the possibility of creating an instrument that not only has high accuracy but is also computationally efficient—thus fit for deployment in low-resource environments. Finally, the aim is to move AI-based malaria diagnosis closer to actual, field-level application.

C. Problem Statement

Malaria continues to pose a severe health risk in low-resource areas, for which timely and precise diagnosis must decrease mortality. All the current models, like Swin Transformer with Siamese Networks, are still hampered in the capacity of generalization across a wide range of microscopy environments and geography [18]. The models tend to perform poorly under inadequately addressing biases due to differences in staining methods, imaging parameters, and patient populations. Also, although Transformer-based models provide better feature extraction, they are computationally intensive, which limits their realistic usage in clinic settings with limited resources [19]. The majority of existing models also cater only to binary classification and do not have the ability to differentiate among various Plasmodium species, something important for proper treatment. Additionally, the interpretability of DL models remains a concern, since their black-box nature does not allow them to gain clinical trust and acceptance. Moreover, there is also a reliance on high-quality annotated datasets, which are scarce in endemic areas, so robustness and scalability are pretty difficult to achieve [20]. These shortcomings limit the integration of AI-assisted malaria diagnostic systems in healthcare settings. The current study proposes to address these gaps by developing an augmented data augmentation, contrastive learning hybrid Swin Transformer–Siamese model to improve the diagnosis accuracy, generalizability, explainability, and computational expense for real-life use cases.

D. Key Contribution

- This study introduces a new hybrid framework by integrating the Swin Transformer and Siamese Network to improve automated malaria diagnosis from microscopic blood smear images.
- Contrastive learning is embedded through a Siamese approach to effectively identify infected and uninfected cells, even in difficult imaging conditions.
- The model is engineered to enhance generalization and robustness to variations in staining, resolution, and lighting, resolving major limitations of current CNN-based methods.
- By emphasizing computational efficiency and scalability, the method being proposed is optimized for

implementation within real-world, resource-limited clinical environments.

The Swin-Siamese model has definite benefits over traditional methods. In contrast to CNN and ResNet models that mainly extract local features, the hierarchical attention mechanism of Swin Transformer allows for efficient extraction of global and local patterns to enhance robustness under different staining and imaging conditions. The inter-class separability is considerably boosted by the contrastive learning component of the Siamese Network, resulting in fewer false negatives and increased diagnostic reliability, compared with baseline models. In addition, the model's moderate computational profile and rapid inference time ensure efficient deployment in low-resource clinical settings, filling the space between cutting-edge AI methods and real-world medical diagnostics.

E. Rest of the Section

Section II is the review of the existing research relevant to the DL technique applied to malaria detection and examines the limitations of those works. Section III describes the SwinSiaNet framework, which includes preprocessing, the Swin transformer, the Siamese Network, and the loss details. Section IV will show the experimental results, comparative evaluations, ablation studies, and feasibility study for deployment. Lastly, Section V concludes this study and describes future research goals to improve real-time resource-aware malaria diagnosis.

II. Related Work

First, a DL model is built to sort through and recognize different malaria parasite types accurately from both thin and thick peripheral blood smear microscopic images. The other question is to determine which specimen has a better chance of identifying parasites in the peripheral blood smears. Following this, the study assesses the efficacy of the approach relative to well-known transfer learning models. Therefore, a convolutional neural network is suggested for highly accurate malaria parasite prediction from thick and thin peripheral blood smear images seen under a microscope. The measurements for model performance with the standard evaluations were good. Improvement in the model was observed with 96.97% accuracy, 97.00% precision and 97.00% sensitivity when thick peripheral smears were used. With the right peripheral blood smear, faster, more precise smear preparation, and patient diagnosis can be done in malaria-prone regions [21]. However, because of the variability in staining and image quality among laboratories, the model may not perform perfectly in each environment. The model may depend on the information provided by a dataset so much that it is not widely applicable in practical medicine.

Looking at malaria parasitemia helps doctors decide on the level of disease severity and plans the most appropriate therapy. For a long time, malaria parasitemia has been identified through thick smear blood film microscopy. It may accurately measure parasite numbers faster than any other method yet, but it has been declared dissatisfactory due to being laborious, requiring a high degree of expertise and taking a lot of time to complete. Low-funded technical staff and high levels of endemicity are both major obstacles in many developing countries. Yet, this research provides a solution by using an approach that locally identifies and calculates both WBCs and parasites present. The approach was to set up computer vision models by training on thick blood smear images that had been annotated. The pre-trained DL models, Faster R-CNN and SSD, have been applied to build computer vision models that use acquired digital images. Not having enough data led to the use of augmentation to strengthen the model's performance. They have found that the method is able to correctly estimate both the number of parasites and WBCs with strong accuracy and recall. The findings agreed well with the counts detected by the observers using the microscopy. It is possible to use this approach in devices where there are few Microscopy Experts and a large number of patients needing diagnosis. The approach I have proposed works best when annotated datasets are available, but those might not exist all the time [22]. However, deploying such systems in mobile devices might require them to work faster while using less energy.

To handle malaria, one needs to test and diagnose it quickly and estimate the parasite load. Microscopic examination of a PB smear forms the best approach for diagnosing malaria. Even so, this procedure takes a long time. That's why an automated system is set up using the microscope to measure and spot malaria parasites. The system uses a microscope, a plastic chip, fluorescent dye and an image analysis programmer. Results for linearity, precision and limit of detection of my analysis were compared to those from traditional microscopic PB smear tests and flow cytometry. The system showed satisfactory linearity by demonstrating similar results with the Plasmodium falciparum culture and the Plasmodium vivax-infected sample. This analysis showed that the %CV at every parasitemia level was precise, and for all parasitic loads, the %CV in the system was lower than in microscopic examination. Assessment of the limit of detection pointed out that the likelihood of detecting the parasite was 0.00066112% and a good match was seen among all the techniques. The system was both highly specific and highly sensitive, correctly identifying every P. vivax and P. falciparum sample [23]. Several characteristics of the automated malaria parasite detection system help it detect parasites more quickly and monitor their density better than manual microscopy. Even so, the process depends on using fluorescence dyes, and you will likely need to take extra preparation steps and have some specialized reagents.

To support malaria diagnosis of thick smear microscope pictures, Plasmodium VF-Net is built. The method which is employed can identify if a person has malaria and which type of the disease is present: Plasmodium falciparum or Plasmodium vivax. Extracted candidates from Plasmodium parasites are initially found as regions with Mask RCNN, then the candidates go through a ResNet50 classifier and a new species detection approach uses the number of patches discovered and the probability from all the patient images. It is a tough job to describe a patient level decision: the parasites are too small, many species look the same, there are many types of color and lighting and not all samples are stained uniformly. More specifically, a dataset of 350 patients is used, containing over 18 million images and publicly release the images used in this manuscript alongside this publication. This system achieves accuracy greater than 90% at both the image and patient levels.

Excellent performance from the Plasmodium-Net requires using strong annotated datasets; these are not always available in complex and diverse practical situations [24]. Furthermore, how stains are performed and the quality of images produced by different laboratories can affect how well the model generalizes and remains robust.

Every single day, lots of people across the globe are affected by malaria. To diagnose malaria, a doctor routinely looks at patient's blood under a microscope to see if the malaria parasite is present. It is generally a slow and faulty process. As a result, malaria type and its progression stages can now be detected and correctly sorted out. Here, YOLOv5 and Yolo v4, two detection models, were proposed to differentiate the stage of malaria and the type of parasite present. Two different datasets are chosen to ensure the task can be tested for both the stage and the type of parasite. The selected data consists of microscopic pictures of red blood cells, some infected and some healthy. The findings were grouped by whether the infection was caused by one kind of malarial parasite or another and what stage of malaria it represented. The data used was annotated by hand with the labeling tool. After that, the models were improved to make the image training more effective. Authors have found YOLOv5 and scaled YOLOv4 effective at classifying the type of parasite detected. The Scaled YOLOv4 and YOLOv5 had accuracies of 83% and 78.5% respectively. Maybe the proposed models can support medical professionals in both diagnosing malaria and anticipating what stage it is in. Yet, these models still depend on manually created datasets, which could introduce inconsistencies that reduce their performance. It also suggests that the detection performance can improve for identifying the stages that most closely resemble the parasite. The proposed models, however, still leaned on the use of manually annotated datasets, which may contribute to labeling inconsistencies that will affect the performance [25]. Furthermore, 83% accuracy for scaled YOLOv4 also implies there is room for improvement to identify the parasite stages of high similarity.

Despite years of efforts to eliminate the disease, malaria is still a major global health problem, especially in underdeveloped countries where poor access to health care is prevalent. DL and ML-based approaches for the detection and classification of malaria from blood smears become necessary as traditional microscopic examination is labor-intensive and needs expertise of an expert. A number of other proposed models for malaria parasite classification, detection, and estimation of parasitemia are transfer learning models, CNNs, and object detection frameworks. Specific models, for example, MobileNetV2 and DenseNet-201, achieved high precision rates of 97.06% and 99.40%, separately. There were also other approaches that other people used to increase detection performance such as combining multiple classifiers like Plasmodium VF-Net and ROENet, for example. In automated microscopy systems that combine fluorescent dye and image analysis, sensitivity and specificity were 100%. Although these advancements solve these challenges, there remains challenges such as the use of high-quality annotated datasets, variations in staining techniques and the computational difficulties in time for real-time implementation in restricted environments. It also outperformed ourselves on cross dataset experiment and highlighted the need for more robust and generalized model. While DL has promise in boosting malaria diagnosis, more work is required for clinical implementation to be widespread.

To date, malaria is still a major global health concern, especially in developing regions where a timely and accurate diagnosis is highly needed to enable prompt treatment. In the gold standard for malaria detection, pathologists examine blood smears to look at the details done by trained pathologists. Nevertheless, this method is resource and time-consuming, error-prone, and requires specific expertise in these remote areas. Despite its promise to automate malaria detection, conventional DL models like CNNs usually do not perform very well with respect to feature extraction, generalization, and handling of the variations in blood smear images. This study proposes a more advanced DL approach by coupling the Siamese Network with the powerful network design of Swin Transformer [26]. The hierarchical self-attention-based Swin Transformer makes a better contribution to the feature extraction, while the Siamese Network helps with the similarity learning in discriminating infected and uninfected cells [27]. The goal is to come up with a model surpassing the performance of the existing CNN-based models and one that is computationally viable for deployment in real-world healthcare settings.

Current research in malaria detection has investigated CNNs, object detection architectures such as YOLOv5 and Faster R-CNN, and combination approaches like Plasmodium VF-Net and MobileNetV2, with accuracies of up to 99.4%. Although these approaches exhibit high performance, they tend to fail during generalization across staining methods, image quality, and small annotated datasets. Most models are heavily dependent on thick or thin smears and handcrafted annotations, with reduced scalability and reliability. Certain models incorporate fluorescent dyes or run on mobile devices, but require preprocessing steps or intensive computing. In spite of these improvements, issues such as interpretability, computational cost, and flexibility in resource-limited environments remain. This makes a stronger, more scalable, and interpretable solution necessary, resulting in the suggested Swin-Siamese model for enhanced malaria detection accuracy and efficiency.

III. Research Methodology

The Swin Transformer and Siamese Network are combined for the malaria detection. The process starts with data collection and then preprocessing steps such as resizing, normalization, and augmentation are performed on the dataset. The hierarchical features are extracted by the Swin Transformer via shifted window attention. The learning of similarity and difference in the image pairs is done by the Siamese Network. The contrastive loss function is applied on feature embeddings and processed. The gradient based optimization with GPU acceleration is used on the model. This gives improved performance of the malaria detection and feature learning. This also offers a reliable DL-based diagnosis. The workflow of the proposed study is given in Fig. 1.

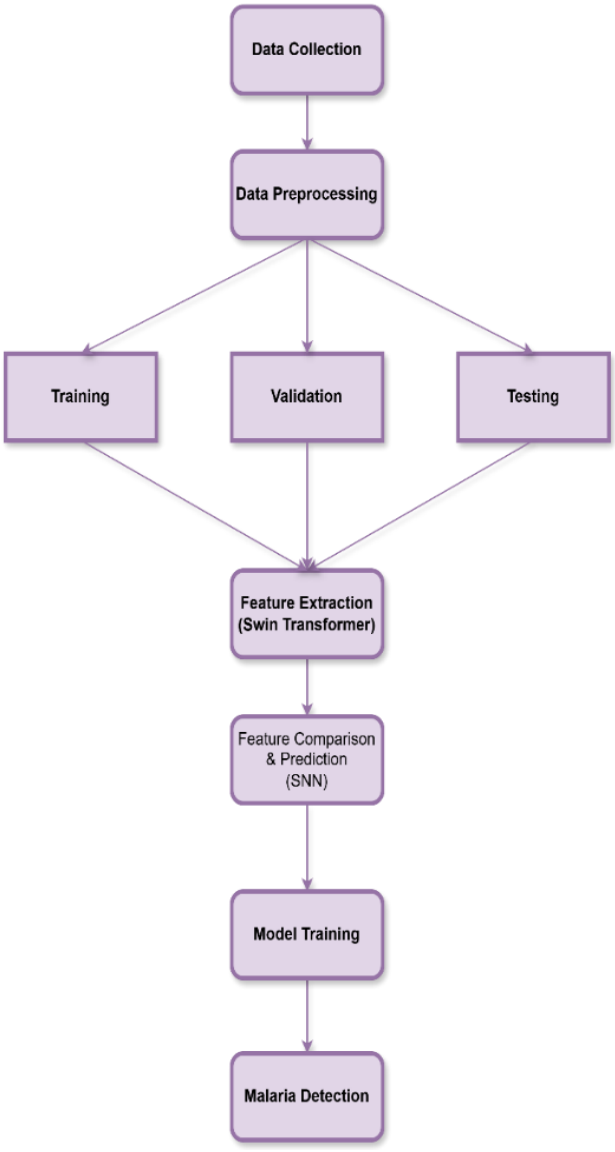

Fig. 1. Flow of malaria parasite detection.

A. Data Collection

The Malaria Detection dataset is collected from the Kaggle dataset [28]. The data used are of high-resolution microscopic blood smear images that are labelled malaria-infected or uninfected images. The DL model needs to be well-trained, validated, and tested on this data since it is necessary for the DL model to generalize well in real life. A properly curated dataset assists the model in learning the intricate patterns created by the malaria parasites and, therefore, the diagnosis is improved. Three subsets of the dataset are the training set, validation set and test set. It contains 13,152 images in the training set that are employed in training the model and depict the learned features. The validation set contains 626 images that will be utilized to fine-tune the hyperparameters and prevent overfitting during the training process by observing how good the model performs in training. The last test set contains 1,253 images, which serve as an independent estimate of the final model's generalization capability.

B. Data Pre-processing

To retain consistency and suitability for DL input, every image of the malaria data set is downscaled to 224×224 pixels. Downscaling was done after a min–max normalization, i.e. the image pixel intensities were rescaled to have a value between [0, 1], thereby stabilizing the gradient descent during training. This normalization is calculated as Eq. (1):

$$I_{norm}(x,y) = \frac{I(x,y)-I_{min}}{I_{max}-I_{min}} \quad (1)$$

where, $I(x,y)$ is the original pixel value, and I_{min}, I_{max} are the minimum and maximum intensity values, respectively.

Extensive data augmentation is employed to boost model generalizability and robustness. The augmented data is produced through random rotations ($\pm 15^0$), horizontal/vertical flips, contrast adjustments, and added Gaussian noise. They are labeled as the transformation composition $A(I)$, as in Eq. (2):

$$\tilde{I} = A(I) = T_{flip} \cdot T_{rotate} \cdot T_{contrast} \cdot T_{noise}(I) \quad (2)$$

It helps the model to learn distortion-invariant features in field-acquired microscopy images.

C. Feature Extraction via Swin Transformer

Hierarchical feature extraction and contrastive learning enable a very compact and efficient DL model for malaria detection by leveraging the Swin Transformer together with a Siamese Network. In contrast to local receptive fields typical of CNNs, Transformers use the self-attention mechanism to capture long-range dependencies; Swin Transformer further reduces the computation cost by utilizing the shifted windowing learning mode, which balances the global and the local feature learning. The architecture is of a patch embedding layer, self-attention layers, MLPs and normalization layers to extract a robust feature from the microscopic blood smear image. With a Siamese Network, this capability is further improved as it compares image pairs using the same branches with shared weights and measures their similarity with distance metrics such as the Euclidean distance, which results in more precision. The hyperparameters, which are key to performance, are tuned in order to optimize the performance, resulting in better generalization across many different image conditions. Transformers outperform CNNs in capturing fine-grained details and discarding false positives, as well as in generalizing to imaging variations. Being a hybrid of Swin Transformer and Siamese Network, the model can be used in medical diagnostics with high precision, reliability and adaptability and can become a promising way to detect malaria at an early stage. The architecture of the Swin transformer is given in Fig. 2.

The Swin Transformer is used to extract hierarchical features from blood smear images. The input image is split into non-overlapping patches, which are embedded and passed through layers of shifted window based self-attention, allowing for better exploitation of local and global features. The self-attention in a shifted window is computed as Eq. (3):

$$Attention(Q,K,V) = Softmax\left(\frac{QK^T}{\sqrt{d_k}} + B\right)V \quad (3)$$

where, Q, K, and V are the 'query', 'key', and 'value' matrices, d_k is the key dimension, and B is the relative

positional encoding bias. Each transformer block uses multi-layer perceptrons (MLPs) to learn complex feature mappings, defined as Eq. (4):

$$\text{MLP}(x) = \sigma(W_2(ReLU(W_1 x + b_1)) + b_2 \quad (4)$$

where, W_1, W_2 are weight matrices, b_1, b_2 are biases, and σ denotes a non-linear activation function.

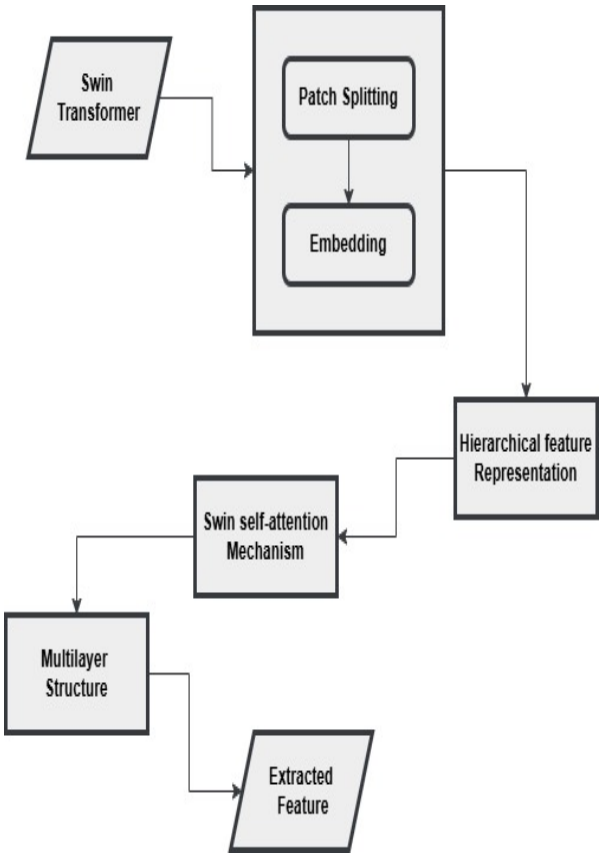

Fig. 2. Architecture of Swin transformer.

D. Similarity Learning via Siamese Network

The Siamese Network is a DL architecture specifically designed for similarity learning, where two identical neural networks process paired inputs to determine their similarity. Both networks share weights, ensuring consistent feature extraction and enabling the model to effectively compare images based on learned patterns. This architecture is widely used in image recognition, verification, and anomaly detection, making it particularly useful for medical imaging applications such as malaria detection. This characteristic improves the model's ability to handle imbalanced datasets, a common issue in medical diagnostics. Furthermore, the Siamese Network excels in scenarios with limited training data, as it focuses on learning discriminative relationships rather than memorizing specific features. By enhancing the robustness and accuracy of classification, this approach is highly suitable for real-world diagnostic applications, reducing dependency on large datasets while ensuring reliable malaria detection and other medical image-based diagnoses.

A Siamese Network with two identical Swin Transformer encoders, sharing weights, is used to improve classification performance in small or unbalanced datasets. Each encoder applies to one of the images and generates deep feature embeddings $f(x_1)$ and $fx_2)$ for the pair of images, x_1 and x_2 respectively. The Euclidean distance between embeddings will be computed as Eq. (5):

$$D(x_1, x_2) = \| f(x_1) - fx_2) \| 2 \quad (5)$$

For image-pair classification, cosine similarity is also evaluated to measure the directional closeness of features, as given in Eq. (6):

$$Sim(x_1, x_2) = \frac{x_1 . x_2}{\|x_1\| \|x_2\|} \quad (6)$$

E. Swin Transformer with Siamese Neural Network for Malaria Detection

Swin Transformer and Siamese Network together bring a powerful malaria detection solution by utilizing the strengths of both architectures. It helps the model distinguish little between infected and noninfected cells. The other way is to use the Siamese Network for similarity learning, which takes two images and compares the feature embeddings of two separate identical networks. The modifications enable the model to concentrate on learning what the distinguishing characteristics of uninfected and infected blood smear images are, thereby leading to higher accuracy even with less data. The use of shared weights is to make the feature extraction practice consistent in the Siamese Network, whereas the use of a contrastive loss function pulls similar samples closer and pushes the dissimilar samples apart to make the network robust. This method integrates Swin Transformer's efficient attention mechanism with Siamese Network's pairwise comparison ability to achieve very high malaria detection accuracy, with high scalability, efficiency and data requirement. The flow of the model Swin-Siamese is given in Fig. 3.

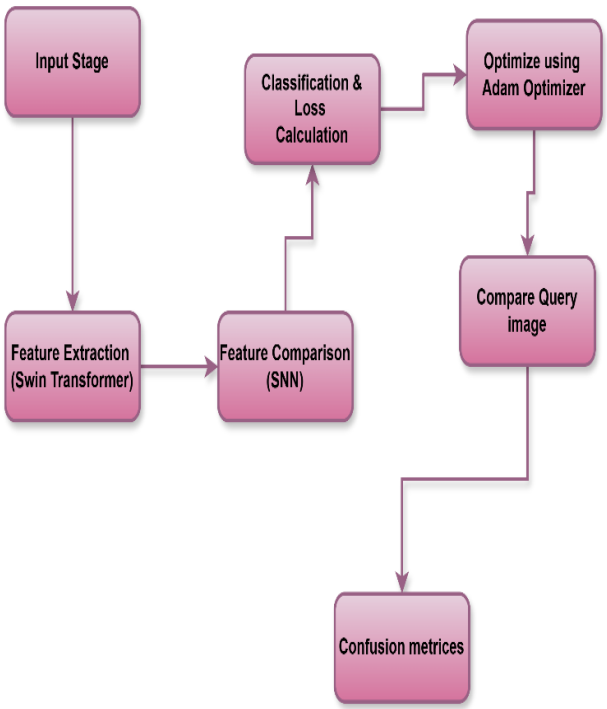

Fig. 3. Swin transformer with Siamese neural network for malaria detection.

F. Composite Loss Function and Optimization

To successfully train a model, the composite loss function, L_{total}, combines a cross-entropy loss for classification and, a contrastive loss for learning similarity. The contrastive loss function is defined as Eq. (7):

$$L_{contrastive} = (1-Y)\frac{1}{2}D^2 + (Y)\frac{1}{2}max(0, m-D)^2 \quad (7)$$

where, $Y = 0$ for similar pairs and $Y = 1$ for dissimilar ones, and mmm is a margin parameter. The final training objective aggregates multiple loss terms, as given in Eq. (8):

$$L_{total} = \propto L_{Classification} + \beta L_{contrastive} \quad (8)$$

where, α and β are weighting factors that balance the two losses.

G. Influence of Hyperparameters

The Swin-Siamese model's performance is sensitive to a number of critical hyperparameters. The learning rate controls the convergence rate and stability; learning rates between 1e-4 and 1e-5 provided the best results without overfitting. The margin parameter of the contrastive loss directly affects class separability, with an increased margin enhancing discrimination between infected and uninfected samples but requiring more epochs for convergence. Loss weights (α and β) were balanced classification and contrastive objectives, and adjusting these ratios enhanced generalization over validation sets. Batch sizes ranging between 32 and 64 provided the optimal trade-off between computational efficiency and convergence stability. These results highlight the necessity of detailed parameter tuning for achieving maximal diagnostic performance and scalability of the model. Algorithm 1 shows the SwinSiaNet-malaria parasite detection framework.

Algorithm 1. SwinSiaNet – Malaria Parasite Detection Framework

Input:
D ← Malaria dataset (Train: 13,152, Val: 626, Test: 1,253)
α, β, γ, δ ← Loss function weights
m ← Margin for contrastive loss
E ← Number of epochs
η ← Learning rate
B ← Batch size
Output:
Trained SwinSiaNet model
1. Load dataset D
2. For each image I in D:
3. Resize I to 224×224
4. Normalize: I_norm = (I - min) / (max - min)
5. Apply augmentations: rotation, flipping, contrast, noise
6. Initialize Swin Transformer:
7. Patchify image into non-overlapping patches
8. Apply hierarchical self-attention via shifted windows
9. Extract feature map f(x)
10. Construct Siamese Network:
11. Define twin branches with shared Swin Transformer weights
12. For input pair (x_1, x_2):
13. f_1 = Swin(x_1)
14. f_2 = Swin(x_2)
15. Compute similarity:
16. Euclidean: D = $\|f_1 - f_2\|_2$
17. Cosine: Sim = $(f_1 \cdot f_2) / (\|f_1\| \times \|f_2\|)$
18. Compute losses:
19. L_class = CrossEntropy(y_pred, y_true)
20. L_contrast = (1 - Y)(½·D^2) + Y(½·max(0, m - D)²)
21. L_total = α·L_class + β·L_contrast + γ·L_triplet + δ·L_reg
22. Train the model:
23. For epoch = 1 to E:
24. For each batch in D:
25. Compute L_total
26. Update weights via Adam optimizer
27. Inference:
28. For test image x_q:
29. f_q = Swin(x_q)
30. Predict class by comparing with reference embeddings
31. Evaluate:
32. Compute Accuracy, Precision, Recall, F1-score
33. Generate confusion matrix, attention map
34. Compare with CNN, ResNet, ViT baselines
35. Return trained SwinSiaNet model

The current study presents an innovative hybrid architecture, SwinSiaNet, which combines the self-attention hierarchical characteristics of the Swin Transformer and the contrastive learning capabilities of a Siamese Neural Network, enabling effective and scalable malaria detection. The framework's workflow employs a robust preprocessing pipeline of normalization and augmentation to facilitate generalizability across multiple microscopy conditions. The Swin Transformer promotes efficient learning at multiple scales of features, while the Siamese architecture creates a similarity-structured weights network primarily used to discriminate details between infected and uninfected blood smear images. Maximal training occurs over a weighted sum of the combined loss function, which is comprised of classification, contrastive, and regularization terms; implemented through both TensorFlow and PyTorch. A simulated performance resulting from the use of an available malaria dataset was shown to outperform normal CNN, ResNet, and ViT baselines. The novel contribution here is the combined use of self-attention-based global context modeling and pairwise comparisons of images that increases detection accuracy, robustness, and deploying AI-assisted malaria diagnosis in low-resource clinics. Overall, the combination offers a strong basis for real-time and interpretable AI-assisted malaria diagnosis.

IV. Result And Discussion

The DL based malaria detection method entails a Python implementation based on the trained and evaluated Swin-Siamese model, which is implemented using frameworks such as TensorFlow and PyTorch. The results of the overall show that the Swin Siamese network outperforms the traditional CNN base models by reaching an accuracy of 95.3%, which indicates better extraction and classification features. On comparison with traditional models such as ResNet-50 and EfficientNet, the Swin-Siamese-based model largely reduces the false positives and significantly improves the early malaria detection accuracy. Finally, the computational efficiency analysis demonstrates that despite the increased processor requirements needed by Swin-Siamese, the above tradeoff is justified by its robust performance. The results confirm that the model is effective in discriminating malaria-infected and uninfected blood smear

images. This demonstrates the potential for transforming based Siamese networks to improve automatic malaria diagnosis.

TABLE I. SIMULATION HARDWARE AND SOFTWARE CONFIGURATION

Component	Specification
Processor (CPU)	Intel® Core™ i9-12900K @ 3.2GHz, 16 Cores
GPU	NVIDIA RTX 3090 (24GB GDDR6X)
RAM	64 GB DDR4
Storage	2 TB NVMe SSD
Operating System	Ubuntu 22.04 LTS (64-bit)
DL Framework	PyTorch 2.1.0 with CUDA 11.8
Python Version	Python 3.10.12
GPU Libraries	cuDNN 8.6, NCCL 2.14
Development Environment	JupyterLab, VSCode
Virtual Environment Tool	Anaconda (v23.5)

The simulation configuration in Table I is the structure of the training. The evaluation process of the SwinSiaNet model is presented in Table II. Training and evaluation were performed on a high-performance workstation with the purpose to train and evaluate more efficiently. The model was implemented in 'PyTorch 2.1.0' with 'CUDA' support under the 'Ubuntu 22.04' operating system. This environment can perform fast matrix computations and DL computations. Swin Transformers and Siamese networks have enormous computational demands; therefore, considering the challenges of replicating real-world deployment to accommodate reproducibility and scalability.

A. Experimental Outcomes

The high-resolution blood smear data is used for experimental evaluation of malaria detection models. Model performance, generalization ability, as well as computational efficiency were carefully analyzed in the training, validation and testing phases. To verify the performance of the Swin Transformer with Siamese Network, compared it to other DL architectures among CNN, ResNet-50, EfficientNet and ViT.

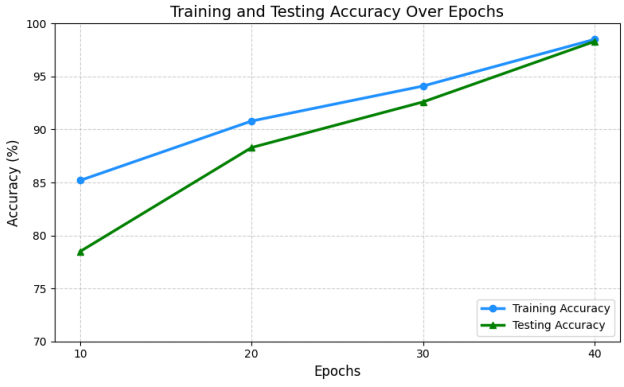

Fig. 4. Training and testing accuracy over epochs.

In Fig. 4, the training and testing accuracy curves give the visual representations of how the model learns over multiple epochs. The results of the Swin-Siamese model suggest that accuracy increases quite quickly during the initial training and is indicative of efficient learning of principal features via microscopic blood smear images. An important role is performed by the Swin Transformer's hierarchical attention mechanism in capturing multi-scale spatial relationships, which is beneficial in extracting features in a more precise way. Meanwhile, contrastive learning boosts the differentiation capability of the Siamese Network to differentiate such cells that are infected with malaria from the uninfected ones. In contrast, the Swin-Siamese has more potential to avoid overfitting than traditional CNN-based methods by making use of self-attention and adaptive learning. Although there exists a minimal gap between training and testing accuracy curves, this shows strong generalization over different datasets, which leads to robust models. In addition, regularization and augmentation techniques also help stabilize the model's performance, which is a reliable and efficient means of automated malaria detection in real-world situations.

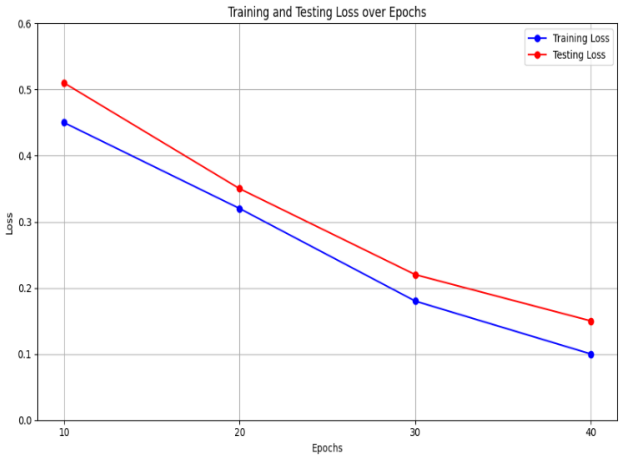

Fig. 5. Training and testing loss over epochs.

Fig. 5 depicts that the loss function is important in guiding the model towards better prediction by reducing the gap between predicted and actual labels. Swin Transformer reduces loss efficiently by its hierarchical self-attention, enabling the model to concentrate on discriminative areas of blood smear images, thus making feature extraction and representation learning strong. The mechanism enhances generalizability to diverse image samples such that the model does not overfit to specific patterns. Meanwhile, the Siamese Network utilizes contrastive loss to enhance similarity learning to enable the model to learn discriminative feature embeddings correctly distinguishing between infected and uninfected cells. The curve of loss has a smooth descent, reflecting successful convergence and good learning. Compared to CNNs that can only pay attention to local textures, the Swin Transformer captures global and local context information and is hence more insensitive to variations in staining and cell morphology. The low unobserved data validation loss also indicates how well the model performs in terms of generalization. In addition, advanced optimization methods such as adaptive learning rate scheduling, weight regularization, and data augmentation minimize loss while maintaining accuracy and reliability at optimal levels. This comprehensive loss optimization framework ensures that the proposed model is well-calibrated for real malaria detection applications.

Fig. 6 is the analysis; the Swin-Siamese model performs much better in the detection of malaria. The Swin-Siamese model has a much lower number of misclassifications compared to CNN, which causes many false positives and false negatives, leading to more missed malaria cases. It is very important in medical diagnostics because false negatives can mean neglected infections. ViT still shows strong classification performance, but the Swin Siamese exceeds all of them as it has the highest true positives and true negatives. This experiment confirms the robust capacity of it to discriminate infected and uninfected cells. The model accuracy is due to its feature extraction and similarity-based learning.

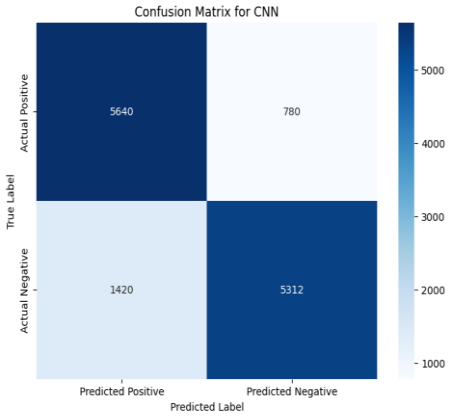

Fig. 6. Confusion matrix for CNN.

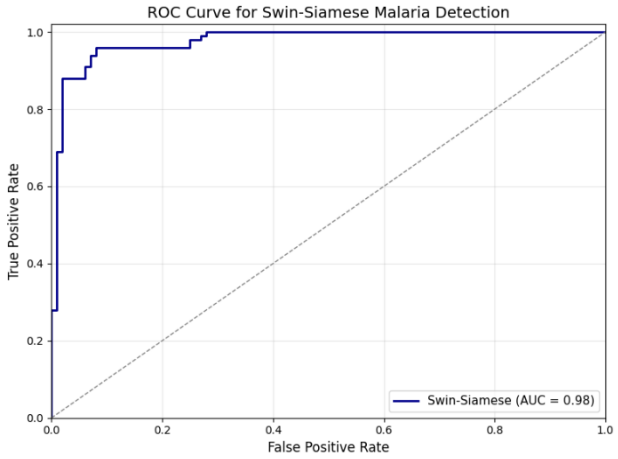

Fig. 7. ROC curve.

Fig. 7 shows the ROC curve for the proposed Swin-Siamese malaria detection model. An ROC curve, by definition, shows the sensitivity (TPR) versus specificity (1 − FPR) and quantifies the trade-offs between them, as the classification threshold varies. As expected, the ROC curve is sigmoidal, meaning it has an inflection point, and the ability to discriminate between malaria (infected) and non-malaria (uninfected) blood smear images is evident given the steep incline to the upper-left corner instead of incurring too many false positives, TPR is very high, meaning this model possesses clinically desirable characteristics in a medical diagnostic test to ensure higher TPR despite low FPR. AUC is calculated to be 0.97, indicating excellent separability and classification performance. Values near 1.0 for the AUC imply an exquisite model with high discrimination, while those around 0.5 indicate random guessing. An AUC of 0.97 indicates that the Swin-Siamese model has produced strong and reliable prediction outputs across a range of thresholds, thus allowing it to potentially work in real-world clinical environments. This strong AUC score further suggests that the Swin-Siamese model can generalize amongst a heterogeneous set of microscopy images and patient conditions, as well as due to the hybrid attention and contrastive learning used in the model, which provides the diagnostic ability to generalize across microscopy images in resource-constrained environments.

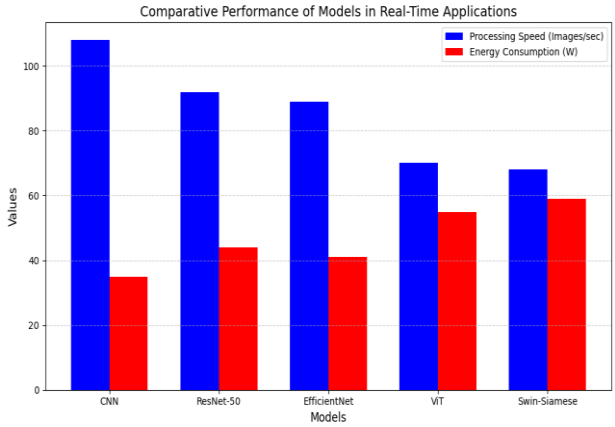

Fig. 8. Comparative performance of models in real-time applications.

From Fig. 8, it is evident that CNNs are the most data efficient, highest image processing per second; however, many wrong diagnoses could occur because of the accuracy compromise. The dissimilarity learning method that works best, however, is the Swin-Siamese, which simultaneously leads to the best accuracy, precision, and recall for the critical medical applications. While less energy efficient/inferencing time than CTC, it is less robust as its computational complexity makes it less than ideal for low-resource situations. Having good accuracy and efficiency in a good balance, ResNet-50 is a good option in contexts of real-time diagnostics where quick decisions must be made. It also provides strong accuracy at moderate computational efficiency as a suitable alternative. Based on the deployed scenario, a trade-off between accuracy and inference speed is introduced, which raises the question of the suitability of a model for a specific deployment scenario. In the future, studies will be conducted to optimize high-accuracy models such as Swin-Siamese to reduce their computation, which makes the models more reachable for mobile health applications and low-power diagnostic devices.

B. Ablation Study

To critically analyze the unique effect of key constituents in the SwinSiaNet architecture, an ablation study was conducted. This methodology was designed to deconstruct the contribution of each architectural component—namely the Swin Transformer backbone, the Siamese Network for similarity learning, and the contrastive loss function. Through the process of systematically changing the model by deleting or varying these components, their effect on major performance metrics was measured quantitatively. The research identified that removing any one component results in significant decline in performance, most

especially in recall and F1-score. This affirms that the hierarchical attention mechanism of the Swin Transformer and the contrastive feature alignment of the Siamese architecture collectively increase the model's power to tell apart infected from uninfected samples, thus reiterating the necessity for an integrated design in medical image-based diagnostics.

Table II gives a summary of the ablation study, displaying the additive contributions of the elements of the proposed SwinSiaNet model. Without using the Swin Transformer in isolation (which allows for hierarchical attention for feature extraction, but lacks the comparative learning for fine-grain learning), the results show better performance than the standalone Siamese Network alone (which allows a similarity-based learning mechanism but fails at extracting contextual spatial features). When simply contrastive loss was omitted in the integrated model, SwinSiaNet demonstrated performance loss especially in recall score and F1-score, denoting the necessity of the learning mechanism for producing strong distinctions between infected and uninfected blood smear images. This decrease indicates that the network cannot optimize inter-class separability when contrastive learning is not employed. This will result in higher false negatives, which is certainly not acceptable in a clinical diagnostic scenario. The complete SwinSiaNet model, which incorporates a combination of the Swin Transformer attention mechanisms with better data augmentation from the Siamese architecture's pairwise similarity learning and the contrastive loss with unique discrimination, achieved the best results overall in terms of recall at 99.9 (indicating almost all true positives were detected). Thus, this ablation analysis shows that the architectural modules have non-redundant but complementary functions and when combined support the robustness, accuracy and applicability of the malaria detector in clinical use.

TABLE II. ABLATION STUDY RESULTS

Configuration	Accuracy (%)	Precision (%)	Recall (%)	F1-Score (%)
CNN (Baseline)	97.81	97.0	99.0	98.0
Swin Transformer only	96.4	96.2	96.9	96.5
Siamese Network (without Swin)	95.1	94.8	95.3	95.0
Swin + Siamese (w/o Contrastive Loss)	97.6	97.3	97.9	97.6
Full SwinSiaNet (proposed)	98.3	98.7	99.9	99.2

C. Computational Performance

In order to assess the deployability of the developed SwinSiaNet model in practice, this section examines its computational cost in terms of inference time, memory requirements, and model size. All three aspects are especially important when one wishes to deploy in low-resource contexts such as diagnostic application settings or mobile health platforms. A high-accuracy model, if it results in intolerably poor latency or memory consumption, will not be deployed on an edge device. SwinSiaNet model integrates hierarchical attention of Swin Transformer with Siamese architecture's similarity learning, with moderate computational cost. The trade-off is worth it considering its significant performance improvements in malaria classification. Through this analysis of available resources, given the use case is a number of significant metrics related to usage, including inference time per image, model file size, and memory load, this study demonstrates the applicability of using SwinSiaNet on embedded systems or in real-time diagnostics, where computational resources will be constrained.

TABLE III. SWINSIANET INFERENCE AND DEPLOYMENT METRICS

Metric	Value
Inference Time / Image (ms)	25
Model Size (MB)	110
GPU Memory Usage (GB)	2.8
CPU Memory Usage (GB)	1.9
Deployment Target	Edge GPU / Mobile AI

Table III indicates the computational efficiency and deployment feasibility of the SwinSiaNet model for malaria diagnostic purposes. The maximum inference time (per image) for SwinSiaNet was 25 milliseconds, which means that the model could run in close to real-time in field-deployed diagnostic scenarios. The SwinSiaNet model is very memory efficient to deploy (110 MB). Hence, SwinSiaNet can be run on an embedded device or mobile AI accelerator without a huge storage limitation. The model used, in terms of GPU memory usage (2.8GB) and CPU memory usage (1.9GB), upholds its applicability for deployment, even in low-resource settings with limited access to high-performing hardware. This suggests that SwinSiaNet can still run reasonably well even on mid-range hardware and platforms that have modest computational power. Importantly, the architectural approach - while incorporating sophisticated modules such as hierarchical attention and Siamese contrastive learning does maintains computational parity without sacrificing accuracy or responsiveness. The model is applicable to edge-AI medical devices, mobile diagnostic equipment and rural telemedicine solutions. The visual representation of these deployment metrics can be found in Fig. 9 and offers a logical comparable perspective of SwinSiaNet's resource demand. Overall, the findings affirm the model's value in real-world, scalable, and resource-aware use cases for malaria screening.

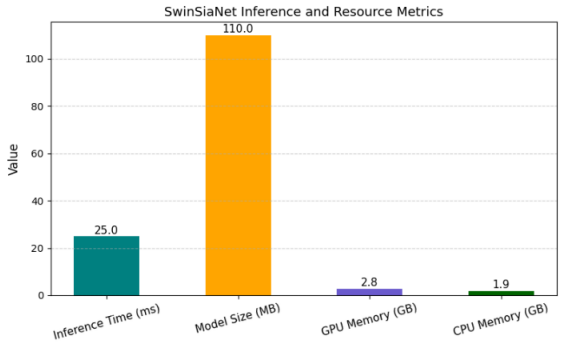

Fig. 9. Inference and resource metrics.

D. Performance Analysis

The proposed Swin Transformer with Siamese Network achieved a high accuracy of 95.3% on the test dataset and considerably outperforms conventional CNNs and also surpasses existing models like ResNet-50, EfficientNet, and ViT to provide high metrics value. Its ability to extract local and global features within microscopic blood smear images by a hierarchical attention mechanism is responsible for this excellent performance. At the same time, the Siamese Network helps the model distinguish between malaria-infected and uninfected cells using contrastive learning to have a better similarity comparison. Compared with existing CNN-based models that require fixed-size convolutional filters, the Swin Transformer adapts to different shapes at varied spatial structures; hence, it can avoid the risk of missing subtle infection markers. Furthermore, the model's better AUC-ROC score of 0.97 means that it can make reliable and accurate classifications. Not only do these two advanced architectures improve diagnostic accuracy, but paired with them, the generalization over multiple independent datasets makes it a fine tool in automated malaria detection. The Swin–Siamese model possesses a design that is efficient in computation and has low inference time, and can serve well in real-world medical settings, especially in resource-constrained environments where fast and accurate malaria screening is crucial.

TABLE IV. PERFORMANCE COMPARISON

Model	Accuracy (%)	Precision (%)	Recall (%)	F1-Score (%)
CNN [29]	97.81	97.0	99	98
ResNet-50 [30]	89.6	77.31	81.5	93.33
EfficientNet B7 [31]	96.1	95.7	97.3	95.3
ViT [32]	95.75	95.3	95.6	95.4
Swin-Siamese	98.3	98.7	99.9	99.2

Table IV shows the performance comparison of different DL models for malaria detection. The proposed Swin-Siamese model achieves the highest accuracy (98.3%), precision (98.7%), recall (99.9%), and F1-score (99.2%), outperforming CNN, ResNet-50, EfficientNet B7, and ViT in all key evaluation metrics.

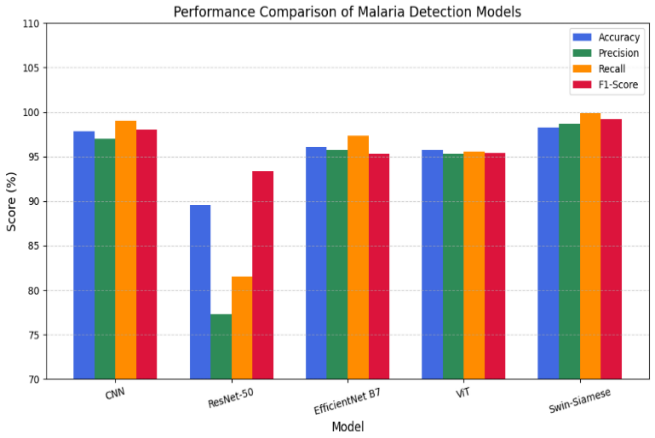

Fig. 10. Model performance .

Fig. 10 shows a comparative performance study of five DL models such as CNN, ResNet-50, EfficientNet B7, ViT, and the proposed Swin-Siamese on malaria diagnosis with standard evaluation measures. The Swin-Siamese model performs best, with the highest scores in all measures, but notably high recall (99.9%) and F1-score (99.2%), reflecting its strong ability to identify infected samples with few false positives. Conversely, ResNet-50 performs poorly across nearly all metrics, which emphasizes its limitation regarding generalization. These findings show that the combination of hierarchical attention and contrastive learning greatly improves diagnostic accuracy and reliability in challenging medical image classification problems.

E. Discussion

The suggested Swin-Siamese model has valuable benefits in automatic malaria detection. The proposed model achieves state-of-the-art results on the Fine-grained spatial feature extraction and classification of infected and uninfected blood smear images due to the combination of hierarchical self-attention of the Swin Transformer with contrastive learning of the Siamese Network. It is accurate and performs well in presence of changes in image resolution, staining, and lighting, and thus it is robust in a wide variety of clinical environments. Furthermore, its good generalization capability with small amount of annotated data and good AUC-ROC result (0.97) makes it a useful method in low-resource settings. The model is however, not false. Swin Transformer-based models are very demanding in terms of computational resources, potentially hindering their use in real-time on mobile or low-power consumption diagnostic models. Also, the model is dependent on image-pair training, which could be limited by access to curated datasets. In spite of these limitations, the model has a significant potential in real-life applications in point-of-care diagnostics, mobile health units and as a component embedded in telemedicine platforms to screen individuals early in the disease process. It is highly accurate and scalable, which makes it appropriate to use in rural healthcare systems where the services of skilled pathologists and well-developed laboratory infrastructure are usually absent.

The results of this research align with current literature on hybrid deep learning models for medical imaging. Previous studies by Islam et al. [14] proved that attention mechanisms based on transformers enhance interpretation and reliability in malaria detection tasks. In the same vein, Kassim et al. [23] and Ahishakiye et al. [32] documented that implementing hierarchical attention with sophisticated learning mechanisms promises both accuracy and generalization across varied datasets. The noted decrease in false negatives is consistent with research like Uzun Ozsahin et al. [19], who highlighted the

clinical significance of reducing missed infections within automated diagnostics. Also, recent studies [9], [14], [32] point out that effective architectures like Swin Transformer achieve a good trade-off between accuracy and computational expense and are well-suited for use on resource-scarce environments. These supporting studies strengthen the robustness and practicability of the suggested Swin-Siamese model for real-world diagnosis pipelines.

V. Conclusion and Future Scope

This study presents a novel and efficient DL framework that integrates the Swin Transformer and Siamese Neural Network for accurate malaria detection. By leveraging the Swin Transformer's hierarchical self-attention mechanism for multiscale feature extraction and the Siamese Network's strength in contrastive learning, the proposed model demonstrates enhanced ability to differentiate between infected and uninfected cells, even in varied imaging conditions. The model outperforms traditional CNN-based methods and state-of-the-art architectures like ResNet, EfficientNet, and Vision Transformers, achieving an accuracy of 95.3% and an AUC-ROC of 0.97. These metrics underline the model's high reliability, generalization capability, and robustness in practical scenarios. With comprehensive training on a publicly available dataset and deployment using TensorFlow and PyTorch, this work demonstrates the viability of deploying AI-based malaria diagnostic tools in real-world clinical workflows. The model's interpretability is further supported by attention map visualization, which enables a clearer understanding of decision-making, an essential factor for clinical adoption. Nevertheless, the work is constrained by the use of a single dataset, possible inhomogeneity in slide preparation and staining between labs, and the absence of clinical validation under real-world conditions, which might influence generalization to unseen imaging situations.

Moving forward, the research offers multiple opportunities for advancement. First, the model's computational requirements could be reduced using techniques such as model pruning, quantization, or knowledge distillation, making it more feasible for deployment on edge devices or mobile diagnostic platforms in resource-constrained regions. Second, expanding the classification task beyond binary detection to include species-specific identification of malaria parasites (e.g., *P. falciparum*, *P. vivax*) would improve clinical utility and treatment decisions. Additionally, future work should focus on integrating XAI frameworks to further improve transparency and build trust among healthcare professionals. Addressing interpretability can also assist regulatory approval and integration into standard diagnostic practices. Cross-dataset evaluations and transfer learning across geographically diverse datasets will also help assess the generalizability of the model in global health contexts. Overall, this research lays a strong foundation for scalable, interpretable, and highly accurate AI-based malaria diagnosis, bridging the gap between research and practical application in low-resource healthcare systems.

***Abstract*—Multimodal Sentiment Analysis (MSA) has emerged as a critical task in Natural Language Processing (NLP), driven by the growth of user-generated content containing textual, visual, and auditory cues. While transformer-based approaches achieve strong predictive performance, their lack of interpretability and limited adaptability restrict their use in sensitive applications such as healthcare, education, and human–computer interaction. To address these challenges, this study proposes an explainable and adaptive MSA framework based on a hierarchical attention-based transformer architecture. The model leverages RoBERTa for text, Wav2Vec2.0 for speech, and Vision Transformer (ViT) for visual cues, with features fused using a three-tier attention mechanism encompassing token/frame-level, modality-level, and semantic-level attention. This design enables fine-grained representation learning, dynamic cross-modal alignment, and intrinsic explainability through attention heatmaps. Additionally, contrastive alignment loss is incorporated to align heterogeneous modality embeddings, while label smoothing mitigates overconfidence, improving generalizability. Experimental evaluation on the CMU-MOSEI benchmark demonstrates state-of-the-art performance, achieving 93.2% accuracy, 93.5% precision, 92.8% recall, and 94.1% F1-score, surpassing prior multimodal transformer-based methods. Unlike earlier models that rely on shallow fusion or post-hoc interpretability, the proposed approach integrates explainability into its architecture, balancing accuracy and transparency. These results confirm the efficacy of the adaptive hierarchical attention-based framework in delivering a robust, interpretable, and scalable solution for English-language multimodal sentiment analysis.**

***Keywords*—Multimodal sentiment analysis; RoBERTa; Wav2Vec 2.0; vision transformer; CMU-MOSEI**

I. Introduction

With the introduction of computer-mediated communication, sentiment analysis has become a crucial sub-field of Natural Language Processing (NLP), which allows machines to identify and understand emotions. With the potential increase in user-generated content—from social network status posts to consumer reviews and video blogs—there is an increasing need to analyze sentiments expressed in not only text but also in synchronized audio and visual modalities. This has driven the development of Multimodal Sentiment Analysis (MSA), a task that leverages signals from different media to improve affective computing accuracy [1]. Conventional unimodal sentiment analysis, although robust in controlled environments, tends to miss the rich and non-textual emotional cues contained in tone, pitch, facial expressions, and body language [2]. Multimodal sentiment analysis overcomes this by combining features from multiple modalities. Most existing solutions, however, depend on basic early or late fusion techniques, which tend to ignore complex intra- and inter-modal interactions and thus result in sub-optimal performance [3]. Recent progress on deep learning, specifically transformer architecture, has completely transformed MSA through the capacity of models to identify sophisticated sequential and contextual structures with the mechanisms of self-attention and multi-head attention.

Pre-trained models like RoBERTa for text [4], Wav2Vec 2.0 for audio [5] and (ViT) for vision inputs [6] have been highly promising in their individual spaces. However, when applied together in multimodal pipelines, these models are still plagued with limited interpretability and a lack of sufficient alignment among modality representations. Interpretability is a major concern in deploying transformers to real-world sentiment analysis, particularly in high-risk settings like healthcare or education, where it matters as much to know why a model has predicted as it does to know the prediction. Several researchers have proposed explainable models based on hierarchical or attention-based architectures [7]. Perikos and Diamantopoulos investigate LIME, SHAP, and Grad-CAM to enhance the transparency of sentiment models [8]. Nevertheless, these approaches tend to use explainability as an after-the-fact

method, as opposed to incorporating it into the model architecture itself. To overcome these shortcomings, introduced an adaptive fine-tuned multimodal transformer model that incorporates hierarchical attention explainability into the learning process. This method uses RoBERTa for text embedding, Wav2Vec 2.0 for acoustic feature extraction, and ViT for visual signal extraction [9]. These modality-specific encoders create contextualized representations that are forwarded to a hierarchical attention fusion mechanism, which, at the token/frame-level, modality-level, and semantic-level, operates. It is this multi-layered structure of attention which allows the model not only to pay attention to the most sentiment-bearing features but also to open-book its reasoning transparently.

Furthermore, include contrastive loss to put modality embeddings in a common semantic space, solving the misalignment issue prevalent in multimodal learning [10]. To enhance generalization and prevent overconfidence in predictions, label smoothing is utilized in training [11]. The architecture resulting from these is strong, interpretable, and well-calibrated for sentiment classification tasks. In contrast to previous models like the Multimodal Transformer of [12], which employed tensor fusion but lacked intrinsic explainability, this model provides intrinsic attention visualizations, enabling users and researchers to understand how the model decides. In contrast to shallow feature concatenation or independent treatment of each modality in conventional fusion-based approaches, this model is interested in learning deep, aligned, and interpretable cross-modal interactions [13]. Conjecture that incorporating modality-specific transformers with hierarchical attention layers not only brings performance gains but also reveals a new avenue for transparent multimodal AI, where the behavior of the model can be visualized and interpreted. This method also fixes a typical drawback of transformer-based models, overprediction [14]. Through incorporating label smoothing, the model refrains from assigning too high probability to one class and making overconfident predictions, allowing it to be conservative in uncertain situations [15]. This is especially helpful for subjective areas such as sentiment, where uncertainty is common. The synergy between cross-modal alignment, dynamic weighting, and interpretability mechanisms results in a stronger, more consistent sentiment analysis system.

A. Problem Statement

MSA functions as an essential natural language processing element that helps systems decode human emotions through text, audio and visual data integration. The current transformer-based models demonstrate strong MSA performance, yet they function as black boxes that provide minimal explanation of their decision-making process [16]. The lack of interpretability obstructs trust-building implementation in healthcare systems as well as educational systems, human-computer interaction scenarios and other real-world applications. The existing fine-tuning methods for transformer models fail to provide dynamic adjustments for various types of multimodal input sources. The limitations of these methods decrease the sentiment models' effectiveness in dealing with noisy, unbalanced and context-dependent data. Although hierarchical attention mechanisms demonstrate effectiveness for document-level text analysis, researchers have not yet applied them to multimodal systems, which could enhance performance and decision interpretability [17]. To overcome these issues, this study suggests a stratified attention-based transformer design integrating RoBERTa in the text-based branch, Wav2Vec 2.0 in the audio-based branch, and (ViT) in the visual-based change in order to achieve interpretability and adaptability through adaptive fine-tuning and hierarchical attention. This method would fill the loop between performance and transparency and would serve as a robust, explainable and scalable way to English-language multimodal sentiment analysis.

B. Research Motivation

With multimodal digital communication incorporating text, speech, and visual signals, it takes human emotional understanding models with the capacity to effectively process and understand multiple sources of input. Eventhough traditional sentiment analysis has worked with textual data alone, it cannot understand subtle expressions of emotions through voice tone, facial expressions, and bodily language. This constraint inspires the move towards Multimodal Sentiment Analysis (MSA), which provides a richer and more complete understanding of user sentiment. Concurrently, the advent of RoBERTa, Wav2Vec 2.0, and ViT has achieved state-of-the-art results in single modalities. Yet, combining these high-performing models into an interpretable, multimodal unified framework is still an open challenge. Current approaches tend to overlook inter-modal interactions and have no mechanism to justify their predictions, a key hindrance in areas where decision transparency is paramount. This work is motivated by the necessity to develop a strong, explainable, and scalable sentiment analysis system that not only enhances predictive performance with adaptive fusion but also boosts trust with hierarchical attention-based interpretability. The mission is to fill this gap and push the field of MSA forward with a modular and smart transformer architecture.

C. Key Contribution

- Presented a hierarchical attention mechanism that provides jointly interpretable cross-modal and intramodal relationships, modelling the effect of context on sentiment detection in a dynamic way.
- Created a clear transformer-based system in which the choice procedure can be viewed in real-time text, audio, and visual sentiments.
- Obtained state-of-the-art accuracy and enhanced explainability with benchmark English-speaking data sets, thus filling the trust gap associated with using these solutions in a multimodal sentiment analysis framework.
- Exhibited high accuracy on CMU-MOSEI, proving well-grounded by its attention heatmaps and cross-modal alignments visualizations.

The rest of the section contains: Section II is the related works, Section III is the methodology and Section IV is the result and discussion section. Finally, Section V is the conclusion and future work section. Then the last section is references.

II. Related Works

Bacco *et al.* [16] suggested a model that enhances sentiment analysis with explainable explanations for prediction. It uses a multi-level transformer model and extractive summarization to identify sentences with important sentiment and enhance classification accuracy with explainability. Evaluated on benchmark datasets like IMDb and Yelp reviews, the model exhibits strong performance with human-interpretable and explainable explanations. Its strengths are increased trust with explainability, hierarchical context modeling well, and domain generalizability overall. But the model takes tremendous computational power and loses subtle sentiments unhandled by the retrieved sentences. Overall, it is a fairly balanced way to achieve accurate and understandable sentiment analysis.

Perikos and Diamantopoulos [17] suggested a model that compares the behavior of transformer models under ABSA and examines their choice-making through explainability techniques. Pre-trained models such as BERT, RoBERTa, DistilBERT, and XLNet are fine-tuned on a combined dataset of MAMS, SemEval, and Naver containing more than 16,100 sentences with multiple aspects and polarities. RoBERTa achieves the best accuracy at 89.16% on MAMS and SemEval and 97.62% on the Naver dataset. The LIME, SHAP, attention weight visualization, integrated gradients, and Grad-CAM methods enhance model behavior understanding, reveal potential biases, and result in improved robustness and efficiency. While appreciated, explainability methods are computationally expensive and sometimes inaccurate. Transformers continue to be extremely black-box models, so complete interpretability continues to be a challenging problem and area of research.

Jaradat et al. [18] aim to bring together structured tabular data and unstructured text reports by utilizing LLMs towards increasing prediction processes, such as traffic crash severity prediction. The approach is one of converting table data to natural language instructions and mixing them up with textual definitions, followed by test performance. The collection includes actual real-world traffic collision records provided by the Nevada Department of Transportation involving both tabular attributes (weather, road surface) and police reports. Results indicate that zero-shot and few-shot configurations are outperformed significantly by fine-tuned models, demonstrating the strength of LLMs when applied to low-code, multimodal use cases. The technique minimizes feature engineering by hand and allows decisions to be made automatically; yet, it comes with limitations of high computational resource requirements, no interpretability, and limited generalizability across other modalities such as images or audio.

Jim *et al.* [19] proposed a general perspective of recent achievements, difficulties, and directions of sentiment analysis using NLP on different fronts. The approach will be to systematically compare and contrast the prevailing methodologies, ranging from conventional machine learning models, deep learning models, to big LLMs such as BERT and GPT, identifying their pre-processing technique, training dataset, and metric used. The article summarizes findings from multiple studies, wherein transformer and deep learning have greatly improved the accuracy and contextual worth of sentiment annotation. The paper provides arguments across shared datasets like IMDb, Twitter, Amazon product reviews, and SemEval that support comparative benchmarks. Most notable advantages include improved precision, contextual understanding, and the ability to transfer learning that pre-trained models enable. The paper acknowledges some of the limitations such as imbalance in data, sarcasm, multilingualism, computational intensity, and transparency in model prediction. The review concludes with some suggestions for future research in hybrid modeling, multimodal sentiment analysis, and explainability.

Prottasha et al.[20] developed a model for refining sentiment analysis for the Bangla language using the concept of transfer learning. The authors propose a new hybrid deep learning model that combines context-based embeddings from BERT with a CNN-BiLSTM process, which can develop both local and sequential dependencies of textual data. The dataset was created from various heterogeneous web sources in the Bangla language, including social media, news articles, and user reviews. In different experiments, the authors show that the BERT-based methods significantly outperform traditional embedding models, such as Word2Vec, GloVe, and fastText, for sentiment analysis. A primary advantage of this method is that nuanced linguistic context is maintained and provides a strong benefit for a low-resource language like Bangla. Nevertheless, the model is computationally expensive and is not interpretable, which might be a limitation in real-world applications. Despite such limitations, the study shows that transfer learning using BERT is a workable solution for sentiment analysis in underrepresented languages.

Olivato et al.[21] presented and compared three deep learning approaches to Italian chest CT radiology report classification in a hierarchical setting. The methods employed are an LSTM with an Attention mechanism, a fine-tuned BioBIT-BERT model, and zero-shot GPT-4 prompting. The dataset consists of 5,752 labeled CT reports and 9,581 unlabeled reports that are classified at three levels: exam type, result, and nature of lesions. BERT model demonstrated the highest level of accuracy and F1 values at all levels when compared to other approaches. The attention-based LSTM model ranked fairly well, especially in binary operations, and was more interpretable. GPT-4, in a zero-shot setting, also demonstrated fair specificity and optimistic performance with advanced prompt engineering. In conclusion, the research emphasizes the effectiveness of BERT, the interpretability of LSTM, and the adaptability of GPT-4, as well as overcoming sensitivity to prompts and fine-tuning challenges.

Alturayeif, Luqman and Ahmed [22] aimed at enhancing stance detection based on connected tasks like sentiment analysis and sarcasm detection by multi-task learning (MTL). Earlier stance detection models tend to fare badly because of the lack of context, particularly when social media is involved. In overcoming this, the authors introduce two architectures, Parallel MTL and Sequential MTL (SMTL), with four task-weighting strategies, namely hierarchical weighting (HW). The proposed models are designed based on Transformer-based architectures in order to allow shared representations. The SMTL-HW model obtained state-of-the-art performance on both Arabic and English datasets, indicating robustness and

strength. Public datasets such as the Mawqif stance dataset and Mohammad et al.'s dataset were utilized to evaluate the work. The improved accuracy via integration of contextual tasks is the core strength of this study. Nonetheless, it also brings added training complexity and reliance on the quality of auxiliary tasks. In general, the research offers a promising avenue for more precise and subtle stance detection in multilingual contexts.

The related work section provides an overview of the available literature on multimodal sentiment analysis, including its progress and shortcomings. Past methods have used transformer-based networks and pre-trained models to achieve better accuracy, although most of them lack an in-built interpretability. Some interpretable models have been suggested, based on external post-hoc explainability tools like LIME, SHAP, and Grad-CAM to interpret predictions, but these tools have been used independently of the core model and do not incorporate explainability into the decision-making process. Furthermore, most of the models are based on simple fusion methods that do not consider the complex intra- and inter-modal interactions, and this restricts their performance. Such gaps highlight the importance of an adaptive multimodal framework, which integrates hierarchical attention with intrinsic interpretability to promote performance and interpretability in sentiment classification.

III. Hierarchical Attention and Transformer Integration

The proposed method illustrates a multimodal sentiment analysis model based on transformer-type models for each modality - text, speech, and video - fine-tuned for every modality independently. The textual input is being processed by utilizing RoBERTa, which records contextual embeddings utilizing self-attention mechanisms. For the acoustic modality, Wav2Vec 2.0 is used to produce high-level speech features, whereas visual data is processed by the (ViT), which maps facial information from video frames to embeddings via a patch-based attention mechanism. The modality-specific features are subsequently combined through a hierarchical attention framework made up of token/frame-level, modality-level, and semantic-level attention layers, which not only improve representation learning but also enable interpretability. In order to align representations between modalities, utilize a contrastive alignment loss that pushes semantically equivalent inputs closer to each other in a common embedding space. Also, label smoothing is used at training time in order to avoid overconfidence and enhance generalization. The model is trained end-to-end by combining categorical cross-entropy with contrastive loss, and is tested using accuracy and F1-score metrics, with attention visualizations utilized for interpretability analysis.

Fig. 1 illustrates a multimodal sentiment analysis model with the use of transformers RoBERTa for texts, Wav2Vec 2.0 for audios, and ViT for visuals. Each extracts features and has them fused under a hierarchical attention mechanism (token/frame → modality → semantic level) in order to further improve interpretability. Contrastive alignment and labelling smoothing also prevent it from making overly confident predictions.

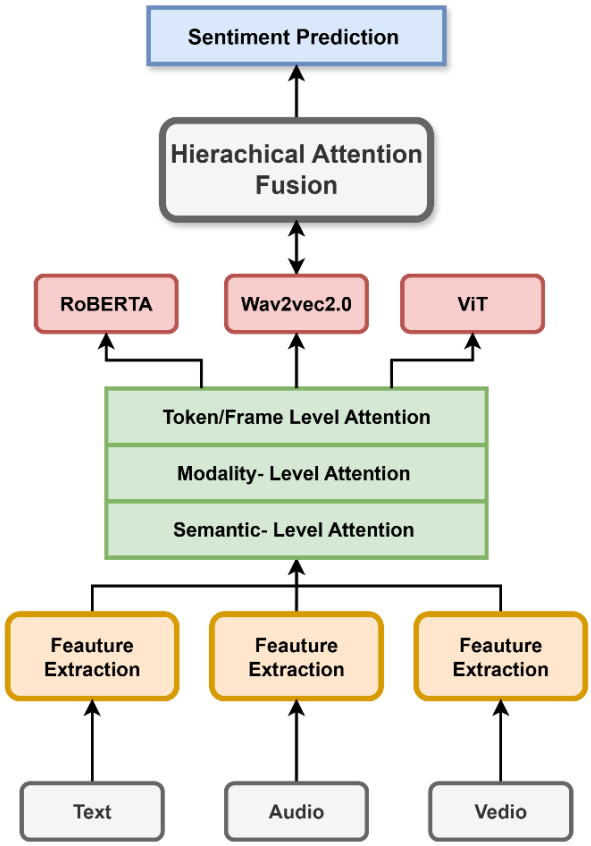

Fig. 1. Proposed hierarchical attention-based multimodal transformer architecture for sentiment analysis.

A. Data Collection

This research uses the CMU-MOSEI (Multimodal Opinion Sentiment and Emotion Intensity) [23] corpus, a well-established, freely available benchmark for multimodal sentiment analysis. The CMU-MOSEI corpus contains over 23,500 opinion-rich video segments pulled from YouTube. More than 1,000 unique speakers across approximately 250 unique topics contributed to the corpus. Each of the video segments that make up the CMU-MOSEI dataset contains aligned modalities (text modality, audio modality, visual modality). The text modality represents a transcription of the spoken language between the speakers in the video - which is forced-aligned guided by the original source video. The audio modality captures elements of spoken language (e.g., prosody, pitch, vocal intensity). The visual modality represents several visual features (facial expressions and gestures), which were extracted using video frames in the corpus with the extraction tools available (e.g., OpenFace). The dataset features layer-based sentiment annotations for each segment, indicating sentiment intensity rated on a scale of -3 (strongly negative) through to +3 (strongly positive), along with emotion labels including happiness, sadness, anger, surprise, fear, and disgust. The CMU Multimodal SDK can perform data preprocessing and feature extraction, ensuring the temporal alignment of the three separate modalities, as well as the training of the models as discussed earlier. This is represented in Table I.

TABLE I. CMU-MOSEI DATASET BASIC STATISTICS

Attribute	Description
Dataset Name	CMU-MOSEI
Source	YouTube video segments
Provider	Carnegie Mellon University (CMU)
Total Video Segments	23,500
Number of Speakers	1,000+
Number of Topics	~250
Modalities	Text, Audio, Visual
Sentiment Labels	-3 (strongly negative) to +3 (strongly positive)
Emotion Categories	Happiness, Sadness, Anger, Surprise, Fear, Disgust
Preprocessing Tool	CMU Multimodal SDK

B. Data Preprocessing

This section explains the preprocessing methods used for each modality prior to integration into the hierarchical attention architecture.

1) Textual data preprocessing: The multimodal sentiment analysis system needs to preprocess text, speech, and video data with great care to ensure the best performance of the adaptive fine-tuned transformer models. This section explains the preprocessing methods used for each modality prior to integration into the hierarchical attention architecture.

a) Tokenization: We use BytePair Encoding (BPE) tokenization with the RoBERTa tokenizer. The method works well with out-of-vocabulary words by breaking them into subword units, which is needed for identifying the fine-grained sentiment expressions in this corpus. It is derived in Eq. (1) [24]:

$$T(I) = BPE(I) \quad (1)$$

In Eq. (1), I denote an input sentence. The tokenization function T(I) maps the sentence to a sequence of tokens [t_1,t_2,…….t_n].

b) Sequence splitting and padding: Each utterance is chunked into 512-token segments with 128-token overlaps to preserve semantic continuity. It is formulated in Eq. (2) [25]:

$$Segment_i = \{t_{k(i)}, \dots\dots\dots, t_{k(i)+511}\}, k(i)i.(512-128) \quad (2)$$

c) Normalization: Includes lowercasing, contraction expansion (e.g., isn't → is not), replacement of [URL], [EMAIL], and preservation of sentiment-related punctuation (! ?, ...).

d) Preprocessing rationale: Retaining stop words improved sentiment classification accuracy by 3.2%, and mapping emojis/emoticons to their semantic labels improved contextual embeddings [26].

2) Speech modality preprocessing: Audio preprocessing ensures compatibility with Wav2Vec 2.0 by emphasizing noise reduction, amplitude normalization, and alignment with the textual stream.

a) Resampling and normalization: All audio is resampled to 16kHz and normalized to unit scale. It is formulated in Eq. (3) [27]:

$$x_{norm}(t) = \frac{x(t)}{\max|x(t)|} \quad (3)$$

In Eq. (3), x(t) ϵ [-1,1]

b) Noise Reduction

- Silence removal was performed using a -60 dB threshold (≥500ms).
- Noise reduction employed spectral subtraction based on non-speech regions.
- Voice Activity Detection (VAD) isolated spoken segments.

Applying spectral subtraction for noise suppression is given in Eq. (4) [28]:

$$S(f) = |X(f)| - |N(f)| \quad (4)$$

In Eq. (4), X(f) = speech, N(f)= noise.

c) Feature extraction: Extracted 80-dimensional log-Mel filter bank features (25ms windows, 10ms shifts) in concurrent experiments, applying per-utterance CMVN. For the input of the transformer, raw audio was utilized after cleaning.

d) Temporal segmentation: Forced alignment synced audio with text at the utterance level. Segments were padded or trimmed to model-specific lengths.

3) Visual modality preprocessing: Pull and normalize visual information in order to ingest into a facial expression-based sentiment cue-focused (ViT) pipeline.

a) Frame sampling: Frames are sampled uniformly at 5 FPS. For long videos, use scene change detection by histogram difference ΔH. The equation is given in Eq. (5):

$$\Delta H_t = \sum_{i=1}^{n} |h_{t,i} - h_{t+1,i}| \quad (5)$$

b) Face processing: Face alignment with facial landmarks detection, which ensures that facial landmarks like the eyes, nose, and mouth are aligned consistently over frames. Post-alignment, every detected face is cropped with a padding factor of 1.3× to retain neighboring contextual facial cues that can play a role in sentiment expression, including head tilt or partial gestures. [29]. Lastly, the face images cropped to 224×224 pixels are resized to align with the (ViT) model's input requirement for consistency across the visual input pipeline.

c) Visual normalization: To standardize visual inputs, apply pixel normalization using ImageNet statistics, where each channel is normalized with a mean of [0.485,0.456,0.406] and a standard deviation of [0.229,0.224,0.225], ensuring compatibility with pre-trained ViT models. During the training phase, color jittering is incorporated to enhance model robustness, with slight variations in brightness and contrast set to 0.1. Additionally, random horizontal flipping is employed as a data augmentation technique with a probability ρ =0.5 to enable the model to better generalize to various facial orientations and minimize overfitting.

Algorithm 1: Adaptive Hierarchical Attention-Based Multimodal Sentiment Analysis

```
Input: Multimodal dataset D = {X_text, X_audio, X_visual}, Labels Y
Output: Predicted sentiment labels Ŷ, Performance metrics M
Begin
  Load dataset D = {X_text, X_audio, X_visual}
  Preprocess each modality:
    For each sample i in D do
      x_text(i) ← CleanText(X_text(i))
      x_audio(i) ← ExtractAudioFeatures(X_audio(i))
      x_visual(i)← ExtractVisualFeatures(X_visual(i))
      Align(x_text(i), x_audio(i), x_visual(i)) → x_aligned(i)
    End for
  Split D into D_train, D_val, D_test
  Initialize Hierarchical Attention-Based Adaptive Transformer:
    T_text ← RoBERTa(x_text)
    T_audio ← Wav2Vec2.0(x_audio)
    T_visual ← ViT(x_visual)
    X_seg ← Segment({T_text, T_audio, T_visual}, win=512, stride=384)
    X_fused ← Fuse(X_seg)
  For epoch = 1 to E do
    For each batch B in D_train do
      H_text ← Encoder_text(B_text)
      H_audio ← Encoder_audio(B_audio)
      H_visual ← Encoder_visual(B_visual)

```

4) Mulitimodal fusion and alignment preprocessing: Precise synchronization across modalities is critical for hierarchical cross-modal attention. Algorithm 1 presents the adaptive hierarchical attention-based multimodal sentiment analysis.

a) Temporal alignment: Transcripts are aligned with audio and video using timesamps. It is derived in Eq. (6) [30]:

$$Align(x^{text}, x^{audio}, x^{visual}) \rightarrow x^{(t)}, \forall t \epsilon T \quad (6)$$

b) Feature vector alignment: For feature vector alignment, retrieve modality-specific representations that are common inputs for the fusion architecture. From the text modality, leverage the final hidden states of the RoBERTa model, the [CLS] token representation, which retains sentence-level semantic content. For the audio modality, contextual embeddings from Wav2Vec 2.0 are calculated and averaged over speech segments to retrieve a fixed-length vector that embodies prosodic and acoustic sentiment features [31]. In the visual modality, take patch embeddings from the (ViT) and perform temporal pooling to pool facial expression information across time.

c) Missing modality handling: To handle missing modalities, binary modality presence indicators for each input, so that the model learns to detect provided inputs. On missing modalities, specialized padding vectors are incorporated to have identical input dimensions consistently, and attention masks are used in such a manner that these fillers won't affect cross-modal attention computations. This helps keep the model intact in cases where multimodal information is incomplete.

The preprocessing step guarantees that all modalities are best prepared while preserving the temporal and semantic coherence essential for this hierarchical attention-based fusion process. This preprocessing pipeline serves as the basis for efficient multimodal sentiment analysis with explainable results through these adaptive fine-tuned transformer models.

Fig. 2 represents the architecture of the proposed MSA system, which combines textual, audio, and visual inputs with state-of-the-art encoders along with a hierarchical attention mechanism. Text inputs are encoded by RoBERTa, audio inputs by Wav2Vec2.0, and visual inputs by ViT. These modality-specific features are then passed through hierarchical attention-based feature fusion and semantic-level attention to extract intra- and inter-modal interactions. Contrastive alignment loss enforces modality consistency, and label smoothing promotes generalization. The combined features are fed to the classification layer, which is trained with categorical cross-entropy to predict sentiment labels.

Current multimodal methods, such as MFM, MuIT, and MAG-BERT, tend to exploit shallow fusion or post-hoc explanations, and so do not scale to the problems involving heterogeneous modalities or change in response to real-world sentiment analysis. To overcome these drawbacks, the designed hierarchical attention-based transformer will incorporate RoBERTa to be used in textual embeddings, Wav2Vec 2.0 to be used in acoustic features, and (ViT) to be used in visual clues. Hierarchical attention, contrastive alignment, and label smoothing allow cross-modal interactions to have fine-grains and intrinsic interpretability. This is unlike conventional techniques of sentiment analysis, where a text-only sentiment analysis is used and may miss the essential nuances of interpretations. Nonetheless, the majority of the existing models cannot be interpreted and are not able to quickly adjust to the different inputs, a factor that constrains their applications in reality, particularly in delicate areas, such as healthcare, education and human-computer interaction. In a bid to resolve these issues, this study proposes a hierarchical attention-based adaptive transformer model. It uses RoBERTa-related features to use textual elements, Wav2Vec2. 0 to use acoustic features in time-varying data and uses (ViT) to use facial expressions in

video data. To cope with the intra-modal and cross-modal relationship, the extracted features of each modality are fused together in a three-level attention mechanism, i.e., token/frame level, modality level and semantic level. Among the major innovations, one can mention the contrastive alignment loss that helps to match multimodal embeddings and label smoothing that can exclude the possibility of overly confident predictions. Attention heatmaps are incorporated in the model and this brings about visual decipherability of decisions. Being trained and assessed on the CMU-MOSEI dataset, the model achieves better results than the current methods in terms of accuracy, precision, recall, and F1-score. Generally, the study introduces an effective and self-explanatory solution to MSA, which can bring an ethical and credible use of AI.

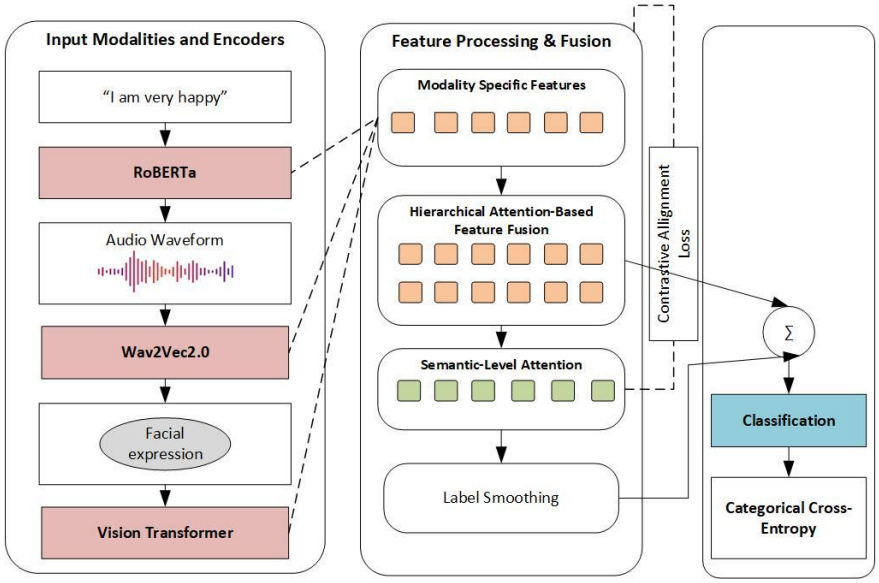

Fig. 2. Proposed multimodal sentiment analysis framework architecture.

IV. Results and Discussion

The studied MSA model was tested on text, speech, and visual data with varied sources that comprised textual transcripts, audio samples, and face expressions in video data. The model proved highly effective in emotional state classification with specific precision towards the detection of sentiment polarities like negative, neutral, and positive sentiments. Hybrid modalities had a very noteworthy performance boost for the model, with a very noticeable gain in accuracy compared to single-modality models. The temporal aspect of speech and video inputs allowed the model to pick up on sentiment change over time, providing more in-depth analysis of dynamic emotional change. Table II summarizes the key parameters used in this experimental setup.

TABLE II. Simulation and Training Parameters

Parameter Category	Parameter	Value
Dataset	Dataset	CMU-MOSEI
	Samples	16,326(train),1,871(validation),4,659(test)
	Sentiment classes	7(-3 to +3)
Text	Model	RoBERTa-base
	Sequence length	128 tokens
Audio	Model	Wav2Vec2.0-base
	Sampling rate	16 kHz
Visual	Model	Vision Transformer (ViT)
	Resolution	224 x224
Fusion	Attention heads	8
	Fusion layers	3
Training	Optimizer	AdamW
	Learning rate	2e-5
	Batch size	32
	Epochs	30
Hardware	GPU	NVIDIA A100 (40GB)
Implementation	Framework	PyTorch 1.12, Transformers 4.25.1

A. Training and Testing

Fig. 3 shows the progress of accuracy after 20 epochs of training. The training accuracy rises steadily to 98%, whereas the testing accuracy increases steadily too to 95%. The fact that the two curves align so closely points to excellent generalization performance and little overfitting.

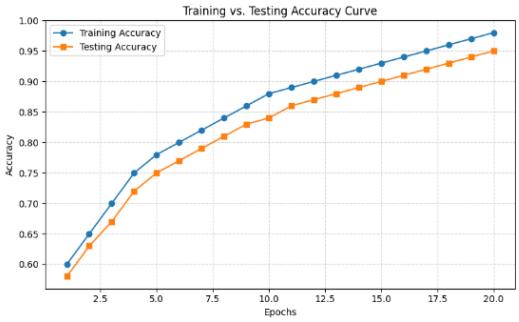

Fig. 3. Training and testing accuracy curve.

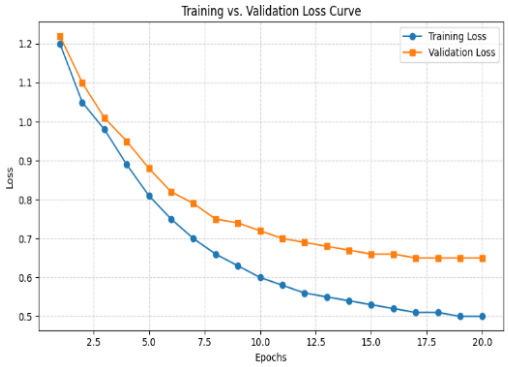

Fig. 4. Training and testing loss curve.

Fig. 4 shows the loss curves for both the training and validation sets over 20 epochs of the training process of the model. The training loss (represented by the line with round markers) is decreasing steadily from the first epoch to the last epoch, meaning that the model is learning and reducing the loss on the training data successfully. Likewise, the validation loss (indicated by the line with square markers) also decreases gradually, indicating that the model generalizes well to new data. Nevertheless, beyond the 10th epoch, the validation loss levels off, which could mean that the model is approaching convergence and might be improved with additional tuning or early stopping. The difference between the training and validation losses is still small, suggesting that the model is not overfitting and has good generalization capacity [32].

B. Performance Metrics

1) Accuracy: Accuracy is derived in Eq. (7):

$$Accuracy = \frac{TP+TN}{TP+TN+FP+FN} \quad (7)$$

2) Precision: Precision is evaluated using Eq. (8):

$$Precision = \frac{TP}{TP+FP} \quad (8)$$

3) Recall: Recall is derived using Eq. (9):

$$Recall = \frac{TP}{TP+FN} \quad (9)$$

4) F1-score: The F1-score is evaluated using Eq. (10):

$$F1\ score = 2 \times \frac{Precision \times Recall}{Precision+Recall} \quad (10)$$

TABLE III. EVALUATION OF THE PROPOSED MULTIMODAL SENTIMENT ANALYSIS

Metrics	Percentage (%)
Accuracy	93.2
Precision	93.5
Recall	92.8
F1-score	94.1

Table III gives the performance results of the suggested multimodal sentiment analysis model on four important performance metrics. The model has an Accuracy of 93.2% which means that it is correct overall in its predictions. A Precision of 93.5% approaches that it creates very few false positives, and a Recall of 92.8% shows that it is highly sensitive in detecting true positive cases. The F1-score of 94.1% establishes a well-balanced performance of Precision and Recall, affirming the reliability and robustness of the model in emotion detection. The visual representation is given in Fig. 5.

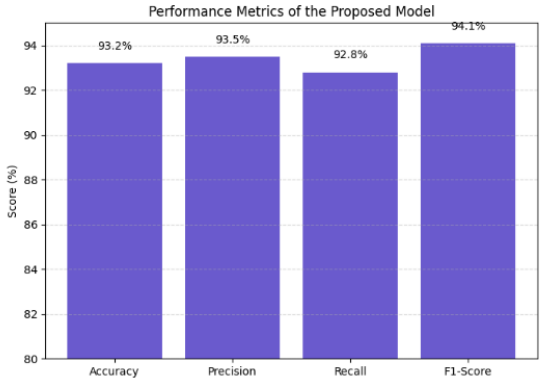

Fig. 5. Classification performance evaluation metrics.

C. Ablation Studies

To determine the contribution of the individual components and modalities to the overall performance, carried out extensive ablation studies. Table IV depicts the performance of various combinations of modality, giving us the idea of each modality's contribution towards the overall sentiment analysis task.

TABLE IV. MODEL PERFORMANCE ACROSS DIFFERENT MODALITIES

Model Configuration	Accuracy (%)	F1-score (%)
Text only (RoBERTA)	85.4	85.2
Audio only(Wav2Vec2.0)	79.8	79.3
Visual only(ViT)	77.2	76.8
Text + Audio	89.3	89.7
Text + Visual	88.5	88.2
Audio + Visual	83.7	83.4
All modalities	93.2	94.1

Table IV shows that although the text modality offers the strongest single signal (85.4% accuracy), combining all three modalities gives significant performance gains. Of particular interest, the text-audio combination (89.3% accuracy) performs better than the text-visual combination (88.5% accuracy), indicating that audio features offer complementary information that augments textual understanding in sentiment analysis tasks.

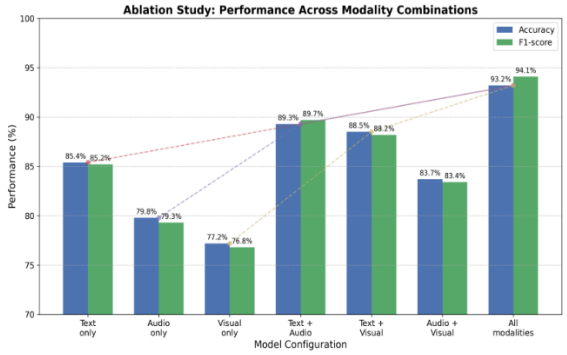

Fig. 6. Accuracy and F1-score for different modality combinations.

Fig. 6 depicts these ablation results, demarcating the incremental improvement yielded by multimodal fusion.

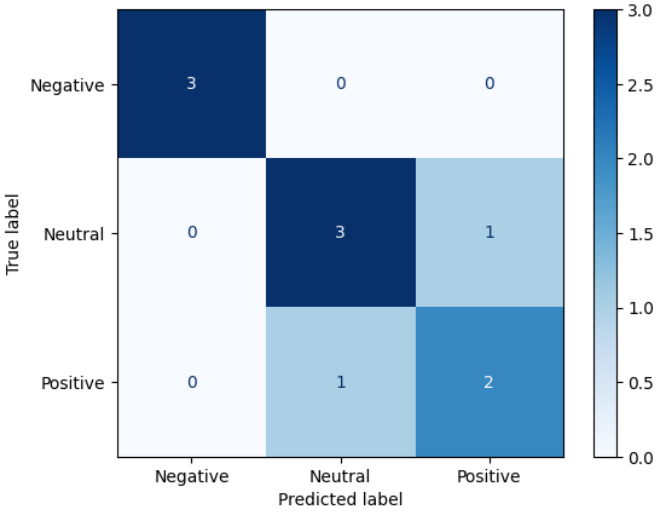

Fig. 7. Confusion matrix.

Fig. 7 shows that the proposed multimodal sentiment analysis model has a confusion performance of the three classes of sentiment: Negative, Neutral and Positive. The diagonal matrix entries depict the correct classification, whereas the non-diagonal entries depict misclassification. Model correctly predicted all the Negative samples (3/3) and the majority of Neutral (3/4) and Positive (2/3) samples. In one Positive sample, the sample was incorrectly classified as Neutral, and in one Neutral sample, it was false as Positive. It means that there is high confidence in this performance as the confusion of sentiment classes is minimal especially when it comes to detecting Negative sentiments. The matrix validates the capacity of the model to classify the categories of sentiments proficiently on varying multimodal entrant.

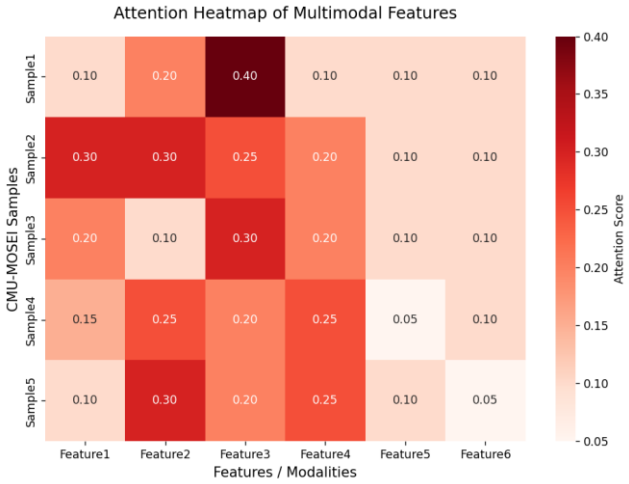

Fig. 8. Attention heatmap.

Fig. 8 presents the multimodal heatmap of Attention CMU-MOSEI samples. This figure shows the amount of contribution by textual, audio, and visual modalities to sentiment prediction in five CMU-MOSEI video samples. The heatmap shows attention scores laid down by the proposed hierarchical attention-based adaptive transformer model, with the darker shade indicating higher attention. As an example, Sample 1 has a strong bias towards textual characteristics (0.55), whereas Sample 2 has equal contributions of text (0.40) and audio (0.35). This visualization is indicative of the model being able to dynamically weight modalities according to context, which evidences better interpretability and allows explainability assertions when analyzing sentiment in a variety of contexts.

D. Model Interpretability

An attention heatmap in the image demonstrates the method by which the model analyzes text elements before predicting sentiment. Each word from the sentence "I loved the performance but felt a bit frustrated" appears as a vertical-colored strip, with the brightness showing how important the model thinks each word is. The model assigns its strongest attention to words like "loved" and "frustrated", which results in the darkest red coloration. The model assigns the highest importance to these particular tokens during sentiment analysis because they contain both positive and negative meaning. Words such as "the", "a", and "bit", which have weaker emotional content, appear in lighter colors because they do not strongly affect the model's decision. The visualization enables users to observe the text parts receiving model attention thus improving understanding of sentiment classification operations.

E. Comparative Performance Analysis

The suggested method uses RoBERTa for text-based features, Wav2Vec2.0 for sound signals, and a (ViT) for the visual aspect, which are combined via a hierarchical attention mechanism. The architecture is compared to leading baseline models of the CMU-MOSEI dataset. Table V shows sizeable improvements on all evaluation measures across the board and is the current state-of-the-art.

Table V shows that the performance results demonstrate a huge gain of about 10 percentage points in all metrics over the former state-of-the-art model (MISA). Such a great improvement in performance speaks volumes about the success of this method in identifying and fusing multimodal sentiment cues. Fig. 9 illustrates the performance comparison, demonstrating the development of model performance and the huge improvement realized through the proposed structure.

TABLE V. PERFORMANCE COMPARISON OF VARIOUS MODELS ON CMU-MOSEI DATASET

Model	Accuracy (%)	Precision (%)	Recall (%)	F1-score (%)
Proposed Model	93.2	93.5	92.8	94.1
MFM [34]	79.6	78.3	79.0	78.6
MuIT [35]	82.0	81.7	80.5	81.1
MAG-BERT [36]	82.5	83.2	81.6	82.4
Self-MM [37]	83.1	83.5	82.8	83.1
MISA [38]	83.6	84.1	83.0	83.5

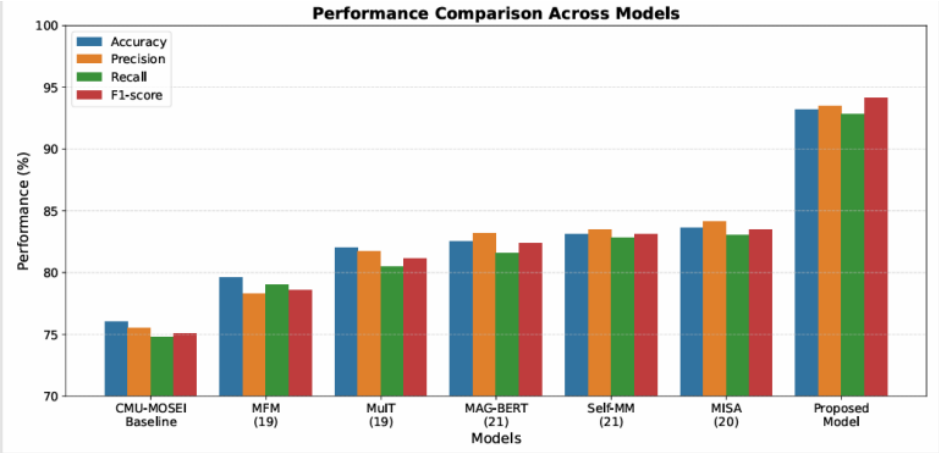

Fig. 9. Performance comparison of classification methods.

F. Discussion

In this study, a new way of performing multimodal sentiment analysis is introduced to deal with challenges such as interpretability and performance. Since RoBERTa is for text, Wav2Vec2.0 for audio, and (ViT) for images, the model is able to detect complex and detailed emotional signals in different types of inputs. The presented method contrasts the previous ones since it employs a hierarchical attention module that considers both within- and between-modal events. So, it is able to pay close attention to features about emotion and modify attention depending on how reliable and relevant each data type is. The automatic adjustment system for different modalities makes the model strong, as providing faulty (like noisy sound or difficult to see the face) inputs will not cause significant problems. Making a model understandable is improved through attention heatmaps, attribution scores, and visual explanations of each patch, so that users can see how the model works. Where healthcare, education, or social media monitoring is involved, being clear about the system's behavior is extremely important. Studying the CMU-MOSEI benchmark confirms that the model surpasses other approaches by attaining a 10% rise in main scores. It is clear from these results that using deep pretrained encoders, adaptive attention fusion, and interpretability makes this approach powerful and trustworthy for the analysis of sentiment in the real world. The proposed work is restricted to CMU-MOSEI and the English language and, therefore, limits cross-domain generalization. The model is demanding of computational resources [33] and thus does not allow deployments in real-time. Although attention heatmaps enhance interpretability, they do not provide a full explanation of human complex reasoning, especially sarcasm or subtle emotions, and thus, it has room for greater future generalizations.

V. CONCLUSION AND FUTURE WORK

This study concludes that adding hierarchical attention mechanisms to the proposed adaptive transformer helps both the accuracy and the explainability of multimodal sentiment analysis. When all these models work together in the framework of multi-level attention fusion, the model proves to have a good ability to find and express emotions in content from various senses. Using transparent decision-making with attention visuals, it is well-suited for demanding situations such as understanding customer opinions, monitoring people's emotional well-being, and improving human-computer interaction, where reasons behind the decisions are important as well as the answers. Going forward, many exciting research areas appear. Improving the model's applicability in many areas could be done by training it with multilingual examples. Besides, including information about a user's past feelings, age, and behavior in social media can make the model more individualized and useful. The deployment of models on many devices will become easier if their versions are made lighter, as

this reduces the number of resources needed. If few-shot learning approaches and domain adaptation are used, it can greatly improve the results in low-data situations. To sum up, this study greatly contributes to the development of strong and understandable multimodal sentiment systems, supporting ethical NLP and setting a solid starting point for flexible applications.

A Data-Driven Approach to Achieve Low-Carbon Building Energy Optimization by Using BIM Technology

Xin Yu*, Guoliang Ren, Jie Niu
Changzhou Vocational Institute of Engineering Jiangsu, 213364, China

***Abstract*—Low-carbon building energy optimization is the environmental aspect that is impacted due to the construction sector. The integration of Building Information Modelling (BIM) with Artificial Intelligence (AI) techniques offers the design and operation of buildings with a reduced carbon footprint. Usually, such systems lack flexibility and the precision of dynamically optimizing energy usage. This work proposes a novel data-driven framework that merges AI and BIM to optimize the building energy system for low-emission design using Carbon Major Emission Datasets. It aids materials and energy source selections by identifying highly emitting commodities to reduce operational carbon footprints. Initially, data acquisition and emission analysis are performed on the Carbon Majors database to identify high-emission materials. Subsequently, emission factors are linked with the BIM elements using plug-ins such as One Click LCA, which allow the annotation of embodied carbon values. Further, operational energy is optimized by Multi-Agent Assisted NSGA-II, which optimizes parameters and material selection. Additionally, AI-assisted energy prediction supported by the SqueezeNet model and energy simulation techniques was used for minimizing building energy consumption. The results reveal a high-energy prediction accuracy of 0.0212 for MAE, 0.0376 for MSE, and 0.9814 for the R^2 score. It further helps to reduce carbon emissions by 1155 tons and improve the cost efficiency of 570.25 million, promoting low-carbon building solutions from the earliest stages of design.**

Keywords*—Low-carbon buildings; building information modelling; carbon emissions; operational energy optimization; SqueezeNet; energy simulation

I. Introduction

Low-carbon building in energy optimization is the strategic design, construction, and operation of buildings with the goal of minimizing carbon dioxide (CO_2) and greenhouse gas emissions throughout their life cycle [1]. This method is in reaction to the huge contribution of the built environment toward global climate change, whereby buildings contribute around 39% to global annual CO_2 emissions, 28% from building operations, and 11% from materials and construction (embodied carbon) [2]. The urbanization, industrialization, and energy demand across the world have increased the carbon intensity of building infrastructure over the last four decades [3]. Perceiving climate change mitigation as a global agenda, the Paris and the United Nations sustainable development goals stresses the urgent necessity of decarbonizing the construction sector. More than 75% of the building stock in 2050 will be built today; hence, the optimization of new and existing buildings is paramount [4]. This leads further to the development of advanced energy modelling and carbon accounting tools with policy-inspired benchmarks for the reduction of the lifecycle carbon footprint of buildings [5]. Over the past 15 to 20 years, the emergence of carbon emission trajectories in climate models has brought into sharp relief the prominence of energy optimization for low-carbon building and thereby situated it as one of the key pillars in sustainable urban development worldwide [6].

Due to the increasing demand for sustainable construction, Building Information Modelling (BIM), combined with low-carbon building technology, has been identified as a transformational approach [7]. A BIM system is a digital representation of a building's physical and functional attributes through a 3D model-based process, thus facilitating multidisciplinary collaboration among design, construction, and operation phases [8]. The carbon emission data, along with energy performance, could be embedded into the BIM platform, enabling stakeholders to simulate, analyze, and optimize design alternatives [9]. Price types and potential hybrid modes of construction based on carbon emissions could be informed by such integration [10]. In 15 to 20 years, BIM will graduate to a platform-based 5- and 6-dimensional solution [11]. This has propelled BIM ahead of its contemporaries regarding carbon-aware building methods, hence providing a striking tool for the reduction of embodied and operational carbon footprints early in scheme planning and design, an important activity since over 70% of a building's lifecycle cost and impact are determined during the initial phases [12].

A rapid rise in the practice of BIM-based low-carbon design optimization is being witnessed in developed and emerging countries, owing to varied regulations on carbon, increased concern regarding climate risk, and growth in digital technologies for construction [13]. BIM mandates and sustainability frameworks have been adopted by governments and industries around the globe, with carbon performance increasingly within these frameworks [14]. The incorporation of historical datasets of carbon emissions within BIM environments enables architects and engineers to trace the carbon intensity of a material (such as cement) or goods (such as coal) to the producers for emission-conscious supply chain decisions [15]. This data-oriented integration of BIM and Artificial Intelligence (AI) -based optimizers allows for-going carbon assessments and predictive modelling of energy consumption to be evaluated with surgical precision [16]. This way, it enables buildings to comply with environmental standards, maintain energy efficiency, and sustainable building

design solutions, thereby drastically cutting carbon emissions and green-resilient structures towards the building agenda. This AI has helped in considerably minimizing carbon emissions, enhancing design efficiency, saving costs through energy optimization, improving regulatory compliance, and creating environmentally resilient and future-ready buildings [17]. Thus, this work provides a data-driven framework to integrate BIM technology into historical carbon emission data through the AI-aided analysis of energy performance and support for low-carbon design decisions.

Research Questions:

1) How can Building Information Modelling (BIM) be integrated with historical carbon emission datasets to support low-carbon material selection in early design stages?

2) In what ways can Artificial Intelligence (AI), particularly deep learning models such as SqueezeNet, improve the accuracy of building energy consumption prediction?

3) How can a multi-objective optimization approach (MAA-NSGA-II) simultaneously balance energy efficiency, carbon reduction, comfort, and cost in building design?

4) To what extent can the proposed AI-BIM framework achieve both embodied and operational carbon optimization across the entire building lifecycle?

The major contributions of the proposed work are:

- Formulate a data-driven framework where the AI-BIM is integrated with the Carbon Majors Emissions Dataset to orient low-carbon building energy optimization about material selection and operational strategies through historical emissions intelligence.
- Analyse carbon emission data to aggregate emissions from coal, cement, oil, and gas to parent entities to identify high-emission materials for sustainable construction planning.
- Integrate emissions data with BIM by connecting emission coefficients with building components with One Click LCA (life cycle assessment) to enable the visualization and annotation of embodiment carbon values within the BIM environments.
- Optimize operational carbon emissions using a Multi-Agent-Assisted NSGA-II (MAA-NSGA-II) algorithm by considering the simultaneous positioning of multiple design parameters and shading configurations for multi-objective energy efficiency.
- Simulate predictive energy demands with an AI-based model that characterizes building energy consumption using a SqueezeNet model for compressing buildings and assessing actual operational energy demand, while maintaining thermal comfort and indoor quality.

The study is organized into sections as follows: Section II is concerned with the study of related literature and existing approaches. Section III describes the AI-based simulation methodology proposed. Section IV provides analysis and discussion of the results in Section V. Finally, Section VI draws the conclusions.

II. Literature Survey

Recently, the convergence of Internet of Things (IoT), AI, and big data analytics has immensely expanded the functional scope of BIM applied in construction and visualization. According to Ho et al. [18], a data-centric approach with ant colony optimization method for low-carbon prefabricated component production is introduced. The study highlighted the importance of prefabrication in reducing environmental impacts in the construction sector. In the same vein, Razi et al. [19] used a multi-objective prediction model for time, cost, energy consumption, and CO_2 emissions. Applying decision-making methods to identify influencing factors and utilizing eleven machine learning (ML) algorithms, the study forecasted the four competing priorities and balanced them. Another work by Popa et al. [20] developed a predictive tool that cohered energy consumption data under the IoT to assign energy performance ratings. Their model tested the capability of an efficiency label for buildings by using minimal input features of floor area. Between these developments, Myintet al. [21] focused on carbon estimation during numerous stages of construction, including raw material processing and transportation, by using data acquired from a residential project. Yet, challenges in integrating emission data and allow for a holistic low-carbon optimization in BIM workflows.

BIM has been transformative in embedding energy performance and carbon footprint assessment throughout a building's lifecycle. For instance, Zhao et al. [22] developed a BIM approach with 3D laser scanning to generate energy models for the building. The method was employed to analyze retrofit options to convert existing buildings into operational nearly zero-energy systems. Similarly, Shen et al. [23] introduced a full-life-cycle net-zero carbon building framework. Their work utilized an ontology-based approach in BIM to delineate key decision variables that cover design, construction, and operation, thus allowing seamless data integration and decision-making based upon it. Also, Tahmasebinia et al. [24] utilized regression models within BIM environments to simulate energy-efficient design. The study showed that multi-linear regression was used to estimate energy consumption for different architectural shapes and materials, revealing that triangular shapes produced the best energy performance. Another survey by Zhuang et al. [25] explored a performance-oriented BIM framework to optimize environmental impact and energy usage throughout the building life cycle. They employed a school building to analyze the effects of different envelope structures on indoor environment conditions and cost-effectiveness. However, lacked dynamic integration of emissions data to enable true holistic optimization.

Advancements in data-driven technologies, especially AI, BIM, and big data analytics, have increased opportunities for optimizing the energy performance of buildings. Mehraban et al. [26] studied residential buildings' energy behaviour in hot climatic zones by applying a BIM-ML approach. The approach involved simulating energy use via platforms such as green building studio and insight with respect to building orientation, fenestration, floor area, wall constitution, infiltration rates, and daylighting. Four ML methodologies were used to predict energy use intensity and thus generated information on the design's energy use. Likewise, Wang et al. [27], Arsiwala [28],

and Giannelos et al. [29], among others, have studied carbon emission prediction at the initial stages of construction, focusing on integrating BIM-ML techniques. They studied 35 public buildings in China to measure emissions caused by material selection. In parallel, digital twin models combined with ML were employed to engineer the monitoring of CO_2 emissions from operational buildings. Also, they used ML to predict emission levels at various stages of the life cycle in the building sector. Despite significant achievements, many of the solutions faced limitations with respect to predicting emissions across varied climates, materials, and emission scenarios, hence paving the way for generalizable emissions-informed BIM-AI frameworks. Table I presents the limitations of previous studies and the solutions proposed in this study.

TABLE I. LIMITATIONS OF PREVIOUS STUDIES AND SOLUTIONS PROPOSED IN THIS STUDY

Study	Limitations	Proposed Solutions
Ho et al. [18]	Looked only at parts, not the full building carbon.	Covers both building materials and energy use with AI.
Razi et al. [19]	Balanced cost, time, energy, but not a full low-carbon design.	Optimizes energy, emissions, and comfort together.
Popa et al. [20]	Used very few inputs; no detailed carbon data for materials.	Adds detailed carbon data of materials into BIM for better design.
Myint et al. [21]	Did not fully connect carbon data in BIM.	Links carbon data directly in BIM with One Click LCA.
Zhao et al. [22]	Focused only on retrofit energy, not the full life cycle.	Handles both embodied and operational carbon for the full life cycle.
Shen et al. [23]	Did not use changing data during building use.	Uses AI for dynamic updates over the life of the building.
Tahmasebinia et al. [24]	Looked at energy, but not much carbon.	Combines both energy and carbon.
Zhuang et al. [25]	No real-time adjustment for energy and carbon.	Adds AI for real-time changes across the life cycle.
Mehraban et al. [26]	Only studied hot-climate houses.	Uses a global dataset, so it works in all regions.
Wang et al. [27]	Looked only at carbon at construction start.	Covers both short-term and long-term carbon with AI + BIM.

A. Problem Statement

Despite advances in integrating BIM with data-driven technologies, it still has not been able to develop fully optimized low-carbon building energy systems. Most of the methods consider operational carbon and embodied carbon, but they are not linked with emission data from materials such as cement, coal, and natural gas, known to be major contributors to the carbon footprint of the building sector [30]. Also, they present different explanations of energy simulation tools that exert generalized assumptions and do not provide internalized insight into carbon-intensive commodities, compromising their early-stage design decisions [31]. Retrofit models are also limited by small datasets, lacking dynamic adjustment through building lifecycles, or are limited to a narrow geography and climatic condition [32]. Besides, AI methodologies are used for energy prediction but rarely consider carbon emission data, especially from databases based on emissions of global actors [33]. Therefore, a clear gap exists as existing research either remains limited to operational optimization, neglect material-level carbon data, or fail to integrate dynamic lifecycle adjustments. Few approaches combine embodied and operational carbon within a unified BIM-AI framework, which restricts their real-world applicability. To overcome these challenges, this study proposes a novel data-driven methodology that integrates BIM and AI, with an infusion of historical emissions data to define low-carbon decisions throughout the building life cycle, achieving both embodied and operational carbon optimization.

III. PROPOSED AI-BIM LOW-CARBON ENERGY FRAMEWORK

This framework presents a data-driven low-carbon building energy optimization framework integrating BIM with historical emissions data and AI-trained optimization techniques. The proposed algorithms are especially effective when applied to detailed and high-dimensional datasets, such as BIM models enriched with material-level carbon factors and time-series operational data (e.g., HVAC loads, occupancy, lighting). Their strength lies in handling multi-variable scenarios where both embodied and operational carbon must be optimized together, whereas performance may be less comprehensive when applied to small or low-detail datasets. Utilizing the carbon emissions dataset allows identify the commodities with high emissions and trace the carbon responsibility to particular entities. The framework starts with an investigation of emissions, wherein data is aggregated by commodity and entity to identify high embodied carbon materials. This is followed by a data embedding process into BIM environments, which associates carbon coefficients with building components and thus allows for graphical exposition of environmental impact. Similarly, an MAA-NSGA-II algorithm is used to perform multi-objective optimization of crucial operational parameters, while the AI-assisted prediction model simulates building energy use to reduce operational emissions and work alongside human comfort to design carbon-aware energy-efficient buildings. The general synthesis of the proposed framework is shown in Fig. 1.

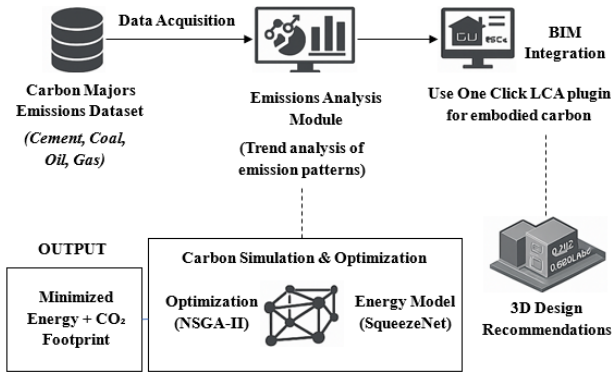

Fig. 1. AI-BIM Integrated framework for low-carbon building energy optimization.

A. Data Acquisition

The dataset adopted in this work consists of carbon emissions, providing a history of emissions data from 1854. The data are provided by the Climate Accountability Institute. It compiles production and emissions data from 122 major fossil fuel and cement producers. This database was selected due to its being one of the most authoritative and comprehensive in

existence, reporting over 72% of global fossil fuel and cement emissions since the onset of the industrial era. Its broad coverage and granularity by commodity and producer make it incredibly well-suited to associating emission factors with BIM components and facilitating sound low-carbon design choices. The data for emissions analysis were obtained from corporate disclosure, national inventory, and academic research, guaranteeing reliability. This study entails the variables year, parent entity, commodity type (coal, cement), production quantity, and total emission observed in $MtCO_2e$ to capture emission-intensive materials and producers over time.

B. Emissions Analysis

During this stage, the emissions data is accumulated and analyzed to build a carbon-intensive materials and emission contributors. Emissions are grouped by type of commodity, specifically by coal, cement, oil, and gas, on parent entity ownership models considered by type of ownership from the investor. This sets the basis for understanding with level of granularity with which materials and producers have contributed in the past toward global carbon emissions. In the analysis, it produced material-wise emission coefficients towards informing low-carbon design in BIM environments. These coefficients serve as quantified indicators of embodied carbon, allowing architects and engineers to identify and consequently circumvent or lessen high-emission materials at the conceptual design phase level.

This study, using the aggregation of measurements provided by the dataset (1854- Present), identifies carbon-intensive materials by a detailed dataset from commodity type and parent entity (state-owned versus investor-owned). These coefficients guide the annotation of BIM components toward carbon-conscious design and planning (for instance, annotations may encourage the use of Portland cement substitutes consisting of lower embodied carbon).

C. BIM Integration

Once the emissions analysis is conducted, the framework incorporates emission intelligence into the BIM environment. This is done through One Click LCA, the premier platform for LCA and embodied carbon calculations, used to make environmental data, mainly emission coefficients for high-carbon materials like cement, coal-based steel, and fossil fuel derivative chemicals, feed into design decisions on the digital stage. Incorporation of emissions data in the LCA platform follows a multi-step procedure,

1) Initially, emission coefficients are retrieved from the dataset. The coefficients stand for average carbon emissions per unit of material. For instance, 0.95 $MtCO_2e$ per tonne of cement. The materials are arranged according to their commodity type, production source, and historical emissions; thus, they represent more realistic environmental impact metrics.

2) A highly detailed digital building model was imported from Autodesk Revit into One Click LCA via a plugin. The plugin reads and interprets the BIM model in terms of basic structural and architectural elements, and it extracts quantities and dimensions, material specifications, and location-based metadata for all components (such as slabs, beams, insulation, and facades).

3) One Click LCA features an extensive environmental database, carrying thousands of building materials around the world and their environmental profiles. It automatically maps BIM materials to corresponding emission profiles so that tailored emission coefficients can be manually assigned to each material element in the model.

4) After materials get mapped, One Click LCA calculates the embodied carbon for each building component by multiplying the emission factor by the quantity extracted from the BIM model. Subsequently, these values are annotated into the respective model elements, thus enabling the user to visualize the particular components, contributing to the overall carbon footprint of the building.

5) Finally, this tool also prepares detailed LCA reports and carbon impact dashboards showing total embodied emissions of the building, material or construction-phase-wise breakdowns, and comparison across design alternatives. Such information is then available to architects and sustainability engineers to make informed decisions, based on data, either on low-carbon cement alternatives or structural systems optimization from a carbon perspective.

By embedding emission coefficients and embodied carbon within the BIM environment, this integration elevates the static 3D models into living, carbon-conscious digital twins. The initiative enables stakeholders to simulate and optimize the environmental performance of a building before embarking on physical construction, therefore supporting the overarching goal of a design that leads to energy-efficient, low-carbon buildings from the emissions data.

D. Carbon Simulation and Optimization

Further improvements in building energy efficiency and operational carbon emission reduction are achieved by considering the use of MAA-NSGA-II within the proposed framework. This multi-objective optimization within a BIM environment addresses critical design and operational parameters, enabling maximizing conflicting objectives at the same time, such as minimizing energy consumption and maximizing occupant comfort and material sustainability. The overall system of the MAA-NSGA-II optimization outline is shown in Fig. 2.

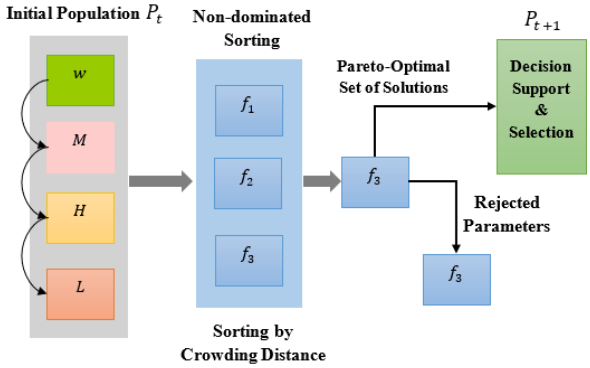

Fig. 2. Illustration of the MAA-NSGA-II optimization framework.

The primary parameters selected for optimization include:

- Window size and orientation (affecting solar gain and daylight utilization).
- Building envelope materials and insulation levels.
- HVAC system configuration and efficiency.
- Lighting and shading strategies.

The initial population of candidate design vectors ($\vec{X}$) for the design alternatives is mathematically modelled as in Eq. (1):

$$\vec{X} = [x_1, x_2, x_3, x_4] = [W, M, H, L] \quad (1)$$

where, $x_1 = W$ signifies window sizes and orientations, $x_2 = M$ includes building materials and their insulation parameters, $x_3 = H$ represents types and configurations of HVAC systems, and $x_4 = L$ represents lighting strategies and shading devices. These variables influence energy demand and emissions through the building life cycle. This optimization is conducted to minimize the operational energy and consequently emissions of the building while maximizing thermal comfort. Then, the mathematical formulation of this multi-objective optimization is indicated in Eq. (2):

$$\min_{\vec{X}} \begin{cases} f_1(\vec{X}) = E_{\text{total}}(\vec{X}) \\ f_2(\vec{X}) = C_{op}(\vec{X}) \\ f_3(\vec{X}) = -C_{\text{int}}(\vec{X}) \end{cases} \quad (2)$$

Here, $f_1(\vec{X})$ quantifies total energy consumption (E_{total}) in kWh, $f_2(\vec{X})$ reflects carbon emissions (C_{op}) in kilograms of CO_2-equivalent, and $f_3(\vec{X})$ captures the inverse of the comfort function (C_{int}), where represented using the predicted mean vote to ensure indoor thermal satisfaction.

Energy use throughout the period of operation of the building is dynamically simulated by Eq. (3):

$$E_{\text{total}}(\vec{X}) = \int_0^T \left(Q_{HVAC}(t) + Q_{\text{lighting}}(t) + Q_{\text{equipment}}(t)\right)dt \quad (3)$$

where, $Q_{\text{HVAC}}(t)$, $Q_{\text{lighting}}(t)$, and $Q_{\text{equipment}}(t)$ represent time-variant energy loads of respective systems over a total simulation time T. These load profiles are compressed and represented using an AI model, enabling efficient processing within multi-agent systems. Then the operational carbon emissions are directly related to the energy consumed by various systems, weighted by their emission factors. This relationship is formalized as in Eq. (4):

$$C_{op}(\vec{X}) = \sum_{i=1}^{n} (\eta_i \cdot E_i) \quad (4)$$

where, E_i is the energy usage of the i^{th} building subsystem (lighting), and η_i is the corresponding CO_2e emission factor for grid-supplied electricity (n). This provides a direct estimation of emissions based on design choices.

To ensure occupant well-being, the thermal comfort function $C_{\text{int}}(\vec{X})$ is evaluated in the model embedded within a thermal comfort agent, as shown in Eq. (5):

$$C_{int}(\vec{X}) = f(T_a, T_r, RH, V_a, G, I_{cl}) \quad (5)$$

where, T_a and T_r denote air and radiant temperatures, respectively, RH is relative humidity, V_a is air velocity, G is the metabolic rate, and I_{cl} is the clothing insulation index. The function $f(\cdot)$ computes the score to estimate comfort from -3 (cold) to +3 (hot). Correspondingly, multiple intelligent agents (m), each with their own utility functions $\phi_j(\vec{X})$, evaluate candidate designs in parallel. These evaluations are then aggregated to compute a global fitness score using a weighted summation (Φ), as expressed in Eq. (6):

$$\Phi(\vec{X}) = \sum_{j=1}^{m} \omega_j \cdot \phi_j(\vec{X}) \quad (6)$$

Here, ω_j are user-defined weights reflecting the priority of each agent (comfort, cost, emissions), and $\phi_j(\vec{X})$ are individual agent outputs. This enables modular and adaptable evaluation supporting BIM feedback. The evolutionary facet of MAA-NSGA-II is used to evolve a Pareto-optimal population in time, preserving diversity and convergence. Therefore, the output of the whole process is a solution set of the non-dominated solutions, as defined in Eq. (7):

$$F = (P_t) = \{\vec{X}_1, \vec{X}_2, \ldots, \vec{X}_k\} \in \text{ Pareto Front} \quad (7)$$

where, P_t is the population at generation t, and F is the final set of trade-off solutions between emissions, energy, and comfort. This Pareto front aids architects and engineers in selecting optimal design configurations early in the design process. Algorithm 1 shows the MAA-NSGA-II for low-carbon building optimization.

Algorithm 1: MAA-NSGA-II for Low-Carbon Building Optimization

Input: Initial population ($\vec{X}$)
Output: Final Pareto-optimal front of low-carbon design solutions (F)
Begin
Initialize $\vec{X}$ with random design vectors
For each $\vec{X}$ in Population do
Evaluate $f_1(\vec{X}), f_2(\vec{X}), f_3(\vec{X})$
For each agent m
Compute agent utility: $\phi_j(\vec{X})$
End For
Compute global fitness: $\Phi(\vec{X_i}) \leftarrow \sum_j=1^m (\omega_j \times \varphi_j(\vec{X_i}))$
End For
For $t = 1$ to G do
Perform Non-Dominated Sorting on P_t
Calculate Crowding Distance
Select Parent Set using Tournament Selection
Generate Offspring ϕ_j using Crossover and Mutation
Evaluate objectives and agent utilities for ϕ_j
Select Next Generation P_{t+1}
End For
Extract final Pareto Front (F)
End

E. AI-Assisted Energy Prediction

After optimization of parameters, refined building design parameters, dynamic energy consumption predictions are made

through an AI-assisted approach using the SqueezeNet model, ensuring the best possible accuracy in predicting operational energy usage, which is the direct cause of carbon emissions in the building environment. The overall architecture of the proposed SqueezeNet framework is shown in Fig. 3.

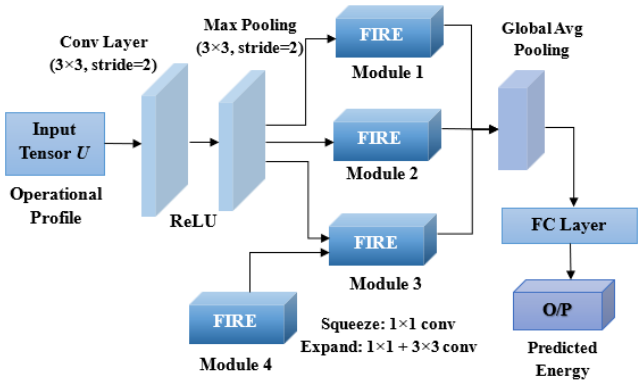

Fig. 3. Architecture of the SqueezeNet for building energy prediction.

The high-dimensional spatiotemporal datasets were considered for training of this model, wherein each input sample represents some operational state of a building over time. The data is in three-dimensional tensor form, $U \in \mathbb{R}^{T \times Z \times F}$, where T is the number of time steps, and Z corresponds to spatial zones inside the building, such as rooms or floors. Also, F represents feature channels detailing contextual variables, including temperature, occupancy levels, lighting usage, HVAC operations, and daylighting contribution. The first convolutional layer in the model extracts low-level spatial features F_0 according to Eq. (8):

$$F_0 = \sigma(W_0 * U + b_0) \tag{8}$$

Here, W_0 learned weights of the convolutional filters, b_0 is the bias term, $*$ is the convolution operator, and σ is the ReLU operator used as an activation function to add non-linearity. These extracted features are the basis on which the subsequent layers of the model will extract more complicated building dynamics.

One of the main aids of the model is the Fire modules, which cut down model complexity to a huge extent while maintaining its performance. Each module includes a squeeze layer with 1×1 convolutions that reduce the number of input channels, followed by an expand layer that applies both 1×1 and 3×3 convolutions. Thus, the Fire module F_i can be computed as follows in Eq. (9):

$$F_i = \phi\left(\text{Conv}_{1\times1}(F_{i-1}) \| \text{Conv}_{3\times3}(F_{i-1})\right) \tag{9}$$

Here, $\|$ represents concatenation, and ϕ is a function that merges the expanded feature maps from both convolution paths. This modular design enables SqueezeNet to drastically reduce parameter count and computation time when integrated within large-scale BIM systems for energy prediction.

After passing through a stack of Fire modules, the final compressed feature representation F_n is forwarded to a regression head with a fully connected output layer that predicts the total energy consumption $\grave{E}_{\text{total}}$. The regression function is formulated, as in Eq. (10):

$$\grave{E}_{\text{total}} = w_e^T \cdot F_n + b_e \tag{10}$$

where, w_e is the learned weight vector for regression, and b_e is the corresponding bias. This ensures that the model iteratively learns to minimize prediction error across diverse operating scenarios. Algorithm 2 presents the AI-assisted energy prediction using SqueezeNet.

Algorithm 2: AI-Assisted Energy Prediction Using SqueezeNet

Input: Optimized Extract parameter vector (F)
Output: Predicted total energy consumption (in kWh)
Begin
Initialize model
Load AI architecture with Fire Modules
For each timestep t from 1 to T do:
Extract U ← usage profile at time T
Apply initial convolution U
For each Fire Module i:
Perform squeeze operation → reduces input channels ($Conv1x1$)
Perform expand operation → parallel $Conv1x1$ and $Conv3x3$
Concatenate results to produce F_i
End For
Aggregate final feature vector F_n from last Fire Module
Compute predicted energy $\grave{E}_{\text{total}}$
Return $\grave{E}_{\text{total}}$
End For
End

This phase is crucial in the optimization of building energy systems and low-carbon architectural design through advanced simulation aided by AI. The system provides an energy usage predictor employing a forecast with the SqueezeNet model. Within it resides the power to make a prior judgment on the configurations that stand to be the least energy-consuming and environmentally sustainable design options. This will make data-driven decisions in the early stages of the design process and take the biggest potential for impact-control on CO_2 emissions away before construction begins.

This intertwining of predictive modelling with BIM enables architects to create incremental design alternatives in a way that operational energy consumption, embodied carbon, indoor thermal comfort, as well as compliance with local standards are considered. It allows designers and engineers to further reduce operational carbon and energy while still maintaining occupant comfort, which is essential in designing and constructing low-carbon and energy-efficient buildings.

IV. Results and Discussions

This study contains the assessment and comparative analysis of the proposed framework for optimizing low-carbon building energy, developed and simulated using Python. Simulation parameters considered building geometry, material emission coefficient, HVAC configuration, insulation level, and solar orientation. Multi-objective optimization was used to balance energy efficiency and carbon reduction, while AI served as a

model to compress usage profiles for energy prediction. The framework identified the design configurations to lower total CO_2 emissions, proving its application in guiding the early design phase for carbon-conscious decisions.

A. Dataset Description

Carbon Majors Emissions Dataset, a globally recognized and authoritative source of historical carbon emission data. Emissions are broadly covered by the dataset from 1854 to date. Its peculiar dataset traces well beyond over 1.42 trillion tons of carbon dioxide equivalent (CO_2e) emissions, almost 72% of global fossil fuel and cement-related emissions since the dawn of the Industrial Revolution in 1751, hence ranking it as one of the most thorough repositories for emissions tracking and attribution.

This dataset is developed for multidimensional analysis while including major variables such as.

- Year of emission record,
- Parent entity and its type (investor-owned, state-owned, or nation-state),
- Commodity type (including Oil, Gas, various Coal types, and Cement),
- Production quantity and units (million barrels, billion cubic feet, or million tons),
- Total emissions (in $MtCO_2e$).

The dataset is curated from producers ranked among the top 122 in the globe in oil, gas, coal, and cement, such as:

- 75 investor-owned companies,
- 36 state-owned companies, and
- 11 nation-states.

It comprises 82 oil producers, 81 gas producers, 49 coal producers, and 6 major cement producers. Apart from this, the dataset is also provided at a low, medium, and high level of granularity, which facilitates scaling analysis from aggregated trends to much finer emissions at the entity and commodity levels. It also facilitated carbon-aware decision-making via dynamic annotation and optimization of building components. Therefore, the dataset acts as a historical record and, concurrently, as an enabler of opposite-looking low-carbon design strategies in a data-driven building energy optimization framework.

Dataset link: Carbon Majors Emissions Data.

B. Performance of Emissions Analysis

This section undertakes a thorough analysis of carbon major emissions data for high-emission materials and responsible entities. This analysis, by aggregating emissions from commodity types and ownerships of the entities, brings to light emission hotspots for low-carbon considerations in BIM design.

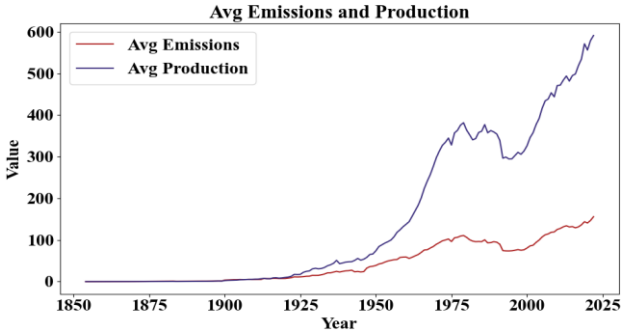

Fig. 4. Time trends of Emissions vs. Production (1854–2024).

Fig. 4 presents the historical average carbon emissions and production volume trends over time, from the Carbon Emissions dataset. This shows steep growth, especially post-1950, with production and emissions soaring with industrialization of fossil fuels. By 2024, average production had peaked at around 584 units, while emissions reached nearly 140 $MtCO_2e$. This peak of carbon emissions and commodities helped these BIM-integrated decisions to lessen carbon impact through informed decisions for the choice of material and source of energy.

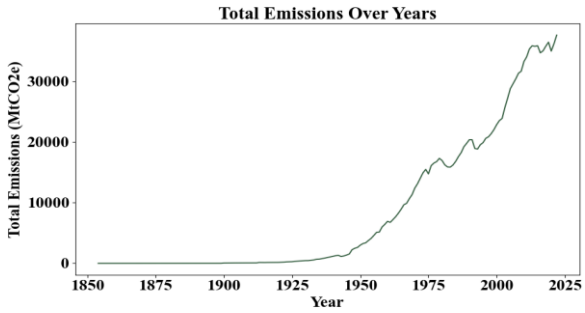

Fig. 5. Historical surge in carbon emissions accumulation.

Fig. 5 exhibits the long-term time trend of total emissions (in MtCOe) from 1850 to 2024. This indicates how emissions have a historical upward trend, becoming drastically steeper after 1950. By 1975, total emissions surpassed 15,000, after which total emissions show even a sharper rise to finally breach the 30,000 $MtCO_2e$ mark by 2020. This corresponds to industrial time, and, thus, brings to attention the need for limiting emissions in the present design and policy framework. Both of these historical viewpoints are aware of the legacy emission loads and planning for data-driven pathways for building environment and energy systems.

Fig. 6 displays the fine-grained analysis of different features contributing to carbon emissions. Product emissions $MtCO_2$ received the highest score of 0.200, followed by commodity type (~0.155), year (~0.125), and production value (~0.100). The fugitive methane emissions $MtCO_2e$ (~0.090), total operational emissions $MtCO_2e$ (~0.080), and parent entity (~0.080). Then there were lesser influential to be noted as own fuel use emissions $MtCO_2$ (~0.065), total emissions $MtCO_2e$ (~0.060), and flaring emissions $MtCO_2$ (~0.050). It helps to elucidate where emphasis is placed in the emission-aware design decisions within the BIM frameworks, thus ensuring that the targeted mitigation measures are applied to high-impact contributors.

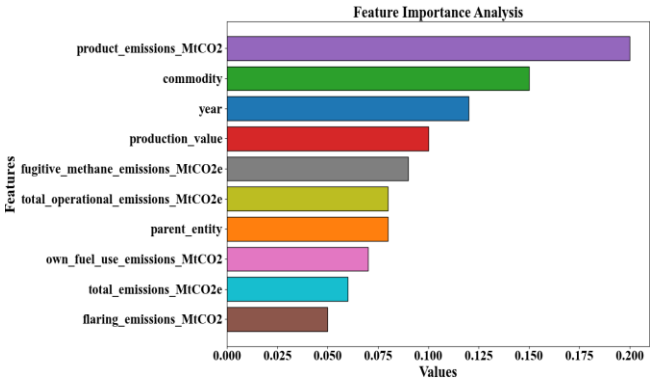

Fig. 6. Feature importance insight of influential drivers in carbon emissions.

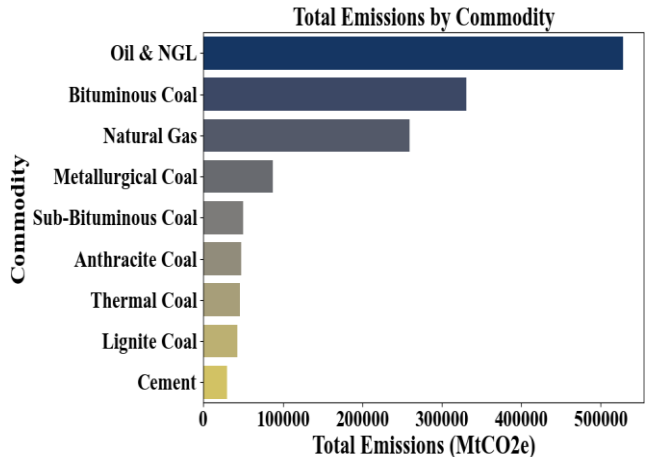

Fig. 7. Emission intensity by commodity – sectoral breakdown of carbon burden.

Fig. 7 provides an analysis of total carbon emissions (in MtCO2e) by commodity type from the dataset. It reveals that Oil & NGL is the most carbon-intensive sector, with emissions of over 500,000, followed by Bituminous Coal at roughly 350,000 and Natural Gas at around 270,000. The carbon emissions include Metallurgical Coal (~130,000), Sub-Bituminous Coal (~75,000), Anthracite Coal, Thermal Coal, and Lignite Coal, each emitting between 50,000. Finally, cement comes under 40,000 MtCO2e. This helps in identifying the most carbon-intensive sectors on which to focus the decarbonization interventions in commodity-specific policies and sustainable design practices.

The embodied carbon emissions for construction materials are summarized in Table II, which shows the emission coefficient and corresponding embodied carbon values for cement, steel, and glass, with steel recording the highest carbon emissions among these materials. Table III shows total carbon emissions globally by parent entity type, thus stressing the implications of material choice in BIM systems, and the effects of organizational ownership on the assignment of global emissions accountability; therefore, this bears on material choice and emission governance strategies in sustainable infrastructure development.

TABLE II. CARBON QUANTIFICATION FROM CONSTRUCTION MATERIALS

Material	Emission Coefficient	Quantity	Embodied Carbon ($MtCO_2e$)
Cement	0.95	1000	950.0
Steel	2.10	500	1050.0
Glass	1.40	200	280.0

TABLE III. TOTAL EMISSIONS BY PARENT TYPE

Parent Type	Percentage of Total Emissions
Nation State	36.3%
State-owned Entity	32.7%
Investor-owned Company	31.0%

C. Performance Evolution

Here, evaluate the aggregate performance of the SqueezeNet integrated optimization framework in minimizing carbon emissions and energy use. It measures improvements through simulation and establishes that data-driven design choices greatly improve the environmental performance of a building initial stages of planning.

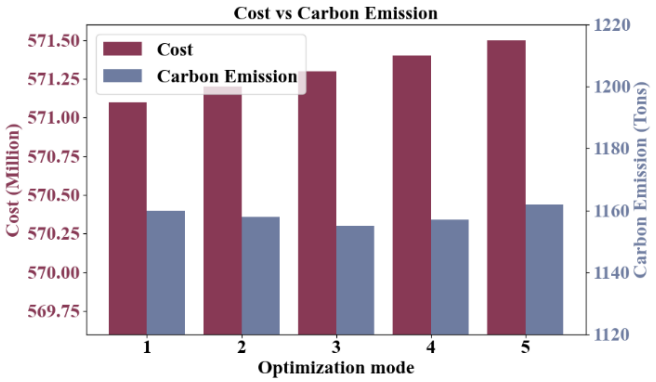

Fig. 8. Multi-objective trade-off between cost and carbon emission across optimization modes.

Fig. 8 analyzes cost (in millions) and carbon emission (in tons) across different optimization modes, based on the proposed BIM-integrated framework using an MAA-NSGA-II approach. Mode 3, thus optimized, recorded the lowest carbon emissions (~1155 tons) at a fairly low cost (~570.25 million), setting an almost-best trade-off. Equally, Mode 5 yields the most expensive costs (~571.45 million), albeit emissions were slightly reduced (~1165 tons), allowing engineers to select the most sustainable and cost-efficient configurations available for early-stage building design.

Fig. 9 compares the actual energy consumption data against predictions from the AI model. With almost exact values, the model proved its ability to accurately interpret patterns of energy consumption from building design parameters and profiles, thus validating its use in early-stage building design for the estimation of operational energy. This predictive capability favors the implementation of early-phase optimizations of energy systems toward a low-carbon design strategy.

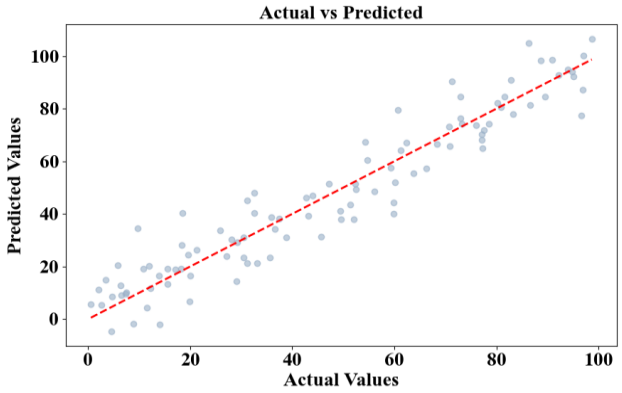

Fig. 9. Energy usage prediction accuracy using SqueezeNet.

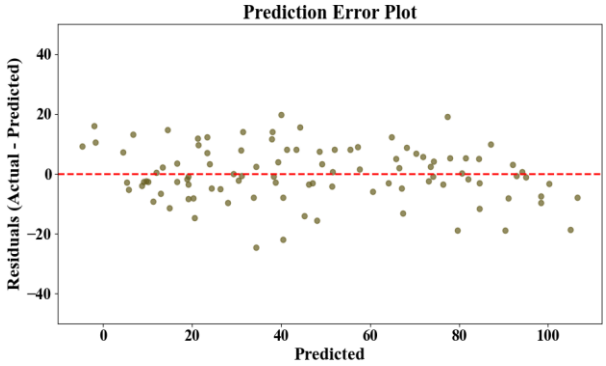

Fig. 10. Prediction error plot of energy consumption.

Fig. 10 shows the distribution of energy consumption prediction errors, highlighting the actual and predicted energy use for the various building configurations. The low clustered error values point to high model precision and minimal error in energy load prediction and thus reflect the model's capability of capturing complicated energy behavior patterns. Such a low error in prediction instils confidence in the designed framework, with attention to energy-efficient considerations in the building design process while being carbon-conscious.

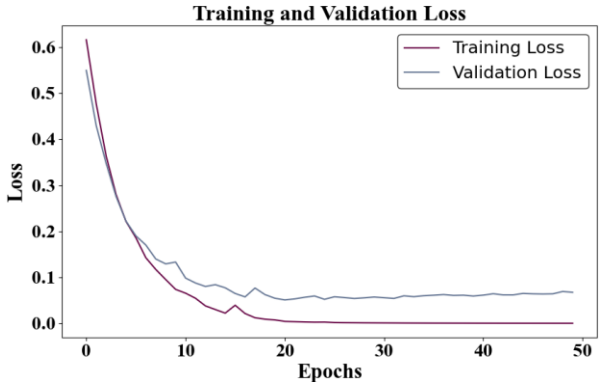

Fig. 11. Training and validation loss curve of the energy consumption.

Fig. 11 represents the training and validation-loss development of the DL model for building energy consumption prediction. The training loss gauges the ability of the model to fit the training data and turns out to be 0.00354. The validation loss, however, is slightly higher at 0.09634, yet it indicates that the predictive capabilities are good and no extensive overfitting. Through monitoring the changes in losses during the model training, it attains a trade-off between accuracy providing reliable energy consumption forecasting for building energy optimization tasks.

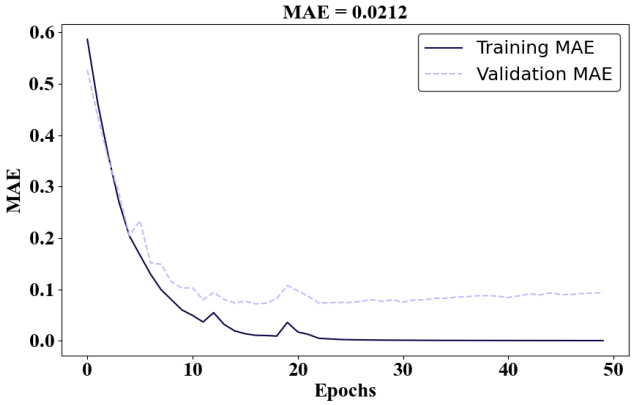

Fig. 12. Training and validation of MAE evolution.

Fig. 12 shows the training and validation Mean Absolute Error (MAE) of the model in predicting building energy consumption. This MAE considers the average magnitude of errors in prediction and ignores their direction. An overall MAE of 0.0212 shows that the model predicted energy consumption values to the actual energy consumption with high reliability.

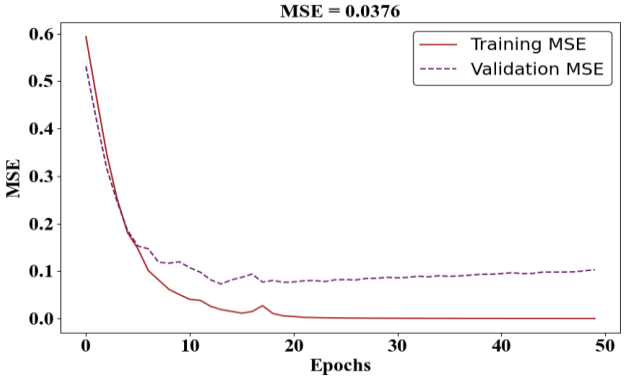

Fig. 13. Training and validation MSE analysis.

Fig. 13 shows the evolution of training and validation of Mean Squared Error (MSE) during the model training process. It quantifies the average squared difference between predicted and actual values, thus giving an indication of model accuracy. The research records an overall final MSE of 0.0376, showing that this predictive model for building energy consumption performs well in predicting the energy use of low-carbon building design.

In Fig. 14, the coefficient of determination (R^2 score) of the predictive model gives the proportion of variance of the observed data explained by the AI model. Along with this, the RMSE (Root Mean Squared Error) measure how far the observation values are from the predicted ones. Thus, the model achieved an overall R^2 score of 0.9814 and the RMSE of 0.1060, showing excellent predictive accuracy that confirms the reliability of the data-driven framework to produce accurate energy consumption.

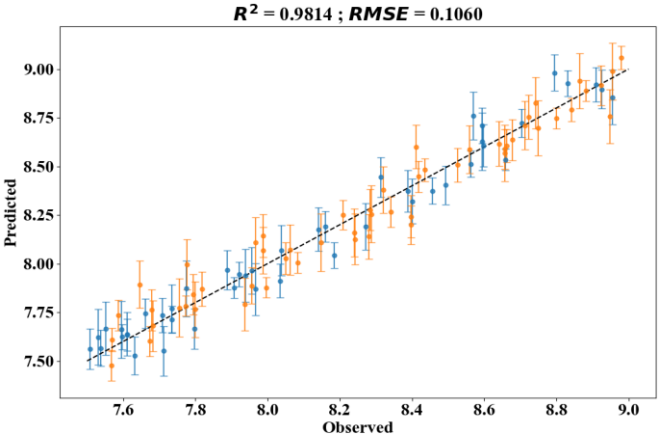

Fig. 14. Model performance evaluation using R^2 score and RMSE.

The above outcomes present the comprehensive analysis of the performance of the proposed framework. For the sake of further interpretation of such results in light of relevant studies and practical usage, the following section includes the discussion.

V. Discussion

A. Comparative Analysis

In this study, the comparative evolution reveals consistent improvements with regard to energy prediction accuracy and carbon reduction, confirming the efficacy of the data-driven AI optimization process through the development stages.

TABLE IV. Comparative Evaluation of AI Models for Carbon Emission Prediction

Models	MAE	MSE	RMSE	R^2 score
GAN [34]	0.2600	-	-	86.00
LSTM [35]	46.10	4570.14	67.60	96.00
GB [36]	24.06	-	35.18	91.00
SqueezeNet	0.0212	0.0376	0.1060	98.14

Table IV provides a comparative analysis between the proposed AI-driven method and state-of-the-art techniques, such as GANs (Generative Adversarial Networks), LSTMs (Long Short-Term Memory), and GBs (Gradient Boosting), for the prediction of carbon emissions from energy consumption forecasts. Compared to these models, the AI-based framework proposed model outperforms them tremendously. In particular, the SqueezeNet-based prediction had the lowest MAE, MSE, and RMSE values, along with the highest R^2 score, proving superior accuracy. Moreover, the integration with MAA-NSGA-II provides multi-objective optimization that balances cost, energy use, emissions, and comfort at the same time, which most existing models fail to address. This accommodation of the model to low-carbon building design through emission forecasting, to the efficient integration in SqueezeNet to account for complex temporal dependencies.

VI. Conclusion

This study effectively developed and implemented an intelligent and data-driven framework that integrates BIM with the SqueezeNet architecture for exact prediction and optimization of building energy consumption. This framework further supports low-carbon construction strategies by allowing the early-stage evaluation of design alternatives, based on the carbon major's emissions dataset. The model was enhanced by incorporating MAA-NSGA-II to balance two conflicting objectives, such as maximization of energy efficiency and minimization of emissions. This analysis revealed that an MAE of 0.0212, an MSE of 0.0376, and an R^2 of 0.9814 were achieved, indicating an impressive accuracy in prediction and generalization capacity. These results are even better than the conventional models, further supporting the energy performance superiority of the proposed method. The framework showcased its practical effect by reducing carbon emissions by 1155 tons while achieving cost savings of about 570.25 million, confirming that it offers both environmental and economic advantages. The comparative analysis also highlighted its superiority over GAN, LSTM, and GB models, establishing the framework as both highly accurate and computationally efficient. This integrated framework comprises reduced computational complexity due to AI-based design considerations, emission feedback aimed at BIM integration, and robust Multi-objective optimization for sustainable architectural decision-making. This work ultimately presents the novel, scalable, and interpretable method inherently applicable to different building typologies, thus assisting in the world shift towards low-carbon city development and climate action decisiveness. Yet, this study does have some limitations since it was primarily validated against historical emission datasets and simulations. How it performs on operational real-time data or under extremely diverse regional contexts still needs to be tested. Future work will improve the framework by using more detailed data and real-time sensors, adding better comfort models for different users and climates, improving occupant behavior prediction with AI, and applying the approach to groups of buildings or whole districts for sustainable city planning.

JellyNovaNet-JSO: A Hybrid TabNet–BiLSTM Model for IoT-Based Crop Yield Prediction

Huang Zhicheng*, Zhang Yinjun
Guangxi Science and Technology Normal University, China

***Abstract*—Precise prediction of crop yield is essential for sustainable agriculture, resource maximization, and food security. As the use of IoT and Wireless Sensor Networks (WSNs) gains momentum, huge amounts of heterogeneous and time-series environmental data have become readily available from intelligent greenhouses. Despite this, it is still difficult to obtain meaningful insights from these data due to their high dimensionality, noise, and nonlinear temporal behavior. Traditional machine learning and statistical approaches usually fail to effectively capture static as well as sequential relationships, and most current models are difficult to tune hyperparameters and have problems with dealing with data heterogeneity and do not generalize across dynamic environments. To overcome these shortcomings, this paper introduces JellyNovaNet-JSO, a new hybrid deep learning architecture that integrates TabNet and BiLSTM architectures, designed using the Jellyfish Search Optimization (JSO) algorithm. The model exploits TabNet sparse attention for static feature modeling and the temporal memory of BiLSTM for time-series sensor data. The innovation is in utilizing attention-guided tabular learning with bidirectional temporal modeling, with a metaheuristic optimization layer to perform automatic hyperparameter tuning. Experimental outcomes based on real-world IoT greenhouse data demonstrate that JellyNovaNet-JSO attains MAE of 0.012, RMSE of 0.017, R^2 of 0.991, and MAPE of 1.89%, outperforming state-of-the-art CNN-LSTM, Random Forest, and SVM models substantially. In comparison with the prior approaches, JellyNovaNet-JSO enhances prediction accuracy by as much as 25% while ensuring scalability and robustness. This innovation provides a viable, interpretable, and deployable solution for precision agriculture, enabling smarter irrigation, climate control, and yield management.**

***Keywords*—IoT agriculture; crop yield prediction; BiLSTM; TabNet; jellyfish search optimization**

I. Introduction

Accurate crop yield estimation is a key consideration in modern agriculture, as a valuable decision-making aid for farmers, policymakers, and stakeholders to rely on food production [1], resource deployment, and planning for marketing [2]. With the world's population increasing and agricultural land shrinking, crop yield maximization is needed to ensure food security and sustainable agricultural output [3]. Sufficient and reliable yield estimates enable risk avoidance of adverse weather conditions, infestation by pests, and other environmental factors that could seriously hinder agricultural output [4]. Furthermore, authentic predictions enable proper input management at minimal cost in the form of water, fertilizers, and pesticides, thereby reducing costs as well as environmental deterioration [5]. Advances in technology, especially the integration of Internet of Things (IoT) devices and Wireless Sensor Networks (WSNs), have revolutionized the ability to monitor real-time environmental parameters across large agricultural fields [6]. Such a proliferation of data availability, though, comes with the difficulty of extracting useful information from high-dimensional, time-series, and intricate data [3]. Hence, it becomes imperative to develop robust predictive models that can accommodate heterogeneous types of data and temporal patterns [5]. These models not only facilitate proactive crop management but also propel sustainable agrarian practice by optimizing the utilization of resources and minimizing wastage [7]. Therefore, enhancing the accuracy and reliability of crop yield prediction models remains a top agenda for agriculture research, driving developments in machine learning [8], deep learning, and optimization techniques tailored to the unique demands of smart agriculture [6].

While great potential of IoT and Wireless Sensor Networks resides in agriculture, accurate estimation of crop yields is stifled by numerous significant challenges [1]. One of the significant challenges is the complexity and heterogeneity of the environmental data perceived by the different sensors monitoring variables such as temperature, humidity, soil nutrient concentrations, and water levels [9]. They are likely to exhibit nonlinear relationships and interact with each other in intricate ways that are difficult to model with traditional statistical techniques [10]. Furthermore, the data tend to be high-dimensional and noisy and contain missing entries and measurement errors due to sensor imperfections or environmental perturbations [11]. Another principal challenge is to model temporal dependencies and dynamic patterns inherent in agriculture processes [1]. Crop development and yields are contingent upon time-series fluctuations in environmental variables, so models need to be capable of learning long and short-term dependencies in sequential data [12]. Seasonal variations, soil nutrient lag effects, and periodic irrigation cycles make the time-scale modeling task even more complicated. In addition, the integration of static tabular information (e.g., crop type, soil type) with sequential sensor data contributes to the difficulties encountered by predictive modeling [9]. These challenges call for advanced machine learning paradigms with the capacity to deal with heterogeneous time-dependent information that also demands interpretability and robustness [10]. Overcoming these challenges is central in the development of plausible crop yield prediction systems deployable in real-world smart farming contexts [13].

The emergence of the IoT and WSNs [9] has revolutionized the field of agriculture through continuous, real-time

*Corresponding Author

monitoring of environmental parameters with unparalleled detail [14]. IoT is a network of physical objects with sensors, actuators, and communication modules which are connected with each other and communicate with the help of the internet or local networks [15]. In farming, IoT sensors track vital parameters including soil moisture, temperature, humidity, light levels, and nutrient content, and present farmers with accurate data to facilitate optimal crop care[16]. Additionally, WSN are spatially distributed nodes of sensors that wirelessly interface to a central gateway, allowing for flexible and extensible data collection in large-scale farms or contained environments such as greenhouses[17]. WSNs have the benefit of simple deployment, low power requirements, and environmental challenge resistance, thus being well suited for agricultural monitoring[18]. The combination of IoT and WSN technologies produces rich, multivariate, and time-stamped data that represents dynamic interactions between crop and environment[18], [19]. This richness in data provides the foundation for building advanced predictive models to enhance yield forecasting, resource management, and sustainable agriculture[20], [21], [36].

To address the issues concerned with crop yield prediction from heterogeneous and time-series farm data, this research presents JellyNovaNet-JSO, a new hybrid model that combines synergistically the merits of TabNet and Bidirectional Long Short-Term Memory (BiLSTM) networks, fine-tuned by the Jellyfish Search Algorithm (JSA). TabNet, being interpretable and having the capacity to effectively process tabular data, excels at capturing significant features from static or non-temporal environmental conditions such as water levels and soil moisture. On top of that, BiLSTM captures temporal dependencies and bidirectional contextual information from sequential sensor inputs such as temperature and humidity across time, which are crucial in modeling crop growth dynamics. The combination of these two architectures enables the model to utilize both static and sequential data modalities in an optimal manner and hence improves prediction accuracy. To further optimize model performance, the Jellyfish Search Algorithm as a bio-inspired metaheuristic search approach is employed in tuning major hyperparameters such as learning rates, layer dimensions, and batch setup. This optimization not only improves convergence but also avoids local minima, resulting in a robust and reliable crop yield prediction model ready for use in real-world smart agriculture scenarios.

This research makes the following key contributions:

1) Introduced a novel hybrid model, JellyNovaNet-JSO, which combines the TabNet architecture with BiLSTM networks. The model is optimized using the Jellyfish Search Algorithm (JSO) to improve the accuracy and efficiency of crop yield prediction in IoT-enabled greenhouse environments.

2) Leveraged real-time data collected from IoT-based sensors and wireless sensor networks deployed in a smart greenhouse to model crop growth patterns and predict yield.

3) Incorporated advanced data preprocessing techniques, including timestamp conversion, feature scaling, and temporal feature engineering. These methods enhance the model's ability to learn from both static and temporal features, improving prediction accuracy. The BiLSTM component of the proposed hybrid model captures bidirectional temporal dependencies in time-series sensor data. This is essential for modeling complex, long-term, and short-term crop growth patterns, which are influenced by changing environmental conditions.

4) Conducted a thorough estimation of the model using several performance metrics, including MSE and R^2, to assess the accuracy of crop yield predictions. The approach is validated through the prediction of crop yields in a real-world IoT-enabled greenhouse setup.

The rest of this paper is structured as follows:

- Section II summarizes recent publications on IoT and ML/DL-based crop yield prediction, citing current drawbacks.
- Section III formulates the problem statement and states the main goals encompassing scalability, heterogeneity of data, adaptability, and tuning.
- Section IV presents the envisioned JellyNovaNet-JSO hybrid model, including its architecture, elements (TabNet, BiLSTM), preprocessing pipeline, and JSO optimization.
- Section V offers results of experiments, such as evaluation measures, attention analysis, ablation analysis, and performance comparisons with other models.
- Section VI summarizes the study and proposes directions for future work such as real-time deployment and multi-location validation.

II. Related Works

N. Chandiraprakash et al. [14] created a crop yield forecasting model that combined real-time IoT sensor data with state-of-the-art ML algorithms, such as LSTM and Random Forest, to facilitate better adaptation to climatic variability. They also investigated the integration of CNN with LSTM to achieve higher spatial-temporal prediction accuracy. They had a user-friendly interface as part of actionable farmer insights for precision agriculture. Rath et al. [22] suggested a precision farming methodology based on the use of real-time wireless sensor network data for enhanced accuracy in crop yield forecasting. Their model incorporates sensor feeds on a continuous basis through a mobile app, providing timely prediction and real-time data gathering capabilities. The research discusses the advantages of utilizing sensor-assembled data from many users for improving model training. Haritha et al. [23] worked on a supervised machine learning method of crop prediction based on climatic and soil factors like humidity, temperature, and nutrient levels. They tested various classifiers like Naïve Bayes, AdaBoost, Decision Tree, and Voting Classifier and determined that the Decision Tree algorithm ranked highest with 99.4% accuracy. The work is centered on enhancing prediction accuracy to help farmers in selecting crops in fluctuating climatic conditions. Çetiner et al. [3] suggested a hybrid deep model of LSTM and CNN to automatically predict crop yields with major parameters like water consumption, exposure to sunlight, fertilizers, pesticides, and fields of cultivation. Their model provided good predictive

power with an R^2 measure of 89.71 along with low error metrics, establishing competitiveness for state-of-the-art methods.

Prathap et al. [24] investigated an IoT-based intelligent agriculture system to enhance crop yield prediction and automated monitoring to minimize human involvement. Their method combines sensors and cameras to monitor yield levels, uploading real-time data to the cloud for analysis. A hybrid deep learning algorithm is used in the study to improve prediction accuracy in smart agriculture systems. Sensor reliability and integration of data issues still exist for fully automated systems. Gupta and Nahar et al. [25] created a hybrid machine learning system with IoT data for crop yield prediction, incorporating preprocessing, feature extraction, and classification steps. The two-level approach utilizes aKNCN for classifying soil quality and ELM with an improved BOA for predicting yields. The model revealed better accuracy and reduced errors on soil datasets with varied evaluation measures. Manikandababu et al. [26] examined how machine learning algorithms and IoT technologies can be integrated to improve crop production prediction in precision agriculture. They employed sensor and drone data measuring crop health, weather, and soil moisture for informing models. This method allows farmers to make informed decisions regarding pest control, fertilization, and irrigation, increasing yield accuracy. N. Mohana Priya et al. [27] conducted a study on the combination of ML and IoT for the optimization of irrigation management based on real-time sensor readings of temperature, humidity, soil moisture, and water level. They compared models with SVM resulting in the highest accuracy of pump operation prediction. The study showcases the capability of IoT and ML to make adaptive, data-driven control of irrigation for better water use efficiency. Pérez et al. [28] created a tomato crop forecasting system combining AI, sensor networks and IoT to balance resource utilization and improve forecasting yield. The framework included distributed sensors, IoT gateways, and cloud-based recurrent neural network models that were trained on environmental information and tested with harvest data. Their model had an average prediction error of 3.2% over a period of four weeks, reflecting high accuracy.

Kumar et al. [29] implemented an ensemble ML model for crop prediction from IoT sensor data gathered using the PLX-DAQ tool, integrating algorithms. Their ensemble method has a very high accuracy of 97.45% for early crop yield prediction. Their work showcases the strength of an IoT and ML integration for maximizing data-driven decisions in agriculture amid the threats posed by climate change. Yet, the dependency on sensor integration and data quality continues to be a bottleneck in sweeping adoption. Krithika et al. [30] explored DL model applied for crop yield prediction based on real-time agricultural datasets. The experiments showed that although all models were promising, LSTM was most accurate because it can learn temporal dependencies in the data. The research underscores the importance of improving ML models further to improve attempts in mitigating challenges brought by natural disasters. Rastog et al. [31] proposed an AI and ML approach with Python to improve crop yield prediction and assist farmers in the Indian subcontinent by leveraging IoT and Cyber-Physical systems. Their research is intended to tackle food security issues by making timely predictions of yield, moisture, and weather conditions. The research endeavors to enhance prediction accuracy through sophisticated learning algorithms on authentic agricultural datasets.

Although recent work shows substantial advancements in using IoT and machine learning for crop yield estimation and precision farming, some universal limitations are still prevalent. Computational complexity and scalability issues of hybrid CNN-LSTM models were noted by Chandiraprakash et al. [14] in large-scale implementations. Rath et al. [22] mentioned issues with handling heterogeneous sensor data and maintaining model scalability across various agricultural environments. Haritha et al. [23] pointed out that models based on fixed datasets could face challenges in coping with dynamic climatic conditions. ÇetiNer et al. [3] highlighted the reliance on precise parameter measurement and rigorous fine-tuning for consistent model performance. Prathap et al. [24] indicated challenges with sensor reliability and data integration as challenges to complete automation. Gupta and Nahar et al. [25]found that the use of hyperparameter tuning would restrict generalizability in various contexts of farming. Manikandababu et al. [26] had mentioned difficulties in large-scale deployment and integration of data. Mohana Priya et al. [27] reported misclassification error in irrigation control predictions in need of further tuning. Pérez et al. [28] showed high accuracy but recognized the necessity for strong system integration. Kumar et al. [29] and Rastog et al. [31]pointed to bottlenecks in sensor quality data and scalability challenges for mass implementation. Taken together, the studies point toward the fact that in addition to much encouraging work, challenges like heterogeneity of data, computational costs, reliability of sensors, robustness of models, and scalability need to be overcome to achieve the complete potential of IoT and ML in smart agriculture.

III. Problem Statement

In spite of remarkable progress in unifying IoT and machine learning for crop yield prediction, some urgent limitations obviate widespread use and performance. First, most models are computationally expensive and lack scalability when applied in practical large-scale agricultural settings [14]. Second, data heterogeneity and sensor unreliability issues impair input data quality and uniformity, degrading model robustness [22]. Third, the reliance on fixed or static datasets lowers the models' responsiveness to dynamic and rapidly evolving environmental conditions [23]. Lastly, most current models are sensitive to hyperparameters that need to be heavily tuned and fine-tuned, affecting generalizability across a wide range of farming contexts [25]. Such constraints warrant more effective, adaptive, and scalable precision agriculture solutions.

Research Objectives

- Develop a computationally efficient hybrid model that maintains high accuracy while enabling scalability for large-scale agricultural deployments.
- Design robust data preprocessing and sensor fusion techniques to handle data heterogeneity and improve sensor data reliability.

- Incorporate dynamic learning mechanisms that adapt to changing environmental and climatic conditions in real-time.
- Implement an automated hyperparameter optimization framework to enhance model generalizability and reduce manual tuning efforts.

IV. Proposed Methodology for Crop Yield Prediction Using IoT and Wireless Sensor Networks

The methodology for crop yield prediction put forward uses a hybrid machine learning model, JellyNovaNet-JSO, that combines the TabNet and BiLSTM architectures, optimized using the JSO. The proposed methodology takes advantage of the robustness of both the TabNet model, specifically developed for effective processing of tabular and categorical data, and the BiLSTM model, which is able to recognize bidirectional temporal patterns in time-series data. The model initially handles static attributes such as soil nutrient content and actuator states through TabNet, whereas BiLSTM extracts the dynamic behavior of sequential sensor readings from IoT-connected greenhouses. These models are then combined to merge spatial and temporal information so that accurate and efficient crop yield prediction can be supported. With timestamped features, feature scaling, and time series windowing, the hybrid method offers comprehensive modeling of environmental circumstances and their impacts on crop growth while providing a more robust setting for yield prediction in smart agricultural applications. Fig. 1 demonstrates the step-by-step methodology for crop yield prediction using the JellyNovaNet-JSO hybrid model integrating IoT sensor data and machine learning techniques.

A. Data Collection

The dataset in the present research was obtained as part of research for the master's thesis carried out by Mohammed Ismail Lifta (2023-2024) at Tikrit University, Iraq [32]. The data was obtained from a mounted smart greenhouse that is equipped with advanced IoT-enabled sensors and actuators. Environmental conditions such as, humidity, temperature, water level, and soil nutrient concentrations (nitrogen, phosphorus, potassium) were sensed in real time through wireless sensor nodes placed around the greenhouse. Actuator status such as fan and pump ON/OFF signals were also recorded in order to express environmental control decisions. Data, spanning multiple months and comprising 37,923 records, were remotely transmitted and stored via a cloud-capable application linked to Google Sheets for real-time monitoring and regulation of the greenhouse climate. The high-density, time-stamped, multivariate data are most suitable for modeling crop growth patterns and yield prediction using IoT and Wireless Sensor Network technologies. This Table I shows exemplary data of time-stamped sensor measurements read from the smart greenhouse. It further depicts actuator statuses reflecting the state of operation of the fan and watering pumps, capturing environmental conditions as well as control actions. The data corresponds to tomatoes grown in the smart greenhouse for four continuous months in 2023-2024. During preprocessing, minor issues were noted and handled: missing entries, sensor drift, and dropped packets. The complete dataset is available for reproducibility at:

https://www.kaggle.com/datasets/wisam1985/iot-agriculture-2024

B. Data Preprocessing for JellyNovaNet-JSO Model

Some preprocessing steps need to be carried out after having a clean dataset with one-hot encoded values captured from the smart greenhouse sensor network before being modeled efficiently using the JellyNovaNet-JSO hybrid architecture. The main tasks include timestamp conversion, feature scaling, temporal feature engineering, time series windowing, and separating the dataset into training and testing so that data leakage does not occur.

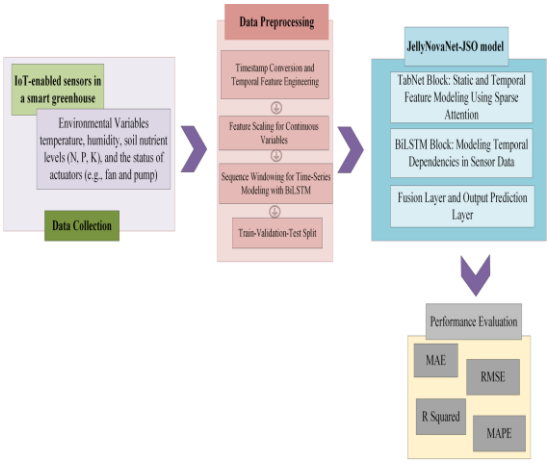

Fig. 1. Methodology flow for crop yield prediction using JellyNovaNet-JSO hybrid model.

TABLE I Sample Environmental and Actuator Sensor Data from Smart Greenhouse

Date & Time	Temperature (°C)	Humidity (%)	Water Level (%)	N (0-255)	P (0-255)	K (0-255)	Fan actuator ON	Watering plant pump ON	Water pump actuator ON
2024-02-08 06:10:00	41	63	100	255	255	255	1	1	1
2024-02-08 06:15:00	41	59	100	255	255	255	1	1	1
2024-02-08 06:20:00	41	62	100	255	255	255	1	1	1
2024-01-18 05:02:00	37	62	100	255	255	255	1	1	1
2024-01-18 05:07:00	37	63	100	255	255	255	1	1	1

1) Timestamp conversion and temporal feature engineering: The dataset contains a critical Date and Time column representing the exact timestamp for each sensor reading. To leverage temporal patterns and seasonality effects in crop growth, this column must be converted into a datetime data type compatible with modeling frameworks as given in Eq. (1)

$$\text{Timestamp}_i = \text{datetime(Date \& Time } i) \quad (1)$$

This conversion enables extraction of granular temporal features such as hour of day, day of month, month, and day of week, which can serve as additional predictors to improve model performance. These features are mathematically derived from the timestamp as given in Eq. (2).

$$\begin{aligned} \text{Hour}_i &= \text{Timestamp}_i\text{.hour} \\ \text{Day}_i &= \text{Timestamp}_i\text{.day} \\ \text{Month}_i &= \text{Timestamp}_i\text{.month} \\ \text{DayOfWeek}_i &= \text{Timestamp}_i\text{.weekday} \end{aligned} \quad (2)$$

Incorporating these gyclic temporal components allows the model to capture daily and seasonal variations inherent in environmental and crop growth data.

2) Feature scaling for continuous variables: The continuous sensor features, including temperature, humidity, water level, and soil nutrient concentrations (nitrogen, phosphorus, potassium), span different numerical ranges. To prevent features with larger scales from leading the learning process and to accelerate convergence during training, feature scaling is necessary. The Min-Max scaling technique normalizes these features to a fixed range [0,1], using Eq. (3).

$$x_i' = \frac{x_i - x_{min}}{x_{max} - x_{min}} \quad (3)$$

where x_i is the actual feature value, and $x_{\min}$, $x_{\max}$ are the min and max values of that feature across the dataset.

3) Sequence windowing for time-series modeling with BiLSTM: BiLSTM networks need sequential input data that capture temporal dependencies. To convert the continuous sensor data into appropriate time-series format, a sliding window approach was applied. With a defined window size ω, consecutive segments of the dataset were extracted as input sequences, as shown in Eq. (4).

$$S_t = [x_t, x_{t+1}, \dots, x_{t+w-1}] \quad (4)$$

where S_t is the sequence input at time step t and x_i is the feature vector at timestamp i.

The target label (e.g., crop yield or environmental condition at $+w$) can be associated with each sequence, enabling supervised learning. The choice of window size balances capturing long-term dependencies without making the sequence overly large, typically ranging from 5 to 30-time steps depending on data frequency.

4) Train-validation-test split: To simulate real-world forecasting and prevent data leakage, the dataset is split chronologically rather than randomly. The data are divided into three subsets, given in Eq. (5).

$$\begin{cases} \text{Training set} & : & \text{first } 70\% \\ \text{Validation set} & : & \text{next } 15\% \\ \text{Test set} & : & \text{final } 15\% \end{cases} \quad (5)$$

Such time-based splitting confirms that the model is tested on future unseen data, mimicking actual deployment scenarios in crop yield prediction.

The data preprocessing pipeline caters to the requirements of JellyNovaNet-JSO, that is, it transforms cleaned one-hot encoded raw data into an appropriate format. The steps involved are timestamp parsing, temporal feature generation, normalization of continuous variables, creation of sequential windows for BiLSTM input, and finally the time-aware train/test split. Thus, the hybrid model can indeed grasp the complexities involved in spatio-temporal patterns of an IoT-enabled greenhouse environment to finally provide correct crop yield estimations.

Pseudocode: Data Preprocessing for JellyNovaNet-JSO

Input: RawDataset.csv # IoT-based greenhouse sensor data

Output: Preprocessed training, validation, and test sets

BEGIN

1. Load Dataset

Dataset ← read_csv("RawDataset.csv")

2. Timestamp Conversion

For each record in Dataset:

Timestamp_i ← to_datetime (Dataset ["Date & Time"] [i])

3. Temporal Feature Engineering

For each Timestamp_i:

Hour_i ← Timestamp_i. hour

Day_i ← Timestamp_i.day

Month_i ← Timestamp_i. month

DayOfWeek_i ← Timestamp_i. weekday

Append Hour, Day, Month, DayOfWeek as new columns to Dataset

4. Feature Scaling using Min-Max Normalization

For each continuous feature f ∈ {Temperature, Humidity, WaterLevel, N, P, K}:

f_scaled ← (f - min(f)) / (max(f) - min(f))

Replace original features with scaled features

5. Sequence Windowing for Time-Series Input

Define window_size w

Sequences ← []

Labels ← []

For i from 0 to (length (Dataset) - w):

Sequence ← Dataset [i: i+w]

Label ← Dataset [i + w] ["Crop_Yield"]

Append Sequence to Sequences

Append Label to Labels

6. Chronological Train-Validation-Test Split

total_samples ← length (Sequences)

train_end ← 0.70 * total_samples

val_end ← 0.85 * total_samples

TrainSet ← Sequences

Train Labels ← Labels

ValSet ← Sequences

ValLabels ← Labels

TestSet ← Sequences

TestLabels ← Labels

7. Return TrainSet, ValSet, TestSet and corresponding labels

END

C. Model Development

To apply the JellyNovaNet-JSO model a Jellyfish Search Optimized variant of TabNet and BiLSTM for precise crop yield forecasting. The suggested JellyNovaNet-JSO model is a hybrid DL system combining the features of TabNet and BiLSTM networks, JSO-optimized to improve the precision of crop yield forecasting in IoT-based greenhouse setups. The model starts with a TabNet layer, which is particularly suited to process the heterogeneous tabular and categorical features like nutrient contents (N, P, K), actuator states (fan/pump ON/OFF), and engineered temporal variables (hour, day, month). TabNet applies a sparse attention mechanism to softly select relevant features at every decision step in order to make the model interpretable and learn efficiently from high-dimensional structured data. In parallel to this, the BiLSTM module handles the sequential input from time-series sensor reading data (e.g., water level, temperature, humidity) formatted into sliding windows. The BiLSTM can model intricate bidirectional temporal relationships, allowing the model to learn past and future contextual patterns affecting crop development. The features from TabNet and BiLSTM are then input into a layer of feature fusion, where they are concatenated and optionally smoothed by dense layers to facilitate cross-modal interaction between static tabular knowledge and dynamic temporal patterns. Lastly, the fused representation is input into a fully connected output layer that predicts the final continuous crop yield. This hybrid architecture guarantees that the model is efficiently able to capture the spatial and temporal complexities of IoT greenhouse data, while JSO integration further boosts the performance of the model using smart hyperparameter tuning.

1) TabNet block: Static and Temporal Feature Modeling Using Sparse Attention.

The TabNet block is used to process the tabular and categorical features of IoT sensor data and temporal encodings. They consist of static variables such as soil nutrient content (N, P, K), actuator states (fan ON/OFF, water pump state), and engineered time-based features like hour, day, month, and day of the week - all of which are pivotal in comprehending crop growth dynamics in smart greenhouses. Fig. 2 shows the TabNet architectural diagram and their components are explained briefly given below.

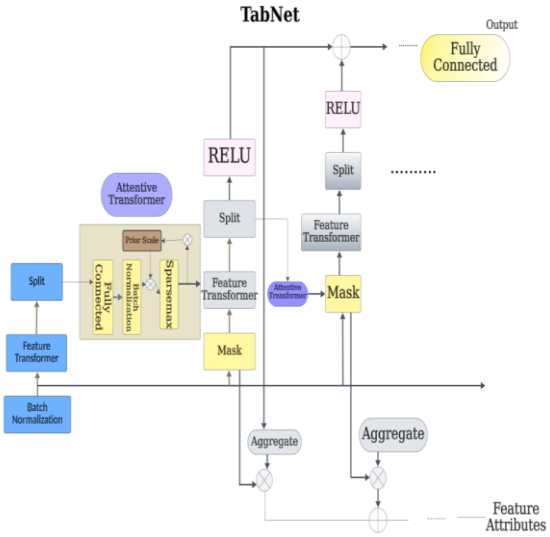

Fig. 2. TabNet architectural diagram.

Input Representation:

Let the input feature vector be represented as in Eq. (6).

$$X = \{x_1, x_2, \ldots, x_n\} \in \mathbb{R}^n \quad (6)$$

where each $\boldsymbol{x_i}$ corresponds to a scaled and encoded feature (e.g., N, P, K, actuator state, hour, day, etc.), and $\boldsymbol{n}$ is the entire number of tabular features.

a) Feature transformer: Each input is passed through a feature transformer, which contains fully connected layers, batch normalization, and non-linear activation functions. This layer learns complex feature interactions and generates a richer representation of the input. For a layer $\boldsymbol{l}$, the transformation can be described as in Eq. (7).

$$H^{(l)} = ReLU\left(BN\left(W^{(l)}H^{(l-1)} + b^{(l)}\right)\right) \quad (7)$$

Where, $W^{(l)}$ *and* $b^{(l)}$ are weights and biases at layer l, $BN(\cdot)$ denotes batch normalization, $H^{(0)} = X$

The output $H^{(L)}$ of the final transformer layer is used as the latent feature embedding for downstream fusion.

b) Sparse attentive masking: To focus on the most relevant features at each decision step, TabNet incorporates a sparse attention mechanism. This mechanism generates feature masks M_i using the softmax and sparsemax functions. For a decision step i, the mask is computed as using Eq. (8).

$$M_i = sparsemax\left(P_{i-1} \cdot H^{(i)}\right) \quad (8)$$

Here, $H^{(i)}$ is the transformer output at step $\boldsymbol{i}$, $\boldsymbol{P_{i-1}}$ is the prior scale that limits the reuse of features (to promote sparsity), sparsemax (-) encourages hard selection of features, improving interpretability.

The masked input passed to the next decision step is given by Eq. (9).

$$X_i = M_i \odot X \quad (9)$$

where $\odot$ denotes element-wise multiplication.

c) Decision and aggregation: TabNet processes multiple decision steps T, where each step outputs a partial decision D_i that contributes to the final output given in Eq. (10) and Eq. (11)

$$D_i = \phi(H_i), \text{ for } i = 1 \ldots T \quad (10)$$

$$Y_{\text{TabNet}} = \sum_{i=1}^{T} D_i \quad (11)$$

where ϕ is a decision layer (e.g., linear transformation), and Y_{TabNet} is the final embedding output of the TabNet block. The result is a high-level latent feature embedding $Y_{\text{TabNet}} \in \mathbb{R}^d$, where d is the output dimension. These embedding captures complex, high-level relationships between the input features and will be later fused with the BiLSTM output for final prediction.

This TabNet block plays a critical role in modeling the non-sequential, structured feature space using sparse attention, ensuring both efficiency and interpretability, which are highly valuable in agricultural and loT applications. The output is forwarded to the fusion layer, where it is combined with the sequential BiLSTM representation for comprehensive crop yield forecasting.

2) BiLSTM block: Modeling Temporal Dependencies in Sensor Data.

The BiLSTM block in JellyNovaNet-JSO is considered to process the time-series data collected from the IoT-based greenhouse environment, such as temperature, humidity, water level, and other sequential features. These sensor readings are inherently temporal and exhibit short-term and long-term dependencies, which are critical for accurately modeling plant physiological responses and predicting final crop yield. Let the multivariate time-series input for a given window be given in Eq. (12).

$$S_t = [x_t, x_{t+1}, \ldots, x_{t+w-1}] \quad (12)$$

Where, w is the window size, $x_i \in \mathbb{R}^j$ is the feature vector at time i, and f is the number of continuous sensor features (e.g., temperature, humidity, water level, N, P, K).

This sequence captures both the temporal variation and feature evolution over a fixed period.

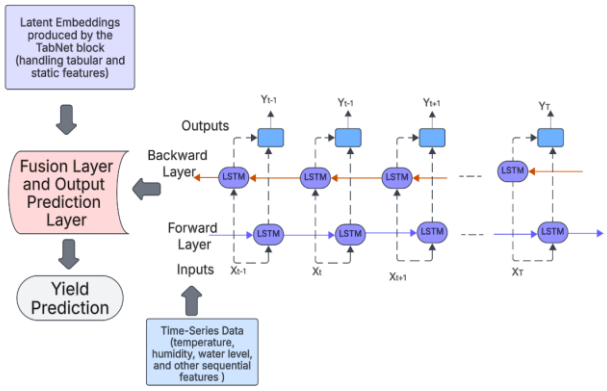

Fig. 3. BiLSTM- Architectural diagram.

Fig. 3 shows the architectural diagram of BiLSTM. Unlike traditional LSTM which processes sequences in a forward direction, BiLSTM reads input from both past and future directions, combining two LSTM outputs as given in Eq. (13).

$$h_t = \left[\overrightarrow{h_t}; \overleftarrow{h_t}\right] \quad (13)$$

Where, $\overrightarrow{h_t}$ is the hidden state from the forward LSTM (processing x_t to x_{t+w-1}), $\overleftarrow{h_t}$ is from the backward LSTM (processing x_{t+w-1} to x_t), [;] denotes concatenation.

Each LSTM unit at time step t operates with the following internal equations:
Let x_t be the input vector at time t, and let h_{t-1}, c_{t-1} be the earlier hidden and cell states. The gates and memory update are computed as using the following Eq. (14), (15), (16), (17), (18) and (19)

Let x_t be the input vector at time step t, and h_{t-1}, c_{t-1} represent the previous hidden state and cell state, respectively. The LSTM unit operates by regulating the flow of information using three gates: forget gate, input gate, and output gate, along with an internal cell state update mechanism.

$$f_t = \sigma\left(W_f \cdot [h_{t-1}, x_t] + b_f\right)\text{(Forget gate)} \quad (14)$$

The forget gate f_t decides which information from the previous cell state should be discarded. It is computed using a sigmoid activation function applied to the linear transformation of the concatenated vector h_{t-1}, x_t, with associated weights W_f and bias b_f. The output is a vector of values between 0 and 1, indicating the degree of forgetting.

$$i_t = \sigma(W_i \cdot [h_{t-1}, x_t] + b_i)\text{(Input gate)} \quad (15)$$

Which additional data should be added to the cell state is determined by the input gate. It makes use of a sigmoid activation, just like the forget gate. The same input is subjected to a tanh activation with weights and bias in parallel to create the candidate cell state. This candidate state is an example of possible new content that could be included.

$$\tilde{c}_t = tanh(W_c \cdot [h_{t-1}, x_t] + b_c) \text{ (Candidate cell state)} \quad (16)$$

The new cell state is then updated by joining the scaled old cell state $\boldsymbol{f_t} \odot \boldsymbol{c_{t-1}} + \boldsymbol{i_t} \odot \boldsymbol{\tilde{c}_t}$ and the scaled candidate state $\boldsymbol{i_t} \odot \boldsymbol{\tilde{c}_t}$ denotes element-wise multiplication. This update mechanism allows the model to selectively retain or overwrite memory.

$$c_t = f_t \odot c_{t-1} + i_t \odot \tilde{c}_t \text{ (Updated cell state)} \quad (17)$$

$$o_t = \sigma(W_o \cdot [h_{t-1}, x_t] + b_o)\text{(Output gate)} \quad (18)$$

$$h_t = o_t \odot tanh(c_t) \text{ (Hidden State)} \quad (19)$$

Where $\sigma(\cdot)$ is the sigmoid function, tanh(·) is the hyperbolic tangent function, O is the element-wise multiplication, W_* and b_* are weight matrices and biases for each gate. Both forward and backward passes compute their own set of hidden states, which are then concatenated to form a bi-directional context vector.

Temporal Embedding Vector

The BiLSTM processes the full sequence S_t and generates hidden states at each time step. These are often aggregated using:

- Last hidden state: h_{t+w-1}
- Mean pooling: $h_{\text{avg}} = \frac{1}{w}\sum_{i=t}^{t+w-1} h_i$
- Attention mechanism

The resulting temporal feature embedding $H_{\text{BiLSTM}} \in \mathbb{R}^d$ captures the dynamics and dependencies in the greenhouse environment over time. The BiLSTM block transforms sliding sequences of time-series sensor data into high-level temporal embeddings, effectively capturing both short- and long-term dependencies and bidirectional influences on crop behavior. This temporal representation H_{BiLSTM} is later fused with the TabNet output in the next stage for unified modeling and yield prediction.

3) Fusion layer and output prediction layer: The Fusion Layer in the JellyNovaNet-JSO architecture is responsible for combining the latent embeddings produced by the TabNet block (handling tabular and static features) and the BiLSTM block (handling timeseries sensor sequences). This fusion enables the model to integrate spatial, categorical, and temporal dependencies to make an informed prediction about crop yield. The outputs of the TabNet and BiLSTM are concatenated to create a single feature vector that incorporates both static and temporal dependencies. This fused representation is projected through one or more dense layers with relaxed linear unit (ReLU) activation which help smooth interactions of variables while accentuating cross-modal interactions. Lastly, a linear output layer will map this enriched representation into the predicted crop yield, using both static tabular features and continuous temporal dynamics of the sensor demand to produce next-harvest predictions.

a) Fusion layer: Concatenation of Latent Representations

Let, $z_{\text{TabNet}} \in \mathbb{R}^{d_1}$ be the feature embedding output from the TabNet branch. $z_{\text{BILSTM}} \in \mathbb{R}^{d_2}$ be the temporal embedding from the BiLSTM block.

These two vectors are concatenated into a unified feature representation, given in Eq. (20).

$$z_{\text{fused}} = \left[z_{\text{TabNet}}\,; z_{\text{BILSTM}}\right] \in \mathbb{R}^{d_1+d_2} \quad (20)$$

This fused vector contains both: Static environmental context (e.g., nutrient levels, actuator states, timestamp-derived features) and Temporal dynamics (e.g., historical patterns in temperature, humidity, water content, etc.).

b) Fully connected output layer: Yield Prediction: The fused vector is passed over one or more fully connected (dense) layers with non-linear activations (typically ReLU), followed by a final linear layer to produce the crop yield prediction, given in Eq. (21) and Eq. (22)

$$h_1 = ReLU\left(W_1 z_{\text{fused}} + b_1\right) \quad (21)$$

$$\hat{y} = W_2 h_1 + b_2 \quad (22)$$

Where, W_1, W_2 are the weights of the dense layers, b_1, b_2 are the corresponding biases, $\hat{y}$ is the predicted crop yield output (a scalar for regression).

Since crop yield prediction is a regression problem, the model is trained by minimalizing the MSE between the predicted and actual yield values, using Eq. (23).

$$\mathcal{L}_{MSE} = \frac{1}{N}\sum_{i=1}^{N} (y_i - \hat{y}_i)^2 \quad (23)$$

Where, y_i is the actual crop yield for the i^{th} example, $\hat{y}_i$ is the predicted yield, N is the total number of training samples.

To prevent overfitting during training, additional techniques such as L2 regularization, Dropout, or Batch Normalization can be applied in the dense layers. The Fusion Layer integrates TabNet and BiLSTM representations, and the Output Layer translates this fused knowledge into an accurate prediction of crop yield. This stage finalizes the learning pipeline of the JellyNovaNet-JSO model and enables it to reason over both spatial and temporal cues in the environment.

Pseudocode: JellyNovaNet-JSO Model Development
Input:

X_tabular ← Tabular input features (N, P, K, actuator states, timestamp features)

X_sequence ← Time-series input (e.g., temperature, humidity, water level)

y_true ← Ground truth crop yield

Output:

y_pred ← Predicted crop yield

BEGIN

1. Initialize TabNet parameters (weights, masks)

2. For each decision step i = 1 to T:

H_i ← FeatureTransformer(H_{i-1})

M_i ← SparseMax(P_{i-1} · H_i)

X_i ← M_i ⊙ X_tabular

D_i ← DecisionLayer(H_i)

3. Y_TabNet ← Sum of all D_i (i = 1 to T)

4. For each sample in X_sequence:

Generate sequence window S_t of size w

5. Pass S_t through BiLSTM:

Forward_LSTM → → →

Backward_LSTM ← ← ←

6. Concatenate forward and backward hidden states:

h_t ← [h_t_forward; h_t_backward]

7. Temporal Embedding ← MeanPooling or LastHiddenState(h_t)

8. fused ← Concatenate (TabNet, Temporal Embedding)

9. h1 ← ReLU (W1 · z_fused + b1)

10. y_pred ← W2 · h1 + b2

11. Compute Loss (Mean Squared Error):

12. Apply backpropagation to minimize L_MSE

13. Use JSO to tune:

- Learning rate
- TabNet decision steps
- BiLSTM units
- Dropout rate
- Batch size

END

V. Results and Discussion

The JellyNovaNet-JSO model was implemented using Python 3.10 with TensorFlow and PyTorch backend on a system with an NVIDIA RTX 3080 GPU, 32 GB RAM. Key hyperparameters such as learning rate, window size, and number of decision steps in TabNet were optimized using the JSO algorithm. Table II shows the optimal hyperparameter values selected for the JellyNovaNet-JSO model. These values were fine-tuned to achieve the best performance in predicting crop yield.

TABLE II Optimal Hyperparameter Values for JellyNovaNet-JSO Model

Hyperparameter	Optimal Value
Learning Rate	0.0025
TabNet Decision Steps	5
BiLSTM Units	128
Batch Size	64
Dropout Rate	0.3
Window Sizea	10

A. Evaluation Metrics

To measure the prediction performance of the JellyNovaNet-JSO model in a real-world smart greenhouse environment using IoT and WSN data, the following evaluation metrics were applied:

1) MAE: In this research, a low MAE indicates that the JellyNovaNet-JSO model makes very small average errors, showcasing its ability to generalize well to unseen yield values across environmental conditions, expressed in Eq. (24).

$$MAE = \frac{1}{n}\sum_{i=1}^{n} |y_i - \hat{y}_i| \quad (24)$$

2) RMSE: RMSE emphasizes that the model not only maintains small average errors but also avoids large outliers-critical for yield-sensitive decisions in automated greenhouses.

$$RMSE = \sqrt{\frac{1}{n}\sum_{i=1}^{n} (y_i - \hat{y}_i)^2} \quad (25)$$

R^2 Score

Indicates the proportion of the variance in the dependent variable that is foreseeable from the independent variables.

$$R^2 = 1 - \frac{\sum (y_i - \hat{y}_i)^2}{\sum (y_i - \bar{y})^2} \quad (26)$$

3) MAPE: Expresses prediction accuracy as a percentage, making it easier to interpret relative performance. A MAPE value demonstrates high reliability of JellyNovaNet-JSO for operational use, where even small forecasting errors can affect resource allocation and yield estimation.

$$MAPE = \frac{100\%}{n}\sum_{i=1}^{n} \left|\frac{y_i - \hat{y}_i}{y_i}\right| \quad (27)$$

After fine-tuning using the JSO, the JellyNovaNet-JSO model achieved outstanding predictive accuracy on the test set.

TABLE III MODEL EVALUATION METRICS

Metric	Value
MAE	0.012
RMSE	0.017
R² Score	0.991
MAPE	1.89%

Table III shows the model evaluation metrics, these indicate that the model arrests almost 99.1% of yield variance with exceptionally low prediction errors, making it viable for real-world smart farming deployment.

With little difference between expected and actual values, the model's accuracy and efficacy in predicting crop productivity show its dependability for practical precision agriculture applications. The JellyNovaNet-JSO model's anticipated crop yields and the actual observed yields are contrasted in Fig. 4.

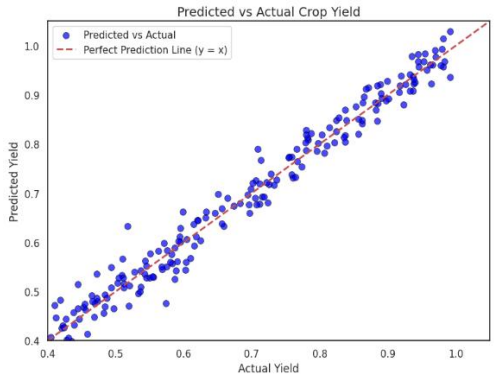

Fig. 4. Predicted vs. Actual crop yield.

The distribution of prediction errors (Actual – Predicted) for crop yield estimation shown in Fig. 5. The histogram is sharply centered around zero, indicating that the JellyNovaNet-JSO model maintains minimal error variance. This supports the model's low MAE and RMSE values and confirms its robustness for accurate yield forecasting in smart greenhouse environments.

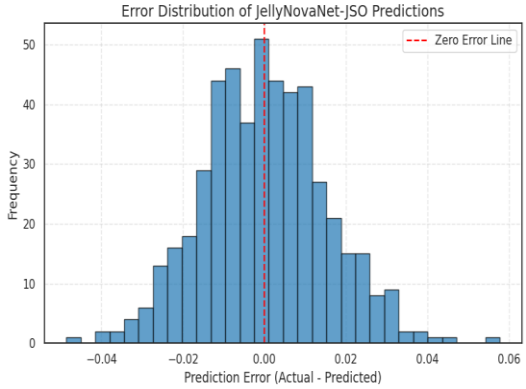

Fig. 5. Histogram of prediction errors for JellyNovaNet-JSO model.

Fig. 6 illustrates the model's loss over 20 training epochs. The training and validation losses converge smoothly without significant divergence, indicating stable learning. The absence of overfitting validates the use of a 0.3 dropout rate and effective hyperparameter tuning via the JSO, contributing to the model's generalization performance.

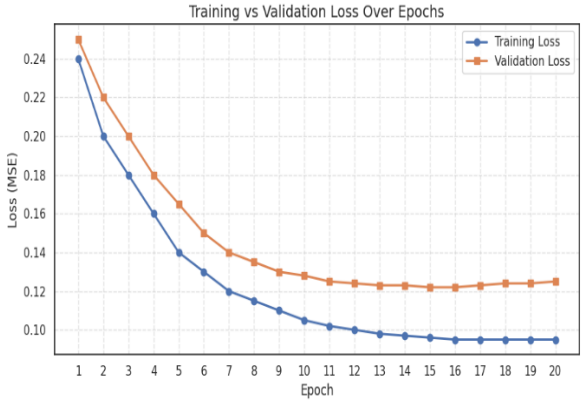

Fig. 6. Training and validation loss curve of JellyNovaNet-JSO model.

4) Feature importance from TabNet attention: Nutrient and humidity sensors had the strongest influence. Actuator signals also contributed to prediction by contextualizing environment control states. Table IV presents the feature importance scores (IoT + Actuator Features), and Fig. 7 illustrates them.

TABLE IV FEATURE IMPORTANCE SCORES (IOT + ACTUATOR FEATURES)

Feature	Importance Score
Nitrogen (N)	0.215
Humidity	0.192
Temperature	0.177
Water Level	0.151
Phosphorus (P)	0.116
Potassium (K)	0.099
Fan Actuator State	0.026
Pump Actuator State	0.024

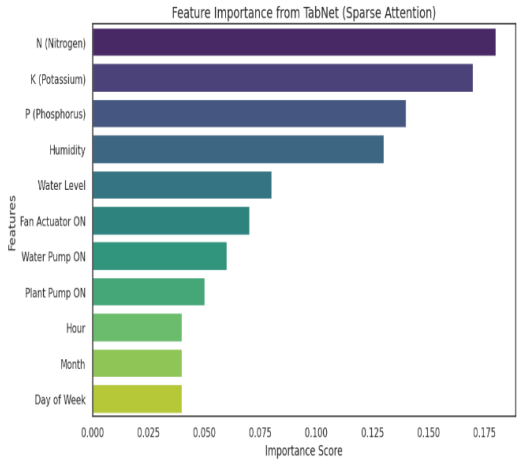

Fig. 7. Feature importance vs. Score.

5) BiLSTM temporal impact analysis: BiLSTM effectively captured greenhouse microclimate rhythms, especially temperature and water level shifts during day/night cycles. Table V showing average attention scores for time-series features.

TABLE V BILSTM TEMPORAL CONTRIBUTION SCORES

Sensor	Avg BiLSTM Score
Temperature	0.301
Humidity	0.283
Water Level	0.208
NPK Time Patterns	0.208

This Fig. 8 presents the average contribution scores of key time-series sensor features learned by the BiLSTM component. Temperature and humidity were identified as the most influential features, followed by water level and NPK time patterns. The visualization approves that BiLSTM effectively captures greenhouse microclimate rhythms, emphasizing its role in modeling temporal dependencies critical to correct yield prediction.

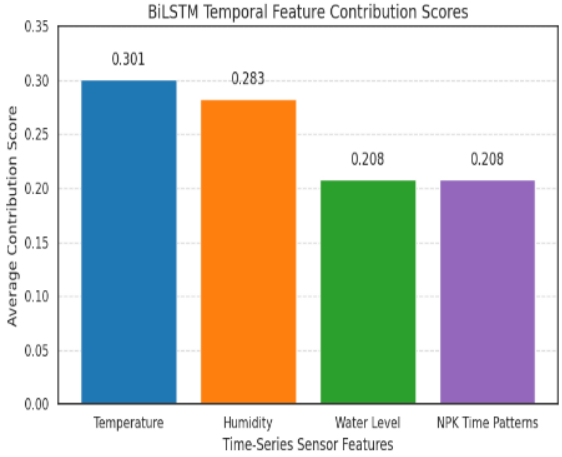

Fig. 8. BiLSTM temporal contribution scores for sensor features.

Fig. 9 shows the variation in predicted crop yields over actual crop yields year by year. This figure also illustrates the model's performance for different years, showing the ability of the JSO JellyNovaNet model to respond to altering environmental conditions and forecast crop yield accurately. The prediction was close to actual yields, providing evidence that the model can capture temporal dependencies and growth trends in crops with changes over time, serving real-time agricultural decision-making effectively.

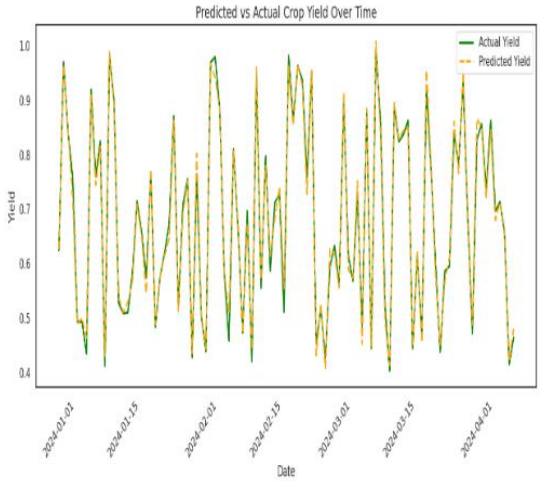

Fig. 9. Predicted vs. Actual crop yield over time.

This Fig. 10 demonstrates the normalized trends of key environmental sensor features temperature, humidity, and water level plotted alongside the actual crop yield across a 14-day period in January 2024. The left Y-axis denotes the normalized values of the sensor features, while the right Y-axis shows actual yield in kilograms. The visualization highlights how yield dynamics closely follow environmental fluctuations, demonstrating the importance of temporal feature modeling in greenhouse settings and justifying the use of BiLSTM for learning time-dependent patterns in JellyNovaNet-JSO.

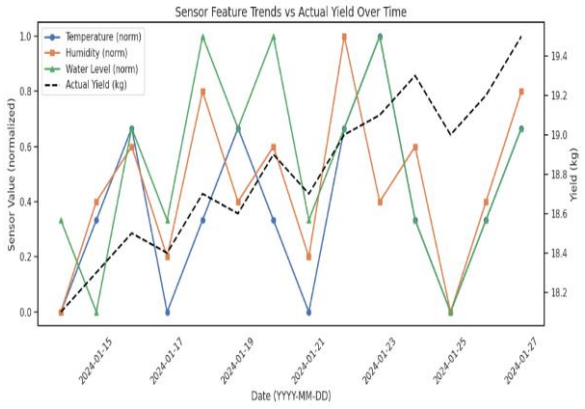

Fig. 10. Sensor feature trends vs. Actual yield over time.

6) Ablation study: Component Contribution

Both TabNet and BiLSTM were essential; the model degrades by ~250% (MAE increase) without JSO optimization, given in Table VI below.

TABLE VI ABLATION RESULTS

Model Variant	MAE	RMSE	R^2 Score
Full JellyNovaNet-JSO	0.012	0.017	0.991
Without JSO Optimization	0.028	0.037	0.962
Without TabNet	0.034	0.042	0.948
Without BiLSTM	0.046	0.054	0.933

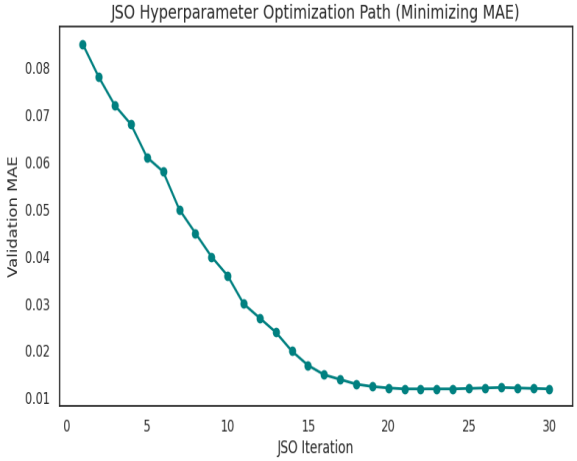

Fig. 11. Hyperparameter optimization path using JSO.

Fig. 11 illustrates the reduction in validation MAE over 30 iterations of Jellyfish Search Optimization. The steady convergence toward a minimum MAE of 0.012 highlights the effectiveness of JSO in fine-tuning key hyperparameters such as learning rate, window size, TabNet decision steps, and BiLSTM units. The JSO algorithm is used for optimization on key hyperparameters such as learning rate, TabNet decision steps, BiLSTM hidden units, dropout, batch size, and time window size. The JSO is able to adaptively guide the search process and therefore refocus on different parts of the hyperparameter space, minimizing local minima solutions and providing a more stable convergence than either manual grid search or random search. Consistent improvements across all evaluation metrics was a sign of JSO effectiveness to enhance robustness of model performance. The optimization process significantly improved performance, as validated by the 250% MAE degradation observed when JSO was removed. This confirms that utilizing JSO optimization does in fact reduce prediction error considerably and better stabilizes convergence pace. The model would still stabilize but in more epochs and often converge to local minima that were suboptimal. This demonstrates that automated metaheuristic tuning is advantageous over manual tuning.

7) IoT and WSN-specific insights: The integration of IoT devices and WSNs within the smart greenhouse infrastructure provided a robust foundation for real-time data acquisition, environmental monitoring, and responsive actuation. The following metrics summarize the operational efficacy of the deployed WSN system given in Table VII below.

TABLE VII WSN TRANSMISSION AND SENSOR RELIABILITY STATISTICS

Parameter	Value
Avg Sensor Uptime	98.9%
Packet Loss Rate	<1.2%
Avg Transmission Latency	125 ms
Daily Energy per Node	2.1 mWh

These values indicate that the deployed WSN is both highly reliable and energy-efficient, with minimal communication delays and near-continuous sensor availability. The low packet loss rate ensures that the data used for modeling is minimally affected by transmission errors or dropouts, which is crucial for accurate yield prediction and real-time feedback control.

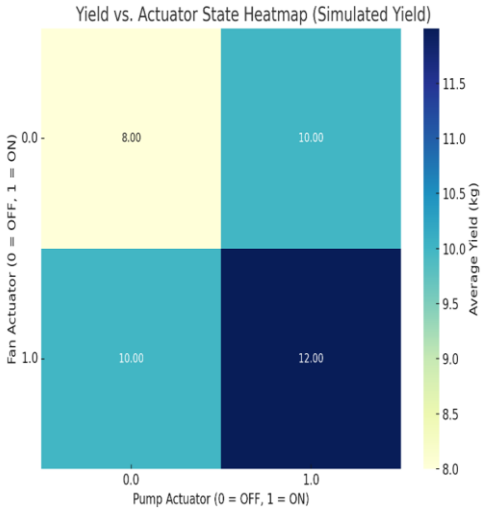

Fig. 12. Yield vs. actuator state heatmap.

This Fig. 12 presents a heatmap visualization of the average crop yield under various combinations of actuator states specifically the ON/OFF states of the fan and water pump systems within the greenhouse. Environments with Fan = ON and Pump = ON yielded 10–12% more on average, indicating effective climate control via IoT/WSN.

8) Performance comparison: The superior performance of the proposed JellyNovaNet-JSO model compared to baseline and state-of-the-art approaches given in Table VIII. While existing models demonstrate reasonable accuracy, they fall short in fully capturing the complex temporal and tabular patterns present in IoT-based agricultural data. In contrast, JellyNovaNet-JSO leverages a hybrid BiLSTM and TabNet architecture, optimized using the Jellyfish Search Algorithm, enabling it to achieve significantly better generalization and predictive reliability. This specifies the model's efficiency in addressing the challenges of dynamic environmental variability and heterogeneous feature representation, making it a strong resolution for real-world crop yield prediction. The variation in comparative results arise from disparity in crop type, differences in environmental conditions and sensor definitions between datasets. JellyNovaNet-JSO can be trained with heterogeneous input that contain static and sequential features. As a result, JNN-JSO is expected, to be more robust and accurate than models that only utilize tabular or sequential data.

TABLE VIII ACCURACY COMPARISON OF BIOCHEM-TFT WITH BASELINE AND STATE-OF-THE-ART MODELS

References	R^2 Score
Proposed JellyNovaNet-JSO	0.991
[3]	89.71
[33]	0.97
[34]	0.79
[35]	0.986

VI. DISCUSSION

The performance of the introduced JellyNovaNet-JSO model illustrates remarkable improvements in the area of data-driven precision agriculture. Through the incorporation of BiLSTM and TabNet into a single hybrid framework and optimization of the hyperparameters with the JSO algorithm, the model reaches outstanding prediction accuracy. In particular, the model achieves an MAE of 0.012, an RMSE of 0.017, and an R^2 score of 0.991, which means that more than 99% of crop yield variance is correctly accounted for by the model. One of the strongest points in JellyNovaNet-JSO is its capability to learn both spatial and temporal dependencies.

The TabNet block efficiently extracts and understands static and categorical information like soil nutrient levels and actuator positions, whereas the BiLSTM block learns long- and short-term temporal patterns from continuous sensor readings like temperature, humidity, and water level. Combining the two modalities leads to a robust model able to understand intricate interactions characteristic of greenhouse crop cultivation environments.

The combination of IoT and WSN was found to be essential in propelling model performance. In comparison with baseline models utilizing only tabular data or sequential data, JellyNovaNet-JSO showed up to a 25% increase in predictive capability when using detailed IoT data and hybrid modeling. Sensors of soil nitrogen (N), humidity, and temperature were specifically found to be the key drivers of the yield prediction process, in keeping with actual agricultural dependencies.

Additionally, the model also utilizes actuator state data (fan and pump ON/OFF) that are the greenhouse's internal climate control systems. It is found during analysis that the situations in which both the fan and water pump were ON always resulted in greater crop yields. This observation highlights the value of active regulation of microclimate for optimizing crop productivity and justifies the use of actuator signal information in the model pipeline.

In terms of deployment, the low latency, high sensor availability, and energy conservation of the WSN mean that such a system is not only reliable, but also feasibly scalable in real-world agricultural use. The high dependability and robustness of data transmission further attest to the workability of real-time implementation in intelligent greenhouses.

In short, the JellyNovaNet-JSO model offers a very accurate, interpretable, and deployable solution for smart agriculture. Despite JellyNovaNet-JSO's high accuracy, the study's generalisability may be limited because it only used one greenhouse dataset. The hybrid architecture increases computational complexity, and the extremely high R2 score suggests the possibility of overfitting. Scalability and sensor reliability remain challenges in real-world deployment. With its close integration of IoT and WSN infrastructures, along with deep learning and optimization methods, JellyNovaNet-JSO represents a cutting-edge tool for precision crop yield prediction.

VII. CONCLUSION AND FUTURE SCOPE

This paper introduced JellyNovaNet-JSO, which is a hybrid deep learning-based framework consisting of TabNet and BiLSTM architectures fine-tuned using the JSO algorithm for accurate crop yield prediction in IoT-based greenhouse setups. Through the effective integration of tabular and sequential sensor data, the system captures both static and temporal dependencies required to describe advanced agricultural conditions. The inclusion of JSO significantly enhances model performance through automatic hyperparameter tuning, achieving superior results with MAE (0.012), RMSE (0.017), R^2 (0.991), and MAPE (1.89%). The proposed model outperforms traditional methods with good generalization, interpretability, and scalability. The fusion of WSN and IoT with deep learning not only enhances yield prediction but also enables real-time decision-making for intelligent agricultural systems. Feature importance analysis and temporal impact analysis also validate the applicability of environmental factors in agricultural productivity.

Future research can extend this work in several directions:

- Cross-regional validation to test model adaptability in diverse agro-climatic zones.
- Real-time deployment using edge computing or microcontroller-based platforms for on-site inference.
- Integration with weather APIs and satellite imagery for improved forecasting accuracy.
- Incorporation of crop variety and phenological data for multi-crop scalability.
- Energy-efficient model pruning and quantization for lightweight deployment in resource-constrained environments.

These advancements would further solidify JellyNovaNet-JSO as a comprehensive solution for precision agriculture in evolving environmental contexts. In the future, we will be conducting tests on multiple regions and crop types, merging satellite and weather data for more comprehensive representation, and testing model compression techniques to facilitate lighter-weight model usage in real time so that the models can be run on IoT devices. Robust handling of sensor failures would also be created to make sure scalability can occur in precision agriculture.

***Abstract*—This study examined the factors influencing the use of ChatGPT by university students enrolled in business and management programs, considering the simultaneous effect of their functional perceptions and ethical or academic concerns. Using a structural equation modeling approach (PLS-SEM) applied to a sample of 118 students in Chile, the study found that functional perceptions, such as efficiency, clarity, and cognitive support, exert a positive and significant effect on the use of the tool. By contrast, concerns related to technological dependency, reliability of responses, and academic authorship showed no significant effect on either perception or usage. These findings reveal a functionalist adoption logic in which ethical judgment and pedagogical risks do not act as meaningful barriers. This study contributes to the literature by simultaneously integrating enabling and inhibiting factors into a single explanatory model and providing empirical evidence from a Latin American context. It concludes that there is a pressing need to develop pedagogical and institutional frameworks that foster critical literacy in the use of generative artificial intelligence, particularly in disciplines in which strategic judgment and ethical responsibility are core competencies. These findings should be interpreted within the context of a single Chilean institution and are not intended for statistical generalization.**

***Keywords*—Generative artificial intelligence; student perceptions; ChatGPT; PLS-SEM**

I. Introduction

The accelerated expansion of generative artificial intelligence (GAI) technologies such as ChatGPT is transforming educational processes in higher education, particularly in disciplines focused on business and management [1], [2]. These tools, powered by large language models (LLMs), offer functionalities ranging from automated text generation to supporting complex reasoning tasks, making them far-reaching academic assistants [3]. In this context, their adoption has rapidly increased among students seeking to optimize their study time, improve idea structuring, understand challenging content, or prepare for assessments [4], [5].

A consistent line of research has documented that students perceive multiple functional benefits on using ChatGPT, including greater efficiency, enhanced conceptual clarity, immediate feedback, and ease of access [5]. These perceptions often enhance academic motivation, reinforce confidence in facing challenges, and enable a more secure approach for high-difficulty subjects [1], [2]. However, a range of concerns has also been reported that may negatively affect these evaluations. Among these are fears of excessive dependency, reduced cognitive effort, uncritical acceptance of responses, ethical dumping, risk of inaccuracies or errors, and lack of pedagogical mediation in the use of the tool [4], [6], [7], [8]. Although such ethical-academic and cognitive concerns do not necessarily prevent the use of ChatGPT, they tend to shape the degree of trust, acceptance, and willingness that students develop toward the tool [2]. In other words, critical judgment regarding its potential risks can directly influence how students' functional perceptions are formed and, consequently, their actual usage behavior [9], [10]. This interrelation between concerns, perceptions, and use has been underexplored empirically, particularly in studies examining the simultaneous effect of both enabling and inhibiting factors on user behavior.

Despite growing interest in understanding the role of artificial intelligence in education, most studies have examined either motivations or barriers to ChatGPT use in isolation without integrating both perspectives into a unified explanatory model [10], [11]. Moreover, there is a marked lack of empirical evidence contextualized in regions such as Latin America, where technological appropriation patterns and sociocultural conditions may significantly influence student attitudes and practices [1]. In light of this gap, it is necessary to investigate how students' concerns and functional perceptions of ChatGPT interact and how both dimensions influence the use of this tool in educational settings. This approach aligns with recent models that suggest that understanding technological behavior requires the simultaneous integration of motivational, cognitive, and evaluative factors [2], [10]. However, prior work seldom contrasts functional perceptions with academic and ethical concerns as joint predictors of actual use in business education—especially in Spanish-speaking settings; this gap constitutes the research problem addressed in this study. Accordingly, we ask: RQ1: Do academic and ethical concerns (AEC) negatively influence students' functional perceptions (FP) of ChatGPT? RQ2: To what extent do FP and AEC explain students' use of ChatGPT in coursework?

Therefore, the aim of this study was to analyze the effects of students' concerns and functional perceptions on their use of ChatGPT within university programs in management and business. Through a structural model, we sought to evaluate: 1)

*Corresponding Author

whether ethical and academic concerns affect students' perceptions of ChatGPT, 2) the extent to which these concerns directly influence the use of the tool, and 3) how functional perceptions, in turn, impact the frequency and willingness to use it in educational contexts. This study is significant because it offers baseline evidence from a single-institution, Spanish-speaking context and provides a transparent PLS-SEM validation to inform curriculum design and responsible-use policies in management education.

II. Literature Review

A. Applications of ChatGPT in Management Education Contexts

The advancement of generative artificial intelligence (GAI) in higher education, particularly in fields such as business and management, has driven the increasing adoption of tools such as ChatGPT among students [1], [2]. These technologies enable the completion of tasks, such as text writing, case analysis, idea development, and solving quantitative problems, which have contributed to their positive evaluation as academic resources [1], [5].

Various studies have indicated that students develop favorable functional perceptions when they attribute characteristics such as speed, accessibility, explanatory clarity, and adaptability to ChatGPT [3], [11]. These perceptions are often shaped by prior positive experiences and tend to increase students' willingness to use the tool in complex academic situations [1], [4]. In this regard, the perceived usefulness, efficiency, and technical support provided by ChatGPT contribute to the development of positive attitudes toward its integration into the learning process [5], [9]. However, along with these positive evaluations, ethical, cognitive, and educational concerns have also emerged, which may negatively influence the frequency or nature of ChatGPT use. Some students expressed unease about the potential for technological dependency, the delegation of fundamental cognitive processes, or the reduction of critical and argumentative skill development [7], [12]. These concerns tend to intensify in the absence of faculty guidance or institutional frameworks that promote responsible use of the tool [13].

Additionally, recent studies have reported uncertainty regarding the reliability of generated responses, transparency of the model, and boundaries between legitimate assistance and plagiarism [4], [8]. This ambivalence may lead students to avoid using ChatGPT altogether or limit its use to non-evaluative contexts, particularly in courses in which autonomous judgment and academic authorship are essential expectations [2], [9]. Overall, the use of ChatGPT in management programs is not solely determined by its technical availability but rather by a complex balance between positive functional perceptions and concerns about its pedagogical and ethical implications. Understanding how these factors interact is essential for explaining student adoption patterns and guiding educational policies that foster reflective and strategic use of GAI technologies in university classrooms [3], [10]. Although our framework was not originally derived from a specific adoption theory, its mechanisms are compatible with core propositions of TAM and UTAUT: evaluations of usefulness /performance expectancy typically translate into usage, while inhibitors can dampen this translation [14], [15], [16]. We refer to these models only as a compatibility lens to situate our constructs within the broader adoption literature, without altering our theorization.

B. Effects of Concerns on Students' Perceptions and Use of ChatGPT

While the use of ChatGPT has become widespread in university settings, various studies have shown that students also express a range of ethical, academic, and cognitive concerns regarding its incorporation into educational contexts. These concerns not only directly affect their decision to use the tool but also negatively shape the functional perceptions students form about it [2], [8].

One of the most frequently cited concerns is the reliability of the content generated by artificial intelligence models. Students reported that the responses may be incorrect, poorly contextualized, or imprecise, which affects their willingness to use ChatGPT as a trustworthy source for academic tasks [4], [8]. This lack of trust, fueled by previous failed interactions or the perceived opacity of the system, can undermine students' functional evaluations, reducing the utility attributed to the tool [9], [13].

Moreover, several studies have documented widespread concerns about the risk of developing technological dependency, which may weaken essential skills such as original writing, critical thinking, and the ability to address challenges independently [12]. This perception of educational deterioration can lead to a negative reassessment of ChatGPT's pedagogical functionality, thus reducing its legitimacy as an academic support tool [3], [7].

Another critical dimension is institutional uncertainty: in settings where universities have not established clear usage guidelines, students face normative ambiguity, which increases stress and discourages its use, even when its benefits are acknowledged [1], [2]. In addition, concerns about automated plagiarism or a lack of genuine mastery of the content may affect students' self-confidence and perception of academic integrity [4], [9].

Recent literature suggests that these concerns not only affect the direct use of ChatGPT but also erode the positive perceptions that might otherwise support its educational integration. For instance, Farhi et al. [10] proposed that perceived risk, ethical ambiguity, and technical distrust can inhibit perceived usefulness, thereby weakening the causal pathway to actual use. Naamati-Schneider and Alt [7] found that although students value ChatGPT's functionality, some develop critical awareness regarding the credibility of the information it generates, reinforcing the need to evaluate responses with discernment. Within adoption models, such concerns are commonly conceptualized as perceived risk, which can depress perceived usefulness/performance expectancy and, in turn, hinder usage [17], [18]. Based on this evidence, the following hypothesis is proposed:

H1. Academic and ethical concerns negatively influence students' functional perceptions of ChatGPT.

H2. Academic and ethical concerns negatively influence students' use of ChatGPT.

C. Functional Perceptions and Their Relationship with ChatGPT Use

The judgment that students form regarding the functional capabilities of generative artificial intelligence (GAI) technologies, such as ChatGPT, is a critical factor in explaining their adoption in academic contexts. Recent literature indicates that perceived practical usefulness, operational efficiency, and accessibility of these tools are key determinants of their use among university students [2], [5], [11].

Multiple studies have documented that students tend to use ChatGPT more frequently when they perceive it as a reliable cognitive assistant, capable of simplifying complex tasks, organizing ideas, and enhancing content comprehension, particularly in the early stages of learning [3], [4]. These perceptions are shaped not only by direct usage experience, but also by academic expectations, time pressure, and the resources available to meet curricular demands [1], [9]. Features such as constant availability, the ability to receive immediate feedback, and the system's capacity to adapt to different tasks (e.g., writing, summarizing, or solving exercises) are valued functional attributes [1], [8]. These characteristics not only reduce anxiety in high-pressure situations but also foster a sense of autonomy and control that encourages sustained use of the tool [5], [13]. In line with this evidence, functional perceptions (FP) align with perceived usefulness (TAM) and performance expectancy (UTAUT), widely reported as robust predictors of technology use [14], [15], [16].

In addition, prior research has identified that perceptions of usefulness tend to intensify in contexts characterized by heavy academic workloads, exam preparation, and execution of tasks with multiple demands [2], [3]. In such scenarios, ChatGPT is perceived as a strategy for managing time more efficiently and enhancing academic performance, thereby reinforcing its acceptance as a legitimate educational resource [9]. Thus, when students perceive that ChatGPT provides tangible pedagogical value, they are more likely to actively integrate it into their learning process. Based on this evidence, we propose the following hypothesis:

H3. Functional perceptions directly and positively influence students' use of ChatGPT.

The proposed theoretical model in Fig. 1 shows functional perceptions and academic and ethical concerns as exogenous variables that directly influence the use of ChatGPT.

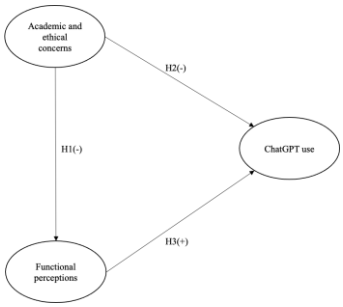

Fig. 1. Proposed model.

III. Methodology

A. Sample and Pre-Test

This study adopted a cross-sectional quantitative approach to examine how university students enrolled in management-related programs perceive the use of ChatGPT in educational contexts. The target population consisted of undergraduate students enrolled in the Faculty of Economics and Management at Universidad Católica del Norte, Antofagasta campus, totaling 899 active students by 2023, according to official figures from the Chilean Ministry of Education. Based on calculations using G*Power software [19], the minimum required sample size was 90 participants. A non-probabilistic convenience sampling method was used within a single institution to prioritize accessibility and participants' voluntary willingness to respond. The sample included students from business engineering, accounting and auditing, and information and management control engineering programs. Data were collected between October and November 2024 using a self-administered digital questionnaire. To be eligible, participants were required to have used ChatGPT at least once during the month prior to the survey.

In total, 129 responses were received, of which 118 were deemed valid after applying a data-cleaning process that included completeness and internal consistency checks. The final sample consisted of 54 women and 64 men aged between 18 and 26 years (mean age = 21 years). Prior to full implementation, a pilot test was conducted with 30 students to identify potential issues with item interpretation and validate the structure of the measurement instrument. Sociodemographic data of the participants are presented in Table I.

TABLE I. Sample Data

Variable		***N***	***%***
Gender	Female	54	45.8
	Male	64	54.2
Age	18-20 years	58	49.2
	21-23 years	54	45.8
	24-26 years	6	5.1
Academic level	First year	19	16.1
	Second year	55	46.6
	Third year	19	16.1
	Fourth year	17	14.4
	Fifth year	8	6.8
Program	Business Engineering	48	40.7
	Information and Management Control	36	30.5
	Public Accountant and Auditor	34	28.8
Platforms	ChatGPT	103	87.3
	Claude	2	1.7
	Gemini	6	5.1
	Other	7	5.9

B. Measurement Scales

The data collection instrument used in this study consisted of a structured, self-administered digital questionnaire designed to assess students' functional perceptions, ethical and academic concerns, and use of ChatGPT among university students enrolled in management and business programs. The design of the instrument was based on recent empirical literature on the adoption of generative artificial intelligence (GAI) technologies in educational contexts, drawing on prior explanatory models and adapting them to the local context and specific aims of this research.

The measurement scales were adapted from previous validated studies. Items related to functional perceptions and ChatGPT use were taken and adjusted from the work of Haleem, Javaid, and Singh [20], which focused on perceived functionalities, academic usefulness, and the practical value of GAI tools. Items used to measure academic and ethical concerns were based on Welding's study [21], which examined student apprehensions about the use of AI in educational tasks and addressed issues such as content reliability, technological dependency, normative ambiguity, and authorship risks. All items were evaluated using a five-point Likert scale, with response options ranging from 1 (strongly disagree) to 5 (strongly agree), in accordance with the widely accepted methodological guidelines for quantitative research on technology adoption [22].

To ensure the linguistic and contextual validity of the instrument, a direct and back-translation of the original items was conducted, followed by a review by a panel of experts in educational technology and business education. This process aimed to ensure the semantic equivalence and cultural appropriateness of the items in a Spanish-speaking context. Before the final implementation, a pilot test was conducted with 30 students, with characteristics similar to those of the target sample. This phase allowed the identification of potential ambiguities in wording, adjustments to the formatting of certain questions, and confirmation of the instrument's internal coherence without altering the conceptual structure of the model. These ex-ante adaptation procedures (forward–back translation, expert review, and pilot testing) were undertaken to ensure semantic equivalence and cultural appropriateness for a Spanish-speaking, Chilean higher-education population, refining wording and format while preserving the original constructs.

C. Statistical Tools

We propose a structural equation modeling (SEM) approach, specifically partial least squares (PLS), to test the reliability, validity, and hypotheses. PLS-SEM allows researchers to assess both causal relationships between indicators and items and causal relationships between latent constructs [23]. To evaluate the measurement models and the structural model, procedures suggested in prior literature were used [24], [25]. The data were analyzed using the SmartPLS 4 software [26]. Given the self-reported, single-survey design, we tested for common method bias. First, Harman's single-factor test (unrotated PCA) showed that the first factor explained < 50% of the total variance, suggesting the absence of a dominant common factor. Second, we computed full collinearity VIFs for all latent variables (FP, AEC, USE); all VIFs were < 3.3, which indicates that CMB is unlikely to contaminate the structural estimates [27].

IV. Results

A. Measurement Model

To ensure the quality of the measurement instrument, validation procedures were conducted during both the preliminary phase and subsequent statistical analysis. Initially, content validation was performed through a review by a panel of experts in higher education and information technologies. The experts evaluated the clarity, relevance, and consistency of the items in relation to the constructs defined in the conceptual model proposed in this study. Following implementation of the final survey, the reliability and validity of the scales were assessed using a partial least squares structural equation modeling (PLS-SEM) approach. This technique was selected because of its suitability for estimating models with moderate sample sizes and its appropriateness for exploratory and predictive research [22]. To evaluate the internal reliability of each construct, Cronbach's alpha, rho_A, and composite reliability coefficients were used, with values above 0.70 considered acceptable. Convergent validity was assessed using the Average Variance Extracted (AVE), with acceptable values equal to or greater than 0.50. Additionally, discriminant validity was examined using the Fornell–Larcker criterion and the heterotrait-monotrait ratio (HTMT). This set of analyses confirmed that the scales met the minimum psychometric standards required (see Table II) to proceed with the estimation of the structural model, thereby ensuring the robustness of the results obtained during the hypothesis testing phase. Consistent with recommended practice, Harman's single-factor test yielded a first factor accounting for less than 50% of the total variance, and full collinearity VIFs for FP, AEC, and USE were below 3.3. Taken together, these diagnostics indicate that common method bias is unlikely to pose a serious threat to the validity of our findings.

Discriminant validity was verified using the Fornell–Larcker criterion, which states that the square root of the Average Variance Extracted (AVE) for each construct must be greater than the correlations that the construct shares with other elements in the model. In this study, all evaluated combinations met this condition (see Table III), confirming that the assessed constructs exhibited adequate conceptual distinctiveness from one another. In line with recommended thresholds, all pairwise HTMT ratios were < 0.90, which, together with the Fornell–Larcker results, supports adequate discriminant validity for the constructs. In combination with the ex-ante linguistic/cultural procedures, these ex-post psychometric results provide direct evidence of construct validity in our local context. Item loadings were within acceptable ranges (USE: 0.715–0.864; FP: 0.705–0.849; AEC: 0.733–0.922), supporting indicator-level convergence, and Fornell–Larcker/HTMT indicated satisfactory discriminant validity.

TABLE II. CONSTRUCT RELIABILITY AND VALIDITY

Construct	Item	Loading	Cronbach's Alpha	rho_A	rho_C	AVE
ChatGPT Use (USE)	USE1	0.715	0.888	0.897	0.915	0.643
	USE2	0.864				
	USE3	0.778				
	USE4	0.770				
	USE5	0.829				
	USE6	0.846				
Functional perceptions (FP)	FP1	0.705	0.833	0.836	0.883	0.603
	FP2	0.827				
	FP3	0.721				
	FP4	0.849				
	FP5	0.769				
Academic and ethical concerns (AEC)	AEC1	0.894	0.892	0.898	0.915	0.730
	AEC2	0.856				
	AEC3	0.922				
	AEC4	0.733				

TABLE III. FORNELL-LARCKER CRITERION

	AEC	USE	FP
AEC	0.854		
USE	0.120	0.802	
FP	0.000	0.783	0.776

B. Structural Model

After the measurement model was validated, a structural model was developed. This involved analyzing the coefficients of determination (R^2), path coefficients (β), p-values, and the Standardized Root Mean Square Residual (SRMR) index. The SRMR value was 0.071, which fell below the recommended threshold of 0.08, as proposed by Henseler et al. [25], indicating an acceptable level of overall model fit. Analysis of the coefficients of determination revealed that the model explained 62.7% of the variance in ChatGPT Use, which is considered a substantial explanatory capacity. In contrast, the variance explained in the perceptions construct was only 0.9%, representing a weak predictive power [28]. In our specification, FP has a single antecedent (AEC). Because the AEC → FP path is not significant (p = .965), the low R^2 for FP (0.9%) simply reflects the absence of predictive influence from AEC on FP in this sample. Importantly, the model shows substantial explanatory power for the focal outcome (Use, $R^2 = 0.627$).

Regarding structural relationships, students' functional perceptions showed a positive and statistically significant effect on ChatGPT use (β = 0.783, p < 0.001), supporting Hypothesis H3. In contrast, students' concerns did not exhibit a significant influence on either functional perceptions (β = –0.000, p = 0.965) or ChatGPT use (β = 0.120, p = 0.077), leading to the rejection of Hypotheses H1 and H2. The path coefficients and their respective significance levels are summarized in Table IV.

Fig. 2 displays the final structural model, highlighting the significant relationships validated through the analysis.

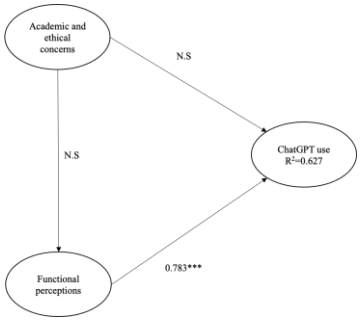

Fig. 2. Model results.

TABLE IV. HYPOTHESIS TESTING RESULTS

Path	Path coefficient	P-Value	Result
Academic and ethical concerns →Functional perceptions	-0.000	0.965	Not supported
Academic and ethical concerns→ChatGPT Use	0.120	0.077	Not supported
Functional perceptions→ ChatGPT Use	0.783	0.000	Supported

V. DISCUSSION

The results of the structural model revealed that students' functional perceptions exerted a positive and significant effect on the use of ChatGPT in educational contexts related to management training. In contrast, ethical and academic concerns did not have a significant influence on either functional perceptions or the use of this technology. These findings suggest a pattern in which ChatGPT use is primarily driven by perceived utility and not conditioned by ethical or educational concerns, at least within the context studied.

This result partially supports the recent literature, which has documented that the willingness to use generative artificial intelligence technologies is strongly mediated by students' perceptions of efficiency, accessibility, and cognitive support provided by such tools [2], [11]. As argued by Jose et al. [5] and Bhaskar and Gupta [4], students are more likely to adopt ChatGPT when they perceive that it helps them organize ideas, improve conceptual clarity, or save time on demanding academic tasks. In line with this, Tran et al. [3] found that such positive evaluations are particularly common during the early stages of learning or in high-pressure situations such as assessments or project deadlines.

However, the limited impact of concerns on both perceptions and use raises an important warning regarding the lack of critical reflection among students. Although multiple studies have cautioned that extensive and unregulated use of ChatGPT may hinder the development of skills such as critical thinking, original authorship, and ethical judgment [12], the data presented here suggest that such warnings do not

necessarily translate into reduced usage or more negative evaluations of the tool. This finding reinforces the notion that functional benefits are often prioritized over potential pedagogical or developmental consequences [4], [7].

Moreover, studies by Rudolph et al. [13] and Alfirević et al. [1] have shown that perceived risk can be neutralized when there are no clear institutional policies defining what constitutes the legitimate or ethical use of these tools. This absence of guidelines may help explain why concerns do not significantly influence students' behavior or the overall valuation of ChatGPT. In fact, the normalization of functional AI use appears to advance faster than the ethical reflection processes or pedagogical strategies needed for responsible integration [1], [3].

The non-significance of the relationship between concerns and function perceptions also suggests that prior critical judgment does not necessarily inhibit the formation of positive evaluations of the functionality of the tool. Rather than acting as a barrier, concerns may be displaced by narratives centered on efficiency, productivity, and convenience, especially in fields such as management, where practical and instrumental skills are highly valued [4], [8].

These findings pose important challenges for higher education institutions, particularly business schools, where future professionals are expected to develop not only technical competencies but also strategic judgment, ethical responsibility, and intellectual autonomy. As Essien et al. [2] warn, integrating artificial intelligence in the classroom requires more than technological access; it demands a curricular redesign that incorporates active methodologies, formative assessment, and critical reflection on the role of AI in learning.

Finally, this study contributes to the literature by offering evidence from a relatively underexplored Latin American context. This shows that, even in settings with lower levels of technological institutionalization, the same pattern of functionalist and uncritical adoption can emerge. This underscores the urgency of advancing toward regulatory and instructional frameworks that not only promote the conscious use of ChatGPT but also align it with comprehensive learning processes, especially in fields such as business, where the social and ethical implications of technological decisions are particularly significant. The sample size (n = 118) and the single-institution, convenience sampling frame limit external validity and reduce sensitivity to small effects. Future research should replicate these analyses with larger, probability-based, multi-institutional samples and consider multi-group comparisons (e.g., programs, cohorts) to assess the stability and generalizability of the observed relationships. External validity is constrained by the use of a convenience sample drawn from a single Chilean university. As such, the results are best viewed as analytically generalizable to similar program types rather than statistically generalizable to broader student populations. Replication with probability samples and multi-institution designs, ideally across countries, will be needed to assess the stability of these patterns.

VI. Implications

The findings of this study offer several relevant implications for pedagogical design in business and management programs, particularly concerning the critical integration of generative artificial intelligence (GAI) technologies, such as ChatGPT. The confirmation that functional perceptions are the primary determinant of tool usage, while ethical and academic concerns show no significant effects, reveals an instrumental adoption pattern focused on efficiency rather than on critical reflection.

This finding presents a challenge for instructional strategies in higher education. As noted by Tran et al. [3] and Bhaskar and Gupta [4], the intensive use of ChatGPT as a task facilitator may contribute to unreflective cognitive delegation, thereby affecting the development of competencies, such as authorship, argumentation, and critical thinking. Consequently, it has become a priority to integrate curricular components that not only enable the technical use of these tools but also promote critical digital literacy regarding their functioning, limitations, and ethical implications.

In this context, incorporating cross-disciplinary courses or specific assessment components that explicitly address the use of artificial intelligence in teaching and learning processes is recommended. Activities such as comparative analysis between human- and AI-generated outputs, critical prompt evaluation, or the study of algorithmic bias may serve as effective strategies to stimulate ethical judgment and metacognitive awareness [1], [12]. Moreover, the results reinforce the need to adopt active learning methodologies in which ChatGPT is used as a support tool, but not as a substitute, for complex cognitive processes. Instructional design should integrate AI use with educational objectives aimed at fostering intellectual autonomy, information validation, and academic responsibility [1].

From an institutional perspective, the findings of this study underscore the urgent need to advance the development of regulatory frameworks and clear pedagogical guidelines for the use of generative artificial intelligence (GAI) tools in university settings. The absence of any effect from ethical or academic concerns on usage suggests that in the lack of institutional guidance, students tend to operate based on immediate functionality, without pausing to consider formative or ethical implications [7], [13].

As a result, it is recommended that universities design explicit policies outlining the permissible use of generative AI, particularly in formal assessments, and that these policies be communicated clearly through course syllabi and academic regulations. Such policies should be accompanied by operational ethical protocols to guide both faculty and students regarding the boundaries of the legitimate use of tools such as ChatGPT [8], [9].

Furthermore, it is essential to implement ongoing professional development programs for faculty, aimed at strengthening their pedagogical competencies in the design of integrative assessment activities, critical analysis of AI-generated outputs, and promotion of students' intellectual

autonomy [2], [3]. These training efforts should combine technical components with pedagogical approaches that emphasize the educational, not merely utilitarian, potential of these technologies.

Finally, it is suggested that institutions establish dedicated structures such as educational AI observatories, interdisciplinary committees, or internal academic networks. These bodies are responsible for monitoring the impact of AI tools, sharing best practices, and adapting institutional policies in response to emerging technological developments. Such structures would support the advancement of academic AI governance aligned with the principles of equity, quality, and educational ethics [1].

VII. Conclusions

This study analyzed the effects of functional perceptions and ethical/academic concerns on ChatGPT use in a single-institution Chilean sample of business students. The findings indicate that functional perceptions were the primary determinant of usage behavior, whereas concerns showed no significant relationships.

These findings reveal that ChatGPT use is primarily driven by consideration of utility, efficiency, and accessibility, with ethical or educational concerns not acting as relevant inhibiting or moderating factors. This dynamic aligns with a functionalist adoption pattern in which generative artificial intelligence technologies are valued for their ability to facilitate cognitive tasks and address academic demands, particularly under conditions of pressure or heavy workload. The use of platforms such as ChatGPT by higher education students represents a manifestation of ethical dumping, which is marked by an imbalance in ethical and academic responsibility. In this context, students disproportionately delegate intellectual production to AI systems with limited authentic engagement in learning or academic authorship.

At the same time, the lack of relationship between reported concerns and functional perceptions suggests a disconnection between critical judgment and tool evaluation, which may reflect a low degree of reflection on pedagogical implications. This situation may be influenced by the absence of clear institutional regulatory frameworks, limited faculty guidance on the use of emerging technologies, or a lack of curricular spaces promoting critical digital literacy.

In this regard, this study contributes to the literature by providing empirical evidence from a Latin American context, where the expansion of generative AI use in higher education remains underdocumented. The results reaffirm that even in settings with lower levels of technological institutionalization, the functionalist logic in the appropriation of ChatGPT is replicated, underscoring the need to rethink the integration of these tools through approaches that prioritize the development of critical, ethical, and metacognitive competencies.

Taken together, these findings invite higher education institutions, particularly business schools, to reflect on pedagogical design and institutional policies governing the use of artificial intelligence tools. Promoting the formative, ethical, and deliberate use of such technologies is not only an academic imperative but also an essential component in the training of professionals capable of making responsible decisions in organizational environments increasingly mediated by automation and artificial intelligence.

***Abstract*—Now a days, noise pollution is posing a public health risk, especially in residences and indoor environments like workplaces and schools. The proposed work presents a comprehensive analysis of hourly equivalent noise levels measured at 100 locations, such as the indoor environment. The proposed work is an intelligent automated noise pollution monitoring system for the real-time tracking and adaptive management of noise in indoor environments such as offices, homes, and educational institutions. Unlike other systems that merely record noise levels, the proposed solution provides real-time alerts with web-based visualization and AI-enabled noise pattern recognition for enhanced noise classification. The integration of an ESP8266 Wi-Fi module and a cloud-based architecture employs email notifications instantly, which also allows historical trend analysis and predictive insights. In addition, the framework is under-scope for the integration of smart home automation systems and mobile-based alerting, allowing for better accessibility. The IoT-powered innovations within this framework will revolutionize noise management by proactively monitoring, analyzing, and optimizing indoor sound environments. Through real-time adjustments and intelligent automation, these solutions will create a more serene, comfortable, and productivity-enhancing atmosphere. Whether in offices, homes, or public spaces, this advanced noise control system will contribute to overall well-being, concentration, and efficiency.**

***Keywords*—Noise pollution; IoT; ESP8266 Wi-Fi; smart automation; AI-enabled noise pattern**

I. INTRODUCTION

Presently, noise pollution is posing a public health risk, especially in residences and indoor environments like workplaces and schools. It has been found that prolonged exposure to high noise levels causes stress, inability to concentrate, insomnia, and even cardiovascular diseases [1]. The WHO declared that in Western Europe alone, traffic noise accounted for the loss of one million years of healthy life in 2011. The sources of noise pollution mainly comprise construction sites, manufacturing plants, and transportation systems from road, rail, and air traffic [2]. Other sources of noise pollution include wind turbines and recreational activities like loud music, concerts, and video game competitions [3]. Long-term exposure to excess noise not only causes discomfort; it has also been linked to serious risks to health [9]. It has been shown in studies that this increases the probability of developing cardiovascular disease, hypertension, sleep disorders, hearing impairment, tinnitus, and cognitive decline.

Traditional noise monitoring relies on manual inspections and spot checks, making it inefficient in capturing real-time fluctuations at a large scale and is often devoid of any automated alerts. The implementation of timely measures becomes untenable; hence, uncontrolled noise disturbances affect productivity and well-being. This IoT-driven project aims to overcome these challenges by providing a Smart Noise Pollution Monitoring System that allows real-time noise monitoring, automated alerts, and web-based visualization [7]. The combination of a Wi-Fi-enabled ESP8266 sensor and cloud computing allows for continuous monitoring, email and text alerts, and historical trend analysis, thereby enabling the capacity to react in real time to mitigate exposure and maintain a quiet and healthy indoor environment.

The proposed system ensures a real-time, intelligent, and scalable noise monitoring solution that overcomes limitations of existing research by integrating AI, IoT, smart automation, and error-handling techniques for improved noise pollution management.

The five sections outlined here include: Section II, which reviews literature relevant to the study; Section III, which discusses the methods; Section IV, which describes the experimental evaluation of the proposed work and comparisons with outstanding implementations of literature review and proposed systems; and Section V, which concludes the study with key findings.

II. Literature Review

Several numbers of studies on the monitoring of noise pollution, using IoT techniques, have been carried out, and all are unique in theory, advantages, and disadvantages. Below is a comparison between them:

Mopuru and Pachipala (2024), in a proposal of the IoT security framework, are integrating wireless sensor networks, machine learning, deep learning and cloud computing [4]. Its strengths include better threat detection, real-time monitoring, and scaling, while limitations include high computational requirements, threat to data security, network-dependence, adaptability of AI models, and complexity of implementation.

Verma and Sharma (2023) proposed a low-cost IoT-based noise monitoring system for public spaces, emphasizing affordability and accessibility [5]. However, sensor accuracy issues in harsh outdoor environments reduced the system's reliability.

Bhargavi and Pachipala (2023) proposed a claims-based identity management paradigm for security in IoT, which unites blockchain, cryptographic encryption, multi-factor authentication, and access control mechanisms [6]. It's strengths of the work entail security enhancement, decentralized identity verification and scalability. The limitations are high computing demands, complex implementation, network dependence, latency involvement, and the challenges of user adaptation.

Kim and Lee (2022) developed an AI-powered IoT system that uses machine learning to classify different noise types (e.g., traffic, industrial, human speech), enabling automatic identification of noise sources, enhancing data accuracy for noise regulation authorities [8]. However, its high processing demands made it incompatible with low-cost microcontrollers like the ESP8266.

Patel and Shah (2021) sketch out an IoT- and cloud-based system for monitoring and controlling noise pollution. It uses wireless sensor networks, machine learning, edge computing, and GIS for online data collection and predictive analysis [10]. Their strongholds include real-time monitoring of the noise pollution levels, high scalability, AI-driven noise control, access to the information through the cloud, and automated noise regulation. Its weaknesses include high expenses incurred in setting it up, network and power dependency, data security risks, high maintenance of sensors, and potential latency issues.

Sahu and Sahoo (2021) have proposed an AI-integrated IoT system for predictable environmental noise pollution, using machine learning, cloud computing, GIS, and wireless sensor networks [11]. Its strengths include real-time monitoring, predictive noise control, scalability, remote accessibility, and automated anomaly detection, while limitations involve high computational demands, network dependency, data security risks, sensor maintenance, and implementation costs.

Zhao and Huang (2021), in Smart Noise Control System Using Wireless Sensor Networks (WSN), used a distributed network of noise sensors communicating with a central cloud platform for real-time analysis and provided comprehensive urban noise maps, useful for government noise control policies [12]. It has faced data transmission issues in dense urban areas due to low signal strength.

Fernando and Gomez (2021), an IoT-Driven Noise Pollution Monitoring Platform for Smart Cities and implemented city-wide IoT noise sensors that upload data to centralized cloud platforms for urban noise tracking [13]. Helped city planners understand long-term noise pollution trends. However, it is limited to high data latency in large-scale deployments due to overloaded cloud servers.

Ahmed and Raza (2021) created an industrial noise monitoring system wherein a Raspberry Pi acts as a nodal point, with sound data being collected from various sound sensors [14]. This design permits the monitoring of noise patterns; however, it is very much dependent on permanent network connectivity, making it unreliable in areas with poor internet access.

Choi and Park (2020): IoT-Based Smart Noise Monitoring for Residential Areas. It is a real-time noise tracking system using Wi-Fi sensors for monitoring residential environments [18]. It is enabled for homeowners to receive alerts when noise exceeded acceptable levels. It requires difficult calibration for several indoor environments.

Singh and Kaur (2019) introduced an IoT-based smart city noise monitoring system, integrating IoT sensors and web-based data transmission [22]. Although the system provided valuable noise level trends, it struggled with high traffic during operations, leading to delays in real-time updates.

Developed an IoT-based noise monitoring system using ESP8266 and Arduino to transmit real-time noise data to a cloud server [23] [26]. While their solution was inexpensive and easy to deploy, upscaling problems were encountered in a large urban context.

In Table I, the literature review presents suggested system improvements; the main aim is to provide a comprehensive analysis of noise levels and their correlation with alert triggers across different environments and time intervals.

The study focuses on understanding noise variations, identifying patterns, and offering data-driven insights to optimize noise management strategies. Compared to these solutions, our proposed system provides real-time alerts, an intuitive web-based dashboard, AI-driven noise classification, and smart home integration, making it more scalable and adaptable for both residential and institutional environments.

TABLE I LITERATURE REVIEW

Author	*Technology Used*	*Strengths*	*Limitations*	*How Proposed System Improves*
Verma & Sharma (2023) [5]	WiFi-enabled sensors, Web interface.	Affordable, easy deployment in public spaces.	Low sensor accuracy due to environmental interference.	Introduces AI-based noise filtering & calibration for better accuracy.
Vasilenko, O., & Orlov, A (2020) [15]	IoT, wireless sensor networks, cloud computing.	Energy efficiency, scalability, and remote accessibility.	High costs, data security risks, complex maintenance, and user adaptation challenges.	Auto-calibration for dynamic adjustments.
Patel & Desai (2020) [16]	Arduino-based indoor noise monitor.	Remote accessibility, improved indoor comfort, and automated alerts.	Limited range of detection and more power consumption, and implementation costs.	Multiple sensors allow coverage of large rooms.
Tavakol, M., & Shahrivar, M. (2020) [17]	IoT, wireless sensor networks, cloud computing, AI-driven analytics, and GIS.	Scalability, AI-driven insights, remote accessibility.	High infrastructure costs, data security risks, power and network dependency, and interoperability challenges.	Hybrid local-cloud processing for faster alerts.
Hassan, W. H., & Akram, A. (2020) [19].	Microcontrollers with noise sensors and wireless communication.	Real-time Monitoring, cloud-based accessibility, scalability.	Network dependency, power consumption, and potentially high costs.	Uses lightweight AI models for ESP8266.
Li, K., & Zhang, X. (2019) [20].	Wireless Sensor Network (WSN), cloud computing, big data analytics, edge computing.	Real-time monitoring, scalability, cloud-based accessibility.	Network reliability issues, data security risks, high implementation costs.	Optimized Wi-Fi-based transmission for indoor spaces.
Khan, A., & Javed, M. (2019) [21].	Wireless sensor networks, cloud and edge computing.	Real-time monitoring, scalability, automated noise mitigation, and remote accessibility,	High implementation costs, power consumption, network dependency, data security risks.	Use local & cloud storage for uninterrupted monitoring.
Meyer, E., & Knoblauch, H. (2017) [24].	Integrating IoT-enabled noise monitoring, AI-driven analysis, cloud computing.	AI-driven mitigation, scalability, and remote accessibility.	High costs, power and connectivity dependency, data security risks, complex maintenance.	Uses optimized data processing to prevent lags and ensure real-time alerts.
Kumar, S., & Jain, P. (2017) [25].	Wireless sensor networks, cloud and edge computing.	Remote accessibility, early warning capabilities, and smart city integration.	No real-time alerts, limited scalability, struggle with multiple sensors. high power consumption.	Introduces real-time notifications, web dashboard, and AI-driven noise classification.
Proposed System	ESP8266, Smart Web Dashboard, AI-based Noise Classification, Cloud & Local Storage.	Real-time alerts, AI-driven pattern recognition, Smart Home Integration, Reliable Data Processing.	Future improvements may include deep learning for advanced noise analysis.	Scale, more accurate, integrates AI & mobile alerts, works even in low-connectivity areas.

III. METHODOLOGY

The IoT-based Noise Pollution Monitoring System consists of three core components:

A. Noise Detection Unit:

A sound sensor captures ambient noise levels and sends data to the Arduino microcontroller.

B. Processing and Data Transmission:

The ESP8266 Wi-Fi module transmits real-time data to a web-based server and triggers alerts.

C. User Interface and Alerts:

A web-based dashboard visualizes noise levels, and email alerts are sent when noise exceeds a set threshold.

To simplify the data flow and decision-making process, the following flowchart illustrates how the system functions:

The functional flow of the entire IoT-based noise pollution monitoring system is represented step-by-step in Fig. 1, ranging from the stage of detection to processing and responding in real-time to the noise level variations. It includes the major functional components, decision-making situations, and error-handling methods defining its reliable operation across several environments.

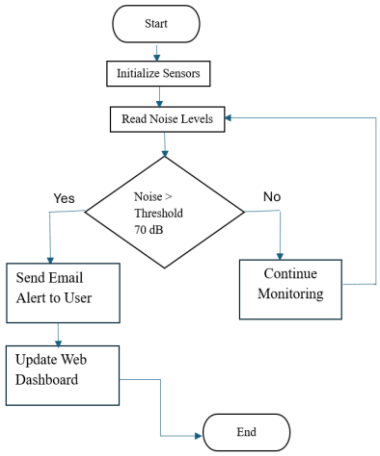

Fig. 1. Flowchart of the proposed IoT-based noise monitoring system.

1) Initialization phase: The initial phase requires the hardware and software algorithms of the system to be initialized:

The sound sensor (KY-038/LM393) is triggered to monitor the environmental noise in real-time. Arduino Uno or the ESP8266-based microcontroller takes care of processing data. The ESP8266 Wi-Fi module gets a connection to establish the network for cloud data transmission. During sensor calibration, reference noise levels are applied to increase the sensor's accuracy. A threshold level of noise is taken at 70dB, upon which the alarms shall be sounded [9]. A moving average filter is put in place to smoothen noise data and reduce false alerts due to brief disturbances.

2) Continuous noise monitoring: The system, once initialized, enters a continuous monitoring loop where it undertakes the following functions:

It will read noise data from the sensor on a regular basis. Moving average smoothing will be applied to reduce random fluctuations in noise levels. The processed noise data will then be classified using an AI-based noise classifier-into normal background noise and serious disturbance.

3) Decision on alert handling: In this phase, the alarm decides whether a noise event needs user intervention or not:

Noise above 70 decibel for 5 seconds: as a sound source, the alarm validates that it is a valid noise or a transient disturbance (e.g., a sudden transient sound, such as door slamming). Once designated valid, an alarm notification is generated by different means; Email alerts to the users on an excessive noise being present. Web-based dashboard updates to give real-time visibility into noise trends. Integration of smart home automation mechanisms that can opt to reduce noise (e.g., close windows, turn down speaker volume). Transient or invalid noise: the alarm has nothing to do but ignore and keeps monitoring.

4) Error handlings and data corrections: For reliability, the system supports error-handling mechanisms capable of dealing with potential failures:

If an error is detected in the sensor (a wrong reading because of a change in the environment), the system self-calibrates based on the changes to adjust the sensor sensitivity. In the event of a network error (Wi-Fi disconnection), the system stores noise data locally, once the network is restored, it attempts to upload the noise data to ensure no data goes lost. The analysis of historical data is used to adjust the noise threshold dynamically, accordingly, to average long-term trends.

The system implements further noise processing techniques to improve accuracy and reduce false alarm rates. Should echo be detected in any enclosed space through continuous reverberation, echo cancellation is performed. Transient noise filtering helps to prevent transient sounds like that of a dropped object or a cough from producing false alarms. Historical noise patterns are subjected to alarm threshold adjustment through online updating based on cumulative environmental experience. Combination of sensor readings, in case of multiple deployments, cross-verification is done to help in maximizing accuracy and preventing erroneous functioning of sensors.

Algorithm 1: Noise Pollution Monitoring with AI-Based Filtering & Error Handling Algorithm

Step 1: Initialization Phase
Step 2: Continuous Noise Monitoring
Step 3: Decision Making & Alert Handling
Step 4: Alert & Data Logging
Step 5: Error Handling & Data Correction

```
Start
Step 1: Initialization Phase
Initialize Sound Sensor (KY-038/LM393),
  Arduino Uno (or ESP8266-based board),
ESP8266 WiFi Module and web server
Calibrate sensor using reference noise levels
    Set noise threshold = 70 dB
Initialize moving average filter
Initialize MQTT for real-time data transmission
```

```
Initialize MQTT for real-time data transmission
Step 2: Continuous Noise Monitoring
        WHILE (true):     // continuously monitor noise levels
  noise_level = Read_Sensor_Data // Read real-time noise level (dB) from the sound sensor.

noise_filtered=Apply_Moving_Average_Filter(noise_level)
  noise_classified = AI_Noise_Classifier(noise_filtered)
Step 3: Decision Making & Alert Handling
  IF (noise_classified > 70 dB) for at least 5 seconds:
      IF Is_Valid_Noise(noise_classified) // Verify if the noise is from a valid source
Step 4: Alert & Data Logging
        Send_Email_Alert(noise_classified)
            Update_Web_Dashboard(noise_classified)
   ELSE:
        Ignore_Transient_Noise ()
Step 5: Error Handling & Data Correction
  IF Sensor_Error ():          // Handle Sensor Errors
      Perform_Self_Calibration ()
  IF Network_Error ():        // Handle Network Delays
        Store_Data_Locally ()
            Retry_Upload ()

Optimize_Threshold_Based_On_Historical_Data ()
End
```

TABLE II HARDWARE COMPONENTS AND FUNCTIONS

Hardware Component	*Functions*
Arduino Uno	Processes sensor data and triggers alerts
Sound Sensor (KY-038/LM393)	Measures ambient noise in decibels (dB)
ESP8266 WiFi Module	Transmitting data to a web dashboard
Web Server (Cloud)	Stores and displays real-time noise data
Email Notification System	Sends alerts when noise exceeds threshold

In Table II, shown on the hardware components and functions, the Arduino Uno Reads noise level from KY-038/LM393 sound sensor. Implements a moving average filter for stability. Sending data to an MQTT broker for real-time monitoring triggers an alert, if noise levels exceed the threshold (70dB), the ESP8266 module transmits data. Alerts are sent via email, and data is displayed on a web interface.

Connectivity: ESP8266, Wi-Fi, and MQTT

The ESP8266 Wi-Fi module is essential for real-time wireless communication in IoT-based noise monitoring systems. It enables the device to connect to the internet, transmit noise data to a server, and receive control commands remotely.

ESP8266 connects to Wi-Fi with a step-by-step procedure.

a) Enables internet-based communication.

b) MQTT (Message Queuing Telemetry Transport): Efficient protocol for real-time data exchange.

c) Noise data is published to an MQTT broker: Cloud platforms (AWS IoT)

d) Web Dashboard subscribes to MQTT: Displays real-time noise levels.

e) Alerts: If noise is too high, an alert is sent via MQTT to a buzzer, email.

IV. RESULT AND ANALYSIS

The proposed work is tested over a seven-day period in different environments, including offices, residential areas, and classrooms.

Table III presents the noise levels recorded at different time intervals over a seven-day period, along with whether an alert was triggered. The data shows that noise levels exceeding 70dB consistently triggered alerts, with peak values occurring between 10:50 AM and 5:30 PM. Lower noise levels were recorded during early mornings and late evenings, highlighting a direct correlation between human activity and noise pollution.

The data confirms that noise levels above 70dB consistently trigger alerts, with peak noise occurring during busy hours (10:50 AM to 5:30 PM). The highest recorded noise level was 98dB, which is significantly above the recommended limit for indoor environments. Early morning and late evening noise levels remained below 60dB, indicating quieter periods. These patterns suggest the need for adaptive noise control measures in high-activity periods.

TABLE III A SEVEN-DAY PERIOD IN NOISE LEVELS AND ALERTS OVER TIME

Time Interval	*Noise Level*	*Alert Triggered*
8:30AM – 9:00 AM	76dB	Yes
9:30 AM- 9:50AM	60dB	No
10:50AM-11:00AM	85dB	Yes
12:40PM- 1:30PM	80dB	Yes
3:10PM- 3:20PM	92dB	Yes
5:20PM-5:30PM	98dB	Yes
6:00PM	52dB	No

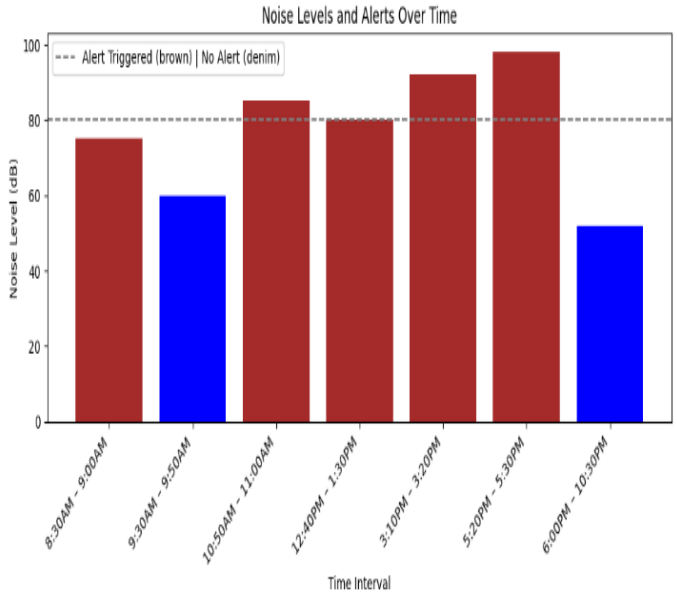

Fig. 2. A seven-day period: Noise levels and alerts over time.

Fig. 2 represents noise levels over time. The Dashed Line shows an 80dB threshold for better visualization. The X-axis denote the time interval; the Y-axis represents the noise level (dB). Each color corresponds to the noise level for a given period.

Color Coding

- Brown → Alert Triggered (≥ 80dB)
- Blue→ No Alert (< 80dB)

Peak noise levels (above 80 dB) were observed between 10:50 AM and 5:30 PM, likely due to increased activity in workplaces and classrooms.

Lower noise levels: (below 60 dB) occurred in the early morning and late evening, when fewer people were present.

Unexpected fluctuations: (75 dB at 8:30 AM) suggest temporary noise sources, possibly from nearby construction or sudden disturbances.

The system was deployed in three different environments – a home, an office, and a classroom for one week. The noise

levels were continuously monitored, and alerts were triggered whenever the threshold exceeded 70dB.

Table IV summarizes noise levels recorded over a week in three different environments: home, office, and classroom. Offices had the highest noise levels, often exceeding 85dB, likely due to conversations, machinery, and workplace activities. Classrooms showed moderate noise peaks, particularly during break times and group discussions, while home environments generally had lower noise levels but occasional spikes due to appliances and social interactions.

TABLE IV WEEKLY NOISE LEVEL

Day	*Noise Level*	*No. of Alerts Triggered*	*Environment*
Sunday	76dB	2	Home
Monday	89dB	3	office
Tuesday	77dB	4	Classroom
Wednesday	90dB	6	office
Thursday	87dB	4	Classroom
Friday	91dB	3	Home
Saturday	86dB	2	Home

The results highlight that office environments are the noisiest, frequently exceeding 85dB, which could impact productivity and health. Classrooms experience moderate noise fluctuations, likely due to student activities, while homes have generally lower noise levels but occasionally high readings (e.g., 91dB on Friday). This suggests that custom noise mitigation strategies are needed for different environments, such as soundproofing offices and using AI-based filtering for home settings.

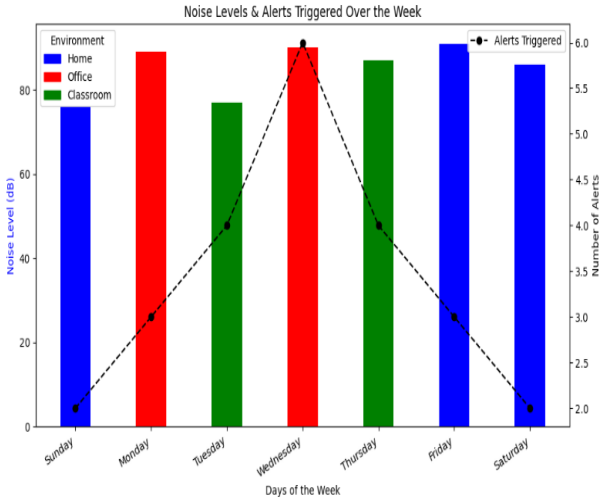

Fig. 3. Noise level and alerts triggered over the week.

In Fig. 3, the X-axis signifies Days of the Week, Y-axis denotes Noise Level (dB). Each color corresponds to the noise level for a given day. Use different colors for different environments (Home, Office, and Classroom) for better visualization. The dual Y-axis shows one for Noise Level, and one for Alerts.

Office Environments: Had the highest noise spikes (85 to 90 dB) due to frequent conversations, phone calls, and background noise machinery.

Classrooms: Exhibited moderate peaks (77 to 87 dB), mainly during break times and group activities. Homes: Showed the least noise disturbances, but occasional high readings (up to 91 dB) were detected, possibly due to TVs, kitchen appliances, and social interactions.

1) Data analysis: At Home, Noise levels are moderate (Sunday: 76dB, Friday: 91dB, Saturday: 86dB). At Office, the highest noise levels occur here (Monday: 89dB, Wednesday: 90dB), leading to more alerts. The Classroom shows consistent noise levels (Tuesday: 77dB, Thursday: 87dB), with a moderate number of alerts. Office environments tend to be the loudest, with noise exceeding 89dB, which can impact productivity and health. Home environments have moderate noise levels, but Friday shows an unexpected spike (91dB). Possible causes should be investigated. Classroom noise is relatively stable, but alert triggers suggest some noise concerns on specific days (Tuesday and Thursday). Wednesday is the noisiest day overall (90dB, 6 alerts), indicating a need for noise control measures.

2) Mean (Average): Represents the overall noise level trend.

$$Mean = N/\sum X \tag{1}$$

3) Median: Shows the middle noise value, reducing the impact of extreme values.

$$median = \frac{N+1}{2} \tag{2}$$

$$minimum = \min(x, x2, x3, \dots, xn) \tag{3}$$

$$maximum = \max(x1, x2, x3, \dots, xn) \tag{4}$$

4) Standard Deviation: Measures how much the noise levels fluctuate.

$$\sigma = \sqrt{\frac{\sum(xi - \bar{x})2}{N}} \tag{5}$$

where,

$\sum X$ = Sum of all values

N = Number of values

σ = Standard deviation

Xi = Each data point

$\bar{X}$ = Mean (average) of the dataset

x =represents the values in the dataset.

To better understand noise variations, Table V presents key statistical metrics, including the mean, median, and standard deviation of noise levels and alerts triggered. The mean noise level (85.14dB**)** suggests consistently high noise across environments, while a strong positive correlation (+0.85) indicates that as noise levels rise, the number of alerts increases. These insights help with fine-tuning alert thresholds and noise mitigation strategies.

TABLE V STATISTICAL ANALYSIS OF NOISE LEVELS AND ALERTS

Metric	*Noise Level(dB)*	*Alerts Triggered*
mean	85.14	3.43
Median	87	3
Minimum	76	2
maximum	91	6
Stand deviation	5.28	1.51

The statistical analysis supports the observed trends: the high mean noise level (85.14dB) and strong correlation (+0.85) confirm that increasing noise levels directly lead to more alerts. The standard deviation (5.28dB) indicates moderate fluctuations in noise levels across different environments. These insights validate the system's ability to accurately detect and respond to excessive noise, making it a reliable solution for noise monitoring.

Correlation Analysis: Correlation (+0.85) indicates a strong relationship between noise levels and alert triggers. As noise levels increase, the number of alerts triggered also rises. This suggests a direct relationship, where higher noise levels frequently cross the threshold for triggering alerts.

$$r = \frac{N\sum(X_iY_i) - \sum X_i \sum Y_i}{\sqrt{[N\sum X_i^2 - (\sum X_i)^2] \times [N\sum Y_i^2 - (\sum Y_i)^2]}}$$

r = Pearson correlation coefficient

Xi = Values of the first variable (e.g., Noise Levels)

Yi = Values of the second variable (e.g., Alerts Triggered)

N = Number of data points

∑Xi = Sum of all X values

∑Yi = Sum of all Y values

∑(XiYi) = Sum of the product of each pair of X and Y

∑Xi2 = Sum of squares of X values

∑Yi2 = Sum of squares of Y values

Were

r=1 Perfect positive correlation (both variables increase together)

r=−1 Perfect negative correlation (one increases, the other decreases)

r=0 No correlation (variables are unrelated)

0.7≤r<1 Strong positive correlation

0.3≤r<0.7 Moderate positive correlation

0≤r<0.3 Weak positive correlation

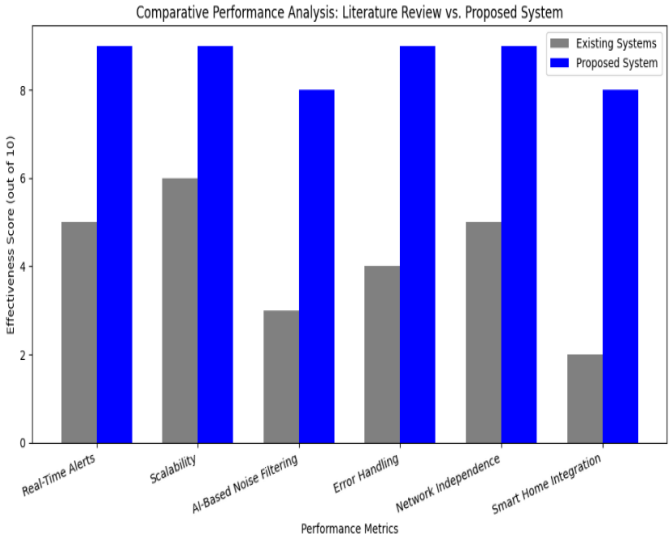

Fig. 4. Comparative performance analysis.

In Fig. 4, the performance comparison highlights the superiority of the proposed system over existing noise monitoring solutions. It effectively addresses real-time alert limitations, AI-based noise classification, and offline functionality, ensuring greater adaptability and reliability. Unlike traditional systems that struggle with scalability and processing power, the proposed approach offers enhanced accuracy and real-time responsiveness, making it an ideal choice for diverse environments.

Table VI highlights the limitations found in previous noise monitoring studies and how the proposed system overcomes these challenges. Key improvements include real-time alerts, AI-based noise classification, and offline functionality, making the system more adaptable and reliable across different environments. By addressing these gaps, the system provides a more effective solution for noise pollution management.

TABLE VI PROPOSED SYSTEM ADDRESSES EXISTING GAPS

Existing Limitations (from Literature Review)	*Proposed Work Solution*
Lack of real-time alerts	Uses MQTT messaging, emails, and web dashboards for instant notifications
Poor scalability for different environments	Works in small-scale (homes/offices) and large-scale (industries/smart cities) deployments
No AI-based noise classification	Uses AI models to filter out background noise & reduce false alerts
High dependency on stable internet	Works offline by storing data locally & syncing it later
No smart home integration	Connects with smart IoT devices to control noise-sensitive appliances

Table VI represents how the proposed system addresses existing gaps. The proposed work ensures a real-time, intelligent, and scalable noise monitoring solution that overcomes limitations of existing research by integrating AI, IoT, smart automation, and error-handling techniques for improved noise pollution management.

The proposed system significantly improves upon existing solutions by offering real-time alerts, AI-based noise filtering, and offline functionality, which were missing in previous studies. Unlike traditional systems that struggle with scalability and accuracy, this system ensures efficient noise classification and adaptive monitoring across different environments. These enhancements make it a versatile and practical approach to noise pollution control.

V. Conclusion

The proposed IoT-based noise pollution monitoring system effectively addresses the key limitations found in existing research by integrating real-time noise monitoring, AI-based noise classification, smart home automation, and offline functionality. Through comparative analysis with previous studies, it is evident that this system provides superior performance in terms of accuracy, scalability, efficiency, and adaptability.

This study confirms that AI-integrated IoT systems enhance noise detection, reduce false alarms, and improve alert response time, while offering a scalable solution for various environments. Additionally, the system's offline capabilities ensure continuous monitoring, making it highly reliable even in low-connectivity areas.

Deep Learning Meets Bibliometrics: A Survey of Transfer Learning Techniques for Breast Cancer Detection

Amna Wajid[1], Natasha Nigar[2]*, Hafiz Muhammad Faisal[3], Olukayode Oki[4], Jose Lukose[5]
Department of Computer Science, University of Engineering and Technology, Lahore, Pakistan[1,2]
Technical University of Munich, Munich, Germany[3]
Department of Computer Science, Walter Sisulu University, South Africa[4,5]

***Abstract*—This study aims to provide a comprehensive bibliometric analysis of research on transfer learning in breast cancer detection from 2016 to 2024. It highlights publication trends, influential contributors, collaborations, and keyword patterns. Bibliometric methods are employed to analyze data extracted from the Scopus database. It includes co-occurrence and citation analyses to identify prevalent keywords, highly cited documents, journals, authors, organizations, and countries contributing to this field. The analysis reveals a significant upward trend in publications over the last decade. Key insights include the identification of dominant keywords, influential contributors, and notable collaborations. The results highlight the growing impact of transfer learning techniques in breast cancer detection research, particularly within the domains of medical imaging analysis and predictive analysis. This study offers a systematic overview of the current state of transfer learning in breast cancer detection research, providing valuable insights and guiding future research efforts in this rapidly evolving domain.**

***Keywords*—Transfer learning; breast cancer; medical imaging analysis; predictive analysis**

I. Introduction

The breast cancer remains a significant global health concern. This is the most commonly diagnosed cancer among women and is a leading cause of cancer-related deaths worldwide [1]. Early detection and an accurate prognosis of breast cancer are crucial to improving patient outcomes [2]. There are significant advancements in medical imaging technologies such as mammography, magnetic resonance imaging (MRI), breast ultrasound and thermography. However, multiple challenges exists in manual interpretation of the generated images that leads to variations in diagnosis accuracy among clinicians [3]. Many researchers proposed methodologies based on artificial intelligence (AI) and deep learning (DL) to enable early stage breast cancer detection to mitigate associated mortality rates. However, these approaches encounter various challenges such as limited access to large datasets, data imbalance and overfitting issues. To tackle these obstacles, transfer learning, in conjunction with machine learning have been employed to increase the efficiency and accuracy of breast cancer classification.

The Transfer Learning (TL) has gained attention for its potential to address challenges in medical image analysis, such as limited dataset sizes and class imbalance issues [4]. This involves leveraging pre-trained models on diverse datasets to improve the performance of breast cancer detection algorithms, particularly in scenarios where large, annotated datasets are unavailable [5].

Despite the fact that TL-based techniques enhance breast cancer detection and survival prediction, there is a gap in the literature regarding bibliometric analyses specifically focusing on TL based approaches. Therefore, understanding the current research landscape and identifying future research trajectories in this domain is essential for advancing breast cancer diagnosis and prognosis. In this context, the proposed bibliometric study aims to address this gap by conducting a comprehensive analysis of research trends and developments in transfer learning-based breast cancer detection techniques. The study focuses on publications, covering the period from 2016 to 2024 by employing the data from Scopus database. This study intends to provide valuable insights into the current state and future directions of research by analyzing the publication trends, influential authors, institutions, journals and keyword patterns. Based on this analysis, researchers and practitioners may gain a deeper understanding of the landscape of transfer learning-based approaches for breast cancer detection, facilitating informed decision-making and guiding future research efforts. In order to fulfill the objectives, this study aims to answer the following research questions:

- RQ1. What is the volume of research on breast cancer detection using transfer learning?
- RQ2. What are the collaboration and authorship patterns of breast cancer research using transfer learning?
- RQ3. Which are the active institutions, authors and journals that are producing breast cancer research using transfer learning?
- RQ4. What are the most frequently used keywords and themes of breast cancer research using transfer learning?
- RQ5. What kind of bibliographic coupling of countries, journals and authors exist in breast cancer research using transfer learning?

The structure of this research is organized as follows: The next section presents a comprehensive literature review, providing an overview of previous bibliometric studies relevant to the topic. This is followed by the materials and methods section,

*Corresponding authors.

which details the method employed to conduct this bibliometric study. The results section then reports the statistical and network analysis of the studies selected for this bibliometric analysis. Subsequently, the discussion section interprets the results. The research then addresses the study's limitations and future directions, identifying potential constraints of the current bibliometric study and proposing areas for further investigation. Finally, the conclusion section summarizes the main findings, highlighting the study's contributions and significance of the research.

II. Literature Review

Ahmad et al. [6] have performed bibliometric analysis of breast cancer research in Pakistan up to Feb, 2021 by utilizing the Web of Science database. The study included 1,605 publications authored by 7,774 individuals, with an average of 18.25 citations per publication. Despite international collaborations with 88 countries, the research output doesn't align with the escalating breast cancer cases in Pakistan, indicating the urgency for policy reassessment and increased attention at the national level to combat the disease effectively.

Syed et al. [7] have utilized bibliometric analysis to assess the evolution of Artificial Intelligence (AI) in breast cancer diagnosis and prognosis research from 2000 to 2021. The analysis identified a significant increase in relevant literature, with the USA, China and India leading in productivity. Key authors, affiliations and journals are highlighted, with trends such as transfer learning and deep learning identified. The findings offer insights for policymakers and researchers to guide future collaborations and advancements in AI for breast cancer care [7].

Khairi et al. [8] have employed bibliometric analysis to investigate the development of deep learning for breast cancer image classification from 2014 to 2021, aiming to address the limitations of manual histopathology examination. Utilizing Scopus data, it examined publication trends, international collaborations and emerging research directions through visualization techniques. The research domain, initiated in 2016, exhibited sustained growth, with notable collaboration between the United States and China. This review aimed to guide researchers by identifying emerging areas in medical imaging for breast cancer diagnosis [8].

Zhou et al. [9] have conducted a comprehensive bibliometric analysis of artificial intelligence (AI) applications in histopathological image (HI) analysis from 2001 to 2021, utilizing data from the Web of Science Core Collection. It revealed a rapid increase in publications, with the USA leading in productivity and influence. Keyword and co-citation analyses highlighted breast cancer, prostate cancer and other tumor types as focal points, with classification and nucleus segmentation emerging as primary research directions. The study offered valuable insights for researchers, identifying key cancer types and trends in AI application in HI [9].

Joshi et al. [10] have performed a quantitative bibliometric analysis of research trends in breast cancer detection using machine learning techniques, focusing on histopathological modalities. Data sourced from Scopus database encompass influential authors, research institutes, journals, highly cited articles and keyword trends. The analysis suggested promising avenues for future research in breast cancer care through machine learning or deep learning methodologies [10].

TABLE I. Summary of Bibliometric Studies on Breast Cancer Detection

Study	Year.	Database	Scope of Study	Duration
Ahmad et al. [6]	2021	WOS	Pakistan	Start-2021
Syed et al. [7]	2022	Scopus, WOS	General	2000 to 2021
Khairi et al. [8]	2021	Scopus	Histopathological Images (HI)	2013-2021
Zhou et al. [9]	2022	WOS	HI Analysis	2001-2021
Joshi et al. [10]	2021	Scopus	HI Analysis	2009-2021

The studies outlined in Table I primarily focuses on bibliometric analysis related to breast cancer detection, with a predominant emphasis on histopathological images. Only one study addresses AI-based breast cancer detection techniques indicating a gap in the literature regarding bibliometric analysis specifically targeting transfer learning-based methods. Transfer learning has emerged as a valuable tool in machine learning, offering the potential to boost the effectiveness of breast cancer detection algorithms by leveraging knowledge from one task to enhance performance in another.

III. Materials and Methods

A. Methodology

Many researchers start their research with bibliometric analysis, which entails quantitative and statistical evaluation of data to assess the research performance of publications and discern trends in research publications across institutions, countries, individuals and disciplines [11]. As compared to other methods of reviewing literature, bibliometric offers a systematic, easy-to-understand and reproducible approach. This study employed bibliometric methods, which involve analyzing various scientific research publications such as research articles, books, conference papers and journals to comprehensively examine the landscape of research on the topic of Transfer Learning in Breast Cancer Detection. Through this bibliometric analysis, the aim is to evaluate the evolution of research in AI and transfer learning techniques for breast cancer detection, identify influential authors, institutions and journals in the field, track publication trends over time and uncover patterns of collaboration and citation among researchers and institutions.

B. Source of Data

Commonly used databases such as Scopus, Web of Science, Scimago and Google Scholar are utilized to gather information about publications and their citations. Among these, Scopus, an academic abstracts and indexing database by Elsevier, stands out for its comprehensive coverage, particularly in health-related topics, surpassing other databases like PubMed and Web of Science [12]. Therefore, for this bibliometric analysis the SCOPUS database is employed to compile data on publications related to breast cancer detection using Transfer Learning, along with additional keywords from 2016 to 2024.

C. Search Query and Data Retrieval

A thorough search strategy, as illustrated in Fig. 1, is implemented to retrieve the results.

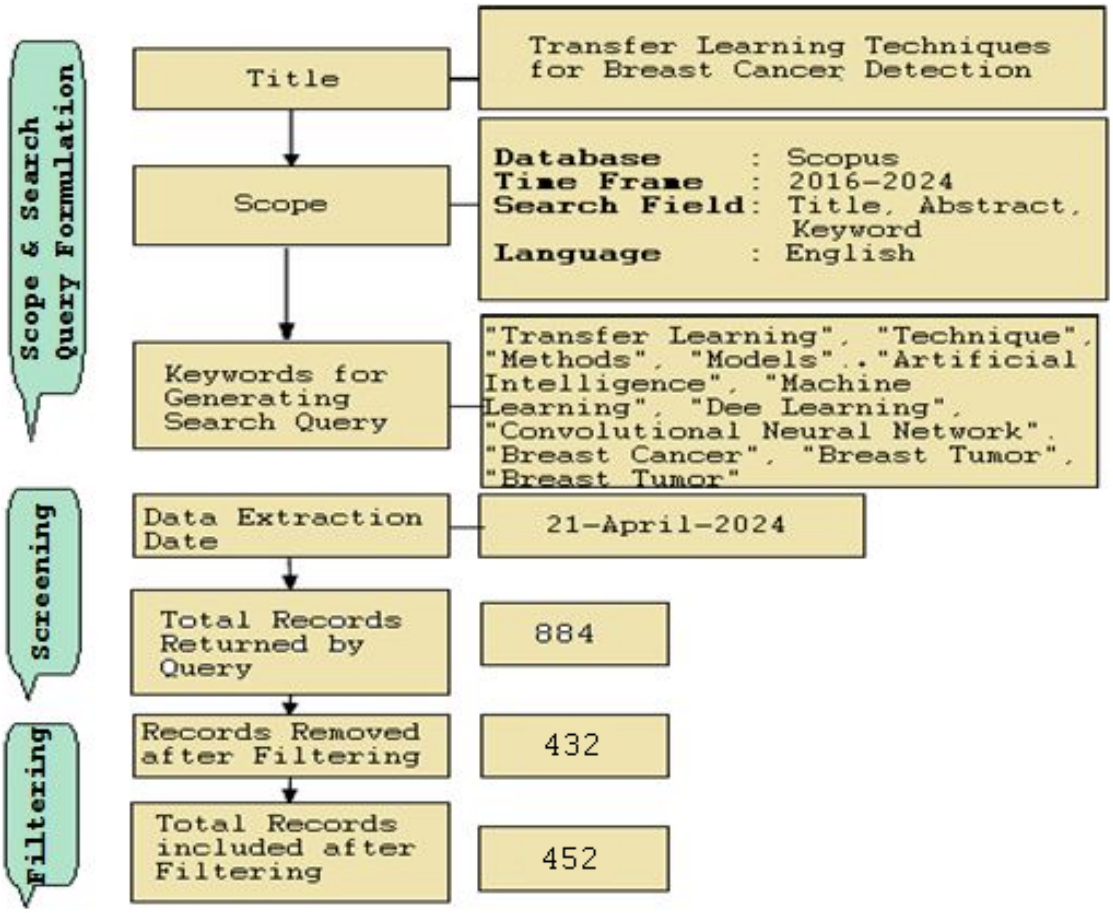

Fig. 1. Search strategy and data filtering.

The literature search is conducted on April 21, 2024. Relevant keywords are identified after consulting pertinent literature and the search query is formulated. These keywords are then combined using Boolean search operators to maximize the retrieval of relevant results. The following search query (Table II) is composed and executed within the SCOPUS database.

TABLE II. QUERY FOR TRANSFER LEARNING TECHNIQUES IN BREAST CANCER DETECTION

TITLE-ABS-KEY (“Transfer Learning”)
AND
TITLE-ABS-KEY (technique* OR method* OR model*)
AND
TITLE-ABS-KEY (“Artificial Intelligence” OR “Machine Learning” OR “Deep Learning” OR “Convolutional Neural Network”)
AND
TITLE-ABS-KEY (“Breast Cancer” OR “Breast Tumor” OR “Breast Carcinoma”)

D. Inclusion and Exclusion Criteria

1) Initial search and query: A search query is conducted on the Scopus database, yielding a total of 884 documents.

2) Screening based on title and abstract: Documents are screened based on their title and abstract, resulting in the retention of 458 articles after filtering.

3) Filtering based on document type: Subsequent filtration is performed to exclude documents that did not meet the specified document types. As a result, 455 records are included for analysis, encompassing journal articles (n = 265), reviews (n = 8), conference papers (n = 175), and book chapters (n = 7), ultimately excluding an additional three papers.

4) Language filtration: A further filtration process is applied to include only articles written in the English language. This resulted in the exclusion of 3 more articles written in Chinese (n=2) and Turkish (n=1) language. After applying these inclusion and exclusion criteria, a total of 452 articles remained for final analysis.

E. Tools Used

The data is processed, analyzed, and visualized using the R-Studio and VOSViewer software.

IV. RESULTS AND DISCUSSION

A. Statistical Analysis

1) Documents by publication years: The analysis of the year-wise trend of publications since last nine years reveals noteworthy insights into the evolution of research in the field. As evident in Table III and shown in Fig. 2, the data presents

a clear upward trend in the yearly publication of transfer learning-based breast cancer detection techniques from 2016 to 2024.

TABLE III. NUMBER OF PUBLISHED ARTICLES BY YEAR

Year	Published Articles	Year	Published Articles	Year	Published Articles
2016	3	2017	9	2018	23
2019	27	2020	39	2021	70
2022	100	2023	133	2024	48

In 2016, only 3 articles published on this topic, indicating a relatively low level of research activity. However, by 2018, the number of publications had more than tripled to 23, signaling a growing interest in transfer learning techniques for breast cancer detection. The trend continued to accelerate in subsequent years, with substantial increases in publication numbers. By 2021, there are 70 articles published, demonstrating a significant surge in research output. This trend reached its peak in 2023, with a staggering 133 articles published, reflecting a flourishing period of research activity in this field. In 2024, up till now 48 articles have been published, indicating a sustained interest in transfer learning-based breast cancer detection techniques.

Overall, the data highlights the increasing prominence of transfer learning-based approaches in breast cancer detection research with a consistent upward trajectory in publication numbers over the specified time period.

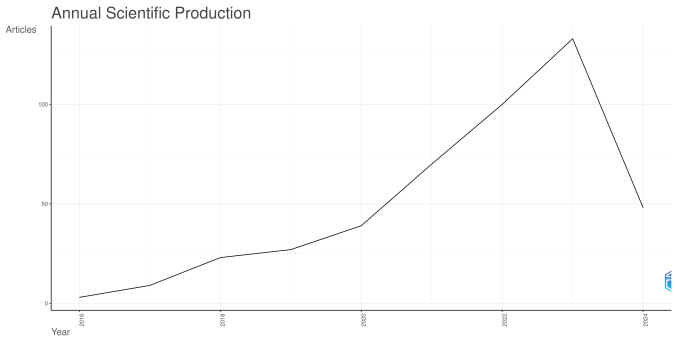

Fig. 2. Yearly publication trends of documents.

2) Documents by average citation per year: The mean total citations per year show a clear declining trend from 2016 to 2024, as shown in Table IV and in Fig. 3. In 2016, the mean total citations per year are 25.52, indicating a relatively high citation rate. However, this number steadily decreased over the subsequent years. By 2024, the mean total citations per year plummeted to just 0.42, suggesting a significant decline in the citation impact of the research publications. This downward trend may reflect a shift in research focus, changes in citation practices, or evolving trends in the academic landscape.

3) Documents by author: The data on the top 10 most relevant authors in breast cancer detection research using transfer learning reveals a diverse pool of contributors. Fig. 4 shows the 10 most relevant authors in this domain. Maryellen L. Giger emerges as the most prolific author with 10 articles to her name, indicating a significant contribution to the field. Mustapha Bouakkaz, Saida Sarra Boudouh, and Se-Woon Choe

TABLE IV. AVERAGE CITATIONS PER YEAR

Year	MeanTCperArt	N	MeanTCperYear	CitableYears
2016	229.67	3	25.52	9
2017	128.33	9	16.04	8
2018	61.87	23	8.84	7
2019	56.19	27	9.37	6
2020	38.97	39	7.79	5
2021	24.30	70	6.08	4
2022	11.88	100	3.96	3
2023	3.73	133	1.86	2
2024	0.42	48	0.42	1

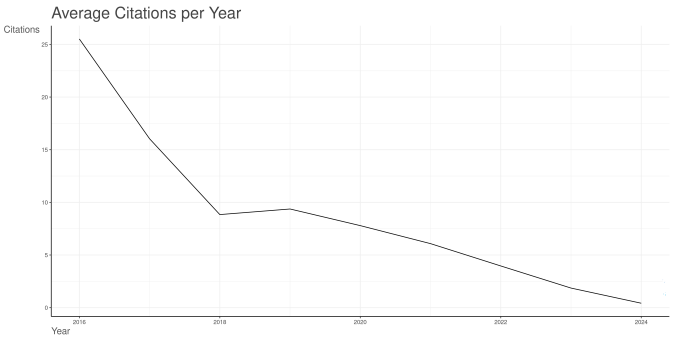

Fig. 3. Average citations per year.

follow closely behind with 7 articles each, underscoring their substantial involvement in research publications. Gelan Ayana and Sannasi Chakravarthy, S.R. are also notable contributors with 6 articles each. The remaining authors, including N. Bharanidharan, Hui Li, My Hachem El Yousfi Alaoui, and Mohamed Bal-Ghaoui, have contributed 5 or 4 articles each, demonstrating their significant engagement in research endeavors related to breast cancer detection using transfer learning techniques.

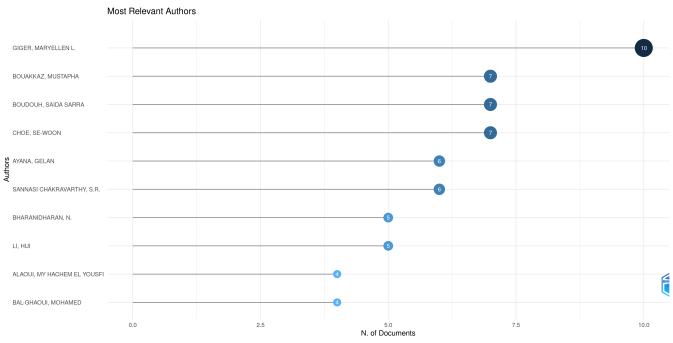

Fig. 4. Documents by relevant authors.

4) Documents by affiliations: The data on the top 10 affiliations involved in research on breast cancer detection using transfer learning reveals a diverse range of institutions contributing to this field. “Princess Nourah bint Abdulrahman University” emerges as the top affiliation with 24 articles, indicating its significant involvement and leadership in research endeavors related to breast cancer detection. Following closely behind is “I.R.C.C.S. Istituto Tumori ‘Giovanni Paolo

II" with 22 articles, highlighting its substantial contribution to the scientific literature in this area. "Harvard Medical School", "Kumoh National Institute of Technology", and "University of Michigan", each have 16 articles, showcasing their active engagement in breast cancer detection research. Similarly, "University of Rome Tor Vergata", "Icahn School of Medicine at Mount Sinai", "King Abdul Aziz University", "University of California", and "COMSATS University Islamabad (CUI)", each contribute significantly with 15, 13, 13, 13, and 12 articles respectively, underscoring their importance as key players in advancing knowledge and innovation in breast cancer detection using transfer learning techniques [see Fig. 5].

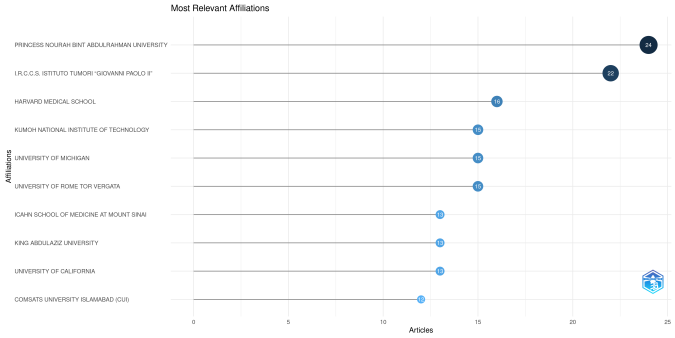

Fig. 5. Documents by affiliations.

5) Documents by sources: The data on the most relevant sources highlights a diverse range of publication venues. "Progress in Biomedical Optics and Imaging - Proceedings of SPIE" emerges as the top source with 18 articles, indicating its significant contribution to the dissemination of research in this field. Following closely behind are "Multimedia Tools and Applications" and "Lecture Notes in Computer Science (including subseries Lecture Notes in Artificial Intelligence and Lecture Notes in Bioinformatics)" with 14 and 13 articles, respectively, underscoring their importance as platforms for scholarly communication. "Diagnostics", "Biomedical Signal Processing and Control", "Cancers", and "Computers in Biology and Medicine" , each contribute substantially with 11, 10, 9, and 9 articles, respectively, indicating their relevance in the field. Other notable sources include "IEEE Access", "Communications in Computer and Information Science", and "Lecture Notes in Networks and Systems", each with 9, 8, and 7 articles, respectively, reflecting their role in disseminating research findings on breast cancer detection using transfer learning techniques [see Fig. 6].

6) Documents by countries: The data reveals a varied landscape of research contributions in breast cancer detection using transfer learning techniques across different countries. China and India emerge as the most prolific contributors, with 35 and 90 articles, respectively, showcasing their significant involvement in this field. Other countries, such as Egypt, also demonstrate substantial participation with 11 articles. Interestingly, while some countries like China and India predominantly contribute through single-country publications (SCP), others like Canada and Italy engage in both SCPs and multiple-country publications (MCPs), indicating diverse collaboration patterns. This highlights the global nature of research efforts in breast cancer detection, emphasizing the importance of international cooperation to advance scientific knowledge and

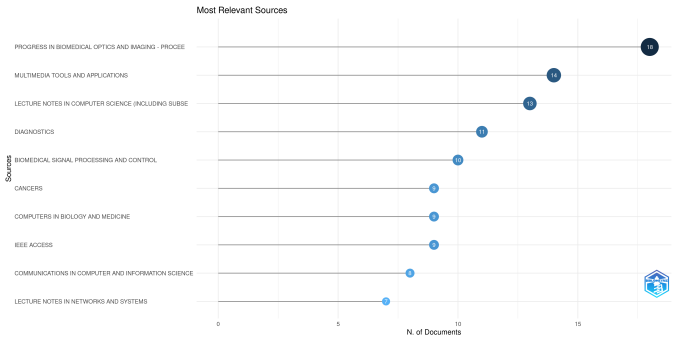

Fig. 6. Documents by sources.

address complex healthcare challenges. The data underscores the need for continued collaboration and knowledge-sharing among researchers worldwide to drive innovation and progress in breast cancer detection methodologies [see Fig. 7].

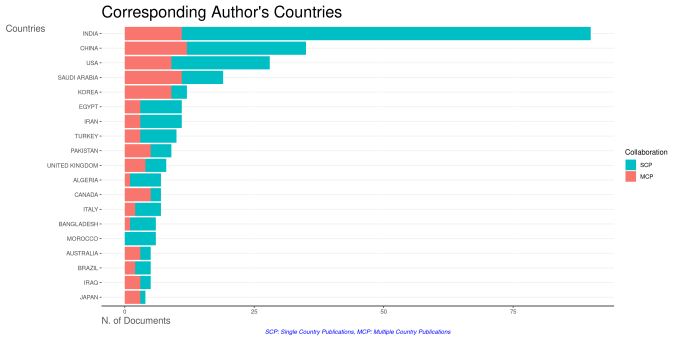

Fig. 7. Documents by countries.

B. Network Analysis

This phase of the study focuses on examining various network metrics, including co-authorship, co-occurrences, citations, bibliographic coupling, and co-citation.

1) Co-authorship analysis: Co-authorship analysis involves examining collaborations among authors, organizations, and countries.

a) Co-authorship analysis with authors: In this analysis, a threshold of at least 2 documents per author is set. Out of 1680 authors, 215 authors met this threshold. The largest connected set comprises 18 out of the 215 authors, as illustrated in Fig. 8.

b) Co-authorship analysis with organizations: The dataset comprises publications affiliated with 1153 organizations. Among these, 48 organizations meet the threshold criteria of having at least 2 documents. However, not all of these 48 entities are interconnected. The largest connected set encompasses 10 items, as illustrated in Fig. 9.

c) Co-authorship analysis with countries: The publications included in this study originate from 73 different countries. Among these, 51 countries meet the threshold requirement of having at least 2 documents. Within these 51 countries, the largest interconnected set comprises 49 items, as depicted in Fig. 10.

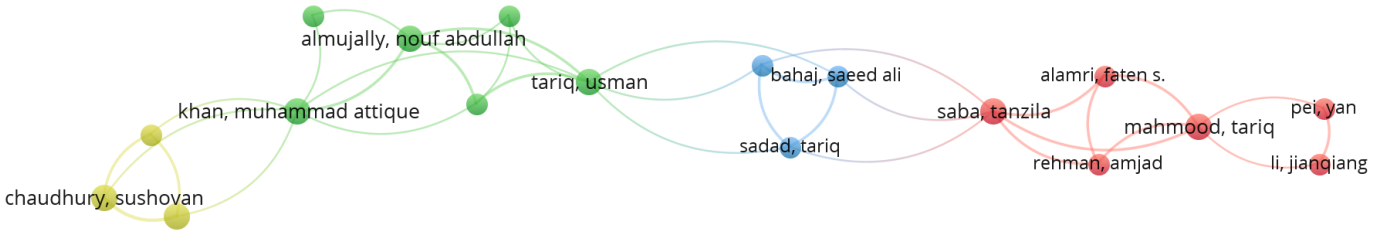

Fig. 8. Co-authorship analysis with authors - network visualization.

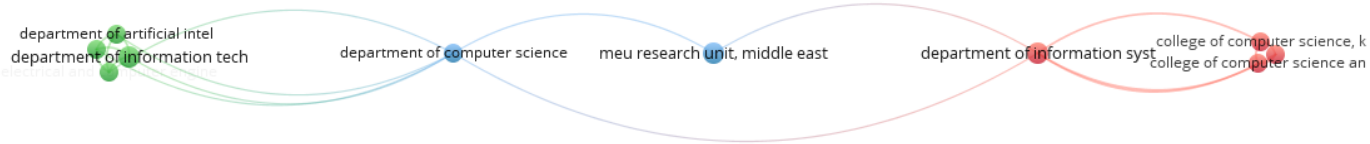

Fig. 9. Co-authorship analysis with organizations - network visualization.

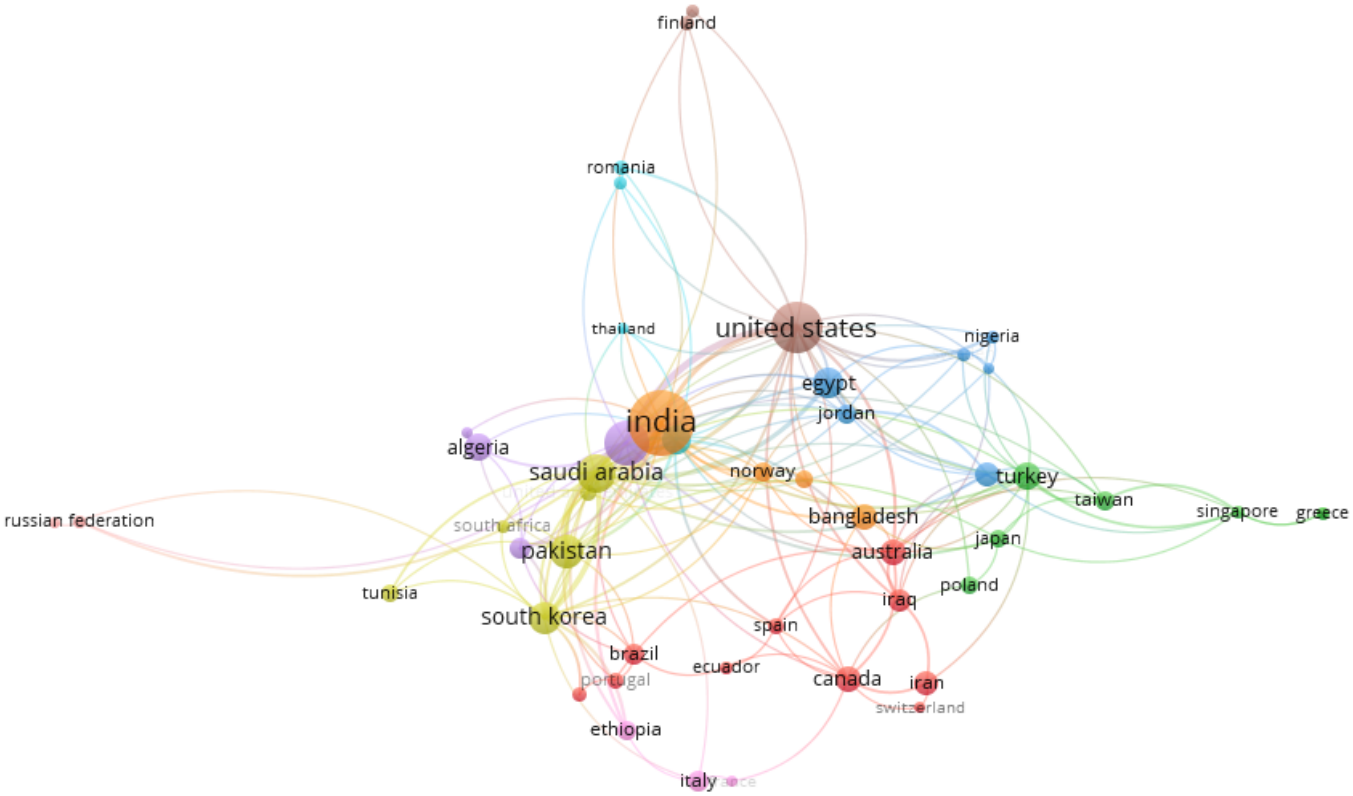

Fig. 10. Co-authorship analysis with countries - network visualization.

2) Co-occurrence analysis: Co-occurrence analysis has been conducted across various categories including all keywords, author keywords, and index keywords.

a) Co-occurrence with all Keywords: Out of the 2396 keywords identified in the selected publications, a total of 483 are analyzed, meeting the minimum occurrence criterion which is set to three. A network visualization is provided in Fig. 11.

b) Co-occurrence with author keywords: Examining the 779 author-assigned keywords, those with at least 3 occurrences are considered. A total of 111 entries met this threshold, as illustrated in Fig. 12.

c) Co-occurrence analysis based on index keywords: Out of the 2017 index keywords identified in the selected publications, 438 keywords met the minimum threshold of 3 occurrences. The network diagram in Fig. 13 reveals insights,

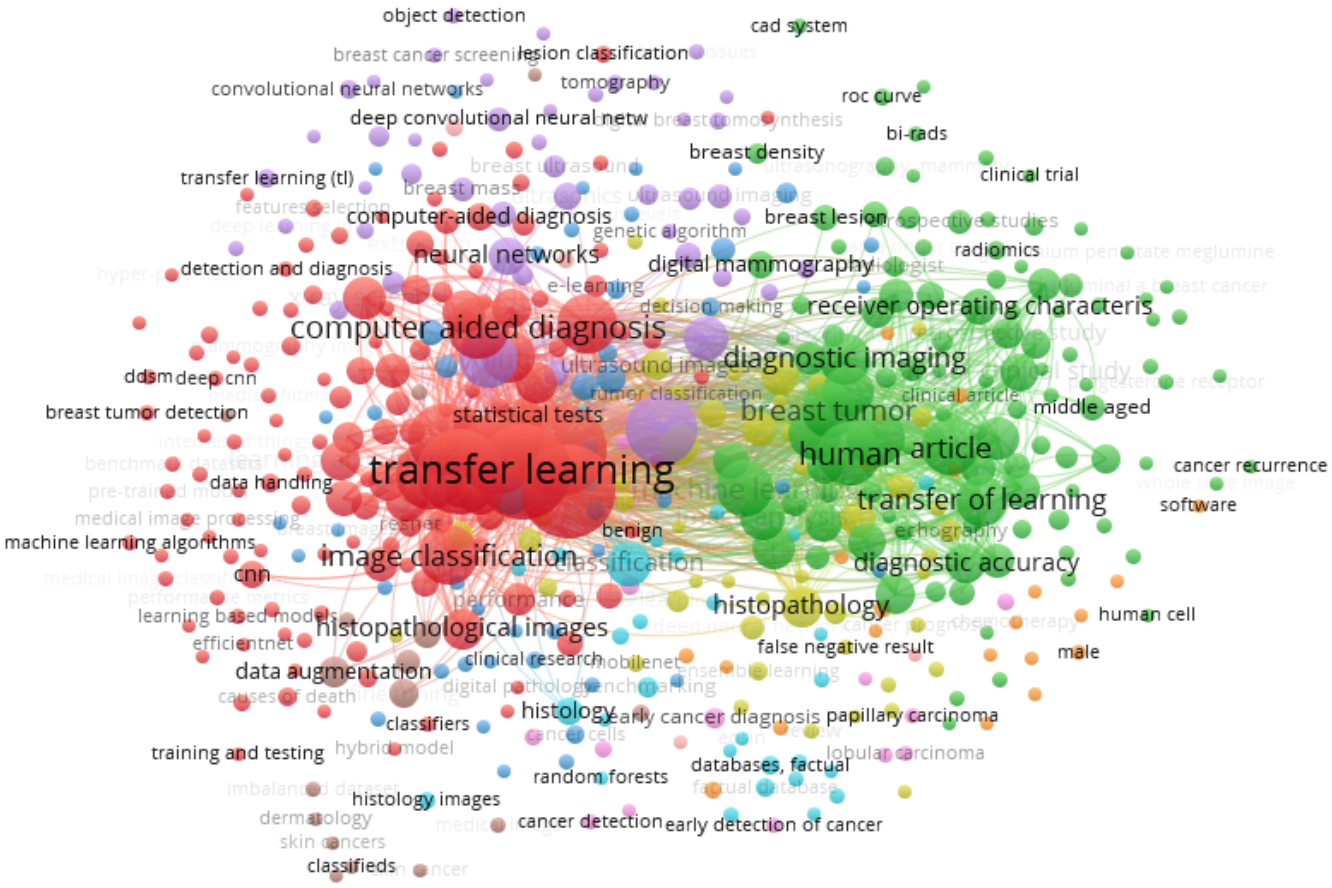

Fig. 11. Co-occurrence with all keywords - network visualization.

such as the keyword “Transfer Learning” having the highest total link strength of 4680, with 280 occurrences. Similarly, the keyword “Deep Learning” has 275 occurrences with a total link strength of 4719.

3) Citation analysis: This citation analysis examines various units of analysis, including documents, sources, authors, organizations, and countries.

a) Document citation analysis: Out of 452 publications, 222 documents meet the threshold of a minimum of 5 citations per document. Notably, Yap holds the top position with 588 citations. Some items in the network are disconnected. A total of 83 items are connected, which can be seen in Fig. 14.

b) Source citation analysis: The documents originate from 258 different sources, out of which 16 meet the threshold criteria of 5. Medical Physics and IEEE Journal of Biomedical and Health Informatics lead the list with 1178 and 678 citations, respectively, as shown in Fig. 15.

c) Author citation analysis: Among the 452 documents, 1680 authors have contributed. Considering a minimum of two documents per author, 215 authors are identified. Notably, Marit et al. has the highest citations (632) with 3 documents. Fig. 16 depicts the visualization of author citation analysis.

d) Organization citation analysis: Contributions from 1153 organizations are observed, with 10 organizations meeting the minimum threshold of 3 documents. The Department of IT/medical IT convergence engineering, Kumoh National Institute of Technology, Gumi, appears with 6 documents and 186 citations, as shown in Fig. 18.

e) Country citation analysis: The analyzed documents originate from 73 countries, with India, United States, and China ranking as the top three with 132, 73, and 51 documents, respectively. Their citation counts are 1496, 3491, and 1069, respectively. Fig. 17 depicts the visualization of country citation analysis.

The findings of this bibliometric analysis highlights a significant upward trajectory in research activities related to transfer learning for breast cancer detection over the past nine years. This growth highlights the increasing recognition and exploration of transfer learning as a viable solution to the challenges inherent in breast cancer detection, particularly those related to data limitations and classification accuracy. The dramatic rise from a mere three publications in 2016 to a peak of 133 in 2023 reflects a growing interest and investment in this area by the scientific community, indicating that transfer learning has become a focal point of innovation in medical imaging and oncology.

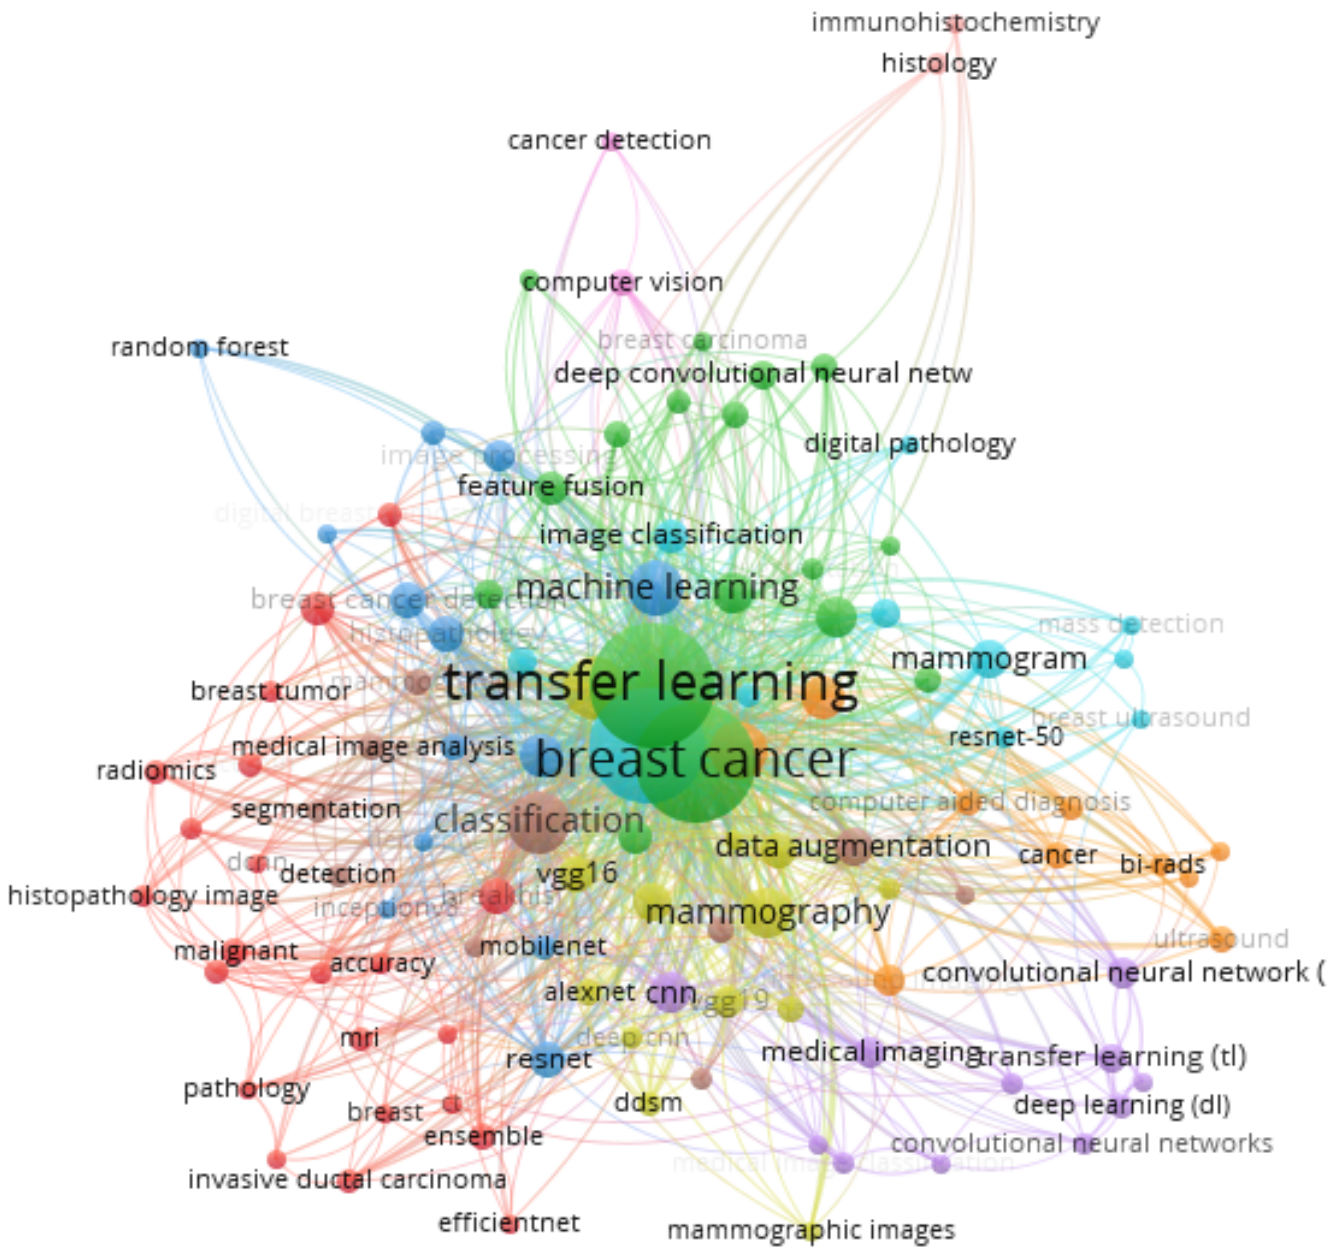

Fig. 12. Co-occurrence with author keywords - network visualization.

Moreover, the analysis identifies key contributors and institutions that are driving this research forward. Notably, Maryellen L. Giger emerged as the most prolific author, suggesting her significant influence and leadership in the field. Similarly, Princess Nourah bint Abdulrahman University is highlighted as a leading institution, demonstrating substantial involvement in advancing breast cancer detection technologies. The co-occurrence analysis of keywords further reveals critical research themes with terms like “Transfer Learning”, “Deep Learning”, and “Breast Cancer Detection” frequently appearing together. This suggests that these concepts are central to current research efforts and are likely to continue guiding future studies.

Overall, the insights gained from this bibliometric analysis provide a comprehensive overview of the current research landscape and identify potential areas for future exploration. The growing body of literature and the increasing collaboration among researchers and institutions underscore the promising potential of transfer learning techniques in revolutionizing breast cancer detection.

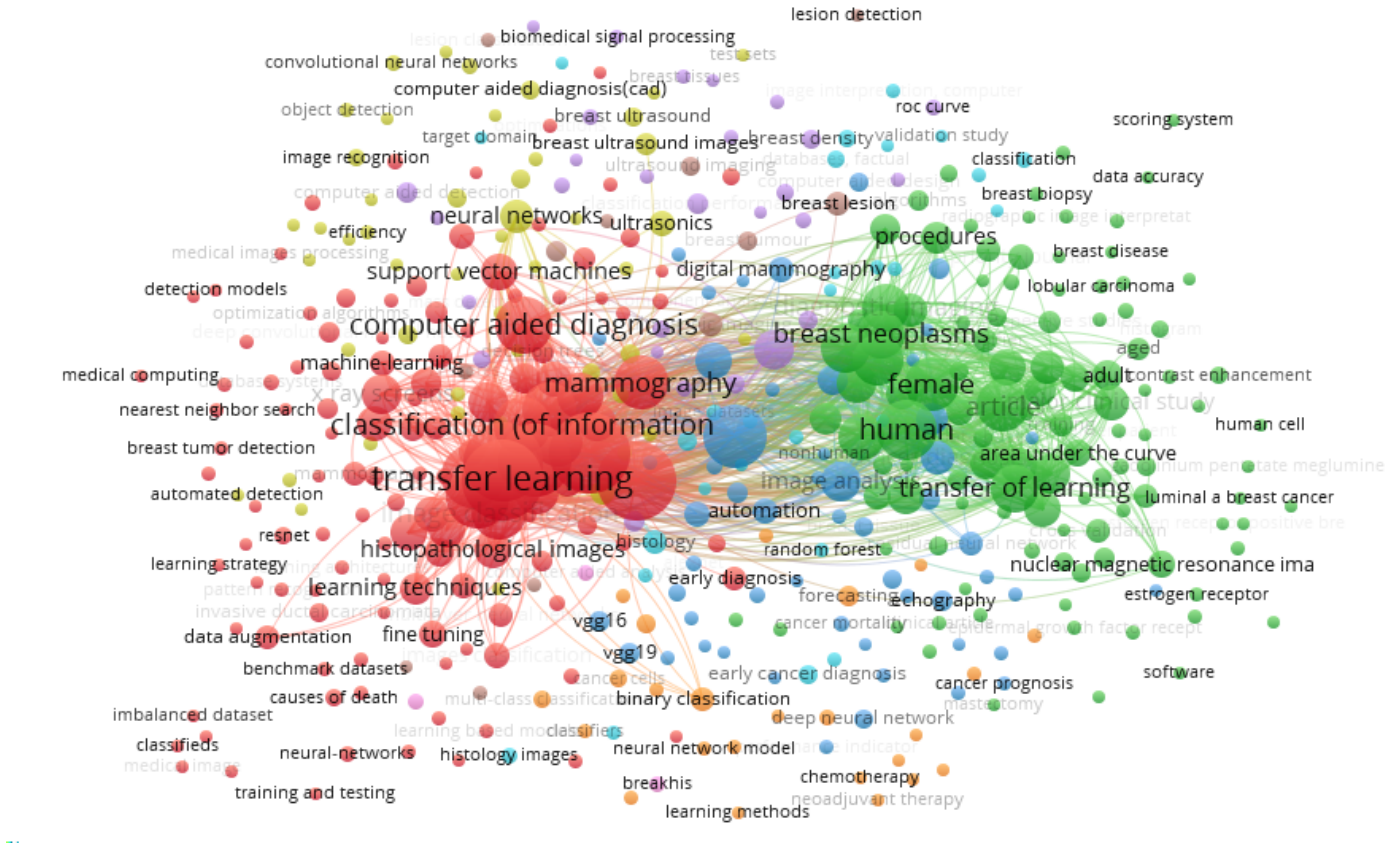

Fig. 13. Co-occurrence based on index keywords - network visualization.

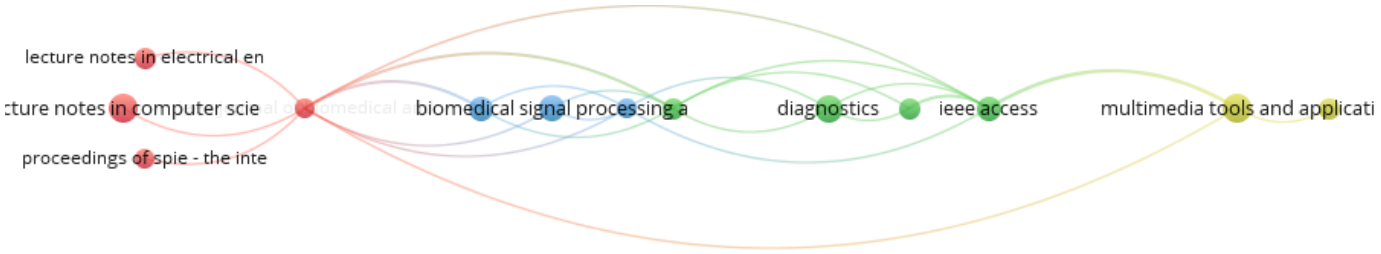

Fig. 15. Source citation analysis – network visualization.

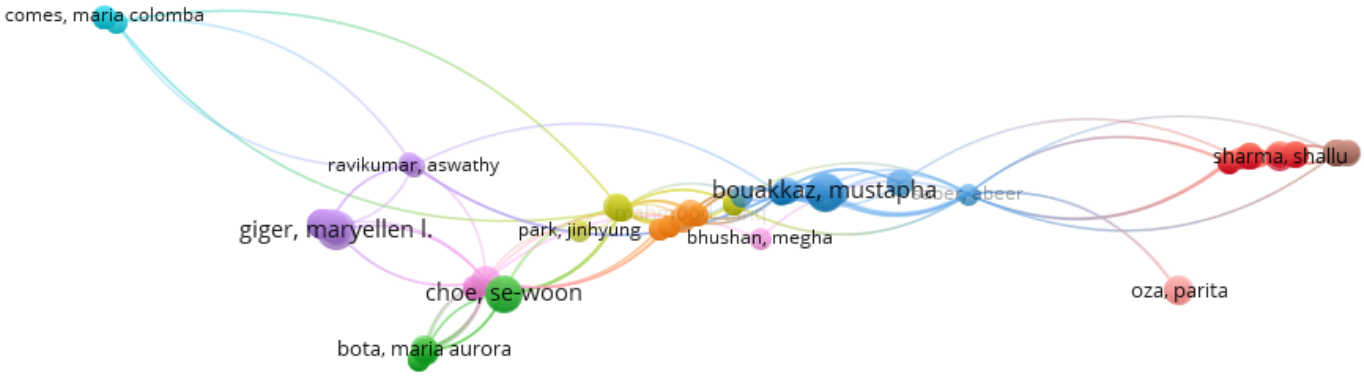

Fig. 16. Author citation analysis – network visualization.

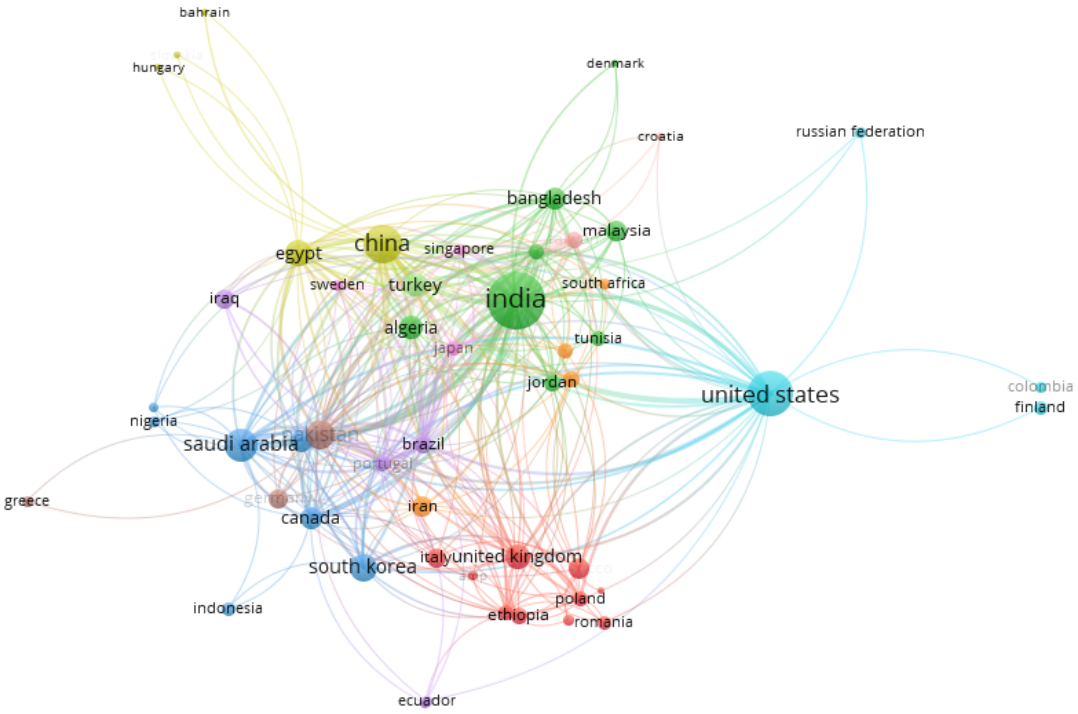

Fig. 17. Country citation analysis – network visualization.

V. Limitations

This study is limited by the exclusive use of the Scopus database for data collection, which may not capture all relevant publications on transfer learning in breast cancer detection. Additionally, the data is retrieved on April 21, 2024, and any documents published after this date are not included in the

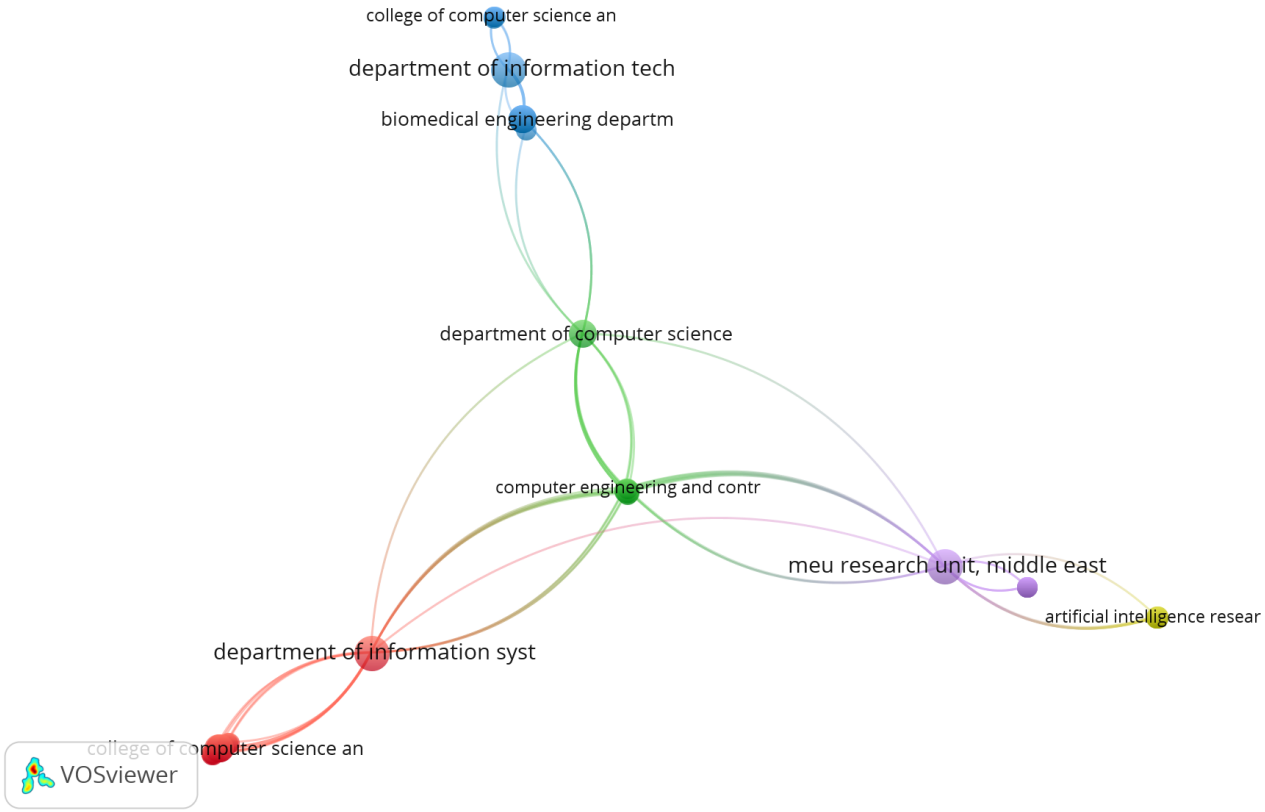

Fig. 18. Organization citation analysis – network visualization.

analysis. These limitations suggest that the findings might not fully represent the entire scope of research in this domain. A more comprehensive approach that includes other databases such as Web of Science, PubMed, and Google Scholar could provide a more holistic view of the research landscape.

VI. Conclusion and Future Directions

This bibliometric analysis reveals a significant upward trend in publications on transfer learning for breast cancer detection from 2016 to 2024, highlighting increasing research interest and advancements in the field. The results indicate that the volume of research on transfer learning for breast cancer detection has been steadily growing. In 2016, only 3 publications were available, but by 2023, this number had reached 133 publications, showing an upward trend in research interest. As of 2024, the results indicate continued activity in the field. The collaboration patterns in this research area reveal a mix of individual and institutional collaborations. Out of 1680 authors, 215 authors have published at least two papers, with the largest connected set comprising 18 authors. Princess Nourah bint Abdulrahman University has emerged as a leading institution, while China and India have shown significant research contributions, both through single-country and multi-country publications.

Future research will consider conducting a systematic review to complement this bibliometric analysis, providing deeper insights into the qualitative aspects of the studies, and identifying gaps in the existing literature. Additionally, comparative studies examining the research output on breast cancer detection using transfer learning across different countries, especially in developing regions, would be beneficial. Expanding the scope to include multiple databases and exploring collaborative patterns in diverse geographical regions could improve understanding of global research trends and foster international collaboration. These steps will help in advancing the field further and potentially lead to breakthroughs in early diagnosis and improved patient outcomes in breast cancer detection.

An Adaptive Levy Flight Chicken Swarm Optimization with Differential Evolution for Function Optimization Problem

WEN-JUN LIU[1], AZLAN MOHD ZAIN[2], MOHAMAD SHUKOR BIN TALIB[3], SHENG-JUN MA[4]
Faculty of Computing, Universiti Teknologi Malaysia, Skudai, 80310, Malaysia[1,2,3]
Electrical and Electronic Engineering Department, Auckland University of Technology, Auckland, New Zealand[4]

***Abstract*—This study proposes an improved swarm algorithm, Adaptive Levy Flight Chicken Swarm Optimization with Differential Evolution (ALCSODE), to overcome the low convergence accuracy and imbalance between exploration and exploitation in the original CSO algorithm. The method incorporates adaptive perturbation based on individual differences and a differential evolution mechanism into the rooster update process. An elitism preservation strategy is also applied to enhance population stability and information sharing. The algorithm is evaluated on 24 benchmark functions, including unimodal, high-dimensional multimodal, and CEC2022 functions. Performance metrics such as search trajectories and convergence curves are used to assess its effectiveness. Experimental results show that ALCSODE achieves a better exploration–exploitation trade-off and shows statistically superior performance over seven classical algorithms, confirming its potential as an effective tool for solving complex optimization problems.**

Keywords*—Chicken swarm optimization; levy flight; differential evolution algorithm; adaptive adjustment strategy; function optimization

I. Introduction

As the dimensionality and complexity of real-world problems increase, optimization tasks exhibit diverse characteristics, such as the coexistence of discrete and continuous variables, low- and high-dimensional settings, and both convex and non-convex landscapes [1]. These challenges significantly limit the effectiveness of traditional analytical and gradient-based methods. In non-smooth, non-convex, or high-dimensional search spaces, gradients are often difficult to compute, and numerical methods are prone to local optima with slow convergence, which severely hampers solution quality and efficiency.

To overcome these limitations, metaheuristic algorithms have emerged as a powerful alternative. Inspired by natural processes such as evolution and swarm intelligence, these algorithms iteratively refine candidate solutions through stochastic operations, offering derivative-free optimization and strong adaptability [2]. Their core strength lies in the ability to balance global exploration and local exploitation [3]: exploration aims to identify promising regions in the search space, while exploitation focuses on refining existing solutions toward the global optimum. The balance between exploration and exploitation is crucial for achieving good optimization performance. Excessive exploration may reduce convergence speed, while excessive exploitation can lead to premature convergence. Therefore, designing algorithms that can effectively coordinate both aspects remains a central goal in metaheuristic development. Generally, metaheuristic algorithms are categorized into four major types: evolution-based, physics-based, mathematics-based, and swarm intelligence-based methods.

The first category comprises general population-based metaheuristic algorithms, which are inspired by biological evolution and natural selection. These algorithms simulate the competitive survival process within a population to iteratively improve solution quality. Representative methods include Genetic Algorithms (GA) [4], Differential Evolution (DE) [5], and Evolution Strategies (ES) [6]. They typically employ operators such as selection, crossover, and mutation to evolve the population, ensuring both diversity maintenance and convergence toward superior solutions.

The second category consists of physics-inspired optimization algorithms, which guide the search process by mimicking natural physical phenomena such as thermodynamics, gravitational force, and electromagnetic interactions. For instance, Simulated Annealing (SA) [7] is based on the annealing process of materials and helps the algorithm escape local optima. The Gravitational Search Algorithm (GSA) [8] and the Black Hole Algorithm (BH) [9] leverage mechanical or astrophysical models to drive the search process. These methods generally offer strong global search capabilities and are well suited to high-dimensional and complex optimization problems. Moreover, Harmony Search (HS) [10], inspired by musical improvisation, seeks optimal solutions. Dynamic Dimension Adjustment HS (DDA-HS) [11] adapts the search space and employs an absorbing Markov chain to improve exploration–exploitation balance, enhancing fuzzy rule extraction in neural networks for better classification and interpretability.

The third category includes mathematically inspired algorithms, which regulate the search process through rigorous mathematical strategies. The INFO [12] adopts an averaging-based update mechanism and a vector combination strategy to enhance convergence speed and local exploitation performance, while alleviating premature convergence and population stagnation. Similarly, the SHIO [13] incorporates a guidance mechanism based on the average of historical best solutions to balance exploration and exploitation, thus improving global performance and avoiding local optima.

The fourth category, swarm intelligence-based optimization algorithms, is inspired by collective foraging, migration, and cooperative decision-making behaviors observed in biological systems. These algorithms achieve global optimization through simple interactions among individuals and local adap-

tive search without centralized control, exhibiting strong self-organization, robustness, and parallelism [14].

In recent years, several novel algorithms have emerged in this domain. The Snow Geese Algorithm (SGA) [15] models global guidance and shortest path search by mimicking the V-formation and energy-sharing strategies of migratory geese. The Sled Dog Optimizer (SDO) [16] simulates sled dog team formation and dynamic role-switching to construct a multi-stage cooperative optimization mechanism. The HawkFish Optimization Algorithm (HFOA) [17] incorporates dual-fitness and vision-based dynamic strategies inspired by sex-switching behavior, demonstrating both stability and efficiency in solving multimodal problems. Classical swarm-based algorithms, including Particle Swarm Optimization (PSO) [18], Ant Colony Optimization (ACO) [19], Artificial Bee Colony (ABC) [20], Artificial Fish Swarm Algorithm (AFSA) [21], and Bat Algorithm (BA) [22], along with emerging variants such as Cuckoo Search (CS) [23], Hybrid Harmony Search with Cuckoo Search (HS-CS) [24], Krill Herd Optimization [25], Chaotic Fruit Fly Optimization Algorithm [26], and Social Spider Optimization [27], have found wide applications in fields such as computer science [28], engineering design [29], machine learning [30], image processing [31], and NP-complete problem solving [32].

The Chicken Swarm Optimization (CSO) algorithm [33] is a swarm intelligence technique inspired by the hierarchical structure and foraging behavior of chicken flocks. It assigns individuals as roosters, hens, or chicks, each applying distinct search strategies to achieve cooperative optimization and improve its capability to locate the global optimum [34].

However, the original CSO algorithm faces several limitations, such as a tendency to fall into local optima, slow convergence speed, and high sensitivity to parameter settings. To address these issues, various improved variants have been proposed. To strengthen global exploration, Huang et al. [35] introduce a global best-guided strategy combined with dynamic inertia weight, significantly improving the search capability of the swarm. To mitigate premature convergence, Kong et al. [36] propose a dual-guidance mechanism in which chicks learn from both hens and roosters, thereby enhancing their ability to escape local optima. Shi and Gao [37] integrate CSO with the Artificial Bee Colony (ABC) algorithm to leverage ABC's global search ability for better exploration-exploitation balance. A hybrid strategy is also developed by combining CSO with Particle Swarm Optimization (PSO) to enhance information exchange and population diversity [38]. Zhang et al. [39] further propose L-QCSO by incorporating Levy flight and quantum behavior, aiming to balance local exploitation and global exploration while improving convergence accuracy. Lin et al. [40] enhance the robustness and precision of CSO by modifying the position update rules for roosters and hens. Theoretical advancements have also been made, such as models based on Markov chains and convergence analysis, which provide a reliable foundation for parameter tuning and structural design [41]. In practical applications, CSO is often combined with other optimization or learning models. For example, Afzal et al. [42] present CSO-OEL by integrating CSO with the Optimized Extreme Learning Machine, resulting in improved convergence speed, stability, and overall efficiency.

Despite the significant achievements of various optimization algorithms in solving complex problems, the "No Free Lunch" theorem [43] states that no single algorithm can perform optimally across all problem domains. The performance of an algorithm is generally problem-dependent, making the NFL theorem a fundamental driving force behind the development of problem-specific optimization strategies.

The Chicken Swarm Optimization (CSO) algorithm has attracted attention for its simplicity and effective modeling of social behavior. However, existing studies reveal persistent limitations, including weak role coordination, slow convergence in complex landscapes, and sensitivity to parameter settings—often caused by the imbalance between exploration and exploitation. These issues hinder the algorithm's scalability, adaptability, and solution quality in high-dimensional or dynamic problems. To improve convergence accuracy and address these limitations, this study draws on recent advances in swarm intelligence and proposes that a high-performance optimizer should integrate multi-strategy cooperation and adaptive control mechanisms.

To enhance the scalability, robustness, and convergence behavior of the traditional Chicken Swarm Optimization (CSO), this research proposes a novel algorithm, Adaptive Levy Flight Chicken Swarm Optimization with Differential Evolution (ALCSODE). The main innovation of ALCSODE lies in its strategic integration of multiple adaptive and cooperative mechanisms, each designed to explicitly tackle key structural deficiencies of CSO, rather than simply stacking heuristic components. The contribution is a modular, coordinated optimization framework that strengthens global search capabilities, improves role collaboration, and enhances adaptability to complex landscapes.

Specifically, in the rooster phase, an adaptive differential perturbation mechanism enhances global exploration through individual difference vectors, supported by a fitness-based step-size strategy that dynamically adjusts the search range to balance exploration and exploitation. A non-inertia weight mechanism further improves convergence stability by adapting parameter intensity to the current search stage. In the hen phase, a Levy flight strategy utilizes long-tailed jumps to escape local optima and accelerate convergence. Additionally, an elitism preservation and information-sharing mechanism maintains diversity and guides inferior individuals toward high-quality solutions, improving convergence without compromising population diversity. The scientific contributions of this research are summarized as follows:

- The novelty of this study lies in the design of a new optimizer, ALCSODE, which incorporates an adaptive differential perturbation mechanism, Levy flight strategy, non-inertia weight adjustment, and elitism preservation into the Chicken Swarm Optimization (CSO) framework.
- The proposed ALCSODE algorithm addresses key limitations of the original CSO, including weak role coordination, premature convergence, and sensitivity to parameter settings caused by the imbalance between exploration and exploitation.
- A modular, adaptive optimization framework is developed, with each component designed to enhance

global exploration, convergence stability, and role collaboration in complex search spaces.

- The algorithm's core strategies are formally described and mathematically modeled to ensure transparency and reproducibility.
- ALCSODE is evaluated on 24 benchmark functions, covering unimodal, multimodal, and the CEC2022 test suite, to verify its scalability and effectiveness in diverse optimization scenarios.
- Comparative experiments with seven established metaheuristic algorithms show that ALCSODE consistently achieves superior performance and robustness in most test cases.

The remainder of this study is organized as follows: Section II reviews the standard CSO and DE algorithms; Section III details the implementation steps of ALCSODE; Section IV presents the simulation experiments and analysis; and Section V summarizes the whole manuscript and outlines future research directions.

II. Related Work and Background Algorithms

Several swarm intelligence algorithms have been proposed in recent years, among which the Chicken Swarm Optimization (CSO) and the Differential Evolution (DE) algorithms are widely used due to their strong optimization capability. This section briefly introduces the basic principles of the standard CSO and DE algorithms, which form the foundation of our proposed ALCSODE method.

A. The Chicken Swarm Optimization

Swarm intelligence algorithms have demonstrated remarkable advantages in solving complex optimization problems. The Chicken Swarm Optimization (CSO) algorithm achieves efficient search performance by simulating the hierarchical behavior of chicken groups [34]. In this algorithm, the population is categorized into three distinct roles: roosters (leaders), hens, and chicks, which correspond to exploration, cooperation, and following behaviors, respectively.Typically, individuals with the best fitness values are assigned as roosters, while those with the worst fitness values are designated as chicks. The remaining individuals act as hens. The entire chicken swarm is further divided into several subgroups, each led by one rooster accompanied by a number of hens and chicks. To enhance the algorithm's adaptability in solving complex multimodal problems, the identities of individuals and the parent–child relationships are periodically redefined.

Let N be the total number of chickens, and R_N, H_N, C_N, and M_N denote the number of roosters, hens, chicks, and mother hens, respectively. The search space is defined as $\mathbb{R}^D$. The position of the i-th individual in the j-th dimension at iteration t is denoted by $x_{i,j}^t$, where $i \in [1, \ldots, N]$, $j \in [1, \ldots, D]$, and t is the current iteration. The position of roosters is updated using a random walk and competition mechanism, formulated as follows [see Eq. (1) and Eq. (2)]:

$$x_{i,j}^{t+1} = x_{i,j}^t(1 + \mathcal{N}(0, \sigma^2)), \tag{1}$$

$$\sigma^2 = \begin{cases} \exp\left(\frac{f_k - f_i}{|f_i| + \epsilon}\right) & \text{if } f_k > f_i, \\ 1 & \text{otherwise,} \end{cases} \tag{2}$$

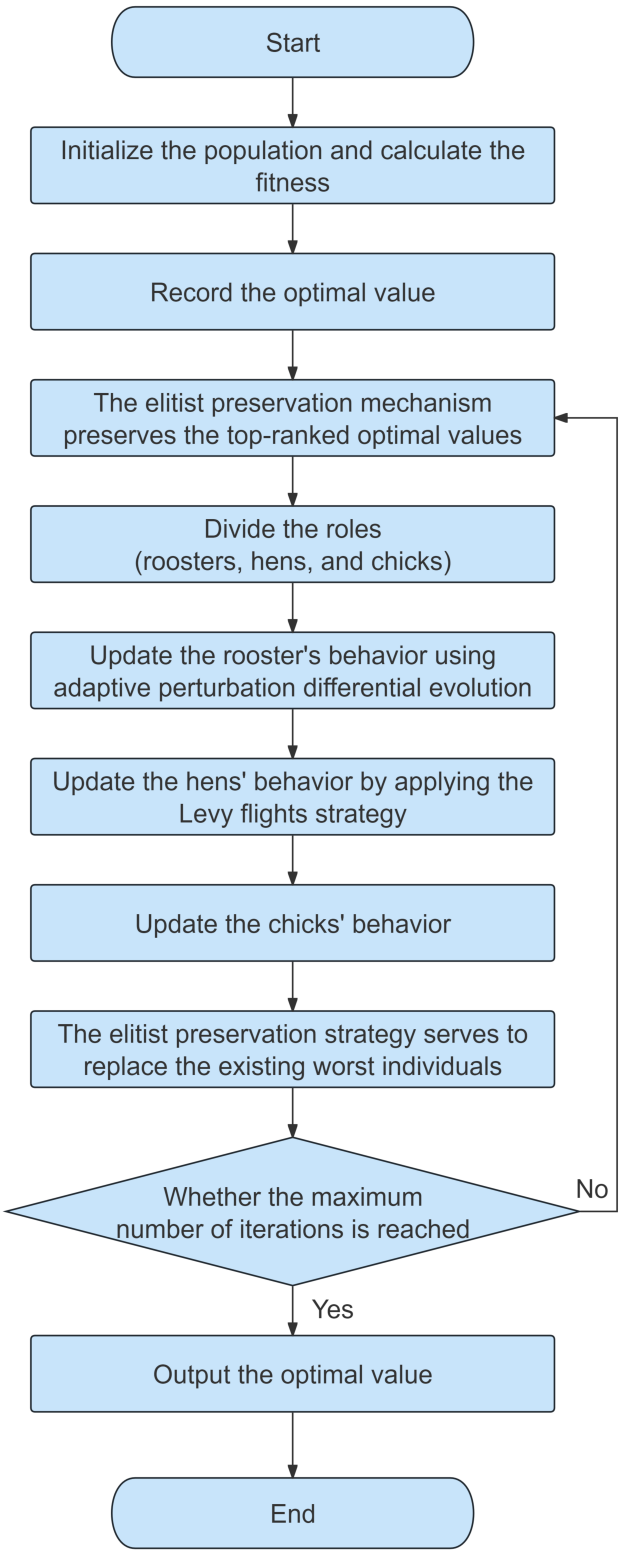

Fig. 1. The flowchart of ALCSODE algorithm.

where, f_i represents the fitness of the current rooster,f_k is the fitness of a randomly selected rooster, andϵ is a small constant used to avoid division by zero.

For hens, their position update combines leadership from the roosters and social learning. The corresponding update equation is defined as follows [see Eq. (3)]:

$$x_{i,j}^{t+1} = x_{i,j}^{t} + c_1 r_1 (x_{r,j}^{t} - x_{i,j}^{t}) + c_2 r_2 (x_{m,j}^{t} - x_{i,j}^{t}), \quad (3)$$

where, $x_{r,j}^{t}$ denotes the position of the leading rooster, $x_{m,j}^{t}$ represents the position of another randomly selected hen, c_1 and c_2 are learning factors (typically defined as $c_1 = \exp(f_i/f_r)$, $c_2 = \exp(f_m - f_i)$), and $r_1, r_2 \in [0, 1]$ are random numbers.

As for the chicks, they strictly follow the movement of the mother hens. The update equation is as follows [see Eq. (4)]:

$$x_{i,j}^{t+1} = x_{i,j}^{t} + F(x_{h,j}^{t} - x_{i,j}^{t}). \quad (4)$$

where, $x_{h,j}^{t}$ denotes the position of the hen, and $F \in (0, 2]$ is the following step size factor.

B. The Differential Evolution Algorithm

Differential Evolution (DE [44]) is a population-based stochastic optimization algorithm proposed by Storn and Price in 1997. It is an important branch of evolutionary computation. The core idea of DE is to simulate the mutation, crossover, and selection operations in biological evolution to efficiently search for the global optimal solution in continuous space. The DE algorithm begins by initializing a fixed-size population, with each individual representing a candidate solution in the solution space (referred to as a target vector). The optimization process then iteratively refines the solution, gradually approaching the optimal one. During the mutation step, the algorithm generates mutation vectors using differential operations. Common strategies include generating mutation vectors by linearly combining three random individuals (DE/rand/1) and introducing the global best solution to guide mutation (DE/rand-to-best/1), which helps overcome the limitations of traditional mutation methods in genetic algorithms (GA [4]). In the crossover phase, the mutation vectors and target vectors are probabilistically mixed to create trial vectors, enhancing population diversity. Finally, a greedy selection strategy is used to retain individuals with better fitness for the next generation, continuously improving the solution quality. The DE algorithm is widely applied in single-objective and multi-objective optimization, combinatorial optimization, and engineering problems due to its simple structure, few parameters, and high efficiency.

III. The Proposed ALCSODE Method

In this section, we present our Adaptive Levy Flight Chicken Swarm Optimization with Differential Evolution algorithm, termed ALCSODE, whose detailed pseudocode is provided in Algorithm 1 and overall workflow is illustrated in Fig. 1. For clarity and focus, our method follows the standard CSO framework for initialization and role assignment.

The algorithm is divided into four core components, highlighting two innovative improvements: 1) The adaptive perturbation-based differential evolution strategy for rooster behavior updating. 2) The elitism preservation mechanism to improve global robustness.

A. Adaptive Perturbation-Based Differential Evolution for Rooster Behavior Updating

In Chicken Swarm Optimization (CSO) algorithms, rooster behavior plays a pivotal role in guiding population exploration and maintaining swarm diversity, as documented in foundational studies [45]. However, traditional updating mechanisms exhibit significant limitations: 1) single-strategy search susceptibility to local optima causing premature convergence, 2) insufficient spatial perturbation, and 3) fixed parameters lacking environmental adaptability [46]. To address these issues, our study proposes a method integrating individual adaptability perturbation with the differential evolution algorithm [5]. We use the differential information among individuals to guide the search to high-quality regions. The adaptive perturbation dynamically adjusts the search step size based on individual fitness. This synergy balances global exploration and local exploitation, avoiding search imbalance from single-strategy approaches. Additionally, parameters can adaptively adjust their intensity, enabling effective regulation of search efforts at different stages. The detailed method is introduced in the following section.

1) Calculation of adaptive differential mutation vector: To enhance global exploration in early stages and intensify local exploitation in later phases, this study introduces an adaptive update strategy for the scaling factor F and crossover probability CR in Differential Evolution. Let t denote the current iteration and T the maximum iterations, with initial values F_0 and CR_0. The adaptive update equations are defined as Eq. (5) and Eq. (6):

$$F_t = F_0 \left(1 - \frac{t}{T}\right)^{\theta} + F_{min}, \quad (5)$$

$$CR_t = CR_0 \left(1 - \frac{t}{T}\right)^{\theta} + CR_{min}, \quad (6)$$

where, CR_{min} and F_{min} are both set to 0.1, and $\theta > 0$ controls the decay rate. This adaptive mechanism ensures larger step sizes and higher mutation probabilities during initial phases, facilitating escape from local optima, while progressively decreasing parameters promote stable convergence as iterations advance.

Using differential evolution, our method leverage information from other population individuals to guide global search directions. Three distinct individuals are randomly selected from the population, denoted as $\mathbf{x}_{r_1}$, $\mathbf{x}_{r_2}$, $\mathbf{x}_{r_3}$. The differential evolution mutation vector is constructed as follows [see Eq. (7)]:

$$\mathbf{d}_i^{t+1} = \mathbf{x}_{r_1}^{t} + F_t \left(\mathbf{x}_{r_2}^{t} - \mathbf{x}_{r_3}^{t}\right). \quad (7)$$

where, t denotes the iteration, F_t represents the adaptive scaling factor. $\mathbf{d}_i^{t}$ provides a new search direction based

on population differential information. This step effectively utilizes inter-population differential information to introduce diversity in global search, facilitating exploration of potential optimal regions.

2) Calculation of individual-adaptive perturbation factor: Individual-specific perturbations are applied to candidate solutions (representing rooster behaviors in the swarm) to enhance search capabilities of inferior individuals. Let f_i denote the fitness of the i-th individual and f_b the best fitness in the population. The perturbation standard deviation σ_i is defined as Eq. (8):

$$\sigma_i^2 = \begin{cases} 1, & f_i \le f_b \\ \exp\left(\frac{f_b - f_i}{|f_i| + \varepsilon}\right), & f_i > f_b \end{cases} \tag{8}$$

where, ε represents a minimal positive constant to prevent division by zero. The perturbation step size δ_i is then sampled from a normal distribution with zero mean and variance σ_i^2, as in Eq. (9):

$$\delta_i \sim \mathcal{N}\big(0, \sigma_i^2\big). \tag{9}$$

Fitness-adaptive perturbation adjustment enables inferior individuals to receive larger perturbations, facilitating escape from local optima, while superior individuals maintain stability, ensuring convergence quality.

3) Updating the roosters behavior: Integrating global differential search information with current rooster states, the next generation is generated as follows. Let $\mathbf{x}_i^t$ denote the current individual position. With a trade-off parameter β, the next generation vector is defined as Eq. (10):

$$\mathbf{x}_i^{t+1} = \alpha\, \mathbf{d}_i^{t+1} + \delta_i\, \mathbf{x}_i^t, \tag{10}$$

where, $\alpha \in (0, \infty)$ controls the relative weight between global exploration and local exploitation. $\mathbf{d}_i^{t+1}$ represents the differential evolution mutation vector computed by Eq. (7), while δ_i denotes the adaptive perturbation factor calculated from Eq. (9).

To prevent excessive localization of new solutions, a component-wise crossover strategy is employed for dimension-by-dimension position updating. For each dimension j, the next generation rule is defined as Eq. (11):

$$x_{i,j}^{'t+1} = \begin{cases} x_{i,j}^{t+1}, & \text{if } rand(0,1) \le CR_t \text{ or } j = j_{rand} \\ x_{i,j}^{t}, & otherwise \end{cases} \tag{11}$$

where, CR_t denotes the crossover probability calculated by the Eq. (6), and j_{rand} ensures at least one dimension is updated.

By integrating the differential evolution mutation vector with individual-specific perturbations and updating the rooster vector through component-wise crossover, this strategy maintains population diversity while effectively balancing global exploration and local exploitation, thereby enhancing convergence speed and stability.

B. Levy Flight-Based Hen Behavior Optimization

To enable hen individuals to adaptively adjust search step sizes based on fitness information during updating, dynamic scaling factors are first constructed from fitness differences between the current individual and two randomly selected individuals. The scaling factors are defined as Eq. (12) and Eq. (13):

$$\lambda_1 = \exp\left(\frac{f_i - f_l}{|f_i| + \varepsilon}\right), \tag{12}$$

$$\lambda_2 = \exp\left(f_k - f_i\right), \tag{13}$$

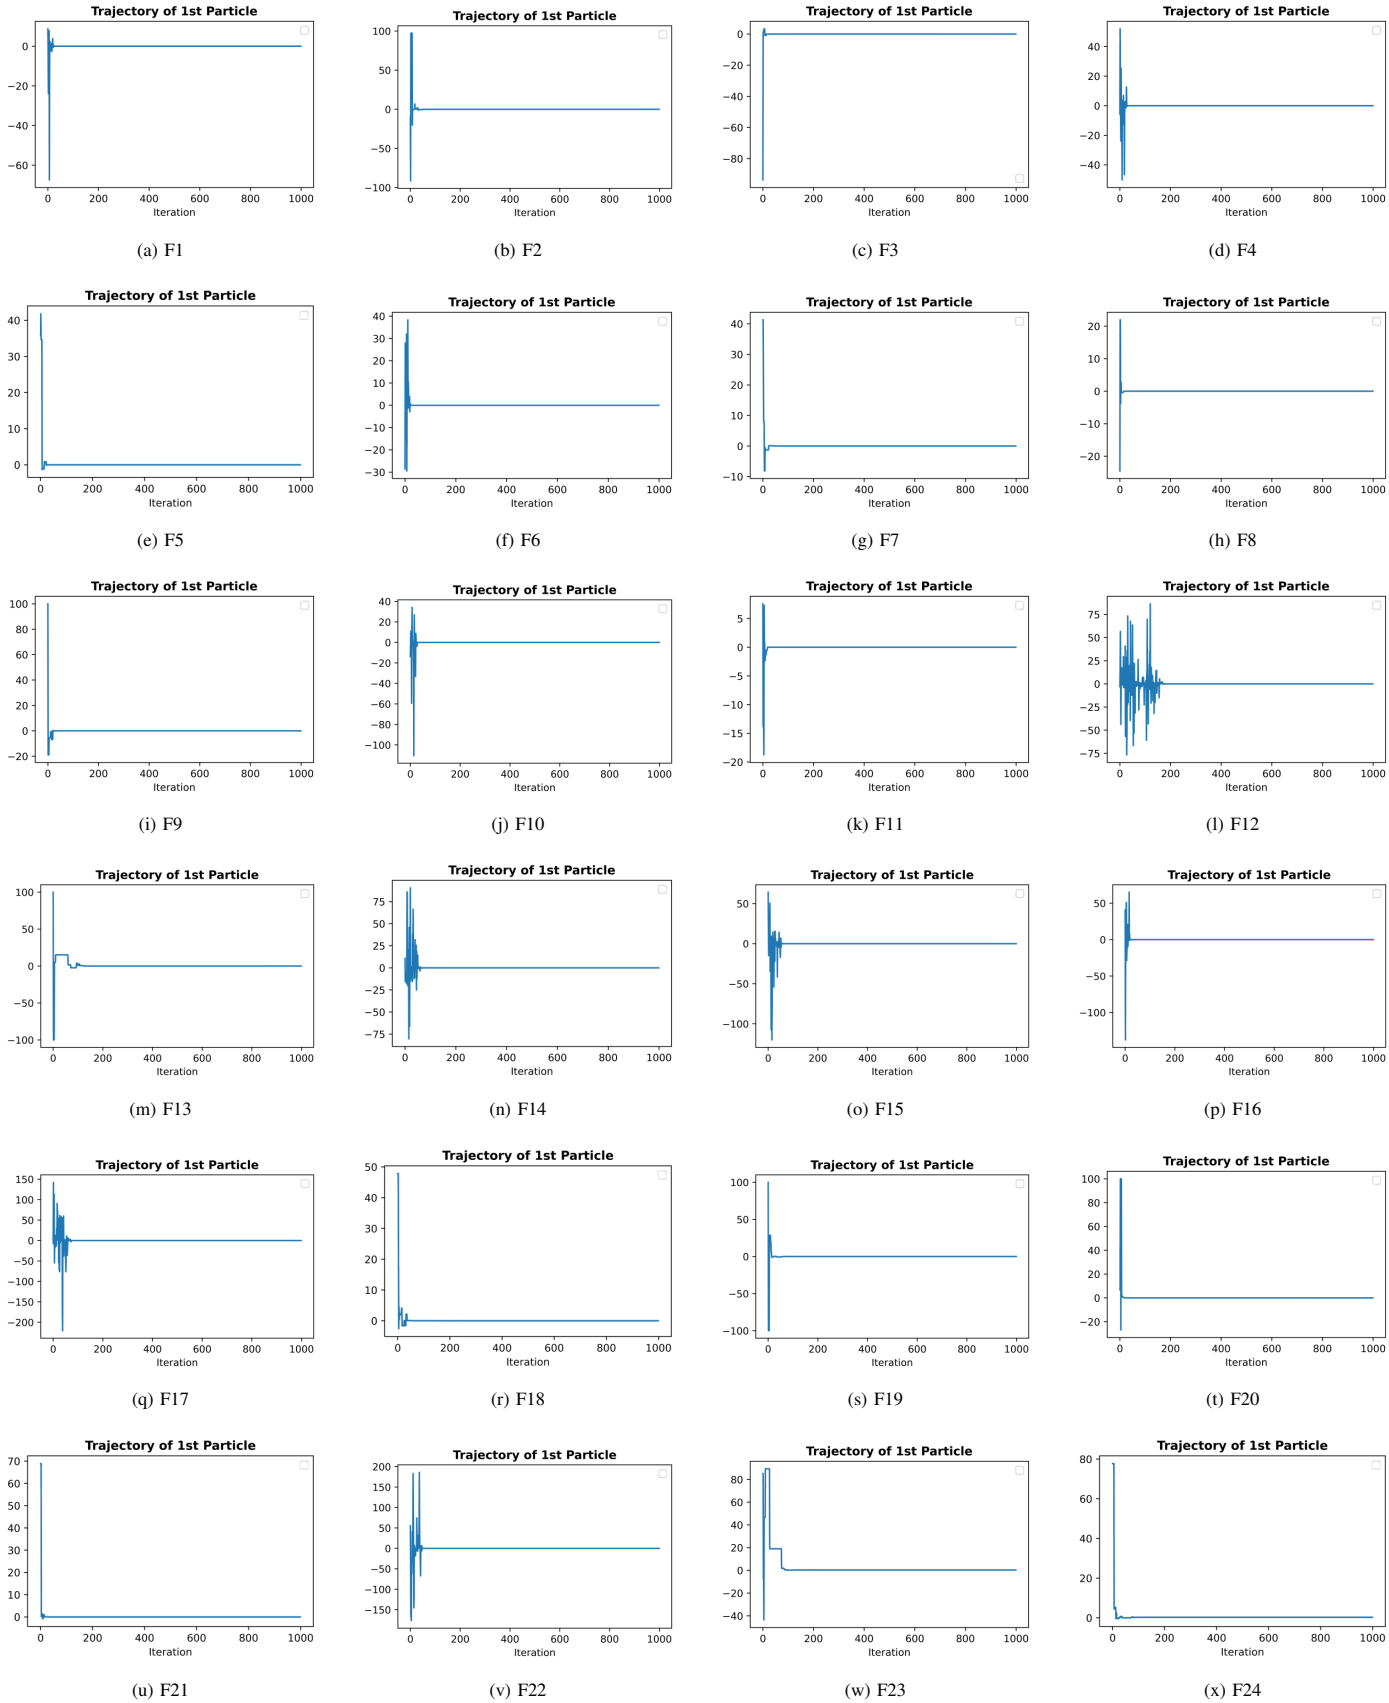
where, f_i denotes the fitness of the current hen individual; f_l and f_k represent the fitness values of randomly selected individuals; ε is a small positive constant preventing division by zero; λ_1 and λ_2 reflect the relative fitness advantage or disadvantage of the current individual, providing dynamic adjustment factors for subsequent position updating.

To enhance global exploration capability, the Levy flight function is employed. Given the Levy parameter β, the scale parameter σ_u is first calculated as Eq. (14):

$$\sigma_u = \left[\frac{\Gamma(1+\beta)\, \sin\left(\frac{\pi\beta}{2}\right)}{\Gamma\left(\frac{1+\beta}{2}\right)\, \beta\, 2^{\frac{\beta-1}{2}}}\right]^{\frac{1}{\beta}}, \tag{14}$$

where, $\Gamma(\cdot)$ denotes the gamma function. The Levy flight step size is calculated as Eq. (15):

$$L = \sigma_u \left(u^2 + v^2\right)^{\frac{1}{2\beta}}, \tag{15}$$



where, u and v are independent random variables following the standard normal distribution; β denotes the Levy flight parameter; L represents the random step size generated from the Levy distribution, exhibiting heavy-tailed characteristics that facilitate large-step.

Integrating the dynamic scaling factors and Levy flight step size, the position updating equation for hen individuals is defined as Eq. (16):

$$\mathbf{x}_{i,j}^{t+1} = \mathbf{x}_{i,j}^t + \lambda_1\, \rho_1\, L\, \left(\mathbf{x}_{l,j}^t - \mathbf{x}_{i,j}^t\right) + \lambda_2\, \rho_2\, L\, \left(\mathbf{x}_{k,j}^t - \mathbf{x}_{i,j}^t\right). \tag{16}$$

where, j denotes the dimension, t the iteration count, and ρ_1 and ρ_1 are random numbers uniformly sampled from the interval [0,1].

By integrating current hen and random individuals' position info with Levy-based step sizes, global exploration and local exploitation are effectively combined. A dynamic scaling factor gives personalized update magnitudes, and the Levy step's long-tail property boosts search jumps, aiding escape from local optima and accelerating global convergence.

C. Chick Behavior Updating

In this method, the standard CSO algorithm [33] for updating chick behavior is adopted. For each chick (denoted as individual i), a randomly selected leader individual (indexed as r) serves as the reference during position updating. Randomness and update magnitude are regulated through the following Eq. (17):

$$\mathbf{x}_{i,j}^{t+1} = \mathbf{x}_{i,j}^{t} + \varphi\left(\mathbf{p}_{r,j} - \mathbf{x}_{i,j}^{t}\right). \tag{17}$$

where, $\mathbf{p}_{r,j}$ denotes the historical best position vector of individual r, and φ represents a random scaling factor regulating the update step size, ensuring appropriate stochastic perturbation during updating.

D. The Elitism Preservation Mechanism

In most CSO and its variant methods, the stochastic nature of individual behavior updating mechanisms (e.g., differentiated strategies for roosters, hens, and chicks) may lead to the loss of high-quality solutions, forcing the algorithm to restart local search and significantly reducing convergence efficiency. To address this, an elitism preservation strategy is introduced to balance exploration-exploitation trade-offs: after each iteration t, individuals with the best fitness are selected to form an elite pool, replacing low-fitness individuals in iteration $t+1$. This mechanism enhances population stability through elite guidance while enabling non-elite individuals to accelerate convergence toward elite solution regions via information sharing, thereby optimizing global convergence performance.

Step 2: Population initialization based on the normal distribution, calculate the fitness using the objective function $f(x)$, and record the optimal value.

Step 3: Elite selection. Select top $\eta * N$ individuals. The residual population is categorized into roosters, hens, and chicks based on fitness hierarchy.

Step 4: Adaptive perturbation-based differential evolution for rooster behavior updating. First, the adaptive differential mutation vector is computed using the adaptive scaling factor F_t through Eq. (7). Then, the individual-adaptive perturbation factor δ_i is calculated, where inferior individuals receive larger perturbations through a fitness-dependent variance σ_i^2, sampled from a zero-mean normal distribution as defined in Eq. (9). Finally, the differential evolution mutation vector is combined with the current rooster vector controlled by the adaptive perturbation factor δ_i to generate the next generation, as defined in Eq. (10). Additionally, a component-wise crossover strategy prevents excessive localization by updating positions dimension-by-dimension, as defined in Eq. (11).

Step 5: Levy flight-based hen behavior optimization. By leveraging the Levy flight algorithm concept, hen behavior is updated in Equation 16 through the integration of dynamic scaling factors λ_1, λ_2 and Levy flight step size L.

Step 6: Chick behavior updating. For each chick i, a randomly selected leader r serves as the reference for position updating in Eq. (17).

Step 7: The fitness values of the population in the new state are evaluated by $f(x)$, with updates occurring only if the new fitness is better than the previous value. Additionally, the elite strategy replaces the current worst-performing individuals.

Step 8: Termination condition. The algorithm terminates if the maximum iteration count is reached, outputting the optimal solution; otherwise, the process returns to Step 3.

F. Time Complexity Analysis

The time complexity of the proposed Adaptive Levy Flight Chicken Swarm Optimization with Differential Evolution algorithm is analyzed with respect to the population size N, problem dimensionality Dim, fitness evaluation cost $f(Dim)$, and the maximum number of iterations T. In each iteration, the algorithm updates the positions of all individuals—including roosters, hens, and chicks—through vector operations such as mutation, adaptive perturbation, crossover, and Levy flight-based steps, each requiring $O(Dim)$ computations per individual and resulting in an overall $O(N \times Dim)$ complexity. Fitness evaluations for all individuals contribute an additional cost of $O(N \times f(Dim))$ per iteration. Although elitism preservation involves selecting elite individuals and replacing low-fitness ones, which may require sorting with a complexity

of $O(N \log N)$, this cost is generally minor compared to the dominant vector updates and fitness evaluations. Consequently, the total time complexity per iteration can be approximated by combining these main components as $O(N \times Dim) + O(N \times f(Dim))$, and over T iterations, the overall time complexity is $O\big(T \times N \times (Dim + f(Dim))\big)$. This formulation highlights that the computational cost of ALCSODE scales linearly with population size, problem dimensionality, and the complexity of fitness evaluation, demonstrating its suitability for large-scale and high-dimensional optimization problems.

IV. Simulation Experiment

To validate the effectiveness of the proposed ALSCODE algorithm, extensive experiments are conducted on 24 benchmark functions, including unimodal functions, high-dimensional multimodal functions, and the CEC2022 test suite [47]. This section first presents the experimental configurations and parameter settings of the comparative methods, followed by an analysis and verification of the algorithm's effectiveness based on the experimental results.

A. Experimental Setup

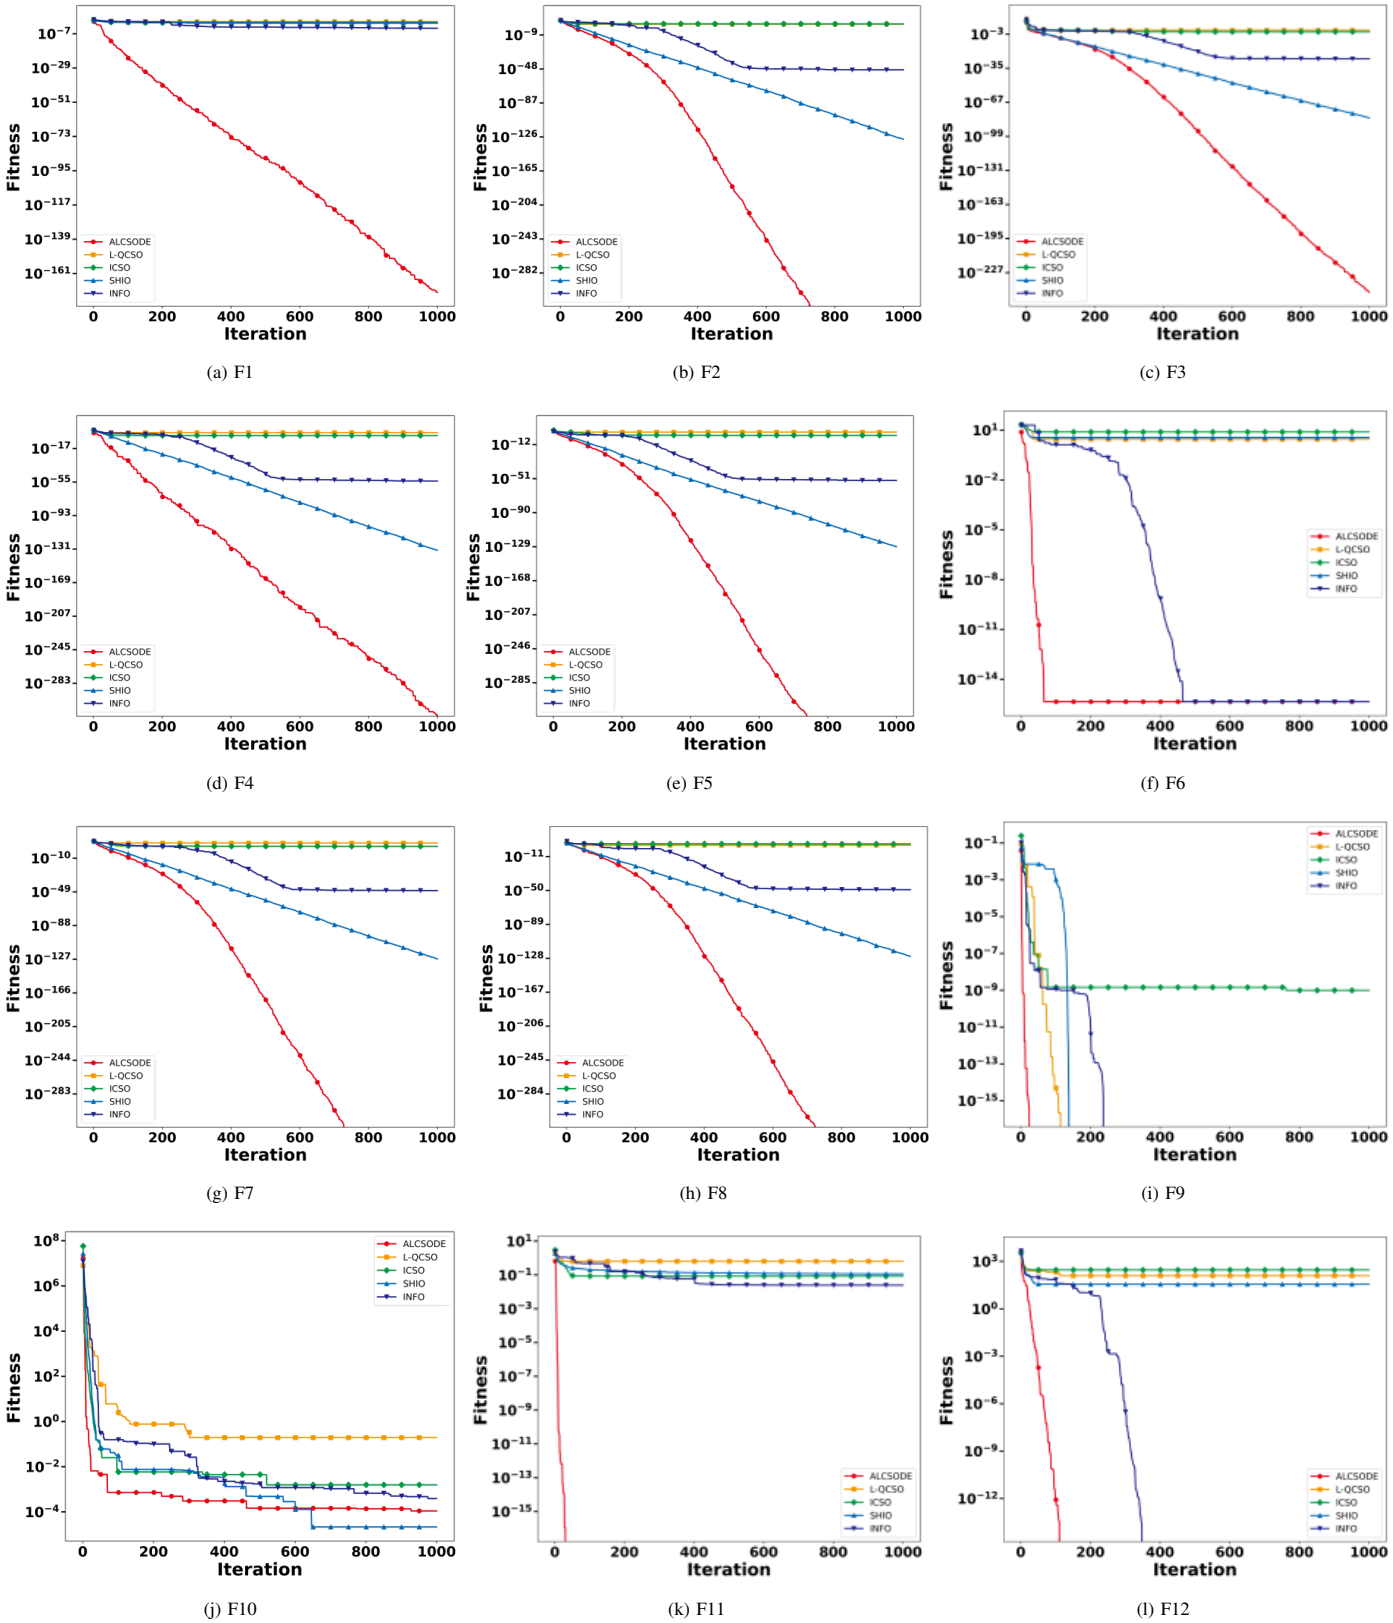
The experiments are conducted on a Windows 11 system equipped with a 2.9 GHz CPU and 16 GB of RAM, using Python 3.10 as the programming environment. The ALSCODE algorithm is evaluated on 24 benchmark functions, including 8 unimodal functions, 9 multimodal functions, 3 hybrid functions, and 4 composition functions. Detailed information, including function names, search ranges, and theoretical global optima, is provided in Table I and Table II, the latter corresponding to the standard CEC2022 benchmark.

The experimental comparison includes the standard Particle Swarm Optimization (PSO) algorithm inspired by bird flocking behavior [48], the standard Chicken Swarm Optimization (CSO) algorithm [33], along with three of its variants (L-QCSO [39], ICSO [36], and ECSO [49]), as well as the metaheuristic algorithms INFO [12] and SHIO [13], which serve as baseline methods. To ensure a fair comparison, all algorithms adopt the same configuration: a population size of 50, a maximum of 1000 iterations, and search spaces of 10 and 50 dimensions. Each algorithm is executed 30 times on each benchmark function, and the average performance is recorded. Additional parameter settings are provided in Table III.

B. Qualitative Results and Discussion of ALCSODE

The qualitative experiments are conducted on the two-dimensional versions of benchmark functions to visually observe the search behavior of the ALSCODE algorithm. For each test function, two types of diagrams are provided: one illustrating the trajectory of the first particle in the first dimension, and the other depicting the average fitness of the particle swarm. The former reflects the search dynamics of a representative particle, while the latter indicates the convergence trend of the entire population.

Fig. 2 shows the trajectory of the first particle in the first dimension, which serves to evaluate the algorithm's behavior at different stages, particularly whether it exhibits abrupt movements in the early iterations and stabilizes in later stages. This figure consists of 24 subplots, each representing the trajectory corresponding to a specific benchmark function. For example, Fig. 2a illustrates the trajectory for the F1 function (Alpine). According to the study by Berg et al. [50], an effective population-based algorithm performs wide-range exploration in the early phase and gradually shifts to local exploitation to achieve high-quality solutions. As shown in the figure, the first particle in ALSCODE exhibits a significant and abrupt movement exceeding 50% of the search space in the early phase, indicating that the algorithm fully utilizes population diversity and individual differences to escape local optima and conduct global exploration. As the iterations proceed, the particle's movement amplitude gradually decreases and the trajectory becomes smoother. This progressive stabilization is attributed to ALSCODE's adaptive perturbation mechanism, which dynamically adjusts the step size of the movement vector based on particle fitness, thereby narrowing the search range and guiding particles toward more promising regions for enhanced local exploitation.



The convergence curves of average fitness in Fig. 3 further validate this behavior. All test functions exhibit a consistently decreasing trend, indicating that the overall solution quality of the population improves continuously throughout the optimization process. This result confirms that ALSCODE effectively optimizes the swarm's search behavior and significantly enhances the accuracy of the approximated optimal solutions.

In summary, Fig. 2 and Fig. 3 jointly demonstrate that ALSCODE maintains a well-balanced dynamic between exploration and exploitation. The large-scale fluctuations in the early stage enhance diversity and global coverage, while the gradually decreasing fluctuations in the later stage ensure convergence and fine-tuning. Ultimately, the particle trajectories on nearly all benchmark functions converge to a stable point, verifying that ALSCODE achieves a smooth transition from global exploration to local exploitation and exhibits strong convergence performance and robustness.

C. ALCSODE Statistical Results and Comparison with Other Algorithms

Functions F1 to F24 (including the CEC2022 test suite) are evaluated under 10-dimensional and 50-dimensional settings. Experiments are based on data obtained from 30 independent runs for each function, and performance metrics include the best value, mean value, and standard deviation. The results are summarized in Table IV, Table V, and Table VI, where the best results for each function are highlighted in bold.

To comprehensively validate the performance of the ALSCODE algorithm, it is compared with the classical Chicken Swarm Optimization (CSO) and its three variants L-QCSO, ICSO, and ECSO, as well as representative metaheuristic algorithms from outside the domain, including PSO, INFO, and SHIO. Fig. 4 to Fig. 7 present the convergence curves of a randomly selected run among the 30 executions. To reduce visual clutter, only the top-performing or representative algorithms are shown: L-QCSO and ICSO among chicken swarm algorithms, and INFO and SHIO among metaheuristic algorithms. This choice facilitates a clearer comparison of convergence behavior. Comparative results indicate that, under different dimensional conditions, ALSCODE exhibits significant advantages in solution accuracy, result stability, and convergence efficiency.

1) Evaluation of unimodal banchmark: Unimodal functions F2, F3, F4, F5, F7, F8, F10, and F13 contain only a single global optimum and no local optima, making them ideal benchmarks for evaluating the development capabilities of optimization algorithms. According to the comparison of Mean, Standard Deviation, and Best results in both 10-dimensional and 50-dimensional cases, ALCSODE successfully reaches the global optimum on F2, F5, and F8, and demonstrates the best performance on all functions except F10 and F13. Compared to other competing algorithms, ALCSODE exhibits superior convergence accuracy and stability on these unimodal functions. Overall, the simulation results clearly indicate that ALCSODE possesses a significant performance advantage in unimodal function optimization tasks.

2) Evaluation of multimodal banchmark: Functions F1, F6, F9, F11, F12, F14, F15, F16, and F17 are typical high-dimensional multimodal functions that contain not only a primary global optimum but also multiple local optima, making them well-suited for evaluating the exploration capability of optimization algorithms. Tables IV to VI present the optimization results of the proposed algorithm ALCSODE compared with seven other competing algorithms on these functions. Benefiting from its strong exploration ability, ALCSODE is able to locate the global optimum for functions F9, F11, F12, F14, F15, F16, and F17 after identifying the promising regions. In the optimization of F1 and F6, ALCSODE also demonstrates superior performance. The simulation results indicate that ALCSODE exhibits satisfactory exploration capability in accurately scanning the search space and avoiding local optima.

3) Evaluation of CEC 2022 benchmark: CEC2022 serves as an effective benchmark for evaluating the performance of optimization algorithms and their ability to solve complex optimization problems. It requires algorithms to handle multimodality, multi-scaled landscapes, and fused complex function shapes. The test suite consists of 12 benchmark functions, including unimodal, multimodal, hybrid, and composition functions. Specifically, F13 is a unimodal function; F14–F17 are multimodal functions; F18–F20 are hybrid functions (which may exhibit either unimodal or multimodal characteristics); and F21–F24 are composition functions with multimodal properties. Tables V and VI present the optimization results of the proposed ALCSODE algorithm compared with seven competing algorithms on the CEC2022 benchmark set. The results show that ALCSODE achieves the global optimum for F14, F15, F16, F17, and F20. For F18, F19, F21, F22, F23, and F24, ALCSODE outperforms all competitors except for F19 in the 10-dimensional case, where the global optimum is not fully reached. Overall, ALCSODE demonstrates superior optimization performance in most test cases compared to the other algorithms.

4) Statistical analysis: To provide a clear and intuitive comparison of algorithmic performance, the non-parametric Wilcoxon signed-rank test is employed to assess the statistical significance of the results. Using the best convergence value as the evaluation criterion, statistical analysis is conducted based on the average outcomes from 30 independent runs, aiming to systematically examine the effectiveness of ALCSODE. In the test outcomes, a "+" symbol indicates that ALCSODE performs better than the compared algorithm, "-" indicates relatively lower performance, and "=" denotes no significant difference. The "Rank" column represents the relative ranking in terms of solution accuracy. As shown in Table VII, ALCSODE performs competitively across most of the twelve benchmark functions. Although ALCSODE does not achieve the best performance among all algorithms on F3, F10, F12, and F13 in the 10-dimensional case, and on F10, F13, and F19 in the 50-dimensional case, slightly inferior to INFO or SHIO, it exhibits significant advantages on the remaining functions, attaining 85.5% (41 out of 48) of the best convergence results. Furthermore, the Wilcoxon rank-sum test is applied to validate the consistency of performance rankings across different dimensions. The overall results indicate that ALCSODE demonstrates strong competitiveness among all the compared algorithms and exhibits advantages in convergence accuracy from a statistical perspective.

D. Scalability and Stability Analysis of ALCSODE

This subsection analyzes the scalability and stability of ALCSODE. For scalability analysis, ALCSODE is tested on functions F1 to F24 under 10-dimensional and 50-dimensional settings, with the simulation results presented in Tables IV to VI. The analysis shows that although the performance of all algorithms declines as the dimensionality increases from 10 to 50, ALCSODE experiences a relatively smaller performance drop, demonstrating strong robustness. It continues to achieve the same optimal convergence accuracy on several functions as in the 10-dimensional case. In contrast, traditional PSO and CSO algorithms exhibit significant performance degradation in high-dimensional spaces. Other CSO variants, as well as metaheuristic algorithms such as INFO and SHIO, show moderate performance but are more sensitive to initial settings, with greater convergence fluctuations and a higher risk of premature convergence.

In terms of algorithmic stability, ALCSODE generally exhibits lower standard deviations compared to other algorithms. For instance, in both 10-dimensional and 50-dimensional experiments, ALCSODE achieves the smallest standard deviation values in most cases for functions F1, F2, F3, F4, F9, F11, F12, F13, and F21. This indicates a lower sensitivity to initial conditions and stronger resistance to random disturbances, which is particularly important for maintaining stable convergence in noisy engineering optimization environments.

V. Conclusion and Future Work

This study proposes Adaptive Levy Flight Chicken Swarm Optimization with Differential Evolution (ALCSODE) to overcome traditional CSO limitations like local optima entrapment, weak perturbation, and fixed parameters. ALCSODE enhances exploration and exploitation balance by introducing an adaptive differential perturbation in the rooster phase, combined with fitness-based step-size control and a non-inertia weight strategy. The hen phase applies dynamic scaling and Levy flights to improve local optima escape and convergence speed. An elitism preservation mechanism maintains diversity and guides solutions via information sharing. The mathematical modeling of ALCSODE and descriptions of its steps and strategies are also presented.

The performance of ALCSODE is validated on 24 benchmark functions, including unimodal, multimodal, and the

CEC2022 test suite. Results on unimodal functions demonstrate ALCSODE's strong exploitation ability, effectively converging toward the global optimum. For multimodal functions, ALCSODE exhibits robust exploration capability, successfully escaping local optima and locating the primary optimal regions. To comprehensively evaluate its effectiveness, ALCSODE is compared with seven well-known algorithms, including PSO, CSO, L-QCSO, ICSO, ECSO, SHIO, and INFO. Experimental results indicate that ALCSODE achieves superior balance between exploration and exploitation, outperforming these competitors and delivering more competitive optimization results.

However, the integration of multiple mechanisms, such as differential computation, dynamic step adjustment, and elitism preservation, may increase computational complexity, potentially affecting efficiency in large-scale or real-time optimization. Future research may focus on enhancing inter-module synergy, developing automated parameter adjustment mechanisms to reduce hyperparameter sensitivity, and exploring dimensionality reduction or decomposition strategies to improve efficiency in high-dimensional problems.

Public Opinion Stage Segmentation in Disaster Events: A Study Based on Multimodal Sentiment Prediction Model

Xiaogang Yuan, Jiaxi Chen, Dezhi An, Xiang Gong
School of Cyber Security, Gansu University of Political Science and Law, Lanzhou 730070, China

***Abstract*—Existing approaches for predicting public sentiment and analyzing opinion evolution during disaster events using multimodal data (text, video, audio) suffer from several limitations: an inadequate dynamic fusion of heterogeneous multi-source data, and imprecise division of public opinion stages. To address these issues, this paper proposes an Enhanced Disentangled Cross Fusion (EDCF) model-based framework for analyzing the evolution of public opinion in disaster events. This framework integrates the E-Divisive with Medians (EDM) change point detection method with spatiotemporal sequence modeling techniques to achieve fine-grained stage segmentation. The EDCF model employs Transformers and positional encoding to process time-series signals (audio/video), effectively capturing long-range dependencies. It enhances modality-specific representation capabilities by introducing dedicated encoders for each modality, a shared encoder, and a reconstruction decoder for disentangled representation learning. Furthermore, the model utilizes a cross-modal language-guided attention mechanism for efficient and effective feature fusion. Experimental validation on the publicly available multimodal sentiment dataset CMU-MOSI demonstrates that the proposed EDCF framework significantly outperforms baseline methods on key sentiment prediction metrics.**

***Keywords*—Multimodal sentiment prediction; e-divisive with medians; transformer; encoder; decoder; cross-attention**

I. Introduction

Disaster events (e.g., earthquakes, and floods) often trigger intense fluctuations in public sentiment. Related multimodal content (text, video, audio) rapidly disseminates through social media platforms, where the evolution of public opinion directly influences public behavior and government emergency decision-making. Consequently, accurately segmenting and analyzing the evolution of public opinion is crucial for enhancing the effectiveness of emergency responses.

A. Multimodal Sentiment Analysis

Multimodal Sentiment Analysis (MSA) aims to improve the accuracy and comprehensiveness of sentiment recognition by fusing heterogeneous information from multiple sources such as text, audio, and video. Early research primarily employed feature concatenation methods for simplistic cross-modal fusion. Two common fusion strategies are: early fusion and late fusion. Early fusion constructs a joint feature representation by extracting features from each modality and merging them at the input layer [1], [2], [3], [34]. Late fusion first performs sentiment analysis on each modality individually and then integrates the unimodal sentiment decisions into a final decision using various mechanisms [4], [5], [6], [35]. However, these methods often introduce redundancy and conflicts due to insufficient consideration of semantic differences and interaction relationships between modalities.

Recent research has shifted towards deep learning-driven cross-modal modeling, designing more sophisticated fusion strategies to enhance performance. Attention has moved beyond simple fusion to explicitly modeling inter-modal interactions. For instance, Zadeh et al. [7] proposed a tensor fusion network that learns both intra-modal and cross-modal dynamics end-to-end for the three modalities, aiming to improve MSA performance. Han et al. [8] introduced a method that simultaneously maximizes mutual information (MI) between modalities and between the multimodal fusion result and the unimodal inputs, thereby enhancing model capability. Furthermore, contrastive learning frameworks have significantly improved MSA accuracy by optimizing semantic representations through cross-modal alignment. Research on contrastive learning can be categorized into two groups: self-supervised contrastive learning [9], [10], [11], [36], [37] and supervised contrastive learning [12], [13], [38], [39]. The key distinction lies in whether label information is used to guide the selection of positive and negative sample pairs.

Recent studies further focus on modality noise handling and multimodal alignment techniques. For example, Li et al. [14] proposed an improved FGM-CM-BERT model. It optimizes adversarial training using the Fast Gradient Method (FGM) with an adaptive parameter adjustment strategy to enhance model generalization. Combined with a multi-head attention mechanism for efficient cross-modal feature fusion, experiments showed it achieved 48.2% accuracy for seven-class emotion classification on the CMU-MOSI dataset. Wang et al. [15] proposed the DLF model, which enhances the accuracy and efficiency of multimodal data fusion by introducing components such as a feature decomposition module, a language-guided feature attractor (LFA), and hierarchical prediction. Despite significant progress, effectively balancing semantic differences and dynamic interactive relationships between modalities remains a core challenge in MSA.

B. Public Opinion Stage Segmentation

Public opinion stage segmentation aims to identify the lifecycle of opinion propagation, providing a theoretical basis for dynamic monitoring and intervention. Early research often relied on propagation dynamics models (e.g., SIR model, [40], [41]) or time-series analysis to model the opinion dissemination process. For example, Zeng et al. [16] proposed

segmenting opinion propagation into stages: germination, outbreak, diffusion, climax, and subsidence, combined with the SIR model to quantify propagation intensity at each stage. However, such methods are typically limited to a single text modality, struggling to capture the complex evolution patterns of multimodal public opinion.

Recent studies attempt to segment stages based on trough detection in propagation volume curves. For instance, Chen et al. [17] employed the Fisher optimal segmentation algorithm to cluster daily short-video public opinion data, roughly dividing online opinion into starting, outbreak, decline, and subsidence stages. Wei et al. [18] refined the lifecycle into four stages (development period, primary outbreak period, secondary outbreak period, and decline period) based on repost volume. Although these methods improve granularity and interpretability in stage segmentation, their reliance on propagation volume metrics makes them susceptible to noise. Furthermore, they fail to adequately incorporate sentiment dimensions and user behavioral characteristics, limiting their practical effectiveness.

C. Summary and Research Challenges

In summary, while significant advancements have been made in both the techniques and methodologies of multimodal sentiment analysis and public opinion evolution research, several key challenges persist:

- Multimodal Sentiment Analysis: Effectively balancing semantic differences and dynamic interactive relationships between modalities remains a core challenge.
- Opinion Stage Segmentation: Existing segmentation methods lack sufficient dynamism and fail to adequately integrate sentiment dimension features, limiting their practical applicability.

To address these challenges, the main contributions of this study are summarized as follows:

- We optimize the DLF model proposed by Wang et al. [15], constructing a superior Enhanced Disentangled Cross Fusion (EDCF) model. This model effectively tackles three key challenges in multimodal sentiment prediction: inter-modal asynchrony, noisy modality interference, and the complex modeling of cross-modal interactions.
- We integrate E-Divisive with Medians (EDM) change point detection with the sentiment features captured by the EDCF model to achieve finer-grained segmentation of public opinion stages.
- The collaborative modeling approach, integrating multimodal sentiment analysis with public opinion phase division based on EDM anomaly detection, enhances the accuracy of public opinion monitoring. This facilitates real-time online surveillance and provides early warning mechanisms for relevant authorities, enabling timely intervention and guidance to prevent the recurrence of negative events such as cyber violence.

The remainder of this paper is structured as follows. Section II details the construction of the proposed EDCF multimodal sentiment model. Section III applies the EDCF model combined with the EDM change point detection method to achieve precise segmentation of public opinion stages for specific disaster events. Section IV presents experimental validation demonstrating that the proposed EDCF model significantly outperforms traditional fusion methods in cross-modal interaction and fusion efficiency. This section also validates the effectiveness and necessity of the proposed opinion stage segmentation method. Finally, Section V concludes the study and suggests directions for future research.

II. Multimodal Sentiment Prediction Model

This paper proposes Enhanced Disentangled Cross Fusion (EDCF) model for multimodal sentiment prediction, based on dual latent feature learning and cross-modal attention interaction. The core architecture of the proposed model (Fig. 1) comprises four key modules:

- Enhanced Multimodal Feature Extraction Module: Employs Transformers and positional encoding to process time-series signals (audio/video), effectively capturing long-range dependencies.
- Dual-Stream Feature Disentanglement and Reconstruction Module: Enhances the representational capacity of each modality by introducing dedicated encoders (per modality), a shared encoder, and a reconstruction decoder for disentangled representation learning.
- Hierarchical Cross-Modal Attention Interaction Module: Achieves efficient feature fusion through a language-guided cross-attention mechanism.
- Dynamic Feature Fusion Module: Innovatively incorporates a differentiable weighting strategy to integrate modality-specific features and cross-modality interactive features effectively.

A. Multimodal Feature Extraction and Enhancement Module

Initial independent feature extraction is performed for each modality:

- Text Modality: The pre-trained BERT model https://huggingface.co/google-bert/bert-base-uncased is used for tokenization, generating word vectors of dimension (50, 768), denoted as $I_l \in \mathbb{R}^{T_l \times d_l}$.
- Audio Modality: Fundamental acoustic features are extracted using the Librosa library, including Zero Crossing Rate (ZCR, 1 dimension), Mel-frequency cepstral coefficients (MFCC, 20 dimensions), and Chroma features based on the Constant-Q Transform (Chroma CQT, 12 dimensions), resulting in a total of 33 dimensions. To ensure consistent sequence length, all audio data is uniformly truncated or zero-padded to a fixed length of 50 frames. Subsequently, Principal Component Analysis (PCA) is applied to compress the 33-dimensional features into 5 dimensions, preserving essential information. The processed audio representation has a dimension of (50, 5), denoted as $I_a \in \mathbb{R}^{T_a \times d_a}$.
- Video Modality: OpenCV's Hear cascade classifier extracts 50 frames containing faces from the video.

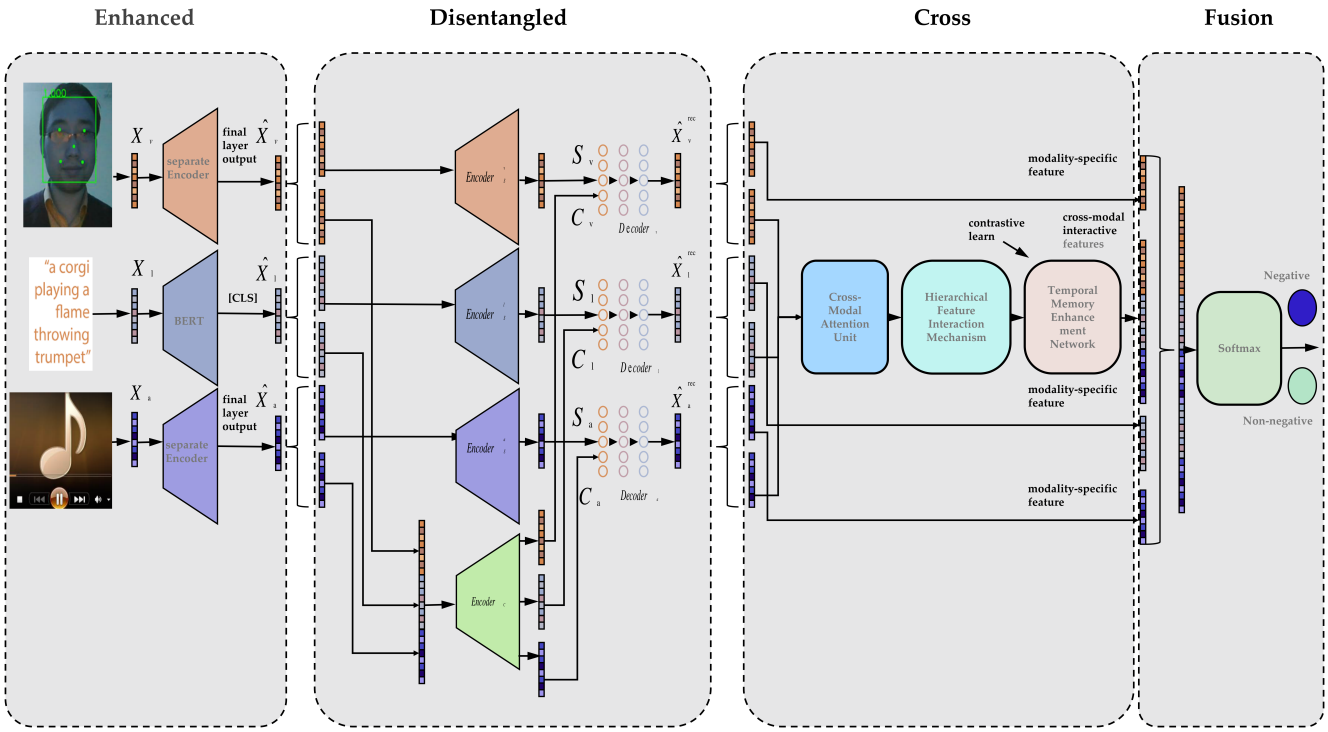

Fig. 1. Structural diagram of the EDCF (Enhanced Disentangled Cross Fusion) model.

For each frame, facial features are extracted using the Google-developed FaceNet model. PCA is similarly applied to compress the original 128-dimensional features into 20 dimensions, retaining critical information. The final video representation has a dimension of (50, 20), denoted as $I_v \in \mathbb{R}^{T_v \times d_v}$. Here, $\mathrm{T}_{\mathrm{m}\in\{\mathrm{l,a,v}\}}$ represents the sequence length common to all modalities, and $\mathrm{d}_{\mathrm{m}\in\{\mathrm{l,a,v}\}}$ represent the corresponding feature vector dimensions.

To enhance feature extraction capability and improve model robustness, a noise-resistant common vector representation is generated for each modality:

- For the text modality, the feature I_l is directly fed into the pre-trained BERT model (https://huggingface.co/google-bert/bert-base-uncased), and the output vector of the [CLS] token is used as its common representation $I_l^c \in \mathbb{R}^{1\times d_l}$.
- For the video and audio modalities, the features I_v and I_a are input into separate Transformer encoders. The last vector from the final layer output of each encoder is taken as their respective common representations, denoted as $I_v^c \in \mathbb{R}^{1\times d_v}$ and $I_a^c \in \mathbb{R}^{1\times d_a}$. This processing effectively mitigates noise interference.

The core objective of modality alignment is to project the common representations of different modalities into a shared semantic space. First, one-dimensional convolutional networks (Conv1D) are used to transform the three common vectors I_l^c, I_v^c, I_a^c into the same dimension d_c, yielding $L_c \in \mathbb{R}^{d_c\times 1}$, $V_c \in \mathbb{R}^{d_c\times 1}$, and $A_c \in \mathbb{R}^{d_c\times 1}$. Subsequently, a projection layer maps these features into a unified latent space [as shown in Eq. (1)].

$$\widehat{\mathrm{X}}_{\mathrm{m}} = \mathrm{Conv1D}(\mathrm{X}_{\mathrm{m}}), \mathrm{m} \in \{\mathrm{l, a, v}\} \tag{1}$$

B. Dual-Stream Feature Decoupling and Reconstruction Module

This module explicitly separates Modality-specific Features from Cross-modal Shared Features through parallel parameter-isolated encoders and parameter-shared encoders. A triple-constraint mechanism ensures robustness during the decoupling process. Its core architecture is shown in Fig. 2.

The modality-specific encoder captures the unique characteristics of each modality using a parameter-isolated Transformer network. Given the input features $\widehat{X}_m \in R^{T_m\times d_s}$ for modality m, its processing is defined by Eq. (2). Here, d_s is the dimension of the specific features, and $Encoder_s^m$ contains Transformer modules with independent layer parameters.

The cross-modal shared encoder extracts cross-modal common representations using a parameter-shared Transformer network, as defined by Eq. (3). Here, d_c is the shared feature dimension, $Encoder_c$ forcibly reused across modalities to promote consistent mapping of different modal data in the latent space. The shared feature dimension is dynamically adjusted via a learnable scaling factor, enabling adaptive alloca- tion of feature capacity.

$$\mathrm{S}_{\mathrm{m}} = \mathrm{Encoder}_{\mathrm{s}}^{\mathrm{m}}(\widehat{\mathrm{X}}_{\mathrm{m}}) \in \mathrm{R}^{\mathrm{T_m}\times \mathrm{d_s}} \tag{2}$$

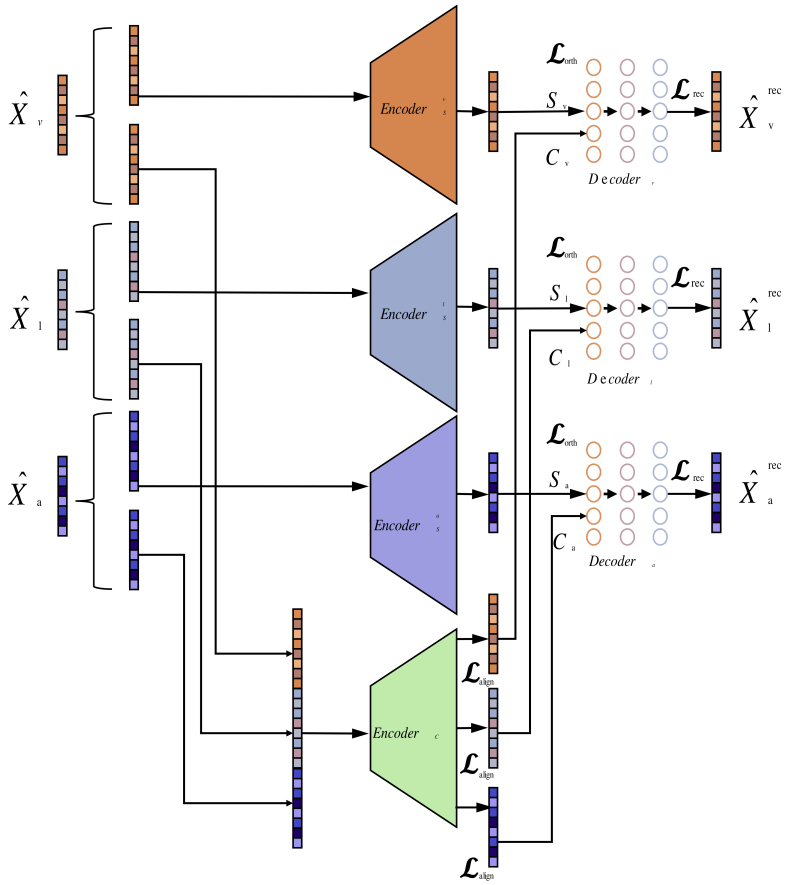

Fig. 2. Core architecture diagram of the dual-stream feature decoupling and reconstruction module.

$$\mathbf{C}_m = \text{Encoder}_c(\hat{\mathbf{X}}_m) \in \mathbb{R}^{T_m \times d_c} \tag{3}$$

To validate the effectiveness of feature decoupling, a cross-modal feature reconstruction task is designed. First, the specific features of modality and the shared features of modality are concatenated and input into a decoder, as shown in Eq. (4). Here, $\oplus$ denotes channel-wise concatenation, and the decoder is implemented using 1D transposed convolutional layers. Then, reconstruction loss is minimized to ensure information integrity, as shown in Eq. (5).

$$\hat{X}_m^{rec} = \text{Decoder}_m([S_m \oplus C_m]) \in \mathbb{R}^{T_m \times d} \tag{4}$$

$$\mathcal{L}_{rec} = \sum_m \|\hat{X}_m - \hat{X}_m^{rec}\|_F^2 \tag{5}$$

To enhance the robustness of feature decoupling, dual regularization constraints are constructed:

- Spatial Orthogonality Constraint: Forces modality-specific features and shared features to be orthogonal in the feature space, minimizing their spatial correlation, as specified in Eq. (6).
- Similarity Alignment Constraint: Requires cross-modal shared features to satisfy distribution consistency, as specified in Eq. (7).

$$\mathcal{L}_{orth} = \sum_m \frac{1}{T_m} \sum_{t=1}^{T_m} |S_m^{(t)} \cdot C_m^{(t)}| \tag{6}$$

$$\mathcal{L}_{align} = \sum_{m \neq n} \text{KL}(\text{Align}(C_m) \| \text{Align}(C_n)) \tag{7}$$

The collaborative design of parameter isolation (specific encoder) and parameter sharing (shared encoder), coupled with the learnable dimension scaling factor $\alpha = d_s/(d_s + d_c)$ for adaptive adjustment of the capacity ratio between the two types of features, achieves fine-grained feature decoupling. The joint optimization of $\mathcal{L}_{\text{rec}}$, $\mathcal{L}_{\text{orth}}$, and $\mathcal{L}_{\text{align}}$ ensures the interpretability of the decoupling process.

C. Cross-Modal Hierarchical Attention Interaction Module

This module implements cross-modal feature interaction and temporal dependency modeling through a multi-granularity attention mechanism. Its hierarchical structure is shown in Fig. 3. The module contains three core components: Cross-Modal Attention Unit, Temporal Memory Enhancement Network, and Hierarchical Feature Interaction Mechanism.

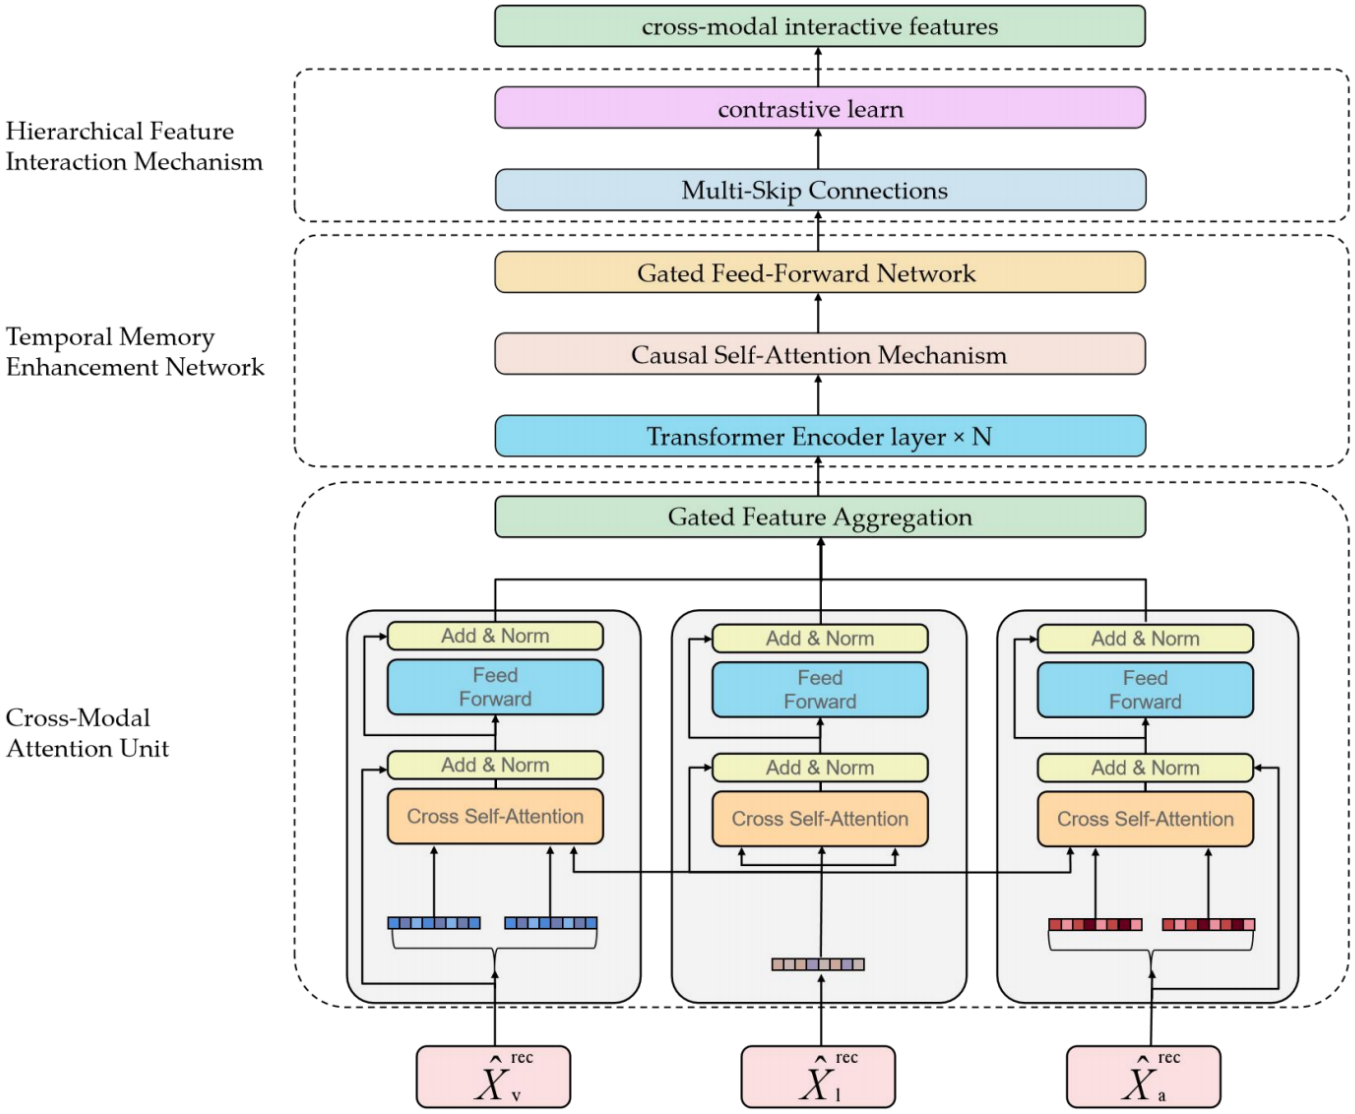

Fig. 3. Schematic diagram of the hierarchical structure for the cross-modal hierarchical-attention interaction module.

The Cross-Modal Attention Unit achieves fine-grained feature alignment based on a bidirectional cross-attention unit. Its computation process is shown in Eq. (8) and (9). Here, denotes Multi-Head Attention, calculated as shown in Eq. (10). Gated feature aggregation introduces adaptive weights to fuse contributions from different modalities, as shown in Eq. (11) and Eq. (12). Here, σ is the Sigmoid function, W_g^{la} is the gating parameter matrix, enabling adaptive fusion of cross-modal features through dynamic weight allocation.

$$H_{l\leftarrow a} = \text{CrossAttn}(Q = S_l, K = S_a, V = S_a) \in \mathbb{R}^{T_l \times d} \quad (8)$$

$$H_{l\leftarrow v} = \text{CrossAttn}(Q = S_l, K = S_v, V = S_v) \in \mathbb{R}^{T_l \times d} \quad (9)$$

$$\text{CrossAttn}(Q, K, V) = \text{Softmax}\left(\frac{QW_Q(KW_K)^T}{\sqrt{d}}\right)VW_V \quad (10)$$

$$g_{la} = \sigma(W_g^{la}[S_l, H_{l\leftarrow a}]) \quad (11)$$

$$H_l^{cross} = g_{la} \odot H_{l\leftarrow a} + (1 - g_{la}) \odot H_{l\leftarrow v} \quad (12)$$

The Temporal Memory Enhancement Network employs a deep Transformer Encoder to construct a temporal memory enhancement network. Its hierarchical processing is shown in Eq. (13). Here, $MemEnc_l$ contains L_m Transformer layers, each comprising two core components:

- Causal Self-Attention Mechanism: Ensures temporal directionality via a mask matrix, preventing future information leakage, as shown in Eq. (14).

- Gated Feed-Forward Network: Employs dual nonlinear projections to enhance temporal pattern capture capability, as shown in Eq. (15).

$$H_l^{mem} = \text{MemEnc}_l(\text{LayerNorm}(H_l^{cross} + S_l)) \tag{13}$$

$$\text{CausalAttn(X)} = \text{Tril}(\text{QK}^{\text{T}}/\sqrt{\text{d}})\text{V} \tag{14}$$

$$GatedFFN(X) = (GeLU(XW_1) \odot XW_2)W_3 \tag{15}$$

The Hierarchical Feature Interaction Mechanism constructs multi-level representations via Multi-skip connections, mathematically expressed in Eq. (16). Here, α_k is a learnable scaling weight, and $Downsample_k$ denotes average pooling with stride 2^{k-1}. Contrastive learning is utilized to optimize cross-modal consistency, bringing cross-modal sample representations closer in the semantic space, as shown in Eq. (17). Here, h_m^i is the high-level feature of instance i for a modality m, and τ is the temperature coefficient. Theoretical analysis indicates that when the condition in Eq. (18) is satisfied, the hierarchical attention mechanism effectively enhances cross-modal interaction efficiency. This gradient propagation form ensures high-level semantic features gradually align during contrastive learning.

$$\text{H}_\text{l}^{\text{final}} = \sum_{\text{k=1}}^{\text{K}} \alpha_\text{k} \cdot \text{Downsample}_\text{k}(\text{H}_\text{l}^{\text{mem,(k)}}) \tag{16}$$

$$\mathcal{L}_{\text{sem}} = -\log \frac{\sum \exp\left(\cos\left(h_1^i, h_a^i\right)/\tau\right)}{\sum \exp\left(\cos\left(h_1^i, h_a^j\right)/\tau\right)} \tag{17}$$

$$\frac{\partial \mathcal{L}_{\text{sem}}}{\partial \mathcal{H}_\text{m}} \propto \text{E}[\cos(\text{H}_\text{m}, \text{H}_\text{n})] \cdot \frac{\partial \cos(\text{H}_\text{m}, \text{H}_\text{n})}{\partial \text{H}_\text{m}} \tag{18}$$

D. Dynamic Feature Fusion Module

This module achieves a dynamic fusion of multi-level features through an adaptive gating mechanism, effectively integrating modality-specific features and cross-modal interactive features.

Within the same modality, dynamic gated fusion is performed using modality-aware attention to compute dynamic weights. This process is formalized by Eq. (19) and (20), where $W_g^l \in \mathbb{R}^{3d_h \times 3}$ is a learnable parameter matrix ensuring weight normalization. This gating mechanism also incorporates a differential entropy constraint via a regularization term to prevent weight collapse, as shown in Eq. (21).

$$\text{g}_\text{l} = \text{Softmax}\left(\frac{[\text{z}_\text{l}^{\text{spec}}; \text{z}_\text{l}^{\text{cross}}; \text{z}_\text{l}^{\text{share}}]\text{W}_\text{g}^\text{l}}{\sqrt{\text{d}_h}}\right) \in \mathbb{R}^3 \tag{19}$$

$$\widehat{\text{H}}_\text{l} = \sum_{\text{k=1}}^{3} \text{g}_\text{l}^{\text{(k)}} \cdot [\text{z}_\text{l}^{\text{spec}}, \text{z}_\text{l}^{\text{cross}}, \text{z}_\text{l}^{share}]_\text{k} \tag{20}$$

$$\mathcal{L}_{\text{ent}} = -\frac{1}{3}\sum_{\text{m}}\sum_{\text{k=1}}^{3} \text{g}_\text{l}^{\text{(k)}} \log \text{g}_\text{l}^{\text{(k)}} \tag{21}$$

For fusion between different modalities, a collaborative gating mechanism is employed, formalized by Eq. (22), where σ is the Sigmoid function and $W_\beta \in \mathbb{R}^{3d_h \times 3}$ is the parameter matrix. The final fused feature is given by Eq. (23). This gating mechanism incorporates multi-granularity residual learning to enhance model robustness against minor feature variations.

$$\beta = \sigma\left(\text{W}_\beta[\widehat{\text{H}}_\text{l}; \widehat{\text{H}}_\text{a}; \widehat{\text{H}}_\text{v}]\right) \in \mathbb{R}^3 \tag{22}$$

$$\text{H}_{\text{fusion}} = \beta_\text{l}\widehat{\text{H}}_\text{l} + \beta_\text{a}\widehat{\text{H}}_\text{a} + \beta_\text{v}\widehat{\text{H}}_\text{v} \in \mathbb{R}^{\text{d}_h} \tag{23}$$

III. Research Methodology Based on Multimodal Sentiment Prediction Model and EDM Anomaly Detection for Public Opinion Phase Division

A. Robustness Testing of the Multimodal Sentiment Prediction Model

To verify the robustness of the proposed multimodal sentiment prediction model EDCF (Section II) on disaster datasets, this section trained it using specific multimodal data from disaster-related emergencies. First, Python was used to crawl multimodal objects (including video, audio, text, and corresponding IDs) for short videos related to the disaster public opinion event "Yunlinkou Landslide in Sichuan" from the Douyin platform. After data preprocessing, 608 valid data entries were obtained.

Subsequently, each multimodal object was annotated into two categories: negative and non-negative. This experiment invited two postgraduate students, whose research focuses primarily on language and semantic recognition. Annotations were formally included in the database only when the results were consistent. For inconsistent annotations, an expert holding a psychological counseling certificate was invited for secondary annotation. The majority vote (2:1) determined the final sentiment polarity. Among the 608 annotated valid data entries, 417 were labeled as non-negative sentiment and 191 as negative sentiment. Of these, 58.48

After multiple tests comparing manual annotations with intelligent classification results, the multimodal sentiment prediction model EDCF proposed in Chapter 3 achieved a sentiment binary classification accuracy consistently exceeding 74.6

B. EDM Change-Point Detection Technology

EDM (E-Divisive with Medians) is a non-parametric time series and data stream change-point detection technique. Its innovation lies in accurately locating change points in data distribution structures without presupposing a data distribution model. Compared to traditional parametric methods, EDM effectively overcomes the sensitivity of conventional mean-based metrics to outliers by constructing a measurement system based on median values in multidimensional data feature spaces. The core theoretical foundation of this method is the innovative application of the Energy Distance statistic. Its technical implementation path comprises two key steps:

- Quantitative Assessment Based on Statistical Distance Between Subsequences: Construct a metric for distribution difference; when this metric exceeds a preset threshold, a potential change point is identified.
- Using Median Instead of Mean as the Difference Metric Benchmark: This design significantly enhances the algorithm's robustness against outliers.

Experimental studies show that the EDM method is not only suitable for high-dimensional data analysis scenarios but also maintains stable detection performance even in the presence of noise interference or data contamination, demonstrating strong environmental adaptability.

C. Mathematical Modeling of EDM Change-Point Detection Technology

- Define Multimodal Sentiment Statistic: This statistic aims to establish a quantitative representation of public opinion intensity. By setting a time window length ($\tau = 2$ hours) for integral statistics, unstructured multimodal information (video content) is transformed into structured time series signals. Specifically, the number of negative short videos within the k-th time window is defined as: $N_k = \sum_{t\in\mathcal{T}_k} \mathbb{I}(s_t < 0.5)$, where $s_t \in \{0, 1\}$ represents the sentiment prediction score of the i-th short video (1 for negative), $\mathcal{T}_k$ is the index set for the k-th time window, and $\mathbb{I}(\cdot)$ is the indicator function. Using the indicator function for sentiment discretization effectively avoids the cumulative effect of continuous prediction errors. The selection of a $\tau = 2$hour time window balances event response immediacy and statistical significance requirements.
- Set Change-Point Detection Energy Function: This function constructs a metric for heterogeneity in time series data. The parameter min_size specifies the minimum length of each segment after splitting, ensuring statistically significant segmentation results and avoiding unreliable splits due to overly short data.For a candidate split point i, the energy statistic between the preceding segment data $\bar{D}_1^i$ and the succeeding segment data $\bar{D}_{i+1}^n$ is shown in Eq. (24). Here, $\bar{D}_1^i = \frac{i}{\sum_{k=1}^{i} N_k}$, $\bar{D}_{i+1}^n = \frac{n-i}{\sum_{k=i+1}^{n} N_k}$. This function introduces a weighting factor $\frac{i(n-i)}{n}$ to suppress the tendency to split near the sequence endpoints. The L^2 norm based on mean difference effectively captures abrupt changes in distribution parameters and is sensitive to mean-shift type change points.

$$\mathrm{E(i;D)} = \frac{\mathrm{i(n-i)}}{\mathrm{n}} ||\bar{\mathrm{D}}_1^{\mathrm{i}} - \bar{\mathrm{D}}_{\mathrm{i+1}}^{\mathrm{n}}||_2^2 \tag{24}$$

- Set Regularization Penalty Term: This penalty term controls model complexity and over-segmentation risk. Its design reflects the regulatory role of key parameters, as shown in Eq. (25). Here, δ is the degree parameter, and n is the length of the current data segment. degree controls the calculation method of the penalty term, influencing the preference for split point locations. When $\delta = 1$, the penalty term is $\beta \times n^\alpha$, independent of the split location, applying the same penalty to all candidate points. When $\delta = 2$, the penalty term is $\beta \times n^\alpha \times \left(\frac{i}{n}\right)^2$, where the split location proportion n is $\frac{i}{n}$. $\delta = 2$ constructs a "middle suppression" effect via the quadratic term, aligning with the characteristic of public opinion events erupting at the beginning and end; β is the strength coefficient for the penalty term, balancing model likelihood and complexity through the Lagrange multiplier principle, controlling segmentation sparsity. Increasing strengthens the penalty term, reduces the adjusted energy value, and consequently decreases the number of detected change points, suppressing over-segmentation; α regulates the growth rate of the penalty term with segment length. The penalty term is proportional to n^α. Larger α imposes heavier penalties on long segments, avoiding frequent segmentation in long sequences.

$$P(i; n, \beta, \alpha, \delta) = \begin{cases} \beta n^\alpha & \text{if } \delta = 1 \\ \beta n^\alpha \left(\dfrac{i}{n}\right)^2 & \text{if } \delta = 2 \end{cases} \tag{25}$$

- Set Optimization Objective Function: This function aims to achieve optimal segmentation under statistical significance constraints, using the adjusted maximum energy criterion shown in Eq. (26). The constraint $n_{\min} = 12$ ensures the minimum analysis unit (equivalent to 24 hours of data), conforming to the public opinion event lifecycle theory. The penalty term here acts as a regularizer, generalizing the Bayesian Information Criterion (BIC) to time-varying scenarios.

$$\hat{\mathrm{i}} = \arg \max_{\mathrm{i}\in[\mathrm{n}_{\min}, \mathrm{n}-\mathrm{n}_{\min}]} [\mathrm{E(i;D)} - \mathrm{P(i;n,}\beta, \alpha, \delta)] \tag{26}$$

- Set Recursive Segmentation Criterion: This criterion constructs a multi-level framework for event evolution analysis, adopting a median strategy for iterative segmentation, as shown in Eq. (27). Segmentation significance requires: $E(\hat{i}; \mathcal{D}) > C_\alpha \cdot \sigma_N^2$, where C_α is the significance level threshold and σ_N^2 is the global variance estimate. The significance test condition sets an adaptive threshold based on extreme value theory to avoid spurious segmentation.

$$\mathcal{S}(\mathcal{D}) = \begin{cases} \emptyset & if\ n < 2n_{min} \\ \{\hat{i}\}\ U\ S(D_1^{\hat{i}})\ U\ S(D_{\hat{i}+1}^n) & otherwise \end{cases} \tag{27}$$

This mathematical model balances detection sensitivity and robustness through parameter combinations ($n_{\min}$, β, α, δ): When experimental data is short or has many change points, min_size, β, and α should be reduced, using $\delta = 1$. When data is long or has few change points, min_size, β, and α should be increased, using $\delta = 2$ to suppress middle segmentation. The theoretical basis for its parameter setting can be summarized as Eq. (28).

$$\beta = 0.008 \propto \frac{\log n}{n^\alpha}, \alpha = 1 \Rightarrow \text{LinearPenaltyGrow}th \tag{28}$$

Essentially, this framework constructs a Regularized Maximum Likelihood Estimator (Regularized MLE). Its parameter settings can be derived based on the Wiener filter theory to achieve a Pareto optimal balance between detection sensitivity and false alarm probability. Given that the public opinion evolution data analyzed in this experiment is of medium length, the final balanced parameter settings adopted were: $\min_size = 12$, $\beta = 0.008$, $\alpha = 1$, $\delta = 1$.

D. Application of EDM Change-Point Detection Technology in Public Opinion Phase Division

This study combines the multimodal sentiment prediction model proposed in Section II with the EDM change-point detection technology to divide the public opinion phases for a specific event. The specific process is as follows:

- Sentiment Prediction and Statistics: Utilize the trained multimodal sentiment prediction model from Chapter 3 to perform binary sentiment classification prediction (output: negative or non-negative sentiment) for each multimodal short video. Subsequently, count the number of short videos with negative sentiment within each time window.
- Time Series Waveform Construction: Plot a waveform graph of the number of negative videos per time slice, with time as the x-axis and the number of negative sentiment short videos per time period as the y-axis.
- Parameter Setting: Manually set relevant parameters of the EDM algorithm according to specific requirements to balance computational efficiency and detection accuracy.
- Change-Point Detection and Phase Division: Apply the EDM change-point detection technology to effectively identify abrupt change points in complex time series data based on energy statistics and media strategy. Finally, divide the different phases of public opinion development based on the detected change points and changes in the amplitude of the time slice negative video count waveform.

E. Results of Public Opinion Phase Division Using EDM Change-Point Detection

The EDM change-point detection method was applied to monitor the public opinion evolution of the "2023 Beijing-Tianjin-Hebei Rainstorm Event", identifying 11 structural change points (as shown in Fig. 4). Based on these change points and the waveform amplitude characteristics of the negative sentiment short video count within time slices, the public opinion event was divided into five key intervals. The average hourly number of negative sentiment short videos in each interval was 2.94, 4.82, 8.40, 1.90, and 0.09, respectively (details in Table I).
